First Series:

Defensive Technical Surveillance Countermeasures Doctrine

Volume 11

Receivers, Spectrum Analyzers, Software-Defined Radios, and RF Measurement Chains

By: James M. Atkinson, PhD

Price $750 USD per volume

Copyright and Lawful-Use Notice

Copyright 2026, James M. Atkinson. All rights reserved.

This volume is written for lawful defensive technical-security, engineering, educational, compliance, forensic, and professional purposes. It does not authorize unlawful interception, intrusion, surveillance, concealment, interference, evasion, or unauthorized access to communications or information systems.

Receiver measurements are configuration-dependent. The practitioner must verify authority, instrument configuration, calibration, bandwidth, reference planes, overload state, environmental conditions, and the governing law or standard before acting on a method or conclusion.

Public, public-release, government, user-supplied, licensed, and copyrighted technical sources are used according to their rights status. Complete third-party pages and traced illustrations are excluded. Redacted text is not reconstructed.

Price $750 USD, per volume, per copy

Author's Introduction

A receiver does not merely display a frequency. It transforms electromagnetic energy through antennas, cables, filters, gain stages, mixers, clocks, detectors, digitizers, software, and decision rules. Every stage can preserve information, remove it, distort it, or create an artifact that resembles a signal of interest.

The purpose of this volume is to place receiver behavior inside a controlled measurement model. Sensitivity, selectivity, dynamic range, phase noise, timing, bandwidth, probability of intercept, and demodulation quality are treated as state-dependent quantities rather than catalog labels. The text repeatedly distinguishes a detected energy component from a classified waveform, an attributed emitter, recovered information, and a legally supportable finding.

The practitioner is expected to challenge the receiver as aggressively as the environment. Alternate preselection, attenuation, reference sources, antennas, clocks, digitizers, locations, polarizations, and analysis methods are used to separate external phenomena from receiver-generated products. A technically responsible report records those controls and the uncertainty that remains.

Scope, Prerequisites, Exclusions, and Reader Route

Copyright 2026, James M. Atkinson

Authoritative Scope

This volume owns receiver-chain theory, spectrum-analyzer and software-defined-radio architecture, front-end and frequency-conversion behavior, IF and detector paths, spectral estimation, dynamic range, clock and phase integrity, calibration, recording, and defensive interpretation. It supports but does not replace V010 for survey antennas and fixtures, V058 for training instrumentation, V074 for monitoring-receiver deployment and survey-data governance, V099 and V104 for general test equipment and methods, or V100 for communications-system theory.

Copyright 2026, James M. Atkinson

Prerequisites

Readers should understand complex quantities, logarithmic units, thermal noise, sampling, modulation, transmission lines, antennas, and uncertainty. V024, V060, V084 through V101, V104, and V110 provide the principal prerequisites.

Copyright 2026, James M. Atkinson

Exclusions and Safety Boundary

The volume does not teach unauthorized interception, content exploitation, surveillance, evasion, or unlawful access. It does not treat one displayed spectral line, decoded identifier, or recovered fragment as proof of hostile purpose. Energized RF and microwave measurements require attention to exposure, equipment ratings, high voltage, electrostatic discharge, and the consequences of inserting or removing components.

Copyright 2026, James M. Atkinson

Reader Route

Chapters 1 through 5 establish receiver architecture, noise, gain, conversion, and IF behavior. Chapters 6 through 10 address analog and digital demodulation, swept and FFT analysis, and software-defined radios. Chapters 11 through 15 develop dynamic range, timing, reference-plane integration, calibration, and recording. Chapter 16 integrates artifact challenge testing, survey use, reporting, acceptance, and lifecycle control.

Worked applications and case adjudications use hypothetical or explicitly stipulated inputs unless a cited passage identifies a particular published measurement. They demonstrate a declared model and its limits. They are not records of a field engagement or acceptance tests of an unspecified instrument.

Study formats and laboratory requirements. This volume is suitable for independent study or an instructor-led two-semester course at a college, university, military school, technical academy, or other institute of learning. Instructor-led teaching requires substantial, appropriately calibrated RF laboratory equipment, including receivers, software-defined radios, spectrum analysers, signal generators, antennas, test accessories, and acquisition systems. Students must undertake supervised RF measurements in a properly isolated or shielded chamber and on designated indoor and outdoor test ranges. These complementary environments permit controlled calibration alongside realistic investigation of propagation, multipath, interference, and measurement uncertainty. All exercises must be authorised, safety-assessed, frequency-coordinated where necessary, and conducted in accordance with applicable law.

Other Volumes in the First Series. S001-V001 to S001-V120

The First Series contains 120 self-contained volumes, numbered S001-V001 through S001-V120. The present book is S001-V011. The following catalogue lists the 119 companion volumes by stable identifier and short title. Every essential definition, derivation, safety qualification, measurement method and worked example remains in this book. Links inside this manuscript navigate to catalogue entries; the availability of a companion manuscript is not implied. Title assignments retained from earlier archives require final catalogue authority review.

Author's Introduction....3

Scope, Prerequisites, Exclusions, and Reader Route....5

Other Volumes in the First Series. 120-Volume Catalogue....10

Source Editions and Access Scope, Checked November 1, 2026....51

Chapter 1. Receiver-System Boundaries, Mission Authority, and Evidence Formation....52

1.1 Receiver as a Measurement System....53

1.2 Mission Authority and Collection Boundaries....55

1.3 Observation, Classification, Attribution, and Content Recovery....57

1.4 Reference Planes and Configuration Identity....59

1.5 Define the measurement before choosing the receiver mode....62

1.6 Treat configuration changes as changes in the measurement law....64

1.7 Keep the evidence chain reversible to its declared inputs....67

1.8 Evidence Record and Closing Verification....69

1.9 Operational Decision Discipline....70

1.10 Quantitative Model for Receiver-System Boundaries, Mission Authority, and Evidence Formation....71

1.11 Model 1A: configured transfer, correction and recoverability....72

1.12 Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation....78

1.12.1 Application 1A.1. Complete a reference-plane correction in both directions....79

1.12.2 Application 1A.2. Remove a software offset before applying the remaining correction....81

1.12.3 Application 1A.3. Combine valid gain states without averaging their decibel labels....83

1.12.4 Application 1A.4. Use an attenuation prediction as a conditional challenge....85

Copyright 2026, James M. Atkinson

1.12.5 Application 1A.5. Retain separate admissible results when the settled state is unknown 87

1.12.6 Application 1A.6. Subtract an additive contribution in linear power before referring it backward....89

1.12.7 Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse....91

1.12.8 Application 1A.8. Preserve a valid power result while refusing to reconstruct lost phase 93

1.12.9 Application 1A.9. Correct resolved frequency components before forming a channel total....95

1.12.10 Application 1A.10. Separate a valid corrected level from an unobserved transition interval....97

1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation....99

1.14 Frame a bounded finding from the completed observation....100

1.15 Assurance cases for receiver-derived evidence under changing system identity....101

1.16 Advanced technical expansion. The receiver as a causal experimental instrument....104

Chapter 1 Assessments....109

Chapter 1 Answer Keys and Guidance....610

Chapter 2. Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal....643

2.1 Thermal Noise as a Bandwidth-Dependent Quantity....644

2.2 Power, bandwidth, and the reference plane....645

2.3 Noise Figure and Noise Temperature....649

2.4 Sensitivity Specifications and Decision Thresholds....652

2.5 Define sensitivity as a reproducible decision....653

2.6 Y-Factor and Comparative Noise Measurements....656

2.7 Uncertainty and Environmental Noise....657

2.8 Operational Sensitivity Verification....658

Copyright 2026, James M. Atkinson

2.9 Quantitative Model for Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal....659
2.10 Hypothetical Applied Calculation: Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal....661
2.11 Hypothetical Case Adjudication: Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal....662
2.12 Measuring-Receiver Scope and System Noise Floor....663
2.13 Worked Example 2A.1. Thermal Noise-Floor Screening....664
2.14 Model 2B: a matched, fixed-state noise cascade....665
2.15 Derive passive loss from thermal equilibrium....670
2.16 Invert the same model with two source temperatures....672
2.17 Turn the cascade into bounded design requirements....675
2.18 Application 2B.1: assemble a four-stage noise budget....677
2.19 Application 2B.2: move an amplifier across a cable....679
2.20 Application 2B.3: distinguish loss from temperature....680
2.21 Application 2B.4: change the source environment....681
2.22 Application 2B.5: solve for the gain that is useful....682
2.23 Application 2B.6: allocate loss to a preselector....683
2.24 Application 2B.7: place attenuation before the vulnerable stage....684
2.25 Application 2B.8: recover noise temperature from two powers....685
2.26 Application 2B.9: expose a change hidden by a ratio....686
2.27 Application 2B.10: propagate the local calibration uncertainty....687
2.28 From a calculated temperature to a defended result....689
2.29 Noise-colour models, covariance and decision performance beyond a scalar noise figure.690
2.30 Advanced technical expansion. Coloured-noise covariance and operational detection limits 693

Copyright 2026, James M. Atkinson

2.31 Noise-floor specification for a 1 Hz reference and a 30 Hz analysis bandwidth.....696

Chapter 2 Assessments.....699

Chapter 2 Answer Keys and Guidance.....1208

Chapter 3. RF Front Ends, Preselection, Gain Distribution, and Input Protection.....1247

3.1 Front-End Purpose and Architecture.....1248

3.2 Find the first stage that can lose validity.....1249

3.3 Preselection and Filter State.....1251

3.4 Use preselection as a measured transfer function.....1253

3.5 Gain Distribution and Attenuation.....1256

3.6 Choose gain from a feasible interval.....1257

3.7 Input Protection and Recovery.....1260

3.8 Measure protection in the small-signal and recovery states.....1261

3.9 Front-End Characterization and Field Decisions.....1265

3.10 An acceptance sequence that separates competing failures.....1266

3.11 Verification and Maintenance Controls.....1268

3.12 Quantitative Model for RF Front Ends, Preselection, Gain Distribution, and Input Protection 1269

3.13 Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection.....1271

3.14 Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.....1272

3.15 Additional analytical treatment: the input plane as a coupled nonlinear system.....1273

3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings.....1276

3.17 Noise, mismatch and gain-order dependencies.....1279

3.18 Protective switching, recovery and transient exclusion intervals.....1281

3.19 Ten worked front-end engineering examples, with stated assumptions.....1283

Copyright 2026, James M. Atkinson

3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget....1284
3.19.2 Example 3.C2. Converting two blockers to a single equivalent power....1285
3.19.3 Example 3.C3. Why filter placement changes intermodulation validity....1286
3.19.4 Example 3.C4. Input attenuation as an overload intervention....1287
3.19.5 Example 3.C5. Passive filter loss and the first-stage noise factor....1288
3.19.6 Example 3.C6. Comparing attenuation ahead of and after an amplifier....1289
3.19.7 Example 3.C7. A conservative frequency-dependent correction....1290
3.19.8 Example 3.C8. Recovery time after a protective intervention....1291
3.19.9 Example 3.C9. A mismatch screening calculation....1292
3.19.10 Example 3.C10. Selecting a feasible gain interval....1293
3.20 Laboratory decision protocol and defensible reporting....1294
3.21 Multitone loading, receiver-generated emissions and the distinction between power and voltage stress....1296
3.22 Front-end noise spectroscopy as an instrument-state test....1299
3.23 Switching architectures and state-machine validity....1302
3.24 Low-level event survival under analogue filtering....1305
3.25 Power-sensitive failure modes and fault isolation....1307
3.26 A graded laboratory qualification matrix....1309
3.27 Evidence interpretation when the reference chain fails....1311
3.28 Impedance-aware transfer functions, scattering parameters and network uncertainty....1313
3.29 Thermal modelling and the time scales of front-end stability....1316
3.30 Calibration-fixture integrity and traceability of source amplitude....1319
3.31 Intermodulation maps and the topology of false spectral components....1322
3.32 Statistical validity of gain-state comparisons....1325
3.33 Extended controlled case studies for complex receiving environments....1327
3.33.1 Case study 3.D1. Intermittent high-power illumination and a false absence claim....1328

Copyright 2026, James M. Atkinson

3.33.2 Case study 3.D2. A two-tone product that coincides with a suspected frequency....1330

3.33.3 Case study 3.D3. The misleading improvement from additional preamplifier gain. 1332

3.33.4 Case study 3.D4. Frequency-edge losses hidden by a centre-band calibration.....1334

3.33.5 Case study 3.D5. A gain-control transition that resembles transmitter fading.....1336

3.33.6 Case study 3.D6. A cable movement that changes the apparent noise floor.....1338

3.33.7 Case study 3.D7. Protection recovery confused with absence of radio activity.....1340

3.33.8 Case study 3.D8. Temperature-dependent drift and the risk of overcorrection.....1342

3.33.9 Case study 3.D9. Weak-event detection after a digital-filter change.....1344

3.33.10 Case study 3.D10. A bounded negative survey statement and its necessary controls 1346

3.34 Synthesis: what the completed front-end record can establish.....1348

3.35 Metrological qualification of system-level front-end conclusions.....1349

3.36 Release-gate checklist for a qualified receiver input chain.....1352

3.37 A research agenda for independent replication.....1355

3.38 Independent challenge of recovered input-referred amplitude.....1357

3.39 Uncertainty-aware interpretation of instrument agreement.....1359

3.40 Closing doctrine on magnitude, event time and source attribution.....1361

3.41 Blocker-dependent front-end state machines and hidden recovery intervals.....1363

3.42 Advanced technical expansion. Multitone stress and the limits of protective front-end linearity.....1366

Chapter 3 Assessments.....1370

Chapter 3 Answer Keys and Guidance.....1874

Chapter 4. Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses.....1922

4.1 Frequency Conversion as Multiplication.....1923

4.2 Model 4A: a declared conversion map.....1924

4.25 Additional study: switching mixers as periodically time-varying multiport networks.....1964

4.26 Experimental protocol: comparing passive and active conversion.....1969

4.27 Advanced technical expansion. Harmonic-mixing lattices and an inverse interpretation of observed spurs.....1972

Chapter 4 Assessments.....1976

Chapter 4 Answer Keys and Guidance.....2463

Chapter 5. Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors 2512

5.1 Intermediate Frequency as a Controlled Band.....2513

5.2 Filter Shape, Selectivity, and Time Response.....2514

5.3 Choose an IF path for the quantity being measured.....2518

5.4 Model 5A: an identified one-pole gain-control response.....2519

5.5 Worked applications with hypothetical inputs.....2525

5.6 Application 5A.1: Read a voltage step and its 95 percent settling time.....2526

5.7 Application 5A.2: Set a gain-error settling requirement.....2527

5.8 Application 5A.3: Convert a control state into an output level.....2528

5.9 Application 5A.4: Check the required control polarity after a level step.....2529

5.10 Application 5A.5: Identify a time constant from two signed residuals.....2530

5.11 Application 5A.6: Carry state across two target intervals.....2531

5.12 Application 5A.7: Use separately identified attack and release constants.....2532

5.13 Application 5A.8: Compare burst duration with control settling.....2533

5.14 Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation 2534

5.15 Application 5A.10: Propagate an initial-state interval.....2535

5.16 Automatic Gain Control and Hidden State.....2536

5.17 Logarithmic Amplifiers, Detectors, and Scaling.....2538

Copyright 2026, James M. Atkinson

5.18 IF Alignment, Calibration, and Failure Localization....2540
5.19 Verify the detector and control path as part of the IF result....2541
5.20 IF Acceptance and Regression Tests....2543
5.21 Quantitative Model for Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors....2544
5.22 Hypothetical Applied Calculation: Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors....2546
5.23 Hypothetical Case Adjudication: Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors....2547
5.24 Intermediate-frequency detector memory, settling and comparable measurement statistics....2548
5.25 Detector dynamics and intermediate-frequency filters as temporally extended measurement operators....2550
5.26 Additional study: IF filters as dynamical systems and the meaning of transient measurement validity....2554
5.27 Calibration and negative-survey validity for dynamic IF paths....2559
5.28 Advanced technical expansion. Filter memory, log detection and hidden IF-state changes....2562
Chapter 5 Assessments....2566
Chapter 5 Answer Keys and Guidance....3059
Chapter 6. Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals....3106
6.1 Carrier, Sidebands, and Modulation Evidence....3107
6.2 Amplitude Modulation and Envelope Detection....3108
6.3 Single Sideband and Coherent Reception....3110
6.4 Model 6A: preserve the complex envelope....3112
6.5 Worked applications with hypothetical inputs....3117
6.6 Application 6A.1: Close the power accounting for sinusoidal AM....3118

Copyright 2026, James M. Atkinson

6.7 Application 6A.2: Infer the conventional-AM envelope parameters....3119

6.8 Application 6A.3: Infer modulation depth from one resolved sideband....3120

6.9 Application 6A.4: Show why an envelope-extrema estimate fails after reversal....3121

6.10 Application 6A.5: Measure phase-dependent coherent-AM recovery....3122

6.11 Application 6A.6: Resolve the two tones caused by a DSB-SC tuning error....3123

6.12 Application 6A.7: Retain SSB sign when the reinsertion frequency is wrong....3124

6.13 Application 6A.8: Compare average power with peak envelope power for two SSB tones 3125

6.14 Application 6A.9: Separate sideband filtering from source modulation depth....3126

6.15 Application 6A.10: Use message mean square rather than a sinusoidal shortcut....3127

6.16 Frequency and Phase Modulation....3128

6.17 Model 6B: phase is the quantity that frequency differentiates....3131

6.18 Worked applications with hypothetical inputs....3136

6.19 Application 6B.1: Convert a sinusoidal FM deviation into phase excursion....3137

6.20 Application 6B.2: Differentiate a sinusoidal PM phase....3138

6.21 Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation....3139

6.22 Application 6B.4: Bound and attain the deviation of a two-tone phase....3140

6.23 Application 6B.5: Integrate a linear frequency ramp without losing phase turns....3141

6.24 Application 6B.6: Expose the ambiguity of sampled phase increments....3142

6.25 Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value....3143

6.26 Application 6B.8: Bound a small-phase approximation before using it....3144

6.27 Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response....3145

6.28 Application 6B.10: Separate reference offset from a deterministic modulation....3146

6.29 Pulse, Radar, and Transient Reception....3147

Copyright 2026, James M. Atkinson

6.30 Preserve pulse and demodulator evidence across representations....3150

6.31 Analog Demodulator Verification....3152

6.32 Quantitative Model for Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals 3153

6.33 Hypothetical Applied Calculation: Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals....3155

6.34 Hypothetical Case Adjudication: Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals....3156

6.35 Analogue demodulation as a source of systematic rather than merely random impairment 3157

6.36 Advanced technical expansion. Complex envelopes, demodulation pathology and transient fidelity....3159

6.37 Analogue demodulation as a chain of estimators rather than a faithful copy of the transmitter....3162

6.38 Amplitude modulation beyond the textbook envelope formula....3164

6.39 Coherent AM, suppressed carriers and single-sideband ambiguity....3166

6.40 Frequency modulation, phase modulation and the dangers of differentiation....3168

6.41 Multipath, fading, capture and the physical limits of an apparently clean audio output...3170

6.42 Pulse shape and analogue information that filters irreversibly discard....3172

6.43 Ten numerical worked examples under declared simplified models....3174

6.44 Laboratory qualification of an analogue-demodulation measurement claim....3177

6.45 Pulse modulation as a measurable time-frequency process and not merely on-off keying 3178

6.46 Ten worked examples for pulse characterisation, ambiguity and false temporal precision 3183

Chapter 6 Assessments....3187

Chapter 6 Answer Keys and Guidance....3686

Chapter 7. Digital Modulation Reception, Synchronization, EVM, and Error Metrics.....3735

7.1 Constellations and Symbol Representation.....3736

7.2 Carrier and Timing Synchronization.....3737

7.3 Matched Filtering, Pulse Shaping, and Channel Effects.....3741

7.4 Define the symbol experiment before fitting the constellation.....3742

7.5 Model 7A: a finite, declared EVM comparison.....3744

7.6 Worked applications with hypothetical inputs.....3751

7.7 Application 7A.1: Show which error a fitted gain removes.....3752

7.8 Application 7A.2: Quantify a fixed phase error.....3753

7.9 Application 7A.3: Preserve a DC impairment when fitting only complex gain.....3754

7.10 Application 7A.4: Expose a conjugate-image impairment.....3755

7.11 Application 7A.5: Compare RMS and constellation-maximum normalization.....3756

7.12 Application 7A.6: Make selection and weighting visible.....3757

7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols.....3758

7.14 Application 7A.8: Keep a residual frequency rotation in a finite symbol record.....3759

7.15 Application 7A.9: Separate constellation rotation from validated symbol mapping.....3760

7.16 Application 7A.10: Audit a complete finite residual vector.....3761

7.17 Error Vector Magnitude and Quality Metrics.....3762

7.18 Defensive Interpretation of Digital Signals.....3763

7.19 Turn a quality metric into a reproducible acceptance record.....3764

7.20 Metric Validation and Held-Out Data.....3766

7.21 Quantitative Model for Digital Modulation Reception, Synchronization, EVM, and Error Metrics.....3767

7.22 Model 7B: finite rate accounting for symbols, coding and payload.....3768

7.22.1 Application 7B.1. Reconcile coded bits, information bits and modulation symbols. 3776

Copyright 2026, James M. Atkinson

7.22.2 Application 7B.2. Separate two overhead populations without counting either twice 3778
7.22.3 Application 7B.3. Count disjoint pilot and nonpayload slots explicitly....3780
7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval....3782
7.22.5 Application 7B.5. Weight changing modes by their actual durations....3783
7.22.6 Application 7B.6. Remove duplicate payload before reporting unique throughput 3785
7.22.7 Application 7B.7. Retain integer frames and last-frame padding....3787
7.22.8 Application 7B.8. Test a positive target against the declared rate limit....3789
7.22.9 Application 7B.9. Propagate a positive timing enclosure through an exact count...3790
7.22.10 Application 7B.10. Preserve discrete coding alternatives rather than inventing a single payload rate....3791
7.23 Hypothetical Applied Calculation: Digital Modulation Reception, Synchronization, EVM, and Error Metrics....3793
7.24 Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics....3794
7.25 Digital-demodulation validation by error covariance and synchronisation-state segmentation 3795
7.26 Advanced technical expansion. EVM as an imperfect inverse problem....3798
7.27 I/Q-derived modulation identity: distinguish discriminating features from unique source attribution....3801
Chapter 7 Assessments....3804
Chapter 7 Answer Keys and Guidance....4308
Chapter 8. Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity 4359
8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method....4360
8.1.1 Learning outcomes, measurement purpose, and the nature of a spectrum....4361
8.1.2 Front-panel controls, connections, and the signal path....4365

Copyright 2026, James M. Atkinson

8.1.3 Frequency coordinates, span, and horizontal resolution....4369

8.1.4 Amplitude scale, reference level, input attenuation, and overload....4373

8.1.5 Resolution bandwidth, selectivity, and noise measurement....4377

8.1.6 Video bandwidth, smoothing, and averaging....4381

8.1.7 Sweep time, dwell, triggering, and temporal coverage....4385

8.1.8 Detector modes, trace functions, and truthful displays....4389

8.1.9 Markers, delta measurements, and amplitude corrections....4393

8.1.10 Calibration, traceability, reference planes, and daily verification....4397

8.1.11 Ten worked examples: elementary calculations and their limitations....4401

8.1.12 Supervised laboratory exercises and acceptance criteria....4408

8.1.13 Swept Architecture and Frequency-Time Mapping....4416

8.2 Resolution Bandwidth and Selectivity....4422

8.3 Video Bandwidth, Averaging, and Detector Choice....4426

8.4 Noise averages, detector statistics, and the meaning of a decibel trace....4429

8.4.1 A stated statistical model....4431

8.4.2 Power averaging before the logarithm....4434

8.4.3 Ten worked applications....4437

8.4.4 Measurement consequence....4440

8.5 Sweep Time, Triggering, and Transient Signals....4441

8.6 Interpret a swept trace through its frequency-time trajectory....4442

8.7 Choose bandwidth from the quantity being estimated....4444

8.8 Validate transient and gated measurements with the intended waveform....4446

8.9 Amplitude Accuracy and Analyzer Self-Tests....4448

8.10 Sweep Method Acceptance....4449

8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity....4450

Copyright 2026, James M. Atkinson

8.12 Hypothetical Applied Calculation: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity....4452
8.13 Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity....4453
8.14 Sweep-time adequacy as a dynamic measurement rather than a display preference....4454
8.15 Swept-spectrum observation as a sampling-design and probability problem....4456
8.16 Additional study: swept observation as a space-time sampling experiment....4461
8.17 Distinguishing a spectral estimator from a persuasive-looking display....4466
8.18 Advanced technical expansion. Swept observation as a sampling problem in time and frequency....4470
8.19 Swept analysis as a moving, state-dependent measurement aperture....4473
8.20 Resolution, equivalent noise bandwidth and distortion of transient waveforms....4475
8.21 Detector laws, video filtering and the asymmetry of logarithmic statistics....4477
8.22 Periodic sweeps and the probability of observing a rare event....4479
8.23 False alarms, maximum hold and selected displays....4481
8.24 Ten worked calculations and controlled counterexamples....4482
8.25 A robust acceptance test for transient and stationary measurements....4485
8.26 Why a swept analyser cannot certify continuous capture of an unknown wideband pulse 4487
8.27 Quantitative worked contrasts: sweep coverage, channelised capture and resolution claims 4490
Chapter 8 Assessments....4493
Chapter 8 Answer Keys and Guidance....4994
Chapter 9. FFT Analyzers, Windowing, Averaging, and Spectral Estimation....5024
9.1 Discrete Records and Spectral Estimates....5025
9.2 Spectral Leakage and Window Selection....5027

Copyright 2026, James M. Atkinson

9.3 Windowed DFT normalization: line amplitude, noise density, and finite-record energy.....5028

9.3.1 Define the record before interpreting the display.....5029

9.3.2 Noise density uses a different denominator.....5033

9.3.3 Energy closure and its limits.....5036

9.3.4 Ten worked applications of the normalization model.....5039

9.3.5 Measurement consequence.....5050

9.4 Averaging and Statistical Stability.....5052

9.5 Cross-Spectra, Coherence, and Multichannel Analysis.....5053

9.5.1 Define the ensemble before normalizing.....5055

9.5.2 The projection interpretation and its boundary.....5058

9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization.....5060

9.6 Time-Frequency and Nonstationary Methods.....5071

9.7 Estimator Validation and Reporting.....5072

9.8 Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.....5073

9.9 Hypothetical Applied Calculation: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.....5075

9.10 Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.....5076

9.11 Multitaper spectra, estimator covariance and uncertainty under intermittent observation 5077

9.12 Spectral confidence intervals and why averaging is not the same as independence.....5081

9.13 Advanced technical expansion. Spectral-estimator confidence beyond a clean FFT display 5084

9.14 Thirty-hertz spectral resolution is a measurement design, not a guarantee of pulse detection 5087

9.15 Numerical reality checks for resolution, noise density and detection.....5090

Copyright 2026, James M. Atkinson

9.16 Long-duration multiresolution spectrum retention and the limits of thirty-hertz FFT bins 5091
9.17 The spectral measurand: differentiating a line, a density, a band power, and a probability of observation..... 5094
9.18 Window families as measurement decisions rather than decorative software choices..... 5098
9.19 FFT frequency resolution, physical time, and the illusion of finer displays..... 5102
9.20 Welch averaging, overlapping records, and statistical dependence..... 5105
9.21 Multitaper spectra, bias, variance, and the meaning of several views of one record..... 5108
9.22 Transient-spectrum analysis, time gating, and the interpretation of spectrograms..... 5111
9.23 Real-time spectrum analysis, overlapping FFT engines, and probability of intercept..... 5114
9.24 Spectral confidence intervals, model adequacy, and the danger of a single smooth curve 5118
9.25 Cross-spectral analysis, coherence, and causal restraint in multichannel measurements 5121
9.26 Phase noise, close-in skirts, and the limits of interpreting narrow spectral features..... 5124
9.27 Noise-floor measurement, gain distribution, and the difference between a displayed floor and an environmental floor..... 5127
9.28 Multiple comparisons, threshold design, and weak-line detection in a searched spectrum 5131
9.29 Parametric spectral estimation: when a model buys apparent resolution..... 5134
9.30 Sinusoids in noise, model order and the limits of super-resolution..... 5137
9.31 Filter-bank analysis, Capon spectra and aperture-dependent selectivity..... 5139
9.32 Frequency stability, oscillator noise and the distinction between drift and random phase 5141
9.33 Spurious-response searches, hybrid sweep-and-FFT acquisition, and search-time economics 5143
9.34 Pulsed RF, gating, coherent repetition and missing transient evidence..... 5146
9.35 EMI receivers, quasi-peak detection, time-domain scan and measurement compliance.. 5148

Chapter 11. Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization 6359

11.1 Dynamic Range Is a Family of Conditions.....6360

11.2 Compression and Gain Change.....6363

11.3 Measure compression without confusing it with control action.....6365

11.4 Intermodulation and Intercept Metrics.....6366

11.5 Model 11A for cubic intermodulation and intercept metrics.....6367

11.6 Fix the voltage convention and operating domain.....6368

11.7 Derive the retained spectral amplitudes.....6370

11.8 Construct the intercept from the linear asymptote.....6373

11.9 Ten worked applications of Model 11A.....6376

11.10 Application 11A.1 Locate the products before measuring their powers.....6377

11.11 Application 11A.2 Evaluate the cubic amplitudes and extraction bias.....6378

11.12 Application 11A.3 Resolve unequal parent amplitudes.....6379

11.13 Application 11A.4 Keep each tone separate in the intercept calculation.....6380

11.14 Application 11A.5 Recover a coefficient without confusing voltage and power gain.....6381

11.15 Application 11A.6 Test the slope over a declared power interval.....6382

11.16 Application 11A.7 Compare attenuation before and after the nonlinear stage.....6383

11.17 Application 11A.8 Separate formal compression from the working domain.....6385

11.18 Application 11A.9 Propagate calibration bounds with their dependencies.....6386

11.19 Application 11A.10 Bound a coherent contaminating product.....6388

11.20 Carry the conditions into receiver interpretation.....6390

11.21 Blocking and Reciprocal Mixing.....6391

11.22 Model 11B for reciprocal mixing and admitted noise.....6393

11.23 Define the phase spectrum before converting decibels.....6394

11.24 Translate one blocker through the fluctuating oscillator.....6396

Source Editions and Access Scope, Checked November 1, 2026

IEC CISPR 16-1-1:2019, edition 5.0, published May 22, 2019. The official public scope identifies radio-disturbance measuring apparatus from 9 kHz to 18 GHz, including EMI receivers and spectrum analyzers. This scope check is not a reading of the complete standard or a compliance claim. https://webstore.iec.ch/en/publication/60774.

IEEE 1241-2023, IEEE Standard for Terminology and Test Methods for Analog-to-Digital Converters, published October 6, 2023. The official record lists this published edition as active. Only public status and scope were checked; instrument compliance requires the controlling standard and applicable test evidence. https://standards.ieee.org/ieee/1241/6797/.

IEEE 1057-2017, IEEE Standard for Digitizing Waveform Recorders, published January 26, 2018. The official record lists this edition as active. The active revision project is not a published replacement. Only public status and scope were checked. https://standards.ieee.org/ieee/1057/5945/.

Kast, Manurkar, Remley, Williams, and Horansky, “System-Level Calibration of a Millimeter-Wave Vector Signal Analyzer with Uncertainties,” IEEE Transactions on Microwave Theory and Techniques 73, no. 11 (November 2025): 9085–95. The NIST-hosted manuscript’s method and results text on pages 1–9 was read for the published calibration example in Chapter 14. Full citation and read scope appear in the footnote and bibliography. https://doi.org/10.1109/TMTT.2025.3597240.

Chapter 1. Receiver-System Boundaries, Mission Authority, and Evidence Formation

Copyright 2026, James M. Atkinson

1.1 Receiver as a Measurement System

A receiver should be modeled as a sequence of physical and computational transformations rather than as a frequency display. Energy enters through an antenna or conducted port, encounters protection and preselection, is amplified or attenuated, translated in frequency, filtered, detected or digitized, and finally represented by software. Each boundary has a reference impedance, bandwidth, gain, linearity limit, noise contribution, timing state, and configuration identity. A finding is only as defensible as the least controlled transformation in that chain. When the selected input, preamplifier state, local oscillator, detector, sample rate, or analysis window is unknown, a numerical readout can be precise while the measurand remains undefined.[1]

The system boundary extends beyond the instrument enclosure. Antenna pattern and polarization, cable loss, adapters, external filters, bias tees, splitters, limiters, attenuators, remote digitizers, computers, drivers, and scripts can change what is observed. Even passive components can introduce mismatch, common-mode current, temperature drift, or nonlinear contact behavior. The receiver log therefore identifies every component between the environment and the stored result, including the physical location to which amplitude and phase are referred. This chain record

1 United States Navy, Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles, NAVEDTRA 14189 (September 1998), 2-10–2-14, reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388–8392; title and edition at page 8345. These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

Copyright 2026, James M. Atkinson

permits a later reviewer to distinguish an environmental signal from an effect created by the measurement system.

Copyright 2026, James M. Atkinson

1.2 Mission Authority and Collection Boundaries

Technical authority defines what may be energized, disconnected, recorded, demodulated, retained, and disclosed. A lawful spectrum survey may authorize measurement of occupancy and technical characteristics while prohibiting recovery of communications content. Another engagement may permit controlled laboratory analysis of a seized device but not continuous monitoring of unrelated emitters. The receiver plan converts those legal and institutional limits into frequency ranges, locations, times, detector modes, recording policies, minimization rules, and stop conditions. This is an engineering control because acquisition settings determine what information is captured.

Minimization begins before collection. The practitioner selects only the bandwidth, duration, channels, and metadata needed to answer the defensive question, and separates incidental content from technical evidence. Triggered recording, masked bands, reduced audio output, cryptographic access control, retention limits, and documented deletion can all reduce unnecessary acquisition. A capable receiver does not justify the broadest available configuration. The record states the authorized objective, the data actually collected, deviations, and who approved any extension.

Figure 1. Receiver-system evidentiary boundaries.

Copyright 2026, James M. Atkinson

1.3 Observation, Classification, Attribution, and Content Recovery

Receiver evidence supports several different propositions, and they must not be collapsed. Detection establishes that energy or a structured component exceeded a stated decision rule. Classification associates the component with a waveform family, modulation, timing behavior, or service type. Attribution links it to a physical emitter or system through direction, timing, identifiers, controlled state changes, or other evidence. Content recovery reconstructs information carried by the signal. Each successive proposition demands additional controls and can fail even when the preceding proposition is sound.

A narrow peak may be real but unmodulated, or it may be a local oscillator leak, analyzer spur, clock harmonic, or intermodulation product. A decoded network name may identify a configuration string without proving the device location or owner. A waveform that correlates with activity may show state dependence without revealing intelligible content. Reports should therefore use verbs such as detected, classified, correlated, localized, attributed, or recovered according to the evidence actually obtained. This language prevents a receiver display from becoming an unsupported narrative.

1.4 Reference Planes and Configuration Identity

Cross-volume technical interface. S001-V010(Survey Antennas Probes Fixtures and Direction Finding Apparatus) develops the geometrical and probe-specific provenance of the antenna-side reference plane;S001-V020(Field Operations Evidence Handling Chain of Custody and Litigation Support) treats the continuity of custody after the instrument record is created. In the present volume, the measured quantity must nevertheless be defined at a named reference plane, with cable loss, gain state, mismatch, and software correction explicitly attached to the observation before any attribution is attempted.

Reference planes are declared at the antenna terminals, cable ends, preamplifier input and output, receiver input, digitizer, and software output whenever corrections cross those points. A reading at the display is not automatically the field strength at the antenna or the power at the source. Converting among those quantities requires antenna factor or effective aperture, cable and adapter loss, mismatch, gain state, detector response, and geometry. If one element changes, the prior calibration may no longer apply.

Configuration identity includes hardware serial numbers, option keys, firmware, driver, software build, calibration data, preselector state, attenuation, gain, detector, sweep or sample parameters, reference source, and clock arrangement. Automatic modes are documented because they can silently alter these settings. Screenshots are useful illustrations, but native trace files and setup exports are stronger evidence. The examiner

Copyright 2026, James M. Atkinson

preserves enough information to reproduce the observation on a verified system.

Copyright 2026, James M. Atkinson

Example: reference-plane correction

$$P_{ant} = P_{rx} + L_{cable} + L_{filter} - G_{LNA}$$

$$-103 + 2 + 1 - 20 = -120 \text{ dBm}$$

TECHNICAL INTERPRETATION

The indicated receiver power is not automatically antenna-terminal power.
Every gain, loss and calibration correction must state its reference plane.

Figure 3. Receiver measurement reference planes.

Copyright 2026, James M. Atkinson

1.5 Define the measurement before choosing the receiver mode

Begin a receiver investigation by writing the quantity or proposition that the observation is intended to resolve. Received power in a stated bandwidth, a carrier frequency, a modulation characteristic, an event time, and the presence of an authorized device are different targets. Each requires a different chain of transformations and a different supporting record. A wide scan may discover an unexpected component without supplying the amplitude calibration needed to quantify it. A narrow coherent capture may measure phase accurately while providing little information about emissions outside its instantaneous passband.

Translate that target into a reference plane, frequency interval, time interval, receiver state, estimator, and decision criterion. The reference plane fixes where power, voltage, or phase is defined. The frequency and time intervals identify which signal energy and events can contribute. The state fixes the gains, filters, clocks, and adaptive functions. The estimator defines the mathematical operation that turns retained data into a number. The decision criterion explains how the number will be used and which uncertainty or validity conditions must be met before it can support that use.

This discipline prevents a display label from carrying more meaning than its calibration supports. A power marker may describe a detector bucket, an integrated channel, or a fitted tone. A frequency marker may be an FFT-bin label, an interpolated estimate, or a swept local-oscillator setting. A timestamp may identify a sample aperture, a trigger comparator, or

Copyright 2026, James M. Atkinson

software receipt. The chapters that follow develop these distinctions individually; the system record must keep them connected so a correction applied at one stage does not silently redefine another.

Copyright 2026, James M. Atkinson

1.6 Treat configuration changes as changes in the measurement law

Equation 1 represents the configured transformation of the input into the recorded output. Its operator can include memory, frequency conversion, sampling, nonlinear limits, and adaptive control. It is therefore a system description, not a promise that every receiver obeys one linear time-invariant law. A local linear model becomes useful only after its operating state and range are declared. Model 2B, for example, assumes specified scalar gain and noise relations in the selected equivalent channel; Model 4A fixes a conversion convention; Model 5A identifies a bounded dynamic control response.

An automatic gain change can alter amplitude calibration, overload margin, recovery time, and the validity of a previously measured noise floor at once. A sample-rate change can alter alias locations, digital filter responses, sample timing, and recording throughput. A preselector change can improve blocker rejection while adding loss and phase delay. Record the transition and retain separate state intervals. Combining them into one average is justified only when the intended estimator and calibration explicitly account for the different transformations.

Copyright 2026, James M. Atkinson

Recommendation: encode gain, attenuation, overload, clock-lock and calibration changes in the evidence log.

Figure 4. Receiver state transitions.

A useful configuration identity is sufficiently detailed to distinguish states that would produce different answers to the question. It need not reproduce irrelevant menu settings, but it must include concealed automatic behavior when that behavior changes the measurand. Exported setups, machine-

Copyright 2026, James M. Atkinson

readable logs, and operator notes complement each other. The setup records the requested configuration, the status log records the accepted or actual state where available, and the observation record shows what was captured. A disagreement among them is a measurement issue to resolve before averaging away its effects.

Copyright 2026, James M. Atkinson

1.7 Keep the evidence chain reversible to its declared inputs

Preserve native samples or traces before applying corrections that discard information. A scalar path correction can be reversible when its value and state are known. Clipping, magnitude detection, decimation without adequate rejection, and loss of samples generally remove information that cannot be restored by a later offset. A derived spectrum can still be useful, but its limits should be tied to the actual retained representation. Chapter 9 distinguishes spectral estimators, Chapter 10 follows sample-domain transformations, and Chapter 15 binds those transformations to recording continuity and metadata.

Calibration also has a direction. A level referred to the receiver connector is not automatically the level at an antenna terminal, and neither is automatically field strength at a location. Chapter 13 treats the passive and protective path, while Chapter 14 defines the correction and uncertainty model. Keep the original indication, each correction, the applicable reference plane, and the result. That record exposes whether a loss was counted twice, a gain belonged to another state, or a correction crossed a boundary that was never calibrated.

Separate evidence from the model used to interpret it. A measured pair of tone levels is evidence; a cubic law explaining their intermodulation is a bounded model. A phase-noise curve is evidence under its stated normalization; a reciprocal-mixing prediction requires blocker power, conversion gain, weighting, and cross-power conditions. A list of usable acquisition intervals is evidence; a capture probability requires an event-start distribution and a capture criterion. The distinction is productive

Copyright 2026, James M. Atkinson

because it tells the reviewer which additional observation could challenge the interpretation.

Table 1A. Route the measurement question to the developed model

Question at the system boundary	Developed treatment	Condition that must travel with the result
How much desired signal and noise reach the selected channel?	Model 2B and Chapters 3, 13 and 14	Reference planes, gains, temperatures, bandwidth and calibration state
Which RF component becomes the observed IF or complex frequency?	Model 4A and Chapter 10	Signed conversion, image rejection, filtering and sample-clock convention
How does control or demodulation alter the observation?	Models 5A, 6A, 6B and 7A	Valid dynamics, phase alignment, normalization and held-out checks
Can a weak event survive strong signals and timing limits?	Models 11A, 11B, 12A, 12B and 15A	Working range, blocker state, covariance, usable windows and event criterion

1.8 Evidence Record and Closing Verification

A complete receiver record includes time basis, location, antenna and polarization, orientation, height, cable route, reference-plane corrections, environmental conditions, instrument configuration, overload indicators, raw or native data, analysis steps, and operator notes. Synchronization sources and clock uncertainty are recorded when several channels or sensors are compared. The record also identifies any omitted bands, blanked transmitters, failed captures, or inaccessible settings. Negative and unsuccessful tests are retained because they constrain competing explanations.

Closing verification challenges the measurement chain after the important observation. A known source or injected reference tests the functions actually traversed or exercised, in the state and at the time of the check. Functions bypassed by the injection path require complementary checks. A successful closing check alone does not establish uninterrupted validity throughout the preceding acquisition. Alternate attenuation or preselection can challenge receiver linearity within the tested conditions. A second receiver, different antenna, moved location, or changed reference clock alters the error structure. Agreement is persuasive only when the tests are sufficiently independent. The closing record states what was verified, what remained untested, and whether the observation survived the challenge.

Copyright 2026, James M. Atkinson

1.9 Operational Decision Discipline

Receiver operations are planned around decision points rather than around the available instrument menus. The operator identifies which observation would support continued search, which result would require a configuration challenge, and which condition would terminate collection or trigger specialist escalation. This prevents indefinite accumulation of traces without a defensible analytical purpose. Decision points include receiver overload, inability to reproduce a result, loss of clock lock, unauthorized content exposure, unverified calibration, and evidence that the measurement system has altered the environment.

The chapter's methods are released to field use only through a controlled survey plan, trained operators, known reference sources, and a record system capable of preserving configuration and native data. Lessons learned from one instrument or site are treated as hypotheses for future validation, not universal rules. The practitioner distinguishes procedure from judgment and records deviations so that subsequent reviewers can determine whether the technical conclusion remains valid.

1.10 Quantitative Model for Receiver-System Boundaries, Mission Authority, and Evidence Formation

Equation 1. Configured receiver-chain representation

$$y(t) = H\left(x(t)\right) + n_{\text{int}}(t)$$

The recorded output $y(t)$ is represented as the configured receiver transformation H acting on input $x(t)$, plus internally generated noise and artifacts $n_{\text{int}}(t)$. H includes analog and digital filtering, gain, frequency translation, detection, sampling, and software processing. The relation is not assumed linear when overload, limiting, quantization, or adaptive control is present.

Equation 1 defines the system boundary; it does not assert a linear, time-invariant receiver. The scalar noise path in Model 2B, frequency conversion in Model 4A, control response in Model 5A, and the digital treatments in Chapter 10 each replace part of this representation with a narrower, testable model.

Equation 2. Corrected input power

$$P_{\text{in,dBm}} = P_{\text{ind,dBm}} + L_{\text{path,dB}} - G_{\text{ext,dB}}$$

Input power at the declared reference plane equals the indicated power plus passive path loss and minus external gain, with all terms using compatible calibration conditions. Mismatch, detector correction, antenna conversion, and uncertainty must be added when applicable.

This backward level correction is the logarithmic form of the scalar transfer used in Model 2B. Chapters 3 and 13 establish the physical path and Chapter 14 works the correction signs and uncertainty. A correction cannot repair overload or restore a component that the selected filter removed.

Copyright 2026, James M. Atkinson

1.11 Model 1A: configured transfer, correction and recoverability

Equations 1 and 2 answer different parts of one measurement question: what transformation produced the retained indication, and which input quantity can be recovered from it? Equation 1 names the complete configured operation. Equation 2 is an inverse for one restricted part of that operation. A calculation can be arithmetically reversible while the acquisition that supplied its inputs is not. The VIM distinguishes a measurement model from the function or algorithm used to obtain its output value. Here that distinction requires a physical domain for the inverse, not merely a formula that accepts numbers.[2]

In Equation 1, time t is measured in seconds. The input x may be a real waveform, a complex representation, or another explicitly identified input record. The output y and the residual contribution at that output must use compatible quantity types and units. The operator H includes any conversion of units or representation; it is not necessarily a dimensionless gain. For sampled data, the sample times and indexing belong to its definition. The internal residual need not be independent of the input or state. No independence, stationary noise law, or unique inverse follows from writing an additive residual at the output.

---

These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

The scalar specialization uses mean powers referred to specified planes and one declared observation band. Let P be the desired input power, S the indicated output power before external software offsets, and N a separately characterized additive output contribution. These physical powers are nonnegative and are all measured in watts. Let a be the positive dimensionless power transfer from the selected input to that output. A gain G and loss L denote numerical values in decibels, so a is ten raised to (G minus L) divided by ten. The power level p is the numerical value expressed in dBm, with one milliwatt as its reference. An exponent or logarithm therefore acts on a dimensionless number.

Equation 2A. Power coordinates and fixed-state transfer

$$P_0 = 1\ \text{mW}\,;\, p(P) = 10\log_{10}\left(\frac{P}{P_0}\right)$$
$$P = P_0 \cdot 10^{\frac{p}{10}}\,;\, a = 10^{\frac{G-L}{10}}$$

For an isolated component in a linear, characterized path, output signal power is input signal power multiplied by a. If a separate contribution has zero mean cross-power with that signal under the stated averaging operation, its mean power can be added as N. This is the bounded power-combination condition used in Model 2B. Coherent components, a changed loading condition or a different detector statistic need their own justified relation. The word noise does not establish zero cross-power by itself.

Equation 2B. The qualified forward law and its inverse

$$S = aP + N\,;\, a > 0\,;\, P \geq 0\,;\, S \geq 0\,;\, N \geq 0$$
$$P = \frac{S-N}{a}\,;\, S - N \geq 0$$
$$p_{\text{in}} = p_{\text{sig,out}} + L - G$$

Copyright 2026, James M. Atkinson

The last expression requires a strictly positive signal-only output, with $p_{\mathrm{sig,out}}$ obtained from S minus N in linear power. Equation 2 follows when the original indication already represents that signal power, or when the added contribution is negligible at the required accuracy. Subtracting two dBm values yields a power ratio in decibels; it does not subtract two physical powers. A negative estimated difference cannot become a negative physical signal power or a finite logarithmic result merely by passing it to software.

The inverse is useful only while its inputs describe the actual observation. Require a supported gain and loss at the relevant frequency, reference planes, loading, state and level; a compatible bandwidth and detector; retained correction conventions; and evidence that limiting or discarded information has not defeated the desired inference. Several differently configured measurements can be combined only after each is referred to the same defined quantity. For nonoverlapping intervals with known durations, the following expression averages their corrected mean powers. It does not average their logarithmic labels.

Equation 2C. Average after each interval has its own valid correction

$$\overline{P}=\sum_{j} w_j \frac{S_j - N_j}{a_j}$$
$$w_j=\frac{\Delta t_j}{\sum_{k} \Delta t_k}$$
$$\sum_{j} w_j=1$$

Copyright 2026, James M. Atkinson

Here j and k index the retained intervals, each duration is in seconds, and the weights are dimensionless and nonnegative. The sum of durations is positive. Each interval must have a valid state and its stated within-interval mean; overlapping records or unequal sampling probabilities require further treatment. The result covers the retained intervals. It covers a wider time span only if omitted intervals are also represented by justified observations or explicit bounds.

Uncertainty in an applicable correction differs from uncertainty about whether the correction applies at all. For the affine level relation, Chapter 14's Model 14B gives the variance from the signed sensitivities and the input covariance matrix. Zero covariance must be stipulated or supported. Deterministic ranges instead give admissible results through the extrema of the same relation. A range is not a standard uncertainty, and a set of possible states is not a probability distribution. NIST's uncertainty guidance requires the measurement function to represent the measurement process and significant influences; a wider numerical interval cannot repair a missing physical premise.[3]

Equation 2D. Bound a positive signal-level correction without inventing a distribution

$$p_{\min} = p_{\mathrm{sig,min}} + L_{\min} - G_{\max}$$
$$p_{\max} = p_{\mathrm{sig,max}} + L_{\max} - G_{\min}$$

---

3 Barry N. Taylor and Chris E. Kuyatt, Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results, NIST Technical Note 1297, 1994 edition (September 1994), Appendix A, A.1–A.5, https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. The functional and covariance framework is used within its stated scope; the synthetic ranges, examples and recoverability conclusions are original.

Copyright 2026, James M. Atkinson

Equation 2D supplies a conservative enclosure when the stated ranges hold jointly. If dependencies exclude a corner combination, the corresponding endpoint may not be attainable. When several separate states remain possible, retain the union of their enclosures rather than silently filling every intervening value or choosing the midpoint. For an additive power contribution, first bound the positive linear-power difference, then transform it. The ten applications below use this same configured-transfer family and concrete failures of its inverse. Their data are synthetic teaching assumptions, not measurements or performance claims about an instrument.

Table 1. Chapter 1 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Authority and minimization	Written objective, frequency scope, content limits, retention, and stop conditions	Defines what the receiver may collect and how the data can be used	Technical capability does not create legal authority
System configuration	Hardware, firmware, options, gain, attenuation, detector, sample or sweep settings	Makes the transformation reproducible	Automatic modes may change state without obvious notice
Reference planes	Antenna, cable, receiver, digitizer, and software correction points	Permits physically meaningful amplitude and phase statements	A display value is not automatically an environmental quantity

1.12 Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation

A receiver indicates -71.4 dBm. A preamplifier provides 18.6 dB measured gain, and the cable and adapters between its output and the receiver input introduce 4.8 dB loss. The corrected power at the preamplifier input is -85.2 dBm before mismatch and uncertainty. If the preamplifier was bypassed during part of the survey, traces from the two states cannot be combined without separate corrections.

Copyright 2026, James M. Atkinson

1.12.1 Application 1A.1. Complete a reference-plane correction in both directions

Complete the preceding −71.4 dBm illustration by declaring its domain. The indication describes one isolated component at the receiver connector. The preamplifier has 18.6 dB power gain and the following cable and adapters have 4.8 dB loss at that component's frequency. Stipulate linear operation, compatible matching and detector conditions, and negligible additive power at the required accuracy. The desired result is power at the preamplifier input, not field strength or transmitter output.

The net forward gain is 13.8 dB, giving a power ratio of 23.988329. Convert the receiver indication using Equation 2A: its power is 72.443596 pW. Dividing by that ratio gives 3.019952 pW at the input. In logarithmic coordinates, $-71.4+4.8-18.6=-85.2\ \mathrm{dBm}$. Predicting forward again gives $-85.2+18.6-4.8=-71.4\ \mathrm{dBm}$. Both directions describe the same named planes and provide an immediate check on the signs.

For a separate illustrative uncertainty budget, assign standard uncertainties of 0.20 dB to the indication, 0.10 dB to the loss and 0.15 dB to the gain, with zero covariance among these three inputs. The sensitivities are plus one, plus one and minus one. Their squared contributions sum to 0.0725 dB squared, so the combined standard uncertainty is 0.269258 dB. No coverage probability follows merely from this standard uncertainty; none is assigned here.

Copyright 2026, James M. Atkinson

The numerical result is conditional on the stated path. An omitted mismatch contribution, an incorrect gain state or compression is not shown to be covered by the three-term budget. A useful released record would retain the original indication, the two component calibrations and their applicability, and the input-plane result. Agreement between the forward and inverse arithmetic checks implementation; it does not independently establish those physical premises.

Copyright 2026, James M. Atkinson

1.12.2 Application 1A.2. Remove a software offset before applying the remaining correction

Use the same physical chain as Application 1A.1, but suppose the export is explicitly documented to include the 4.8 dB cable correction already. Its displayed value is therefore −66.6 dBm, obtained by adding 4.8 dB to the raw −71.4 dBm indication. The export is referred to the preamplifier output under this convention. The remaining task is to move it to the preamplifier input.

Subtract only the 18.6 dB amplifier gain: $-66.6-18.6=-85.2\ \mathrm{dBm}$. Alternatively, recover the raw indication by subtracting the known software offset, then apply the complete original correction: $-66.6-4.8+4.8-18.6=-85.2\ \mathrm{dBm}$. These are two bookkeeping routes through the same relation. Adding the cable loss a second time instead gives −80.4 dBm, an error of plus 4.8 dB and a power overstatement by a factor of 3.019952.

The original 0.269258 dB standard-uncertainty budget still applies if exactly the same three inputs from Application 1A.1 produced the export. Do not add another independent cable uncertainty simply because the same correction appears in both an export and a calculation record. Those occurrences refer to one input, not two independent calibrations. A separate uncertainty would require a separate physical or numerical contribution.

Copyright 2026, James M. Atkinson

If the export's correction state is lost, the problem changes. Under the explicit restricted alternatives that −66.6 dBm is either raw or already corrected for that one loss, the compatible input levels are −80.4 dBm and −85.2 dBm before their uncertainties. The file's numerical precision cannot select between them. Resolve the correction-state evidence or preserve the alternatives; their midpoint would not be a demonstrated calibration result.

Copyright 2026, James M. Atkinson

1.12.3 Application 1A.3. Combine valid gain states without averaging their decibel labels

Two consecutive four-second intervals are fully observed. In interval A, amplifier gain is 20 dB, path loss is 2 dB and the raw mean output level is −62 dBm. In interval B, amplifier gain is zero, the same path loss is 2 dB and the raw mean output level is −92 dBm. The state has settled throughout each interval, and each output value is the logarithm of that interval's mean signal power. Additive output contributions are negligible for this example.

Correct A to $-62+2-20=-80\ \mathrm{dBm}$, or 10 pW. Correct B to $-92+2-0=-90\ \mathrm{dBm}$, or 1 pW. Equal durations give weights of one half. Equation 2C therefore yields 5.5 pW over the combined eight seconds, whose level is −82.596373 dBm. The arithmetic mean of the two corrected dBm values is −85 dBm, 2.403627 dB lower; it represents a different averaging operation.

A second tempting shortcut also fails. Averaging the raw powers first gives −65.005959 dBm, while averaging the two gain values in decibels gives 10 dB. Correcting that aggregate by the average net gain of 8 dB produces −73.005959 dBm. It is not the mean input power because the two output powers were produced by different transfers. The inverse must be attached to each interval before the requested input-plane average is formed.

Copyright 2026, James M. Atkinson

To isolate a shared calibration effect, suppose both corrected input levels may contain the same unknown additive offset between −0.20 dB and +0.20 dB, with all other quantities exact in this constructed bound. The same multiplicative factor then acts on both linear powers, so the combined level has exactly the same ±0.20 dB bound. It does not shrink by taking two intervals. The result covers these eight observed seconds; it does not describe an unrecorded transition or establish a probability of capturing some different event.

Copyright 2026, James M. Atkinson

1.12.4 Application 1A.4. Use an attenuation prediction as a conditional challenge

A controlled comparison inserts an additional attenuator with nominal loss 10.0 dB while the receiver's gain state is held fixed. A known reference changes from −70.0 dBm to −80.2 dBm. Stipulate maximum magnitude errors of 0.10 dB for each reference indication, 0.10 dB for the attenuator's actual loss and 0.10 dB for possible reference-source change between observations. These are deterministic bounds for this comparison, not standard deviations.

An unchanged input under the nominal transfer would give −80.0 dBm after insertion. Define the challenge residual as after-level minus before-level plus inserted loss. The observed reference residual is $-80.2-(-70.0)+10.0=-0.2\ \mathrm{dB}$. The four stated bounds sum to 0.4 dB, so this residual is compatible with the reference comparison's stated enclosure. Compatibility does not prove that every unmodeled influence is absent.

Now a candidate component changes from −71.4 dBm to −78.4 dBm under the same nominal intervention. Its residual is $-78.4-(-71.4)+10.0=+3.0\ \mathrm{dB}$. Under a hypothesis of unchanged candidate input, the two 0.10 dB indication bounds and the 0.10 dB loss bound give only ±0.30 dB for this residual. The observed departure lies outside that enclosure. The complete unchanged-input, fixed-transfer hypothesis cannot account for this pair under those assumptions.

Copyright 2026, James M. Atkinson

The failed prediction does not uniquely locate an internally generated product. A changed candidate input, a consequential connection or loading change, an unrecorded state transition, or a receiver response outside the calibrated domain could break the hypothesis. The reference tests its own input class and conditions. Preserve both comparisons and choose the next intervention to distinguish the remaining explanations. A calibration challenge is strongest when its rejected assumption is stated more precisely than the phrase receiver artifact.

Copyright 2026, James M. Atkinson

1.12.5 Application 1A.5. Retain separate admissible results when the settled state is unknown

An acquisition is known to be settled in one of two calibrated gain states, but the state identifier was lost. The indication is −74.0 dBm with a deterministic ±0.20 dB bound. Path loss lies between 2.9 dB and 3.1 dB. State A has gain between 11.9 dB and 12.1 dB; state B has gain between 17.9 dB and 18.1 dB. These are the only allowed states, and the signal-only scalar relation is stipulated valid in both. The task is to report what the surviving evidence permits.

For A, the nominal correction gives $-74+3-12=-83\ \mathrm{dBm}$. The minimum uses the lowest indication and loss with the highest gain: $-74.2+2.9-12.1=-83.4\ \mathrm{dBm}$. The maximum uses the opposite extrema: $-73.8+3.1-11.9=-82.6\ \mathrm{dBm}$. For B the same calculation gives a nominal −89 dBm and an enclosure from −89.4 dBm to −88.6 dBm.

The supported set is the union of those two intervals. A single outer enclosure from −89.4 dBm to −82.6 dBm is conservative, but it conceals the gap and should be labeled as an enclosure. A midpoint estimate of −86 dBm belongs to neither state's calculated interval. Treating the two states as equally probable would introduce information that the record does not contain.

Copyright 2026, James M. Atkinson

The useful next action is to recover state evidence or make a new qualified observation. It is not to average the gains until one convenient answer appears. If the record had instead allowed continuous gain variation or an unsettled transition, these two intervals would no longer describe all possibilities. The construction distinguishes bounded calibration error within a valid state from missing evidence about which measurement law was active.

Copyright 2026, James M. Atkinson

1.12.6 Application 1A.6. Subtract an additive contribution in linear power before referring it backward

A fixed receiver chain has net power gain 10.0 dB. Its mean output power with a controlled signal present is 2.00 pW, and a compatible signal-off observation gives an additive contribution of 1.50 pW. The observation band, loading, gain and detector are unchanged. Stipulate zero mean cross-power between the signal and added contribution under the defined averaging operation. Turning the controlled signal off changes only that signal in this hypothetical experiment.

Equation 2B gives output signal power of $2.00 - 1.50 = 0.50\ \mathrm{pW}$. The net power ratio is ten, so input signal power is 0.050 pW, or $5.0 \times 10^{-14}\ \mathrm{W}$. Its level is −103.010300 dBm. If the total 2.00 pW output were instead treated as signal-only, subtracting 10 dB from its −86.989700 dBm level would give −96.989700 dBm. The result would overstate the input signal by 6.020600 dB, because the total output is four times the signal-only output.

For a bounded version, let the total output range from 1.98 pW to 2.02 pW, the added contribution from 1.48 pW to 1.52 pW, and the net gain from 9.9 dB to 10.1 dB. The signal-only output is enclosed by 0.46 pW and 0.54 pW. Transforming the lower power with the highest gain and the upper power with the lowest gain gives input-level bounds of −103.472422 dBm and −102.576062 dBm. The positive lower difference makes both logarithms defined.

Copyright 2026, James M. Atkinson

The subtraction is not justified merely by having an antenna-connected reading and a terminated reading. A termination may change the coupling, loading or added contribution itself. Coherence can also invalidate the additive-power law. If the admissible linear difference reaches zero, there is no finite lower dBm bound; if some differences are negative, the supplied estimates and model need reconciliation. Do not conceal that boundary by replacing the result with an arbitrary small positive power.

Copyright 2026, James M. Atkinson

1.12.7 Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse

Use a concrete voltage version of Equation 1 to test recoverability. An ideal memoryless stage multiplies a real input voltage by a dimensionless voltage gain of two, then clips the output at ±0.50 V. The retained samples contain only the clipped voltage and a correct saturation flag. The nominal transfer is $H(x)=\min(0.50\ \mathrm{V},\max(-0.50\ \mathrm{V},2x))$. This is a counterexample to applying a linear inverse beyond its domain, not a device-specific recovery model.

For input samples 0.10 V, 0.30 V, 0.60 V and −0.60 V, the retained outputs are 0.20 V, 0.50 V, 0.50 V and −0.50 V. Dividing by two recovers the first input, but gives 0.25 V, 0.25 V and −0.25 V for the clipped samples. The two different positive inputs have become the same stored value. A positive saturation flag establishes only that the nominal input reached at least 0.25 V; it supplies no finite upper bound without additional information.

Now allow the positive clipping level to lie between 0.49 V and 0.51 V and the voltage gain between 1.98 and 2.02. The possible positive input threshold extends from $\frac{0.49}{2.02}=0.242574\ \mathrm{V}$ to $\frac{0.51}{1.98}=0.257576\ \mathrm{V}$. A reliable positive clipping flag therefore gives a conservative lower bound of 0.242574 V, still with no finite upper bound. This is not a symmetric amplitude uncertainty around the naive inverse.

Copyright 2026, James M. Atkinson

For contrast, an explicitly unsaturated output reading of 0.200 V with ±0.005 V bounded reading error under the same gain range gives an input enclosure from $\frac{0.195}{2.02} = 0.096535\ \mathrm{V}$ to $\frac{0.205}{1.98} = 0.103535\ \mathrm{V}$. The gain inverse is useful there because the state remains inside its declared domain. Preserve the saturation flag and narrow the claim for clipped intervals; a later passed calibration cannot reconstruct the amplitudes that were discarded.

Copyright 2026, James M. Atkinson

1.12.8 Application 1A.8. Preserve a valid power result while refusing to reconstruct lost phase

Two hypothetical inputs have complex RMS voltage phasors $0.6+j0.8\ \mathrm{V}$ and $0.6-j0.8\ \mathrm{V}$ across the same real 50 Ω input reference impedance. The output reference impedance is also real 50 Ω. The imaginary unit j has square −1. Angles denote counterclockwise rotation in the complex plane, with a positive-complex-exponential time convention. Their magnitudes are both 1 V, while their phases are +53.130102 degrees and −53.130102 degrees. A known complex transfer multiplies each phasor by a voltage gain of two and rotates phase by +30 degrees. The recorder then retains only output magnitude.

Both records contain the same magnitude, 2 V, although the output phases before detection are +83.130102 degrees and −23.130102 degrees. Each input power is 1 squared divided by 50, or 20 mW, corresponding to 13.010300 dBm. Each output power is 80 mW, or 19.030900 dBm. The power gain is four, equivalent to 6.020600 dB, and subtracting it correctly recovers the input power level. Thus a valid scalar power correction coexists with irreversible phase loss.

For a magnitude bound, let the recorded output magnitude be 2.00 ± 0.02 V and the calibrated voltage-gain magnitude be 2.00 ± 0.01, with both reference resistances exact in this constructed example. Input magnitude is enclosed by $\frac{1.98}{2.01}=0.985075\ \mathrm{V}$ and $\frac{2.02}{1.99}=1.015075\ \mathrm{V}$. Squaring and dividing by 50 Ω gives 19.407440 mW through 20.607560 mW, or 12.879683 dBm through 13.140266 dBm. The monotonic transformation is valid because all magnitudes are positive.

Copyright 2026, James M. Atkinson

Those amplitude bounds supply no phase recovery. In fact, any input phasor on the nominal unit-magnitude circle produces the same stored magnitude under this transfer. Knowing the +30-degree rotation does not invert the magnitude detector. If the authorized question needs coherent phase, retain a compatible complex record and its reference. If it needs only power, report the supported power result without implying that the missing phase was measured.

Copyright 2026, James M. Atkinson

1.12.9 Application 1A.9. Correct resolved frequency components before forming a channel total

A channel contains two continuous resolved tones at 100 MHz and 101 MHz. Use a rectangular one-millisecond mean, so their cross term integrates to zero, and stipulate negligible added receiver power for the required accuracy. The measured net power gains are 10 dB at the first tone and 4 dB at the second. The corresponding output tone levels are −70 dBm and −76 dBm. The requested quantity is their combined input power at one common plane.

Correcting each component gives $-70-10=-80\ \mathrm{dBm}$ and $-76-4=-80\ \mathrm{dBm}$. Each input is 10 pW, so their total is 20 pW, or −76.989700 dBm. At the output, the powers are 100 pW and 25.118864 pW, totaling 125.118864 pW or −69.026772 dBm. Subtracting an arithmetic average gain of 7 dB from that aggregate gives −76.026772 dBm, which is 0.962928 dB too high.

The effective gain for this particular two-tone input is the ratio of total output to total input, 6.255943, or 7.962928 dB. It depends on the input power distribution across the two gains. It is not a universal channel correction inferred from the two endpoint values. A different distribution between the same frequencies would change that effective gain even if the physical path remained unchanged.

Copyright 2026, James M. Atkinson

As a bounded calibration example, let each tone's net gain have a ±0.20 dB error bound and treat the output tone powers as exact. Each corrected tone then lies between −80.20 dBm and −79.80 dBm. The total is enclosed by −77.189700 dBm and −76.789700 dBm, because both lower endpoints and both upper endpoints bound the monotone power sum. This enclosure does not require independence. The method fails if the tones are not separable under the stated observation or if a component has been rejected entirely; a correction cannot infer its missing power from the retained total alone.

1.12.10 Application 1A.10. Separate a valid corrected level from an unobserved transition interval

A recorded interval extends from 10.000 s to 10.040 s. Independent timing evidence confines the actual start of a gain-state change to 10.019–10.021 s, and settling takes between zero and 0.002 s after that start. State A has 20 dB gain and 2 dB loss; state B has zero gain and 2 dB loss. No output samples during possible transition or settling are accepted for amplitude inference. These time bounds are stipulated evidence, not a uniform distribution of transition times.

The guaranteed valid A interval lasts from 10.000 s to 10.019 s, or 19 ms. The guaranteed valid B interval starts at the latest possible settled time, 10.023 s, and lasts to 10.040 s, or 17 ms. The 4 ms interval between them remains unresolved. Valid retained time is therefore 36 ms out of 40 ms, or 90 percent. That is a coverage fraction, not an event-capture probability.

Suppose the raw mean levels in those valid portions are −62 dBm for A and −82 dBm for B. Applying their respective corrections gives −80 dBm, or 10 pW, in both portions. Their combined valid-interval mean is consequently 10 pW. Their retained input energy is 10 pW multiplied by 36 ms, or $3.6 \times 10^{-13}\ \mathrm{J}$. Equality of the two corrected means does not supply the missing transition energy or prove constant input throughout the gap.

Copyright 2026, James M. Atkinson

If additional, independently justified information bounds input power during the entire 4 ms gap between zero and 100 pW, the missing energy lies between zero and $4.0 \times 10^{-13}\ \mathrm{J}$. Over the full 40 ms, the mean power is then enclosed by 9 pW and 19 pW, corresponding to −80.457575 dBm and −77.212464 dBm. Without that independent upper bound, nonnegative power supplies the same lower bound but no finite upper bound for the full-interval mean. Report the valid-interval result and any separately justified wider enclosure; do not replace the missing interval by an assumed continuation of the convenient −80 dBm level.

1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation

During a conference-room survey, a stable component appears at 433.920 MHz only when the receiver's automatic preamplifier is enabled. Inserting 10 dB input attenuation causes the displayed component to rise relative to the calibrated external reference, while a second receiver does not show it. These observations favor an internally generated product or overload interaction. The report records a configuration-dependent component consistent with a receiver artifact and preserves the raw traces. A comparison that retains the relevant sensitivity, reference plane, frequency coverage, and observation interval is needed before the second receiver's nondetection can exclude an external contribution.

Copyright 2026, James M. Atkinson

1.14 Frame a bounded finding from the completed observation

Consider a constructed survey in which a component is detected during one configured dwell and a later wide scan shows no matching peak. The two results are not contradictory until their time and frequency coverage, detector behavior, and strong-signal conditions have been compared. The later scan may simply have missed the event, admitted a different blocker, or averaged a different statistic. The first task is to reconcile the measurement definitions, then ask whether the remaining difference supports a physical change in the environment.

A defensible finding identifies the observation, the conditions under which it was valid, the alternatives that were challenged, and the uncertainty that remains. It may support continued measurement without supporting attribution. It may establish a receiver artifact without identifying every internal coupling path. It may establish a calibrated absence of events meeting one defined criterion while leaving other event classes untested. Preserving those boundaries makes the finding useful to the next technical decision and prevents a later reader from treating an incomplete inference as a broader conclusion.

Copyright 2026, James M. Atkinson

1.15 Assurance cases for receiver-derived evidence under changing system identity

A scientific receiver investigation can be described as an assurance case rather than a succession of apparently persuasive displays. The top-level proposition is deliberately narrow: a stated physical or statistical quantity was measured by a specified instrument chain during specified eligible intervals, and the conclusion is supported by identified observations, operating conditions and tests of alternative explanations. Beneath that proposition lie subclaims about authority, acquisition fidelity, timing, calibration applicability, processing integrity and inferential limits. Each subclaim must link to an actual record. The record for clock integrity is not interchangeable with the record for front-end linearity; a stable timestamp cannot establish that an amplifier remained below compression, and a successful amplitude reference does not validate digital sample continuity. A disciplined assurance structure exposes a missing premise before the final wording becomes more confident than the available evidence. It also gives the reviewing engineer a rational means of deciding whether one additional experiment would change the conclusion.

Treat configuration identity as an interval-valued variable, not a file-wide declaration. Let $S(t)$ denote the actual instrument state at physical time t, and let $A(S)$ represent the corresponding acquisition transformation. In a simplified record $r[k] = A(S(t_k))\{x(t_k)\} + e[k]$, the sampling instant t_k, unknown electromagnetic input x, recorded data r and residual e must be separately defined. An operator command $C(t)$ is only evidence of requested behaviour; it becomes evidence of actual $S(t)$ only after acknowledgement

Copyright 2026, James M. Atkinson

and independent status or response checks. If a relay changes at an unknown instant within a known bracket, the affected interval should be excluded from any calculation that assumes either settled state. The same principle applies to automatic notch placement, reference-clock switching, adaptive decimation and gain changes triggered by a blocker. Recording one final configuration screenshot cannot retrospectively transform an uncertain state history into a unique measurement law.

An evidential traceability matrix can be constructed with columns for proposition, observation, instrument state, dependency, independent challenge, uncertainty and permitted report language. Consider a hypothetical finding that a weak component persisted for twelve minutes. If the receiver was observing its frequency for only 480 seconds, the directly observed coverage is eight minutes; the remaining four minutes are not negative observations and do not support uninterrupted persistence. If every captured event occurred in a single twelve-second gain state, an assertion about the other states requires a separate transport argument or experiment. This illustrates why measured duration, monitored duration, event count and demonstrated probability of intercept are different quantities. They cannot be rescued by increasing the number of digits in a timestamp or by presenting a particularly smooth waterfall.

A final assurance case should record rejected hypotheses as carefully as its favoured hypothesis. A source-disconnected test can weaken the external-origin explanation only if the disconnection is understood and the instrument remains in a comparable state. A second receiver is independent only to the extent that the relevant inputs, clocks, supply arrangements and processing faults are not shared. A challenged observation may remain

Copyright 2026, James M. Atkinson

scientifically useful even when no individual emitter can be attributed. By making the conditions and failed alternatives explicit, the report permits a later analyst to revise the inference without altering the original evidence, and it reduces the risk that a carefully obtained technical fact is transformed into an unsupported assertion about intent or ownership.

Copyright 2026, James M. Atkinson

1.16 Advanced technical expansion. The receiver as a causal experimental instrument

A receiver is not merely a conduit between incident field and digital display. It is a stateful experiment in which an operator has selected a hypothesis, an observation interval, a transduction chain and an admissible class of conclusions. That proposition becomes operationally useful when the entire apparatus is represented by an ordered causal graph. The graph begins at the electromagnetic field or conducted test port, includes coupling and propagation into a declared antenna reference plane, and continues through protection, selection, gain, conversion, sampling, estimation and storage. Each directed connection represents an observable transformation, not simply a component label. Where a stage changes its law in response to a blocker, temperature, command or previous exposure, the graph must have state variables and transitions. A chain drawn without memory may reproduce a small-signal calibration yet fail to account for a delayed gain recovery or a burst missing from the recorded interval. The question for a forensic examiner is consequently not whether each box bears a familiar name, but whether the particular transformation connecting the observations to the conclusion has been established under the actual conditions of interest.

A useful formal representation defines a state vector $s(t)$, an external electromagnetic input $x(t)$, an acquisition configuration $u(t)$, an environmental disturbance $e(t)$, and a retained output record $y[n]$. The notation $y[n] = F(x, s, u, e; n)$ states that sampling and subsequent computation form an indexed record; it does not assert that F is linear,

Copyright 2026, James M. Atkinson

memoryless, invertible or even stationary. The state vector may include attenuator position, preselector bank, oscillator lock, converter clock, gain-control voltage, filter memory, thermal condition and packet-buffer occupancy. For a numerical example, suppose a commanded gain step occurs at 12.000 seconds, a status register reports its acceptance at 12.001 seconds, and a controlled weak reference returns within tolerance only at 12.004 seconds. It is unwarranted to label the whole four-millisecond transition as a settled new gain state. A conservative validity ledger assigns the affected samples to a transition class until an independently defined acceptance criterion is met. These timings are hypothetical. Their purpose is to demonstrate a method for separating commanded, reported and experimentally validated state.

Counterfactual challenge testing follows directly from this graph. Consider a narrow component at the receiver output: hypotheses may include a genuine external emission, nonlinear mixing at the first amplifier, clock-related leakage or contamination introduced by an export routine. An input attenuator upstream of the amplifier changes the first two hypotheses differently from software scaling performed after conversion; a preselector can reject a distant blocker without necessarily affecting a genuine in-band emitter; an independent reference clock changes a clock-related hypothesis; a raw-sample comparison tests export processing. A useful test is one for which competing models predict measurably different outcomes. Merely making the displayed peak disappear is not enough if the intervention simultaneously reduces sensitivity below the level needed to observe an external counterpart. In an assurance case, every challenge should state the prediction, the actual intervention plane, the observable statistic, the

Copyright 2026, James M. Atkinson

acceptance tolerance and the alternatives that remain compatible with the result.

The semantics of negative evidence deserve the same attention. Let V denote the union of intervals during which the chosen receiver path is demonstrated valid, and let C denote the signal family to which the test is demonstrably sensitive. The statement 'no member of C was detected in V' is narrower than 'no transmitter operated'. Quantifying a probability of capture requires a model of event timing, dwell opportunity, threshold behaviour and failures, rather than an invocation of an attractive noise-floor number. If 72 seconds of valid observation occurred during a two-minute engagement, coverage by duration is 0.60; it is not automatically a 0.60 capture probability. A transmitter could operate solely during the excluded 48 seconds, or could occupy a band outside the receiver's admitted filter. The reporting template should therefore record valid time, valid frequency, tested signal classes, sensitivity conditions, tested interventions and remaining unobserved domains separately.

The evidential release package can be modelled as a dependency graph rather than as an undifferentiated folder of screenshots. Each reported finding points to native record identifiers, sample-index ranges, calibration states, original measurements, software transformations, analyst decisions and the precise experiment used to challenge alternative explanations. Each derivation needs an identifiable input, versioned algorithm and reproducible numerical calculation. A digest of an exported figure establishes integrity of that figure from the time of hashing; it does not certify the antenna state that generated the original signal. The same discipline applies to legal scope: an engineering operation may be technically possible without being

Copyright 2026, James M. Atkinson

authorised by the engagement, and a carefully constructed evidential chain must record collection restrictions rather than silently infer permission from capability. This is a system property, not a footnote added after a technically expansive acquisition.

Copyright 2026, James M. Atkinson

Chapter Summary

Receiver evidence begins with authority and a declared measurement chain. Detection, classification, attribution, and content recovery are separate claims, and every correction or inference must remain traceable to a configuration and reference plane.

Define the authorized objective before selecting the receiver mode. Scope, acquisition, retention and disclosure must follow that objective. The installed antenna path, accessories, receiver transformations and software together form the measurement chain; consequential actual states belong to its configuration identity.

Fix the quantity or proposition, reference plane, frequency and time intervals, estimator and decision criterion. Preserve the original indication and ordered corrections so that sign errors, double counting and calibration from an incompatible state remain detectable. Requested settings do not establish settled operation, and scalar corrections cannot restore clipped or discarded information.

Retain native records, state transitions and the evidence needed to reproduce derived products. Challenge plausible alternatives with comparable observation capability. Closing checks support only the functions and conditions exercised at the check time; they do not prove uninterrupted earlier validity. Report the valid observation, uncertainty, coverage and unresolved alternatives at the strength the evidence supports.

Chapter 1 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C01-MCQ-001. Which statement most completely describes the receiver-system boundary used in this chapter?

A. The selected input connector and final display, excluding intervening accessories

B. The analog stages up to the first digitizer, excluding subsequent processing

C. Only the stages named in the instrument calibration certificate

D. The physical and computational path from environmental input to retained result

Answer: D. An external filter, computer process, or correction can change the result. The declared system therefore includes every consequential transformation, even when it occurs outside the instrument enclosure. Source: §1.1 Receiver as a Measurement System (p. 53)

Why the selected alternative fits: The physical and computational path from environmental input to retained result.

Distinguishing consideration: compare this with option A, “The selected input connector and final display, excluding intervening accessories”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Receiver as a Measurement System.

Review: Chapter 1 — Receiver as a Measurement System.

V011-C01-MCQ-002. A receiver reports a stable frequency with many decimal places, but its active input and clock source were not recorded. Which conclusion is best supported?

A. The uncertainty can be inferred from the number of displayed decimal places

B. Unknown settings can be ignored if the same trace is obtained twice

C. The numerical precision does not establish a defined, reproducible measurement

D. A stable indication establishes frequency accuracy even without the reference record

Answer: C. A precise number can refer to an inadequately specified measurand. Input selection and clock state affect what was observed and how the frequency scale was formed. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: The numerical precision does not establish a defined, reproducible measurement.

Distinguishing consideration: compare this with option A, “The uncertainty can be inferred from the number of displayed decimal places”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Reference Planes and Configuration Identity.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-003. An external adapter is added between the antenna cable and receiver. Why must it enter the system record?

A. Its effect is fully described by the connector designation without installation evidence

B. Its passive construction guarantees that only a constant loss can occur

C. Its effect can be omitted because the receiver input impedance is nominally unchanged

D. Its loss, mismatch, coupling, or nonlinear behavior may affect the observation

Answer: D. The chapter explicitly extends the boundary to passive accessories. Recording the adapter permits the reviewer to determine which changes matter and which earlier configuration remains valid. Source: §1.1 Receiver as a Measurement System (p. 53)

Why the selected alternative fits: Its loss, mismatch, coupling, or nonlinear behavior may affect the observation.

Distinguishing consideration: compare this with option A, “Its effect is fully described by the connector designation without installation evidence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Receiver as a Measurement System.

Review: Chapter 1 — Receiver as a Measurement System.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-004. Which system description is consistent with Equation 1?

A. A universal linear time-invariant receiver

B. A statement that every observed component originated externally

C. A guarantee that all processing can be inverted

D. A configured transformation that may include memory, sampling, conversion, and nonlinear behavior

Answer: D. Equation 1 is a boundary description. The narrower assumptions needed for a linear model must be established separately for the operating state and range. Source: Equation 1. Configured receiver-chain representation (p. 71)

Why the selected alternative fits: A configured transformation that may include memory, sampling, conversion, and nonlinear behavior.

Distinguishing consideration: compare this with option A, “A universal linear time-invariant receiver”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Equation 1. Configured receiver-chain representation; Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Equation 1. Configured receiver-chain representation; Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-MCQ-005. A remote digitizer feeds a computer that scales the samples. Where does the measurement chain end for a reported spectrum?

A. At the digitizer input connector

B. At the first analog-to-digital conversion

C. At the retained spectrum and its documented processing, with earlier representations preserved as required

D. At the computer's network interface

Answer: C. The reported spectrum depends on scaling and analysis after conversion. Those operations belong to the transformation that must be documented for the result to be reproduced. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: At the retained spectrum and its documented processing, with earlier representations preserved as required.

Distinguishing consideration: compare this with option A, “At the digitizer input connector”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Receiver as a Measurement System.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Receiver as a Measurement System.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-006. Which item most directly distinguishes a reference plane from a device name?

A. The declared location at which the reported quantity is defined

B. The name assigned to the retained trace

C. The correction value applied to the display

D. The instrument model used at that location

Answer: A. A reference plane fixes the location of a quantity such as power or phase. A device name alone cannot identify which input, output, or corrected boundary the result represents. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: The declared location at which the reported quantity is defined.

Distinguishing consideration: compare this with option B, “The name assigned to the retained trace”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Reference Planes and Configuration Identity.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-007. An examiner exchanges two apparently identical cables without recording the exchange. What has been weakened?

A. The definition of a reference plane, which changes automatically whenever a cable is exchanged

B. The ability to connect observations to the actual installed path

C. The validity of every earlier measurement, including those completed before the exchange

D. The reproducibility of unrelated calculations that never used either cable

Answer: B. The cables may differ in relevant loss, mismatch, routing, or condition. The missing exchange record prevents a later reviewer from reliably assigning each observation to its physical path. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: The ability to connect observations to the actual installed path.

Distinguishing consideration: compare this with option A, “The definition of a reference plane, which changes automatically whenever a cable is exchanged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Receiver as a Measurement System.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Receiver as a Measurement System.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-008. Which question should precede the selection of a receiver mode?

A. Which mode produced the clearest result in an earlier unrelated engagement?

B. Which mode spans the largest frequency range in the least time?

C. What quantity or proposition must the observation resolve?

D. Which mode maximizes retained information regardless of the target quantity?

Answer: C. A measurement objective determines the appropriate reference plane, interval, state, estimator, and decision rule. Choosing the mode first can capture data that do not answer the intended question. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: What quantity or proposition must the observation resolve?.

Distinguishing consideration: compare this with option A, “Which mode produced the clearest result in an earlier unrelated engagement?”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

V011-C01-MCQ-009. An operator treats the displayed marker value as field strength without recording antenna conversion or geometry. What is the central defect?

A. The conversion crosses an unsupported measurement boundary

B. An antenna-terminal reading always equals the receiver-input reading after cable loss is removed

C. A valid frequency calibration supplies the missing field-amplitude conversion

D. The detector bandwidth alone determines the field-strength reference plane

Answer: A. A receiver indication and field strength are different quantities. The chapter requires the relevant antenna conversion, path corrections, and geometry before the field statement can be supported. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: The conversion crosses an unsupported measurement boundary.

Distinguishing consideration: compare this with option B, “An antenna-terminal reading always equals the receiver-input reading after cable loss is removed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Reference Planes and Configuration Identity.

V011-C01-MCQ-010. Why is the least controlled transformation consequential to the final finding?

A. An uncontrolled stage affects reproducibility only, never the meaning of the reported quantity

B. The best-characterized stage determines the validity of the complete measurement

C. It can limit what the complete chain supports, even when other stages are well characterized

D. A well-calibrated final detector automatically compensates for every earlier uncontrolled stage

Answer: C. The evidential claim depends on the complete transformation. Strong controls elsewhere cannot supply missing validity or configuration information at a consequential uncontrolled stage. Source: §1.1 Receiver as a Measurement System (p. 53)

Why the selected alternative fits: It can limit what the complete chain supports, even when other stages are well characterized.

Distinguishing consideration: compare this with option A, “An uncontrolled stage affects reproducibility only, never the meaning of the reported quantity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Receiver as a Measurement System.

Review: Chapter 1 — Receiver as a Measurement System.

V011-C01-MCQ-011. A survey permits occupancy measurements but prohibits recovery of communications content. Which implementation best reflects that authority?

A. Retain incidental content indefinitely without review

B. Enable all demodulators because the receiver supports them

C. Record every available channel in case later review is useful

D. Select technical measurement modes and recording limits that implement the permitted objective

Answer: D. The receiver plan translates authority into technical settings and retention rules. Instrument capability does not enlarge the information the engagement permits the examiner to acquire. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: Select technical measurement modes and recording limits that implement the permitted objective.

Distinguishing consideration: compare this with option A, “Retain incidental content indefinitely without review”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-012. When should minimization first influence the acquisition design?

A. Only when storage becomes full

B. Only after unauthorized content has been distributed

C. Only after a final report is written

D. Before collection begins

Answer: D. Selecting needed bandwidth, duration, channels, and metadata before acquisition can prevent unnecessary collection. Later handling controls complement, but do not replace, that initial limitation. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: Before collection begins.

Distinguishing consideration: compare this with option A, “Only when storage becomes full”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-013. Which proposed reason is insufficient by itself to justify a wider acquisition bandwidth?

A. The authorized objective requires the wider interval

B. The approved technical plan specifies the wider interval

C. The hardware can record the wider bandwidth

D. A documented authorized extension requires the wider interval

Answer: C. Capability describes what the instrument can do. The justified scope follows the authorized objective and plan, including any properly recorded extension. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: The hardware can record the wider bandwidth.

Distinguishing consideration: compare this with option A, “The authorized objective requires the wider interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-014. An operator needs a scope extension during an engagement. Which record is most relevant?

A. The available bandwidth and storage capacity without the actual authorized objective

B. The deviation, its technical purpose, and who approved the extension

C. The extended acquisition settings without the reason or approving authority

D. The technical desirability of extra coverage without an approval record

Answer: B. The chapter requires the record to connect the authorized objective, actual collection, deviations, and approval. A technical need alone does not document the authority for the extension. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: The deviation, its technical purpose, and who approved the extension.

Distinguishing consideration: compare this with option A, “The available bandwidth and storage capacity without the actual authorized objective”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-015. Which acquisition control most directly limits unnecessary observation duration?

A. Reduce the recorded bandwidth while leaving acquisition time unchanged

B. Lower the display refresh rate while retaining the same continuous samples

C. A recording interval selected to answer the authorized question

D. Apply more averaging after recording the same interval

Answer: C. Duration affects what information is collected. A deliberately bounded interval is therefore a substantive minimization measure, unlike changes confined to presentation or organization. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: A recording interval selected to answer the authorized question.

Distinguishing consideration: compare this with option A, “Reduce the recorded bandwidth while leaving acquisition time unchanged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Operational Decision Discipline; Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-018. Why is mission authority an engineering concern in this chapter?

A. Authority supplies a correction for receiver nonlinearity

B. Institutional approval makes configuration evidence unnecessary

C. Acquisition settings determine which information is captured

D. A permitted objective guarantees that every available detector mode is appropriate

Answer: C. Legal and institutional limits must be implemented through concrete frequency, time, mode, and recording choices. That translation makes authority part of measurement-system design. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: Acquisition settings determine which information is captured.

Distinguishing consideration: compare this with option A, “Authority supplies a correction for receiver nonlinearity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-019. Which statement about a laboratory engagement follows the chapter's boundary approach?

A. Any laboratory permission authorizes all nearby collection

B. A laboratory location removes retention limits

C. A receiver's calibration certificate establishes legal scope

D. Permission to analyze a seized device need not authorize continuous monitoring of unrelated emitters

Answer: D. The chapter distinguishes the authorized target and purpose from neighboring activity. Location or technical capability does not silently broaden the collection boundary. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: Permission to analyze a seized device need not authorize continuous monitoring of unrelated emitters.

Distinguishing consideration: compare this with option A, “Any laboratory permission authorizes all nearby collection”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

V011-C01-MCQ-020. Which record most clearly supports review of a minimization decision?

A. The information needed for the objective and the acquisition limits chosen to obtain it

B. An assurance that unnecessary material will be identified after unlimited acquisition

C. The maximum tuning and recording capability of the chosen receiver

D. The total storage capacity available during the engagement

Answer: A. A reviewable decision connects the authorized question with bandwidth, duration, channels, metadata, retention, and disclosure controls. The justification must be recoverable from the record. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: The information needed for the objective and the acquisition limits chosen to obtain it.

Distinguishing consideration: compare this with option B, “An assurance that unnecessary material will be identified after unlimited acquisition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

V011-C01-MCQ-021. A component exceeds a declared decision threshold. Which proposition is established first?

A. Physical attribution to a named owner

B. Detection under the stated criterion

C. Recovery of intelligible content

D. Proof of hostile intent

Answer: B. Detection concerns the observation crossing a criterion. Classification, attribution, content recovery, and intent require additional evidence that a threshold crossing does not itself provide. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: Detection under the stated criterion.

Distinguishing consideration: compare this with option A, “Physical attribution to a named owner”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-022. The examiner identifies a waveform family from modulation and timing features. Which verb best describes that result?

A. Recovered all content

B. Classified

C. Attributed to an owner

D. Proved unauthorized

Answer: B. Classification connects observed features to a waveform family or service type. It does not by itself establish the physical source, ownership, or legal status of the emission. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: Classified.

Distinguishing consideration: compare this with option A, “Recovered all content”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-023. A decoded network name appears in a capture. What should the report avoid claiming without additional evidence?

A. That the decoder produced a particular output

B. That a configuration string was recovered

C. That the name proves device location and ownership

D. That the capture used a specified receiver state

Answer: C. An identifier can describe a configuration string without locating the emitting hardware or proving its owner. The stronger attribution requires corroborating evidence. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: That the name proves device location and ownership.

Distinguishing consideration: compare this with option A, “That the decoder produced a particular output”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

V011-C01-MCQ-024. A waveform changes when activity in a room changes, but no intelligible information is recovered. Which finding is appropriately bounded?

A. The waveform is correlated with the recorded activity under the tested conditions

B. Repeatable state dependence establishes recovery of the information involved in the activity

C. The activity correlation alone attributes the signal to the device being used

D. A lack of intelligible content proves that the component cannot be external

Answer: A. State dependence can be informative while leaving content and mechanism unresolved. The report should preserve the observed relationship and the conditions of the comparison. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: The waveform is correlated with the recorded activity under the tested conditions.

Distinguishing consideration: compare this with option B, “Repeatable state dependence establishes recovery of the information involved in the activity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-025. Which observation most directly belongs to attribution rather than mere classification?

A. A controlled state change that links a component to a particular physical emitter

B. A peak exceeding the display threshold

C. A general modulation-family label

D. An unverified signal-strength screenshot

Answer: A. Attribution requires a supported connection to a physical emitter or system. A controlled state change can contribute to that connection when its assumptions and alternative explanations are addressed. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: A controlled state change that links a component to a particular physical emitter.

Distinguishing consideration: compare this with option B, “A peak exceeding the display threshold”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-026. Which description of content recovery is correct?

A. Recording only that energy exceeded a threshold

B. Reconstructing information carried by the signal

C. Assigning a waveform family without decoding information

D. Determining cable insertion loss

Answer: B. The chapter separates reconstruction of carried information from detecting energy and recognizing waveform characteristics. The distinction matters both technically and for collection authority. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: Reconstructing information carried by the signal.

Distinguishing consideration: compare this with option A, “Recording only that energy exceeded a threshold”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-027. An unexplained narrow peak is stable. Which alternative remains compatible with that observation?

A. Only an external surveillance transmitter

B. Only measurement noise with no structure

C. Only a legitimate broadcast station

D. A receiver clock harmonic

Answer: D. Stability does not distinguish all external signals from internally generated components. The chapter lists clock harmonics, oscillator leakage, spurs, and intermodulation among the competing explanations. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: A receiver clock harmonic.

Distinguishing consideration: compare this with option A, “Only an external surveillance transmitter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-028. Which reporting verb requires the strongest support for a claim about where a component originated?

A. Displayed

B. Observed

C. Detected

D. Attributed

Answer: D. Attribution connects the observation to a source. It therefore demands more than reporting a display feature or a threshold crossing under a documented measurement state. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: Attributed.

Distinguishing consideration: compare this with option A, “Displayed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-029. Two sensors agree, but both share the same clock and input route. What limits the evidential value of agreement?

A. Separate hardware makes the shared reference irrelevant to error independence

B. Agreement removes the need to characterize the common input path

C. Shared errors can explain the common result

D. A common clock establishes physical attribution whenever both channels show the component

Answer: C. Agreement is persuasive only to the degree that the comparisons change relevant error sources. Shared hardware or references can preserve the same artifact in both observations. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: Shared errors can explain the common result.
Distinguishing consideration: compare this with option A, “Separate hardware makes the shared reference irrelevant to error independence”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.
Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-030. Which sentence preserves the distinction between observation and interpretation?

A. A component was detected in the declared interval; the tested changes favored a receiver artifact

B. A decoded identifier established the owner before any source comparison

C. The absent comparator peak excluded an external signal without a sensitivity check

D. A stable component was classified as hostile because it appeared repeatedly

Answer: A. The preferred sentence states what was observed and the bounded interpretation supported by tests. It does not expand that interpretation into unsupported ownership or intent. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why the selected alternative fits: A component was detected in the declared interval; the tested changes favored a receiver artifact.

Distinguishing consideration: compare this with option B, “A decoded identifier established the owner before any source comparison”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Observation, Classification, Attribution, and Content Recovery; Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery; Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-031. A receiver indicates minus 71.4 dBm, with 4.8 dB path loss and 18.6 dB external gain. What is the corrected preamplifier-input level before other corrections?

A. Minus 48.0 dBm

B. Minus 57.6 dBm

C. Minus 94.8 dBm

D. Minus 85.2 dBm

Answer: D. Equation 2 gives indicated level plus loss minus gain: minus 71.4 plus 4.8 minus 18.6 equals minus 85.2 dBm. The result retains the stated reference plane and calibration conditions. Source: §1.12 Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 78)

Why the selected alternative fits: Minus 85.2 dBm.

Distinguishing consideration: compare this with option A, “Minus 48.0 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Equation 2. Corrected input power.

V011-C01-MCQ-032. When referring a downstream receiver indication backward across a passive loss, which sign applies to the loss term in Equation 2?

A. Subtract the loss in decibels

B. Add the loss in decibels

C. Replace the indicated power with the loss

D. Square the loss in decibels

Answer: B. The downstream signal has been reduced by the loss. Recovering the upstream level adds that known loss, subject to compatible state and reference-plane conditions. Source: Equation 2. Corrected input power (p. 71)

Why the selected alternative fits: Add the loss in decibels.

Distinguishing consideration: compare this with option A, “Subtract the loss in decibels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-033. When referring a downstream indication backward across an external amplifier, which sign applies to its gain?

A. Add the external gain in decibels

B. Ignore gain whenever a cable follows it

C. Multiply the indicated dBm value by the gain in decibels

D. Subtract the external gain in decibels

Answer: D. The amplifier raised the downstream level. Removing its contribution requires subtracting the external gain from the indication after accounting for the intervening loss. Source: Equation 2. Corrected input power (p. 71)

Why the selected alternative fits: Subtract the external gain in decibels.

Distinguishing consideration: compare this with option A, “Add the external gain in decibels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-034. A gain correction restores the displayed level after an amplifier is bypassed. What still requires separate review?

A. Only whether both traces use the same displayed amplitude range

B. Only whether the corrected central values match after rounding

C. Whether the actual state, noise, and validity conditions support combining the records

D. Only whether the same file format was used for both records

Answer: C. A corrected central value does not establish equal noise or operating validity. The chapter requires state-specific corrections and examination of the transformations before combining observations. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: Whether the actual state, noise, and validity conditions support combining the records.

Distinguishing consideration: compare this with option A, “Only whether both traces use the same displayed amplitude range”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-035. Which case cannot be repaired merely by adding a scalar path correction?

A. An overloaded receiver record

B. A valid calibrated passive-loss correction

C. A known constant scale factor in a reversible path

D. A documented correction at the declared plane

Answer: A. Overload can discard or distort information through a nonlinear transformation. Adding an offset cannot recreate the input information lost during that event. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: An overloaded receiver record.

Distinguishing consideration: compare this with option B, “A valid calibrated passive-loss correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-036. An operator applies the same cable-loss correction twice. Which retained information most readily exposes the error?

A. The original indication and each separately identified correction

B. Only the receiver setup without the retained indication

C. Only the cable identifier without the sequence of applied corrections

D. Only the final corrected value and its rounded display

Answer: A. Preserving the correction chain permits the result to be reconstructed. A final number alone hides whether a loss has been counted twice or assigned to the wrong boundary. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: The original indication and each separately identified correction.

Distinguishing consideration: compare this with option B, “Only the receiver setup without the retained indication”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-037. Which information is necessary before treating an antenna-terminal power as field strength?

A. Only the antenna model name without the applicable conversion conditions

B. The applicable antenna conversion and relevant geometry, along with path conditions

C. Only the cable-loss value and the nominal receiver impedance

D. Only the calibrated receiver indication and its resolution bandwidth

Answer: B. A terminal quantity and a field quantity are connected through a physical conversion model. The chapter requires the corresponding antenna and geometric conditions rather than an automatic relabeling. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: The applicable antenna conversion and relevant geometry, along with path conditions.

Distinguishing consideration: compare this with option A, “Only the antenna model name without the applicable conversion conditions”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Reference Planes and Configuration Identity.

V011-C01-MCQ-038. The preselector is changed after calibration. Which response best follows the chapter?

A. Assess whether the calibration still applies to the new path and state

B. Assume all passive filters are transparent

C. Reuse the old calibration without identifying the change

D. Declare every prior measurement false

Answer: A. A filter change can alter loss, phase, rejection, and mismatch. The earlier record remains associated with its earlier state, while validity for the new state must be established. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: Assess whether the calibration still applies to the new path and state.

Distinguishing consideration: compare this with option B, “Assume all passive filters are transparent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-MCQ-039. For Equation 2, what does a common logarithmic unit convention accomplish?

A. It proves that every component is linear

B. It eliminates uncertainty

C. It makes the gain and loss corrections compatible with the indicated power calculation

D. It establishes the transmitter's radiated power

Answer: C. Compatible dB and dBm conventions permit the scalar level calculation. They do not establish its physical assumptions, eliminate uncertainty, or extend the result beyond the declared plane. Source: Equation 2. Corrected input power (p. 71)

Why the selected alternative fits: It makes the gain and loss corrections compatible with the indicated power calculation.

Distinguishing consideration: compare this with option A, “It proves that every component is linear”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Equation 2. Corrected input power; Chapter 1 — Equation 2A. Power coordinates and fixed-state transfer.

Review: Chapter 1 — Equation 2. Corrected input power; Chapter 1 — Equation 2A. Power coordinates and fixed-state transfer.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-040. A result is referred to the receiver input, but the report labels it as source power. What is missing?

A. A frequency calibration at the same receiver input

B. A repeat of the same scalar receiver-input correction

C. A supported transfer model between those two reference locations

D. A narrower resolution bandwidth at the receiver plane

Answer: C. The source and receiver are separated by a propagation and measurement path. The receiver-input correction does not by itself establish the power at the source. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: A supported transfer model between those two reference locations.

Distinguishing consideration: compare this with option A, “A frequency calibration at the same receiver input”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Reference Planes and Configuration Identity.

V011-C01-MCQ-041. A trace was collected through a software-controlled external gain stage. Which omitted item most directly threatens a backward amplitude correction?

A. The identifier assigned to an unchanged retained record

B. The compression setting of a lossless export file

C. The order in which already acquired traces are displayed

D. The actual gain state during the trace

Answer: D. The actual gain state determines the scalar transfer applied to the observation. An unchanged record identifier, display order, or lossless export setting does not supply that missing physical gain value. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: The actual gain state during the trace.

Distinguishing consideration: compare this with option A, “The identifier assigned to an unchanged retained record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

V011-C01-MCQ-042. A command requests one sample rate while the status log reports another. Which rate should govern analysis of the retained samples?

A. The established actual rate for the relevant record

B. The average of all advertised rates

C. The largest rate the hardware supports

D. The requested rate without further review

Answer: A. A command expresses intent, not proof of execution. Timing, frequency mapping, and throughput must be tied to the actual state supported by the status and observation records. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: The established actual rate for the relevant record.

Distinguishing consideration: compare this with option B, “The average of all advertised rates”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-043. Why may an undocumented automatic mode be more consequential than an omitted cosmetic setting?

A. Its requested setting is sufficient evidence of the actual state

B. It guarantees improved sensitivity in every installed state

C. Its effects disappear when corrected traces have the same central value

D. It may change the measurement law while the observation continues

Answer: D. Configuration identity is driven by consequences for the measurand. An automatic change to gain, filtering, timing, or another transformation can invalidate a previously assumed state. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: It may change the measurement law while the observation continues.

Distinguishing consideration: compare this with option A, “Its requested setting is sufficient evidence of the actual state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-044. After a sample-rate change, which group of consequences is identified in the chapter?

A. Only file size, because frequency mapping remains unchanged at every sample rate

B. Alias locations, digital filtering, timing, and recording throughput

C. Only display span, because the physical sample intervals are set by the file format

D. Only alias locations, with digital filtering and timing guaranteed unchanged

Answer: B. The rate affects the mapping and handling of sampled data. A transition therefore requires a separate state record and examination of the analysis applied to each interval. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: Alias locations, digital filtering, timing, and recording throughput.

Distinguishing consideration: compare this with option A, “Only file size, because frequency mapping remains unchanged at every sample rate”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-045. What is a state interval in this chapter?

A. The complete service life of an instrument regardless of settings

B. A declared part of a record for which the relevant configuration and calibration remain applicable

C. A period in which one center frequency is selected

D. Any period selected after seeing a convenient result

Answer: B. State intervals connect samples or traces to a valid measurement transformation. They must follow consequential configuration changes rather than conceal them within an undifferentiated average. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: A declared part of a record for which the relevant configuration and calibration remain applicable.

Distinguishing consideration: compare this with option A, “The complete service life of an instrument regardless of settings”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-046. Which comparison can reveal that a requested configuration was not achieved?

A. Two repetitions of the requested command without an actual-state record

B. The command log compared only with the nominal instrument capability

C. Setup export versus status log versus observed record

D. Two screenshots generated from the same exported trace

Answer: C. The setup describes the request, the status may describe accepted state, and the data show what was captured. Their disagreement can expose a consequential configuration failure. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: Setup export versus status log versus observed record.

Distinguishing consideration: compare this with option A, “Two repetitions of the requested command without an actual-state record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-047. An operator averages traces acquired before and after an undocumented gain change. What is the principal concern?

A. Equal display units establish that the two transformations are interchangeable

B. Averaging automatically converts the two gain states to one common reference plane

C. The average may combine different transformations without a valid common calibration

D. A sufficiently long average removes every state-dependent calibration difference

Answer: C. A numerical mean does not reconcile state-dependent gain, noise, or validity. The estimator and correction model must explicitly support combining the different intervals. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: The average may combine different transformations without a valid common calibration.

Distinguishing consideration: compare this with option A, “Equal display units establish that the two transformations are interchangeable”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Equation 2C. Average after each interval has its own valid correction.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Equation 2C. Average after each interval has its own valid correction.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-048. Which configuration record is most useful for a reproducible result?

A. The receiver model and nominal bandwidth without accessories or software identity

B. The consequential hardware, software, calibration, accessory, and acquisition states

C. The final corrected value without the state that produced it

D. Only nominal path labels without actual operating-state records

Answer: B. The chapter calls for enough identity to distinguish states that would change the answer. Relevant hidden or automatic behavior matters more than exhaustive recording of unrelated interface preferences. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: The consequential hardware, software, calibration, accessory, and acquisition states.

Distinguishing consideration: compare this with option A, “The receiver model and nominal bandwidth without accessories or software identity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-049. Firmware changes between two surveys. What should the examiner do before treating the results as directly comparable?

A. Use the previous calibration without checking the firmware-dependent behavior

B. Assume identical hardware serial numbers establish an unchanged transformation

C. Determine whether the change affects the measurement or processing state

D. Combine the surveys first and inspect state differences only if their means disagree

Answer: C. Firmware belongs to configuration identity. The comparison requires an assessment of its effect on the actual transformation, with each original state preserved in the record. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: Determine whether the change affects the measurement or processing state.

Distinguishing consideration: compare this with option A, “Use the previous calibration without checking the firmware-dependent behavior”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Reference Planes and Configuration Identity.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-050. Which record best connects a configuration transition to retained data?

A. A time-linked record of the command, accepted state, settling, and affected samples

B. A single requested setup saved before all subsequent transitions

C. A status sample taken after the survey without a link to the affected data

D. A final setup export assumed to describe the complete preceding acquisition

Answer: A. The relevant question is which valid state produced each observation. A time-linked transition record prevents requested, transient, and settled states from being treated as interchangeable. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: A time-linked record of the command, accepted state, settling, and affected samples.

Distinguishing consideration: compare this with option B, “A single requested setup saved before all subsequent transitions”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

V011-C01-MCQ-051. Which measurement definition is most complete for an amplitude result?

A. The displayed level and center frequency without the acquisition interval

B. The maximum marker value without a specified plane or estimator

C. Power at a named plane, over stated frequency and time intervals, using a declared state and estimator

D. The receiver model and nominal sensitivity without the active measurement state

Answer: C. The definition must identify the quantity and how it was formed. Plane, intervals, state, estimator, and decision conditions make the result interpretable and reproducible. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: Power at a named plane, over stated frequency and time intervals, using a declared state and estimator.

Distinguishing consideration: compare this with option A, “The displayed level and center frequency without the acquisition interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

V011-C01-MCQ-052. A wide discovery scan reveals a component. What further support is needed before assigning a calibrated amplitude?

A. Only the nominal sensitivity specification of the instrument

B. The applicable amplitude measurement definition and calibration

C. Only the maximum scan span used to locate the candidate

D. Only repeated visibility of the component in the discovery mode

Answer: B. Discovery and quantitative amplitude measurement are different tasks. The scan may locate a candidate without establishing the detector, bandwidth, reference-plane, and calibration conditions needed for its level. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: The applicable amplitude measurement definition and calibration.

Distinguishing consideration: compare this with option A, “Only the nominal sensitivity specification of the instrument”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-053. A narrow coherent capture provides good phase information. Which claim does that achievement alone fail to support?

A. Phase analysis within the declared capture conditions

B. Use of the retained samples for the intended estimator

C. A documented observation within the captured interval

D. Comprehensive coverage of emissions outside its instantaneous passband

Answer: D. A measurement can be strong for one target while leaving other targets unobserved. Narrow passband phase performance does not establish broader spectrum coverage. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: Comprehensive coverage of emissions outside its instantaneous passband.

Distinguishing consideration: compare this with option A, “Phase analysis within the declared capture conditions”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-054. Why must the estimator be named in a measurement definition?

A. It proves that adaptive or nonlinear behavior is absent from the receiver

B. It makes the physical reference plane unnecessary once a unit is attached

C. It establishes source identity whenever the same value is reproduced

D. It identifies the operation that converts retained data into the reported number

Answer: D. A detector bucket, integrated channel, and fitted tone can yield different numerical quantities. Naming the estimator prevents a display label from concealing those differences. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: It identifies the operation that converts retained data into the reported number.

Distinguishing consideration: compare this with option A, “It proves that adaptive or nonlinear behavior is absent from the receiver”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-055. Two instruments report a value labeled power. What should be reconciled before comparing the numbers?

A. Whether both labels are expressed in the same units, without examining the estimators

B. Whether their central frequencies match, regardless of bandwidth and time coverage

C. Whether they measure the same plane, bandwidth, interval, state, and statistic

D. Whether both instruments passed a self-test, regardless of the installed paths

Answer: C. Matching labels do not establish matching measurands. The comparison must first establish which energy, transformation, and mathematical summary each result represents. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: Whether they measure the same plane, bandwidth, interval, state, and statistic.

Distinguishing consideration: compare this with option A, “Whether both labels are expressed in the same units, without examining the estimators”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-056. Which timestamp description is insufficient for multichannel interpretation?

A. A stated sample-aperture time

B. A time value with no definition of the event it marks

C. A stated trigger-comparator time

D. A stated software-receipt time

Answer: B. Different timestamp events can have different delays and uncertainties. The time basis must identify which event the number marks before channels are compared. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: A time value with no definition of the event it marks.

Distinguishing consideration: compare this with option A, “A stated sample-aperture time”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-057. What does the frequency interval in the measurement definition delimit?

A. Whether the acquisition contains the entire time history of the event

B. Which physical emitter owns the observed component

C. Whether the reported estimator is unbiased under every signal condition

D. Which signal components can contribute to the reported quantity

Answer: D. The interval defines the admitted frequency scope. Ownership and broader authority remain separate evidential and institutional questions. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: Which signal components can contribute to the reported quantity.

Distinguishing consideration: compare this with option A, “Whether the acquisition contains the entire time history of the event”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

V011-C01-MCQ-058. What does the decision criterion add to a numerical estimate?

A. A universal acceptance threshold transferable to every receiver state

B. The conditions under which the number may support the intended use

C. A replacement for the uncertainty and validity conditions of the measurement

D. An automatic source attribution from any threshold crossing

Answer: B. The criterion connects a result to an action or conclusion, including relevant uncertainty and validity conditions. A value alone does not specify how it should be used. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: The conditions under which the number may support the intended use.

Distinguishing consideration: compare this with option A, “A universal acceptance threshold transferable to every receiver state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-059. A frequency marker could be an FFT-bin label or an interpolated estimate. Why does the distinction matter?

A. The event times that were not included in the recorded acquisition

B. The source ownership implied by the chosen frequency label

C. The full physical bandwidth of the emitter, regardless of the acquired path

D. The reported quantity and estimation assumptions differ

Answer: D. The same display role can represent different mathematical constructions. Its interpretation must follow the actual estimator rather than a generic marker name. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: The reported quantity and estimation assumptions differ.

Distinguishing consideration: compare this with option A, “The event times that were not included in the recorded acquisition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

V011-C01-MCQ-060. An amplitude correction changes the reference plane. What must remain explicit?

A. Only the final rounded number

B. Only the display scale chosen for the report

C. Only the instrument's model designation

D. The original indication, correction, destination plane, and applicable state

Answer: D. Preserving the complete correction chain makes the transformation reviewable and exposes sign, state, and boundary errors. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: The original indication, correction, destination plane, and applicable state.

Distinguishing consideration: compare this with option A, “Only the final rounded number”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Reference Planes and Configuration Identity.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-061. Which operation can be reversible under the chapter's stated conditions?

A. Clipping an unknown waveform

B. Replacing complex data with magnitude alone

C. A known scalar path correction applied in its valid state

D. Discarding samples with no continuity record

Answer: C. A known scalar correction may be undone when its value and applicability are retained. Information-discarding operations generally do not share that property. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: A known scalar path correction applied in its valid state.

Distinguishing consideration: compare this with option A, “Clipping an unknown waveform”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-062. Why retain native data before magnitude detection when the objective may later require phase?

A. Magnitude detection retains the original phase whenever enough bins are stored

B. The phase can always be reconstructed from the corrected power level

C. Magnitude detection can discard the phase information needed for that analysis

D. A later calibration offset can restore phase removed from the retained representation

Answer: C. The retained representation controls which later analyses remain possible. A magnitude-only record cannot be assumed to contain the original complex information. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: Magnitude detection can discard the phase information needed for that analysis.

Distinguishing consideration: compare this with option A, “Magnitude detection retains the original phase whenever enough bins are stored”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.8. Preserve a valid power result while refusing to reconstruct lost phase.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.8. Preserve a valid power result while refusing to reconstruct lost phase.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-063. A processing chain clips a waveform and later reduces its displayed amplitude. What remains true?

A. The original peaks are determined uniquely by the surviving clipped samples

B. The later scale change does not restore the clipped information

C. A smaller reported level establishes that the original input was within range

D. The later reduction reverses the nonlinear limiting at each sample

Answer: B. Clipping is an information-losing transformation. A later offset or scale factor changes the representation of the surviving data, not the lost waveform detail. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: The later scale change does not restore the clipped information.

Distinguishing consideration: compare this with option A, “The original peaks are determined uniquely by the surviving clipped samples”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-064. An analysis deletes missing-sample locations and joins the remaining samples. Which concern should be recorded?

A. The joined sequence can retain the original time basis without any missing-index record

B. The retained sequence may no longer preserve the original timing relationship

C. A checksum of the joined file proves that no acquisition samples were lost

D. Deleting gaps establishes a continuous physical-time record at the nominal rate

Answer: B. Loss and removal of samples can change the relationship between stored order and physical time. The analysis must preserve the limits of the representation it actually uses. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: The retained sequence may no longer preserve the original timing relationship.

Distinguishing consideration: compare this with option A, “The joined sequence can retain the original time basis without any missing-index record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-065. Which retained pair most directly supports reconstruction of a scalar correction?

A. The acquisition file name and the default setup used on another day

B. The final result and a nominal accessory specification without the applied state

C. Two separately rounded copies of the corrected result

D. The uncorrected indication and the applicable correction value

Answer: D. A reversible correction requires the starting value and the transformation. State and reference-plane information are also needed to establish that the correction applies. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: The uncorrected indication and the applicable correction value.

Distinguishing consideration: compare this with option A, “The acquisition file name and the default setup used on another day”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-066. A derived spectrum is the only surviving record. Which statement is appropriate?

A. Its usefulness is limited by the information retained in that representation

B. The retained spectrum establishes the same timing information as the original acquisition

C. Every later estimator can be reproduced from a magnitude-only export

D. All original complex samples can be recovered because frequency bins are retained

Answer: A. A spectrum may answer defined questions while omitting phase, timing, or processing context. The report must tie its claims to what the representation actually retains. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: Its usefulness is limited by the information retained in that representation.

Distinguishing consideration: compare this with option B, “The retained spectrum establishes the same timing information as the original acquisition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-067. Which example illustrates evidence being distinguished from an explanatory model?

A. A fitted law is labeled as a field observation

B. A predicted trace replaces the original measurement

C. A model coefficient is treated as the transmitter's identity

D. Measured tone levels are retained separately from the cubic law used to interpret a product

Answer: D. The distinction preserves both what was observed and the assumptions used to interpret it. It also identifies what further evidence could challenge the model. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: Measured tone levels are retained separately from the cubic law used to interpret a product.

Distinguishing consideration: compare this with option A, “A fitted law is labeled as a field observation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-068. A phase-noise curve is available. What additional conditions can a reciprocal-mixing prediction require?

A. Only the oscillator curve at one offset, independent of admitted blocker level

B. Only the final resolution-bandwidth label, independent of channel weighting

C. Only the receiver gain value, with no condition on the blocker or cross-power

D. Blocker level, conversion gain, weighting, and cross-power conditions

Answer: D. The curve is evidence under its normalization, but the prediction concerns a configured system. The chapter names the additional inputs and assumptions that must accompany the inference. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: Blocker level, conversion gain, weighting, and cross-power conditions.

Distinguishing consideration: compare this with option A, “Only the oscillator curve at one offset, independent of admitted blocker level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-069. A list of usable observation windows is known. What is still needed for a probability-of-capture statement?

A. An event-start distribution and a capture criterion

B. Only the total recording duration, without defining successful capture

C. Only the longest usable window, with every event phase treated as equivalent

D. Only the number of windows, independent of their placement and the event model

Answer: A. Usable intervals are observations about coverage. A probability claim additionally depends on how events are modeled and what counts as successful capture. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: An event-start distribution and a capture criterion.

Distinguishing consideration: compare this with option B, “Only the total recording duration, without defining successful capture”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

V011-C01-MCQ-071. Why retain unsuccessful challenge tests?

A. They can constrain competing explanations and show what was actually attempted

B. They can be discarded once another test produces a preferred result

C. They automatically count as successful verification of the measurement chain

D. They establish absence independently of the capability of the attempted test

Answer: A. An unsuccessful or negative test carries information about the examination and its limits. Its meaning depends on the test's capability and conditions, not merely on its outcome. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: They can constrain competing explanations and show what was actually attempted.

Distinguishing consideration: compare this with option B, “They can be discarded once another test produces a preferred result”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

V011-C01-MCQ-072. Which record is particularly important when comparing several sensors in time?

A. Only file-creation timestamps without their event definitions

B. Only nominally equal sample rates without a time-reference record

C. Only matching display times without clock-state or uncertainty information

D. Synchronization sources and clock uncertainty

Answer: D. Temporal comparison requires a defined time basis and its limitations. Shared or different references can change the error structure and the interpretation of apparent coincidence. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: Synchronization sources and clock uncertainty.

Distinguishing consideration: compare this with option A, “Only file-creation timestamps without their event definitions”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-073. What is the immediate purpose of a closing reference check?

A. To establish that every earlier acquisition state was identical to the closing state

B. To test specified measurement-chain functions at the time of the closing check

C. To convert an unresolved source hypothesis into attribution

D. To replace missing native data with a later known-reference observation

Answer: B. A known or injected reference tests the functions exercised at the time of the check. It does not by itself establish uninterrupted validity during earlier acquisition, source attribution, or authority. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: To test specified measurement-chain functions at the time of the closing check.

Distinguishing consideration: compare this with option A, “To establish that every earlier acquisition state was identical to the closing state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

V011-C01-MCQ-074. A second receiver fails to show a component seen by the first. Which condition is essential before using that nondetection against an external-source explanation?

A. Equal total recording durations despite different instantaneous coverage

B. A nominally lower advertised noise floor without testing the relevant state

C. Comparable relevant sensitivity, coverage, reference plane, and observation opportunity

D. Matching center-frequency labels despite unverified sensitivity

Answer: C. A nondetection can reflect inadequate capability or different coverage. The chapter requires a comparison that preserves the conditions needed to observe the component before the absence becomes discriminating evidence. Source: §1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 99)

Why the selected alternative fits: Comparable relevant sensitivity, coverage, reference plane, and observation opportunity.

Distinguishing consideration: compare this with option A, “Equal total recording durations despite different instantaneous coverage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-075. Which challenge most directly changes the receiver's admitted spectral conditions?

A. A preselection change

B. Renormalizing an already retained trace at the display

C. Relabeling the frequency axis without changing acquisition

D. Changing the vertical axis on the same retained samples

Answer: A. Preselection can alter admitted blockers, desired transfer, and phase. Its consequence should be measured and interpreted as a change to the physical transformation. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: A preselection change.

Distinguishing consideration: compare this with option B, “Renormalizing an already retained trace at the display”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-076. What does moving an antenna potentially change in a challenge comparison?

A. Only propagation distance, with installed coupling and polarization unchanged

B. Both environmental coupling and the installed measurement conditions

C. Only desired-signal amplitude, with all artifact paths guaranteed unchanged

D. Only source direction, so a disappearance establishes localization directly

Answer: B. Location is part of the system record. Movement may help discriminate explanations, but it also changes coupling and must be interpreted within the declared measurement definition. Source: §1.1 Receiver as a Measurement System (p. 53)

Why the selected alternative fits: Both environmental coupling and the installed measurement conditions.

Distinguishing consideration: compare this with option A, “Only propagation distance, with installed coupling and polarization unchanged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Receiver as a Measurement System; Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Receiver as a Measurement System; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-077. Which closing statement is most reviewable?

A. The closing state proves every earlier gain and clock state was valid

B. The reference passed the stated checks; untested functions and remaining limits are listed

C. The tested function passed, so all untested functions are also accepted

D. A successful reference demonstrates that the chain cannot generate artifacts

Answer: B. A closing check supports only the functions it exercised. Recording untested functions prevents the result from being silently extended into a universal instrument assurance. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: The reference passed the stated checks; untested functions and remaining limits are listed.

Distinguishing consideration: compare this with option A, “The closing state proves every earlier gain and clock state was valid”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-078. Why are native trace files generally stronger supporting evidence than screenshots alone?

A. They automatically preserve every hidden setting regardless of the export content

B. Their native format guarantees the absence of acquisition errors

C. Their existence alone supplies any missing authority for collection

D. They can preserve data and configuration information needed for reconstruction

Answer: D. Screenshots are useful illustrations but omit aspects of data lineage and settings. Native records can support reconstruction, provided their actual content and configuration are retained. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: They can preserve data and configuration information needed for reconstruction.

Distinguishing consideration: compare this with option A, “They automatically preserve every hidden setting regardless of the export content”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

V011-C01-MCQ-080. What makes an alternate instrument comparison more persuasive?

A. It reproduces the same analysis on the same native record

B. It uses separate hardware while retaining the same unchallenged shared fault path

C. It produces a closer numerical match after selecting only favorable intervals

D. It changes relevant error sources while preserving the observation capability needed for the test

Answer: D. Independence concerns the mechanisms capable of producing the error, not the appearance of separate instruments. Adequate comparable capability remains necessary. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: It changes relevant error sources while preserving the observation capability needed for the test.

Distinguishing consideration: compare this with option A, “It reproduces the same analysis on the same native record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

V011-C01-MCQ-081. A stable component appears only with the automatic preamplifier enabled. Which next interpretation is most cautious and useful?

A. The component is configuration-dependent and warrants an artifact or overload challenge

B. The gain dependence by itself establishes an external emitter operating near the threshold

C. The component can be attributed to the preamplifier circuit without further discrimination

D. A stable frequency makes the gain-state dependence irrelevant to interpretation

Answer: A. The observed state dependence narrows the technical question. It does not by itself identify the source or establish the information carried by the component. Source: §1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 99)

Why the selected alternative fits: The component is configuration-dependent and warrants an artifact or overload challenge.

Distinguishing consideration: compare this with option B, “The gain dependence by itself establishes an external emitter operating near the threshold”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Review: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-082. In the chapter's hypothetical 433.920 MHz case, why is the second receiver's nondetection qualified?

A. A lower advertised noise floor alone establishes equivalent comparator capability

B. Nondetection excludes an external source regardless of instantaneous coverage

C. A second enclosure supplies independence even when the relevant measurement conditions differ

D. Its capability and observation conditions must support the comparison

Answer: D. The case favors an artifact explanation but retains the possibility that comparison conditions differ. Sensitivity, coverage, reference plane, and timing determine the force of the negative test. Source: §1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 99)

Why the selected alternative fits: Its capability and observation conditions must support the comparison.

Distinguishing consideration: compare this with option A, “A lower advertised noise floor alone establishes equivalent comparator capability”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Review: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

V011-C01-MCQ-083. A later wide scan fails to reproduce a component found during an earlier dwell. What should be compared first?

A. The nominal instrument sensitivity specifications without the active states

B. The final peak values after forcing both plots to the same scale

C. The two measurement definitions and usable coverage

D. The total number of stored traces without their acquisition definitions

Answer: C. Different time coverage, detectors, blockers, or statistics can explain the apparent disagreement. Physical change should not be inferred before these measurement differences are reconciled. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why the selected alternative fits: The two measurement definitions and usable coverage.

Distinguishing consideration: compare this with option A, “The nominal instrument sensitivity specifications without the active states”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-084. Which finding remains useful without establishing attribution?

A. An unrestricted absence claim based on one valid but limited interval

B. A calibrated observation supporting a specified next measurement

C. A source attribution inferred only from repeated detection

D. An owner assignment inferred solely from a stable frequency label

Answer: B. The chapter treats findings as inputs to bounded decisions. A well-defined observation can justify additional work while leaving source identity unresolved. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why the selected alternative fits: A calibrated observation supporting a specified next measurement.

Distinguishing consideration: compare this with option A, “An unrestricted absence claim based on one valid but limited interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-085. Which statement best expresses a bounded negative finding?

A. No events meeting the defined criterion were observed within the demonstrated valid coverage

B. No possible emitter exists anywhere

C. Nothing happened outside the measured interval

D. Every conceivable waveform was excluded

Answer: A. The finding must remain limited to the event class, sensitivity, intervals, and conditions actually tested. Unobserved classes or intervals cannot be included by implication. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why the selected alternative fits: No events meeting the defined criterion were observed within the demonstrated valid coverage.

Distinguishing consideration: compare this with option B, “No possible emitter exists anywhere”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-086. What is the appropriate consequence of loss of clock lock during a timing-dependent observation?

A. Apply an amplitude correction to compensate for the missing clock-state evidence

B. Apply the planned stop or escalation condition and identify the affected interval

C. Combine the affected interval with locked intervals before judging timing validity

D. Continue using timestamps as valid because the nominal sample rate is unchanged

Answer: B. Clock validity affects the time basis. The operational response and data treatment should follow the declared plan, with the affected interval preserved in the record. Source: §1.9 Operational Decision Discipline (p. 70)

Why the selected alternative fits: Apply the planned stop or escalation condition and identify the affected interval.

Distinguishing consideration: compare this with option A, “Apply an amplitude correction to compensate for the missing clock-state evidence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-087. A field lesson from one receiver is applied to another model. What status should it initially have?

A. A substitute for examining the new receiver architecture

B. A hypothesis requiring validation for the new configuration

C. A calibration result transferable without checking the new installed path

D. An established universal rule because the original observation was carefully documented

Answer: B. The chapter restricts transfer of lessons to what the evidence supports. A different architecture or state can change the mechanisms and validity conditions.

Source: §1.9 Operational Decision Discipline (p. 70)

Why the selected alternative fits: A hypothesis requiring validation for the new configuration.

Distinguishing consideration: compare this with option A, “A substitute for examining the new receiver architecture”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-088. Why plan receiver operations around decision points?

A. To connect observations with justified next actions and prevent purposeless trace accumulation

B. To ensure that every unreproduced component is classified as an artifact

C. To collect the greatest number of traces before defining their analytical purpose

D. To make the available menu sequence determine the authorized objective

Answer: A. Decision points specify when to continue, challenge, stop, or escalate. They give acquisition a defined analytical purpose without pretending to eliminate professional judgment. Source: §1.9 Operational Decision Discipline (p. 70)

Why the selected alternative fits: To connect observations with justified next actions and prevent purposeless trace accumulation.

Distinguishing consideration: compare this with option B, “To ensure that every unreproduced component is classified as an artifact”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-089. Which record best supports review of a procedure deviation?

A. The deviation, its reason, the affected state or data, and its consequence for the conclusion

B. The original procedure alone, omitting how actual execution differed

C. The receiver identity without a connection to the affected data

D. The final favorable result without the changed conditions

Answer: A. A reviewer needs to determine whether the conclusion remains valid under the actual procedure. The deviation must therefore be connected to the measurement and its interpretation. Source: §1.9 Operational Decision Discipline (p. 70)

Why the selected alternative fits: The deviation, its reason, the affected state or data, and its consequence for the conclusion.

Distinguishing consideration: compare this with option B, “The original procedure alone, omitting how actual execution differed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

V011-C01-MCQ-090. Which report claim exceeds a successful bounded artifact challenge?

A. Every internal coupling path has been identified

B. The component depends on the tested receiver state

C. Further mechanism localization may require additional observations

D. The tested changes favor an artifact explanation under the stated conditions

Answer: A. An artifact finding can be useful without fully resolving the internal mechanism. Establishing every coupling path demands evidence beyond a limited diagnostic comparison. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why the selected alternative fits: Every internal coupling path has been identified.

Distinguishing consideration: compare this with option B, “The component depends on the tested receiver state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-091. A receiver indicates minus 60 dBm after 3 dB path loss and 10 dB external gain. Which reference-plane result follows Equation 2 before other corrections?

A. Minus 67 dBm

B. Minus 53 dBm

C. Minus 73 dBm

D. Minus 47 dBm

Answer: A. The backward correction is minus 60 plus 3 minus 10, giving minus 67 dBm. This arithmetic remains conditional on the declared path, gain state, and absence of invalidating behavior. Source: Equation 2. Corrected input power (p. 71)

Why the selected alternative fits: Minus 67 dBm.

Distinguishing consideration: compare this with option B, “Minus 53 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-092. An unamplified path has 6 dB calibrated loss and the receiver indicates minus 90 dBm. What upstream level does the scalar correction give?

A. Minus 96 dBm

B. Minus 15 dBm

C. Minus 84 dBm

D. Minus 540 dBm

Answer: C. With zero external gain, Equation 2 adds the 6 dB loss to the indication. The result is minus 84 dBm at the stated upstream plane, before any additional applicable corrections. Source: Equation 2. Corrected input power (p. 71)

Why the selected alternative fits: Minus 84 dBm.

Distinguishing consideration: compare this with option A, “Minus 96 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-093. The receiver indication is minus 50 dBm, with 2 dB loss and 20 dB gain. A report states minus 28 dBm upstream. What sign error is present?

A. Path loss was correctly omitted

B. The reference plane is proved by the number

C. The calculation correctly implements Equation 2

D. External gain was added instead of subtracted

Answer: D. The correct scalar result is minus 68 dBm. Adding the 20 dB gain reverses the backward correction and creates a 40 dB error relative to the stated model. Source: Equation 2. Corrected input power (p. 71)

Why the selected alternative fits: External gain was added instead of subtracted.

Distinguishing consideration: compare this with option A, “Path loss was correctly omitted”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-094. Two records have identical corrected power but different noise floors. Which conclusion is justified?

A. A lower corrected noise floor establishes the physical identity of the component

B. Equal corrected values establish equal sensitivity despite different noise floors

C. Equal corrected level alone does not establish equal observation capability

D. A scalar amplitude correction makes the two detection criteria equivalent

Answer: C. Sensitivity and validity are properties of the complete state. Matching a corrected signal value does not show that weak components or negative findings are equally supported. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why the selected alternative fits: Equal corrected level alone does not establish equal observation capability.

Distinguishing consideration: compare this with option A, “A lower corrected noise floor establishes the physical identity of the component”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Frame a bounded finding from the completed observation.

V011-C01-MCQ-095. A report uses an image of a spectrum as proof that an acquisition mode was configured as intended. What should supplement the image?

A. Setup export, actual-state information, and native record lineage

B. A second screenshot of the same unchanged display

C. The requested mode alone without evidence that it was accepted

D. The description of the mode in the instrument manual without the acquired configuration

Answer: A. A screenshot can show a display but may omit hidden settings, transitions, and actual processing. The complementary records help establish what transformation produced it. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why the selected alternative fits: Setup export, actual-state information, and native record lineage.

Distinguishing consideration: compare this with option B, “A second screenshot of the same unchanged display”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-MCQ-096. An examiner selects only intervals containing the strongest response and then describes the result as representative of the whole survey. What must be addressed?

A. Only the receiver calibration certificate, without the interval-selection rule

B. The selection rule and the scope of the resulting estimate

C. Only the number of selected files, without their time coverage

D. Only the peak value after normalization across the selected records

Answer: B. The time interval and estimator define the measurand. A selected subset can support a conditional result, but its relation to the full survey must be justified and disclosed. Source: §1.5 Define the measurement before choosing the receiver mode (p. 62)

Why the selected alternative fits: The selection rule and the scope of the resulting estimate.

Distinguishing consideration: compare this with option A, “Only the receiver calibration certificate, without the interval-selection rule”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Equation 2C. Average after each interval has its own valid correction.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Equation 2C. Average after each interval has its own valid correction.

V011-C01-MCQ-097. The same processing script gives matching results on two computers. Which issue remains unresolved by that agreement alone?

A. A shared algorithm or configuration error

B. That the same named script was used for both executions

C. That two separate computer executions were performed

D. That the two executions produced matching reported values

Answer: A. Two executions can agree because they share the same transformation and fault. Independence must be assessed in terms of relevant error mechanisms, not merely separate machines. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: A shared algorithm or configuration error.

Distinguishing consideration: compare this with option B, “That the same named script was used for both executions”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-MCQ-098. Which final record most clearly distinguishes measurement from model-based extrapolation?

A. A fitted law establishes that all unobserved configurations behaved identically

B. The observed interval is stated separately from any assumption about unobserved intervals

C. The predicted unobserved interval is described as directly measured coverage

D. The model assumptions replace the need to state the original observation interval

Answer: B. A model can support a conditional extension, but it does not convert unobserved conditions into measurements. The evidence and its interpretive assumptions must remain distinguishable. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why the selected alternative fits: The observed interval is stated separately from any assumption about unobserved intervals.

Distinguishing consideration: compare this with option A, “A fitted law establishes that all unobserved configurations behaved identically”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

V011-C01-MCQ-099. A known reference passes after a survey, but a recording channel was never exercised by the check. Which statement is justified?

A. The untested recording path is accepted because the analog reference response passed

B. A later reference pass supplies any missing earlier sample record

C. The untested recording function remains outside the closing assurance

D. The check establishes successful export even when the export path was not exercised

Answer: C. A check validates only the function and conditions it actually tests. Its scope must identify the recording path as untested if that path was not exercised.

Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why the selected alternative fits: The untested recording function remains outside the closing assurance.

Distinguishing consideration: compare this with option A, “The untested recording path is accepted because the analog reference response passed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

V011-C01-MCQ-100. Which overall practice best implements Chapter 1?

A. Acquire the widest possible record and infer authority from its later usefulness

B. Define authority and measurand, preserve consequential states and native evidence, challenge alternatives, and bound the finding

C. Retain only final corrected values once the original processing has succeeded

D. Treat repeated detection as source attribution whenever the display is stable

Answer: B. The chapter connects institutional scope, measurement definition, configuration, evidence preservation, and discriminating tests. A defensible finding retains the limits established by that complete chain. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

Why the selected alternative fits: Define authority and measurand, preserve consequential states and native evidence, challenge alternatives, and bound the finding.

Distinguishing consideration: compare this with option A, “Acquire the widest possible record and infer authority from its later usefulness”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 1 — Mission Authority and Collection Boundaries; Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Frame a bounded….

V011-C01-FIB-021. Energy exceeding a declared decision rule first supports _____.

Answer: detection. That observation is narrower than identifying a waveform family, source, or carried information. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why this term is required: “detection” completes the stated technical proposition.

Question context: Energy exceeding a declared decision rule first supports _____

Basis and qualification: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-FIB-022. Association with a modulation family or timing behavior is called _____.

Answer: classification. Classification concerns signal characteristics and does not itself establish physical source or ownership. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why this term is required: “classification” completes the stated technical proposition.

Question context: Association with a modulation family or timing behavior is called _____

Basis and qualification: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-FIB-023. Linking an observed component to a physical emitter or system is called _____.

Answer: attribution. This stronger proposition needs source-linking evidence such as controlled state changes or other corroborating observations. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why this term is required: “attribution” completes the stated technical proposition.

Question context: Linking an observed component to a physical emitter or system is called _____

Basis and qualification: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-FIB-024. Reconstructing information carried by a signal is content _____.

Answer: recovery. Recovery must be distinguished from observing energy or recognizing a waveform family. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why this term is required: “recovery” completes the stated technical proposition.

Question context: Reconstructing information carried by a signal is content _____

Basis and qualification: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-FIB-025. A decoded network name may be a configuration string without proving device location or _____.

Answer: ownership. The meaning of the decoded identifier must not be extended beyond what the evidence supports. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why this term is required: “ownership” completes the stated technical proposition.

Question context: A decoded network name may be a configuration string without proving device location or _____

Basis and qualification: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-FIB-026. A component correlated with recorded activity can demonstrate state dependence without establishing intelligible _____.

Answer: content. Correlation may narrow the technical problem while leaving the carried information and source mechanism unresolved. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why this term is required: “content” completes the stated technical proposition.

Question context: A component correlated with recorded activity can demonstrate state dependence without establishing intelligible _____

Basis and qualification: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-FIB-027. A stable narrow peak can originate from local-oscillator _____ rather than an external emitter.

Answer: leakage. Stability does not by itself separate genuine external components from instrument-generated ones. Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)

Why this term is required: “leakage” completes the stated technical proposition.

Question context: A stable narrow peak can originate from local-oscillator _____ rather than an external emitter

Basis and qualification: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

V011-C01-FIB-031. Equation 2 refers a downstream indication backward by adding passive path _____.

Answer: loss. The upstream signal is higher than the downstream indication by the applicable loss, within the scalar model. Source: Equation 2. Corrected input power (p. 71)

Why this term is required: “loss” completes the stated technical proposition.

Question context: Equation 2 refers a downstream indication backward by adding passive path _____

Basis and qualification: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-FIB-032. Equation 2 refers a downstream indication backward by subtracting external _____.

Answer: gain. The amplifier raised the downstream level, so its contribution is removed when estimating the upstream level. Source: Equation 2. Corrected input power (p. 71)

Why this term is required: “gain” completes the stated technical proposition.

Question context: Equation 2 refers a downstream indication backward by subtracting external _____

Basis and qualification: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-FIB-033. In the chapter's calculation, minus 71.4 plus 4.8 minus 18.6 gives minus _____ dBm.

Answer: 85.2. The result is the preamplifier-input level under the stated model, before mismatch and uncertainty are included. Source: §1.12 Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 78)

Why this term is required: “85.2” completes the stated technical proposition.

Question context: In the chapter's calculation, minus 71.4 plus 4.8 minus 18.6 gives minus _____ dBm

Basis and qualification: Chapter 1 — Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Hypothetical Applied Calculation: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-FIB-034. An indication of minus 90 dBm through an unamplified 6 dB loss corresponds to minus _____ dBm upstream.

Answer: 84. With zero external gain, the scalar backward correction simply adds the calibrated loss to the receiver indication. Source: Equation 2. Corrected input power (p. 71)

Why this term is required: “84” completes the stated technical proposition.

Question context: An indication of minus 90 dBm through an unamplified 6 dB loss corresponds to minus _____ dBm upstream

Basis and qualification: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-FIB-035. An indication of minus 60 dBm, 3 dB loss, and 10 dB gain gives minus _____ dBm at the upstream plane.

Answer: 67. The calculation is minus 60 plus 3 minus 10. Its applicability remains conditional on the actual chain and calibration state. Source: Equation 2. Corrected input power (p. 71)

Why this term is required: “67” completes the stated technical proposition.

Question context: An indication of minus 60 dBm, 3 dB loss, and 10 dB gain gives minus _____ dBm at the upstream plane

Basis and qualification: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-FIB-036. The gain and loss terms in Equation 2 are expressed in _____, while absolute power is expressed in dBm.

Answer: decibels. Compatible logarithmic units permit the additive correction without equating a ratio with an absolute power. Source: Equation 2. Corrected input power (p. 71)

Why this term is required: “decibels” completes the stated technical proposition.

Question context: The gain and loss terms in Equation 2 are expressed in _____, while absolute power is expressed in dBm

Basis and qualification: Chapter 1 — Equation 2. Corrected input power.

Review: Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-FIB-037. The original indication and every applied correction should be retained as a correction _____.

Answer: chain. This record exposes double counting, wrong signs, and corrections belonging to a different state or reference plane. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why this term is required: “chain” completes the stated technical proposition.

Question context: The original indication and every applied correction should be retained as a correction _____

Basis and qualification: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-FIB-038. A display level is not automatically a measurement of environmental field _____.

Answer: strength. The conversion requires an applicable antenna relationship, geometry, and the rest of the measurement path. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why this term is required: “strength” completes the stated technical proposition.

Question context: A display level is not automatically a measurement of environmental field _____

Basis and qualification: Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Reference Planes and Configuration Identity.

Copyright 2026, James M. Atkinson

V011-C01-FIB-039. Adding a scalar correction cannot repair receiver _____.

Answer: overload. An invalid nonlinear record can lose information that a later numerical offset does not restore. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why this term is required: “overload” completes the stated technical proposition.

Question context: Adding a scalar correction cannot repair receiver _____

Basis and qualification: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse.

V011-C01-FIB-042. An automatic mode must be documented when it can silently change measurement _____.

Answer: settings. Hidden changes can alter the measurand, validity, or applicable corrections even when the operator makes no manual adjustment. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “settings” completes the stated technical proposition.

Question context: An automatic mode must be documented when it can silently change measurement _____

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-FIB-043. The requested setup and the accepted or actual state are not necessarily _____.

Answer: identical. A command can be rejected, delayed, or followed by an automatic change, so status and observation records are needed. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “identical” completes the stated technical proposition.

Question context: The requested setup and the accepted or actual state are not necessarily _____

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-FIB-044. A gain change can affect amplitude calibration, overload margin, recovery time, and noise _____.

Answer: floor. These coupled effects prevent a gain-state change from being treated solely as a display offset. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “floor” completes the stated technical proposition.

Question context: A gain change can affect amplitude calibration, overload margin, recovery time, and noise _____

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-FIB-045. A sample-rate change can move alias locations and alter recording _____.

Answer: throughput. The rate affects both the measurement mapping and the handling of the sampled record. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “throughput” completes the stated technical proposition.

Question context: A sample-rate change can move alias locations and alter recording _____

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-FIB-046. A preselector can improve blocker rejection while adding loss and phase _____.

Answer: delay. The gain in selectivity may carry other measurement consequences that must remain visible in the comparison. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “delay” completes the stated technical proposition.

Question context: A preselector can improve blocker rejection while adding loss and phase _____

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-FIB-047. Separate state _____ identify portions of a record governed by applicable configurations and calibrations.

Answer: intervals. State-dependent transformations should not be hidden within one undifferentiated average. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “intervals” completes the stated technical proposition.

Question context: Separate state _____ identify portions of a record governed by applicable configurations and calibrations

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-FIB-048. A setup export principally records the _____ configuration.

Answer: requested. The accepted state and captured observation provide additional evidence needed to determine what actually occurred. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “requested” completes the stated technical proposition.

Question context: A setup export principally records the _____ configuration

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-FIB-049. A status log may record the accepted or _____ receiver state.

Answer: actual. Status information can expose a difference between the intended setup and the state associated with the data. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “actual” completes the stated technical proposition.

Question context: A status log may record the accepted or _____ receiver state

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-FIB-050. Configuration detail is relevant when it would change the answer to the measurement _____.

Answer: question. The chapter calls for consequential identity rather than indiscriminate recording of every cosmetic menu preference. Source: §1.6 Treat configuration changes as changes in the measurement law (p. 64)

Why this term is required: “question” completes the stated technical proposition.

Question context: Configuration detail is relevant when it would change the answer to the measurement _____

Basis and qualification: Chapter 1 — Treat configuration changes as changes in the measurement law.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-FIB-068. A capture probability requires both an event-start distribution and a capture _____.

Answer: criterion. Usable windows are evidence about coverage; the probability adds assumptions about events and success. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why this term is required: “criterion” completes the stated technical proposition.

Question context: A capture probability requires both an event-start distribution and a capture _____

Basis and qualification: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-FIB-069. Recording each processing step creates a reviewable analytical _____.

Answer: lineage. The record connects the retained input to the derived output and supports reconstruction or challenge. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why this term is required: “lineage” completes the stated technical proposition.

Question context: Recording each processing step creates a reviewable analytical _____

Basis and qualification: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-FIB-070. Reversibility is weakened when the corrected output _____ the only copy of the native input.

Answer: overwrites. Preserving the original representation prevents later processing choices from erasing the evidence on which the result rests. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Why this term is required: “overwrites” completes the stated technical proposition.

Question context: Reversibility is weakened when the corrected output _____ the only copy of the native input

Basis and qualification: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-FIB-071. A complete receiver record includes antenna orientation, height, polarization, and cable _____.

Answer: route. Installed geometry and routing can affect coupling and must accompany a reproducible observation. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “route” completes the stated technical proposition.

Question context: A complete receiver record includes antenna orientation, height, polarization, and cable _____

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-072. When sensors are compared, record synchronization sources and clock _____.

Answer: uncertainty. A common displayed time does not by itself establish the accuracy or independence of the underlying time bases. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “uncertainty” completes the stated technical proposition.

Question context: When sensors are compared, record synchronization sources and clock _____

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-073. Negative and unsuccessful tests are retained because they constrain competing _____.

Answer: explanations. Their evidential value depends on the capability and conditions of the test, including any limitations. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “explanations” completes the stated technical proposition.

Question context: Negative and unsuccessful tests are retained because they constrain competing _____

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-074. A known source or injected reference can support closing _____ of the measurement chain.

Answer: verification. The check assesses specified functions at its own time and conditions. It alone does not establish uninterrupted validity throughout the preceding acquisition. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “verification” completes the stated technical proposition.

Question context: A known source or injected reference can support closing _____ of the measurement chain

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-075. Alternate attenuation or preselection can challenge receiver _____.

Answer: linearity. The response to a controlled state change can help distinguish external components from overload-related or instrument-generated behavior.

Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “linearity” completes the stated technical proposition.

Question context: Alternate attenuation or preselection can challenge receiver _____

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-076. Agreement between instruments is persuasive only when relevant errors are sufficiently _____.

Answer: independent. Separate displays may still share an input route, clock, or processing fault that explains common behavior. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “independent” completes the stated technical proposition.

Question context: Agreement between instruments is persuasive only when relevant errors are sufficiently _____

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-077. The closing record should identify both verified functions and functions that remained _____.

Answer: untested. A bounded assurance prevents the check result from being extended to capabilities it never exercised. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “untested” completes the stated technical proposition.

Question context: The closing record should identify both verified functions and functions that remained _____

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-078. Native trace files and setup exports generally preserve stronger supporting evidence than screenshots _____.

Answer: alone. Images can illustrate an observation while omitting data and configuration needed for reconstruction. Source: §1.4 Reference Planes and Configuration Identity (p. 59)

Why this term is required: “alone” completes the stated technical proposition.

Question context: Native trace files and setup exports generally preserve stronger supporting evidence than screenshots _____

Basis and qualification: Chapter 1 — Reference Planes and Configuration Identity.

Review: Chapter 1 — Reference Planes and Configuration Identity.

Copyright 2026, James M. Atkinson

V011-C01-FIB-079. Failed captures and inaccessible settings are examples of record _____.

Answer: limitations. They identify aspects of coverage or control that may restrict the resulting finding. Source: §1.8 Evidence Record and Closing Verification (p. 69)

Why this term is required: “limitations” completes the stated technical proposition.

Question context: Failed captures and inaccessible settings are examples of record ____

Basis and qualification: Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-FIB-080. A suitable alternate receiver must retain the observation _____ relevant to the negative comparison.

Answer: capability. Nondetection is not discriminating when sensitivity, frequency coverage, or timing prevented the comparator from observing the candidate.

Source: §1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 99)

Why this term is required: “capability” completes the stated technical proposition.

Question context: A suitable alternate receiver must retain the observation _____ relevant to the negative comparison

Basis and qualification: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Evidence Record and Closing Verification.

V011-C01-FIB-081. Receiver operations should be organized around decision _____ rather than menu availability.

Answer: points. These connect observations to continuation, challenge, stopping, and escalation actions. Source: §1.9 Operational Decision Discipline (p. 70)

Why this term is required: “points” completes the stated technical proposition.

Question context: Receiver operations should be organized around decision _____ rather than menu availability

Basis and qualification: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-FIB-082. Loss of clock lock is one potential reason to stop or _____ a timing-dependent examination.

Answer: escalate. The operational plan should define a response to validity failures and preserve the affected interval. Source: §1.9 Operational Decision Discipline (p. 70)

Why this term is required: “escalate” completes the stated technical proposition.

Question context: Loss of clock lock is one potential reason to stop or _____ a timing-dependent examination

Basis and qualification: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-FIB-083. An inability to reproduce a result should trigger examination of the configuration and measurement _____.

Answer: conditions. Nonreproduction can arise from changed state or coverage and should not be converted immediately into a broad environmental conclusion.

Source: §1.9 Operational Decision Discipline (p. 70)

Why this term is required: “conditions” completes the stated technical proposition.

Question context: An inability to reproduce a result should trigger examination of the configuration and measurement _____

Basis and qualification: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-FIB-084. Lessons learned from one instrument or site become _____ for validation elsewhere.

Answer: hypotheses. The evidence does not establish a universal rule for every architecture or installed state. Source: §1.9 Operational Decision Discipline (p. 70)

Why this term is required: “hypotheses” completes the stated technical proposition.

Question context: Lessons learned from one instrument or site become _____ for validation elsewhere

Basis and qualification: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-FIB-085. A deviation record allows later reviewers to assess whether the conclusion remains _____.

Answer: valid. The reason, affected data, and consequence of the change must be available for that judgment. Source: §1.9 Operational Decision Discipline (p. 70)

Why this term is required: “valid” completes the stated technical proposition.

Question context: A deviation record allows later reviewers to assess whether the conclusion remains _____

Basis and qualification: Chapter 1 — Operational Decision Discipline.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-FIB-086. A later wide scan and an earlier dwell may differ because their time and frequency _____ differ.

Answer: coverage. The apparent disagreement may reflect different observation opportunities rather than a physical change in the environment. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why this term is required: “coverage” completes the stated technical proposition.

Question context: A later wide scan and an earlier dwell may differ because their time and frequency _____ differ

Basis and qualification: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-FIB-087. A defensible finding identifies the observation, valid conditions, challenged alternatives, and remaining _____.

Answer: uncertainty. Those boundaries show what the record can support and what further work may be required. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why this term is required: “uncertainty” completes the stated technical proposition.

Question context: A defensible finding identifies the observation, valid conditions, challenged alternatives, and remaining _____

Basis and qualification: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-FIB-088. A useful finding may support continued measurement without supporting source _____.

Answer: attribution. The next technical decision can be justified before emitter identity has been established. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why this term is required: “attribution” completes the stated technical proposition.

Question context: A useful finding may support continued measurement without supporting source _____

Basis and qualification: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-FIB-089. A calibrated absence claim applies to the defined event _____ that was tested.

Answer: class. Other waveforms, durations, levels, or times can remain outside the demonstrated observation. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why this term is required: “class” completes the stated technical proposition.

Question context: A calibrated absence claim applies to the defined event _____ that was tested

Basis and qualification: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-FIB-090. Identifying a receiver artifact does not necessarily identify every internal coupling _____.

Answer: path. A bounded diagnostic result can be useful while detailed mechanism localization remains incomplete. Source: §1.14 Frame a bounded finding from the completed observation (p. 100)

Why this term is required: “path” completes the stated technical proposition.

Question context: Identifying a receiver artifact does not necessarily identify every internal coupling _____

Basis and qualification: Chapter 1 — Frame a bounded finding from the completed observation.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

V011-C01-FIB-091. The unexpected 433.920 MHz component in the chapter's case appeared only with the automatic _____ enabled.

Answer: preamplifier. Its dependence on that setting motivates a configuration-specific artifact or overload challenge. Source: §1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 99)

Why this term is required: “preamplifier” completes the stated technical proposition.

Question context: The unexpected 433.920 MHz component in the chapter's case appeared only with the automatic _____ enabled

Basis and qualification: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Review: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Copyright 2026, James M. Atkinson

V011-C01-FIB-092. The second receiver's nondetection cannot exclude an external contribution without comparable sensitivity and observation _____.

Answer: interval. A difference in opportunity to observe the event can explain the negative result independently of its source. Source: §1.13 Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation (p. 99)

Why this term is required: “interval” completes the stated technical proposition.

Question context: The second receiver's nondetection cannot exclude an external contribution without comparable sensitivity and observation _____

Basis and qualification: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Review: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C01-ESSAY-001. Develop a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and analysis script. Explain why the instrument enclosure is an inadequate boundary.

- Opening: Present a thesis that answers this precise question: Develop a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and analysis script. Identify which evidence would falsify the proposed conclusion Source: §1.1 Receiver as a Measurement System (p. 53)
- Core terminology and scope: Define defensible, remote, digitizer in the question's particular technical setting; explain how script, enclosure, inadequate differ if that distinction would change the analysis of "Develop a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and analysis script" Source: §1.1 Receiver as a Measurement System (p. 53)
- Problem statement and purpose: Frame the actual measurement or decision in the question. A strong answer follows the physical and computational transformations to the reported result Source: §1.1 Receiver as a Measurement System (p. 53)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and… to the claimed result, following "Reference Planes and Configuration Identity";

Copyright 2026, James M. Atkinson

name the intermediate states and measurable outputs Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and…. It identifies input and output planes, path loss and gain, filtering, reference and clock states, digitization, and processing Source: §1.4 Reference Planes and Configuration Identity (p. 59)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 1A.5. Retain separate admissible results when the settled state is unknown” that resolves the question about a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and…; derive the relevant result with units and stated validity conditions Source: §1.12.5 Application 1A.5. Retain separate admissible results when the settled state is unknown (p. 87)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and…. It explains which accessories or software choices could change the measurand, rather than merely listing equipment Source: §1.1 Receiver as a Measurement System (p. 53)
- Worked application or illustrative case: Build a worked example of “a defensible system boundary for a receiver connected to an antenna,

Copyright 2026, James M. Atkinson

remote amplifier, switching path, digitizer, computer, and…", addressing this associated condition: Explain why the instrument enclosure is an inadequate boundary. A strong answer follows the physical and computational transformations to the reported result Source: §1.4 Reference Planes and Configuration Identity (p. 59)

- Alternative explanations and failure modes: Construct two plausible technical explanations for "a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and…". Using "Application 1A.5. Retain separate admissible results when the settled state is unknown", specify a discriminator and the result expected under each explanation Source: §1.12.5 Application 1A.5. Retain separate admissible results when the settled state is unknown (p. 87)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and…, including the effect of missing measurements and inconsistent operating conditions Source: §1.12.3 Application 1A.3. Combine valid gain states without averaging their decibel labels (p. 83)
- Scholarly synthesis and implications: Explain what the result about a defensible system boundary for a receiver connected to an antenna, remote amplifier, switching path, digitizer, computer, and… authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §1.1 Receiver as a Measurement System (p. 53)
- Closing: Conclude by answering "Develop a defensible system boundary for a receiver connected to an antenna, remote amplifier,

Copyright 2026, James M. Atkinson

switching path, digitizer, computer, and analysis script" using only the demonstrated evidence; state the remaining decisive verification step Source: §1.1 Receiver as a Measurement System (p. 53)

V011-C01-ESSAY-003. Compare detection, classification, attribution, and content recovery using one hypothetical component observed during a lawful survey. State the additional evidence needed to move between propositions.

- Opening: Present a thesis that answers this precise question: Compare detection, classification, attribution, and content recovery using one hypothetical component observed during a lawful survey. Identify which evidence would falsify the proposed conclusion Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)
- Core terminology and scope: Define classification, attribution, content in the question's particular technical setting; explain how hypothetical, lawful, propositions differ if that distinction would change the analysis of "Compare detection, classification, attribution, and content recovery using one hypothetical component observed during a lawful survey" Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)
- Problem statement and purpose: Frame the actual measurement or decision in the question. The answer should begin with a declared detection criterion and then distinguish waveform characterization, a supported link to a physical emitter, and reconstruction of carried information Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting detection, classification, attribution, and content recovery using one hypothetical component observed during a lawful survey to the

Copyright 2026, James M. Atkinson

claimed result, following “Mission Authority and Collection Boundaries”; name the intermediate states and measurable outputs Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for detection, classification, attribution, and content recovery using one hypothetical component observed during a lawful survey. It should show that success at one stage does not establish the next Source: §1.2 Mission Authority and Collection Boundaries (p. 55)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 1A.5. Retain separate admissible results when the settled state is unknown” that resolves the question about detection, classification, attribution, and content recovery using one hypothetical component observed during a lawful survey; derive the relevant result with units and stated validity conditions Source: §1.12.5 Application 1A.5. Retain separate admissible results when the settled state is unknown (p. 87)
- Evidence and method: Specify the native observations, control records and calculations that would resolve detection, classification, attribution, and content recovery using one hypothetical component observed during a lawful survey. Suitable examples include a stable peak, a modulation-family label, an identifier, and a controlled device-state comparison Source: §1.3 Observation, Classification, Attribution, and Content Recovery (p. 57)
- Worked application or illustrative case: Build a worked example of “detection, classification, attribution, and content recovery using

V011-C01-DISCUSSION-001. Should a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the authorized question? Develop a position grounded in Chapter 1.

- 01. Moderator, opening proposition: Introduce the exact dispute, “Should a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the authorized question? Develop a position grounded in Chapter 1.” Put this particular dispute to the panel: Should a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the authorized question? Develop a position.... Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

- 02. Student A, terminology and scope: Agree the operational meanings of survey, storage, acquisition and limited, authorized, position in “Should a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the authorized question? Develop a position...”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the

Copyright 2026, James M. Atkinson

outcome and request a specific example from the stated receiver scenario. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of whether a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the…; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §1.9 Operational Decision Discipline (p. 70)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Operational Decision Discipline”. Identify cases in which native data are necessary and cases in which broader capture exceeds the objective Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §1.9 Operational Decision Discipline (p. 70)

Copyright 2026, James M. Atkinson

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the…; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Operational Decision Discipline”. Identify cases in which native data are necessary and cases in which broader capture exceeds the objective Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §1.9 Operational Decision Discipline (p. 70)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Discuss analytical reversibility alongside minimization, content limits, retention, and disclosure Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without

Copyright 2026, James M. Atkinson

changing the measurand. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

- 08. Student D, answer to Student E: Design a discriminating experiment involving whether a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the…: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the…; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §1.7 Keep the evidence chain reversible to its declared inputs (p. 67)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving whether a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the…: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §1.2 Mission Authority and Collection Boundaries (p. 55)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving whether a receiver survey preserve more raw data whenever storage is inexpensive, or should the acquisition remain limited to the…, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §1.9 Operational Decision Discipline (p. 70)

- 12. Student G, revised experimental answer: Address Student H’s confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving

Chapter 1 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C01-ESSAY-001 — A strong answer follows the physical and computational transformations to the reported result. It identifies input and output planes, path loss and gain, filtering, reference and clock states, digitization, and processing. It explains which accessories or software choices could change the measurand, rather than merely listing equipment. The answer should show how the boundary permits external signals to be distinguished from measurement-system effects and how native data and configuration identity support later reconstruction.

Review: Chapter 1 — Receiver as a Measurement System; Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

V011-C01-ESSAY-002 — Define the technical objective and permitted observations before choosing receiver modes. Explain how frequency ranges, duration, channels, detector settings, recording, and metadata implement that objective. Discuss incidental information, access, retention, deletion, and stop conditions without inventing a universal legal rule. A complete answer identifies who may approve a scope extension and what must be recorded. It should distinguish technical capability from authority and connect minimization to actual data acquired.

Review: Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-003 — The answer should begin with a declared detection criterion and then distinguish waveform characterization, a supported link to a physical emitter, and reconstruction of carried information. It should show that success at one stage does not establish the next. Suitable examples include a stable peak, a modulation-family label, an identifier, and a controlled device-state comparison. Credit depends on explicit conditions and alternative explanations, including receiver artifacts and identifiers that do not establish ownership.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

V011-C01-ESSAY-004 — State the indication, desired upstream plane, gain, loss, and compatible calibration state. Apply Equation 2 with correct signs and retain the original indication and each correction. Explain why the scalar result does not automatically become field strength or source power. A complete answer identifies mismatch, detector response, uncertainty, and invalidating overload as matters outside the simple correction when relevant. Numerical inputs must be labeled hypothetical and the arithmetic must be shown.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Equation 2. Corrected input power.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-005 — Distinguish the setup request from the state that actually governed acquisition. Discuss rejection, transition, settling, and automatic changes. Link commands, status events, and data intervals through the declared time basis. The answer should identify what remains unresolved when one record is absent and explain why averaging across the disagreement can conceal a measurement defect. It should give a concrete example, such as a rate or gain change, and retain both the original records and the resulting limitation.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-ESSAY-006 — For each target, specify plane, frequency and time intervals, state, estimator, decision criterion, and relevant validity conditions. The amplitude definition should explain which energy and detector operation contribute. The timing definition should distinguish sample aperture, trigger event, and software receipt as possible timestamp meanings. The comparison should show why one acquisition configuration may suit one target while leaving the other inadequately supported, without treating precision alone as proof of accuracy.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-007 — Identify the input, output, configured transformation, and internal contribution. Explain that conversion, sampling, memory, adaptive control, limiting, and software can belong to the transformation. A strong answer distinguishes this boundary description from narrower models whose operating domains must be demonstrated. It should use an example such as gain control or overload to show how a global linear interpretation can fail while a local, explicitly bounded approximation remains useful.

Review: Chapter 1 — Equation 1. Configured receiver-chain representation; Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-ESSAY-008 — Identify the representation retained and the operations that produced it. Explain that magnitude, clipping, sampling loss, and other irreversible transformations can remove information needed for later questions. The answer should not claim that every derived spectrum is useless. Instead, state which bounded quantity it can still support and what additional phase, timing, or estimator claims would require the missing native data. Conclude with a preservation and processing-lineage policy tied to the intended objective.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.8. Preserve a valid power result while refusing to reconstruct lost phase.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-009 — Describe the requested changes, accepted states, transition and settling intervals, and samples assigned to each valid state. Explain the different consequences of preselection, gain, and rate for transfer, blockers, aliasing, timing, and throughput. State when separate corrections are necessary and what would justify combining intervals. The answer should avoid treating a common display scale as proof of comparability and should preserve unresolved state information explicitly.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

V011-C01-ESSAY-010 — Explain why agreement can arise from a shared input path, reference, clock, or processing assumption. Identify changes that could alter relevant errors while preserving the capability to observe the component. Discuss the limits of a comparator's nondetection and the need to match useful sensitivity, coverage, reference plane, and time opportunity. A strong answer gives a bounded conclusion from the proposed comparison rather than claiming that independence can be established merely by using different enclosures.

Review: Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-011 — Tie the known reference to the functions needed for the original claim, including the path, scale, detector, recording, and export where applicable. Identify which states and functions were exercised and which remained untested. Discuss the time relation to the field observation and the meaning of a pass or failure. The answer should preserve the original data and avoid converting a limited functional check into proof of source identity, unrestricted validity, or authorization.

Review: Chapter 1 — Evidence Record and Closing Verification.

V011-C01-ESSAY-012 — Begin with the stated preamplifier dependence, attenuation behavior, and comparator nondetection. Identify competing explanations and predict what each follow-up change would test. Preserve sensitivity, physical-frequency coverage, relevant reference planes, and observation intervals while changing one useful causal condition. A strong answer records actual rather than merely requested states and retains unsuccessful results. The conclusion should express whether alternatives are favored, weakened, or still unresolved without asserting complete mechanism localization prematurely.

Review: Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-013 — Compare the two measurement definitions, including time opportunity, instantaneous frequency coverage, detector behavior, averaging, state, blockers, and validity. Determine whether the later acquisition could have observed the earlier event class. Explain how differences in definitions can be resolved through matched or otherwise defensible observations. Only then discuss what residual disagreement might support about environmental change. Preserve both records and explicitly separate untested intervals from demonstrated negative coverage.

Review: Chapter 1 — Frame a bounded finding from the completed observation; Chapter 1 — Define the measurement before choosing the receiver mode.

V011-C01-ESSAY-014 — Explain what each attempted test was intended to discriminate and whether its required capability was demonstrated. Record the conditions, outcome, failure modes, and any missing coverage. Distinguish an instrument failure from a valid nondetection and a nondetection from universal absence. A complete answer shows how this evidence constrains later interpretation, prevents selective reporting, and guides the next experiment without imposing indiscriminate retention beyond the authorized objective.

Review: Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Frame a bounded finding from the completed observation; Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-015 — Discuss the missing original indication, individual corrections, planes, state, native data, timing, and processing lineage as applicable. Explain how their absence can conceal double-counted loss, wrong gain state, detector differences, or overload. Propose a record adequate for the actual measurement rather than an unlimited checklist. The answer should distinguish information that can still be recovered from logs or exports from information irreversibly lost and should narrow the report's claim accordingly.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Reference Planes and Configuration Identity.

V011-C01-ESSAY-016 — Explain that each objective requires a different scope and transformation. A wide scan may locate a component without supporting its calibrated level, while a narrow coherent capture may support phase without broad coverage. Identify the plane, intervals, state, estimator, and decision criteria for each. Credit depends on showing concrete tradeoffs and a sequence that connects discovery to a justified follow-up, not merely asserting that one instrument mode is always superior.

Review: Chapter 1 — Define the measurement before choosing the receiver mode.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-017 — Consider cable loss and route, adapters, antenna orientation, polarization, external filtering, mismatch, and common-mode paths. Explain how an accessory or movement can change the desired transfer or an artifact mechanism. The example should preserve the distinction between observed change and assumed cause. Identify records and a suitable comparison that would help isolate the effect, and state how earlier observations remain bound to the earlier installation.

Review: Chapter 1 — Receiver as a Measurement System; Chapter 1 — Reference Planes and Configuration Identity.

V011-C01-ESSAY-018 — Connect each event to the validity or authority condition it threatens. Define when acquisition stops, when data are marked as affected, when a diagnostic challenge is appropriate, and when specialist or authorized oversight is needed. Preserve the actual events, states, and records. A strong answer avoids a single automatic response for all failures and shows how the plan protects both evidential integrity and the permitted scope of the engagement.

Review: Chapter 1 — Operational Decision Discipline; Chapter 1 — Mission Authority and Collection Boundaries.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-019 — Suitable pairs include measured tone levels and a cubic explanation, phase-noise data and a reciprocal-mixing prediction, or usable windows and capture probability. Identify the observed quantities and the extra parameters or assumptions required by the model. Explain what further observation could challenge the interpretation. The answer should preserve the usefulness of modeling while rejecting the substitution of a prediction for an actual field observation.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Table 1A. Route the measurement question to the developed model.

V011-C01-ESSAY-020 — Explain how antennas, accessories, state changes, software, estimators, reference planes, and operating limits affect the actual result. Identify what the certificate may support and which parts of the installed chain remain outside its scope. A strong answer ties calibration applicability to the declared measurement definition and retained state, then proposes relevant checks. It should not dismiss calibration; it should show how to use calibration evidence within its supported boundary.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-021 — Choose an upstream level, external gain, and passive loss, calculate the downstream indication, and then recover the original level by adding loss and subtracting gain. Define units and reference locations. Discuss state compatibility, mismatch, detector response, uncertainty, and overload as appropriate. A complete answer recognizes that algebraic consistency verifies signs and arithmetic, while empirical validity requires separate evidence about the installed chain.

Review: Chapter 1 — Equation 2. Corrected input power; Chapter 1 — Model 1A: configured transfer, correction and recoverability.

V011-C01-ESSAY-022 — The proposed finding should state the observed event, valid state and coverage, relevant challenge outcomes, and remaining alternatives. Choose verbs consistent with detection, classification, or limited localization. Identify the next decision the evidence supports and the information still needed for attribution. Credit depends on precise scope and a useful consequence, not on making the finding sound more conclusive than the evidence allows.

Review: Chapter 1 — Frame a bounded finding from the completed observation; Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-023 — Identify which observations share timing, input, correction, or software paths. Define timestamp events and uncertainties, retained native representations, and comparison conditions. Propose changes that test relevant shared errors without destroying the capability needed for the question. A strong answer explains why agreement and disagreement are both conditional on the design and retains a bounded interpretation rather than assigning unsupported numerical confidence.

Review: Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Define the measurement before choosing the receiver mode.

V011-C01-ESSAY-024 — Identify the original mechanism, configuration, tested domain, and limits. Compare them with the new architecture, accessories, environment, and intended measurement. Determine which assumptions require a fresh check and what evidence would support or contradict transfer. Treat the earlier lesson as an informed hypothesis until the relevant conditions are established. Record deviations and avoid replacing a configuration-specific argument with a universal rule.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-ESSAY-025 — Trace the objective through measurement definition, system boundary, configuration identity, acquisition, preservation, correction, challenges, and bounded interpretation. Identify failures of authority, state knowledge, validity, continuity, comparison capability, or model support. Explain what evidence remains usable and which claim must be narrowed when a failure occurs. A strong synthesis connects the elements causally and preserves the difference between a documented observation and a stronger conclusion that requires further support.

Review: Chapter 1 — Mission Authority and Collection Boundaries; Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-C01-DISCUSSION-001 — Discuss analytical reversibility alongside minimization, content limits, retention, and disclosure. Identify cases in which native data are necessary and cases in which broader capture exceeds the objective. The discussion should produce a justified acquisition scope and an explicit treatment of incidental information, rather than treating low storage cost as a sufficient reason for indiscriminate collection.

Review: Chapter 1 — Mission Authority and Collection Boundaries; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

V011-C01-DISCUSSION-002 — Distinguish settings that change the answer from cosmetic preferences. Compare hardware identity, automatic behavior, software builds, calibration data, and state transitions. Ask how a later reviewer would detect a consequential difference. A useful conclusion states a criterion for relevance and identifies circumstances in which the required detail increases.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Reference Planes and Configuration Identity.

V011-C01-DISCUSSION-003 — Map shared inputs, clocks, reference sources, software, and correction assumptions. Discuss how to change relevant error structure while retaining comparable capability. Consider whether a different instrument brand or enclosure establishes independence. End with a bounded statement of what a proposed comparison would and would not test.

Review: Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-004 — Start with the authorized decision and the expected event class. Compare coverage, calibration, phase, timing, and information preservation. Discuss what each choice leaves untested and whether discovery can support a targeted follow-up. The result should be a reasoned measurement definition and an explicit residual gap, not a preference based on display appearance.

Review: Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Mission Authority and Collection Boundaries.

V011-C01-DISCUSSION-005 — Compare detected, classified, correlated, localized, attributed, and recovered. Discuss how different readers might overinterpret an identifier or an unexplained peak. Draft a sentence that is useful for a next decision and preserves the actual evidence. Explain which additional observations would justify stronger wording.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery; Chapter 1 — Frame a bounded finding from the completed observation.

V011-C01-DISCUSSION-006 — Consider setup exports, status logs, native data, transition timing, and potential reconstruction. Discuss whether a state can be established retrospectively and what must remain qualified if it cannot. Preserve the original record. A responsible outcome separates usable observations from unsupported amplitude or sensitivity claims instead of accepting or rejecting the entire record without analysis.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-007 — Distinguish continued function after the event from knowledge of the earlier state. Discuss which faults the check could reveal and which historical ambiguities it cannot resolve. Define a useful closing test and a report statement that acknowledges its time and scope. Avoid treating the check as either universal assurance or wholly irrelevant.

Review: Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-DISCUSSION-008 — Examine command timing, acceptance, settling, and automatic behavior. Discuss whether the trace itself can discriminate the states and what additional records are needed. Consider the risks of averaging through the disagreement. The discussion should produce a documented resolution or a bounded limitation attached to affected data.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law.

V011-C01-DISCUSSION-009 — Identify the event class, threshold or sensitivity conditions, frequency and time coverage, and exclusions. Discuss which omitted conditions would matter to the client's decision. Draft a negative finding that preserves practical meaning while directing any justified follow-up to an actual gap. Avoid both unsupported certainty and empty general caution.

Review: Chapter 1 — Frame a bounded finding from the completed observation; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-010 — Distinguish complete evidence preservation from proportionate presentation. Discuss which tests materially affect alternatives, coverage, or confidence in the finding. Explain how the final report can link to a reviewable record without concealing unfavorable outcomes. The decision must remain consistent with authorized retention and disclosure.

Review: Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Mission Authority and Collection Boundaries.

V011-C01-DISCUSSION-011 — Consider changed coupling, polarization, path sensitivity, intermittent behavior, and the actual observation opportunity. Identify a suitable return or reference comparison. The discussion should separate a useful location-dependent observation from a definitive source location and specify what evidence would narrow the alternatives.

Review: Chapter 1 — Receiver as a Measurement System; Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

V011-C01-DISCUSSION-012 — Compare a known scalar correction with clipping, magnitude-only retention, missing samples, or inadequate rejection before decimation. Discuss which transformations can be reconstructed and which require missing information. The conclusion should guide preservation and reporting, including when a corrected number would give a false impression of recovery.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.7. Show why a clipping flag defeats an ordinary gain inverse; Chapter 1 — Application 1A.8. Preserve a valid power result while refusing to reconstruct lost phase.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-013 — State the detection criterion and configured chain. Discuss external components and instrument-generated alternatives, then propose discriminating observations. Examine how authority, state identity, and valid comparison conditions constrain the next step. The discussion should produce a testable question instead of assigning ownership or intent from the display.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery; Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

V011-C01-DISCUSSION-014 — Compare usable time and frequency coverage, estimator, detector, gain, blockers, and sensitivity. Discuss what a matched follow-up would establish. Only after those conditions are reconciled should the discussion assess the residual evidence for change. Preserve the possibility that the original and later records answer different questions.

Review: Chapter 1 — Frame a bounded finding from the completed observation.

V011-C01-DISCUSSION-015 — Discuss planned decision points, controlled deviations, specialist escalation, and the evidence needed to assess validity afterward. Consider a case in which a rigid menu sequence misses a consequential state change. A strong discussion keeps judgment reviewable through reasons and records without pretending that a checklist eliminates technical interpretation.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-016 — Begin with the chapter's warning that a configuration string does not alone establish location or ownership. Discuss controlled state changes, physical correlation, timing, and competing mechanisms. Specify which inference each observation supports. The discussion should avoid both automatic acceptance and an unsupported assertion that identifiers can never be useful.

Review: Chapter 1 — Observation, Classification, Attribution, and Content Recovery.

V011-C01-DISCUSSION-017 — Compare the intended estimator, gains, losses, noise, validity, timing, and calibration applicability. Discuss whether separate corrections or a state-aware model can support the combination. Identify what must be retained for reconstruction. The final position should explain the conditions of a valid combination and when separate results are necessary.

Review: Chapter 1 — Treat configuration changes as changes in the measurement law; Chapter 1 — Equation 2C. Average after each interval has its own valid correction.

V011-C01-DISCUSSION-018 — Use concrete examples to examine the interaction rather than choosing a slogan. A capable receiver can be poorly configured, while a controlled system can still lack necessary sensitivity or coverage. Discuss how the objective determines required capability and how records and checks establish that it was available during the observation.

Review: Chapter 1 — Receiver as a Measurement System; Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-019 — Identify retained observations, model parameters, assumptions, and the predicted domain. Discuss how to label extrapolation and what evidence would test it. A useful conclusion preserves the model's analytical value without presenting unobserved intervals or configurations as measured coverage.

Review: Chapter 1 — Keep the evidence chain reversible to its declared inputs; Chapter 1 — Application 1A.10. Separate a valid corrected level from an unobserved transition interval.

V011-C01-DISCUSSION-020 — Discuss the authorized scope, the operational stop rule, preservation of the incident record, and the process for any valid extension. Keep technical interest separate from authority. The discussion should identify what can be reported about the incomplete acquisition and what additional permission or redesign would be required for further collection.

Review: Chapter 1 — Mission Authority and Collection Boundaries; Chapter 1 — Operational Decision Discipline.

V011-C01-DISCUSSION-021 — Propose a record containing the original indication, ordered path, gain and loss signs, relevant states, and destination plane. Discuss a forward arithmetic check and the limits of the scalar model. The conclusion should make it possible to identify double counting or unsupported conversion without requiring the reviewer to infer missing settings.

Review: Chapter 1 — Equation 2. Corrected input power; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-022 — Discuss illustration, communication, context, and the limits of a screen image. Consider whether the screenshot documents a display state that the native file omits, while retaining the need for data lineage and actual configuration. A proportionate package uses each representation for its supported purpose and avoids treating visual appearance as complete technical proof.

Review: Chapter 1 — Reference Planes and Configuration Identity; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

V011-C01-DISCUSSION-023 — Connect the required depth to the decision and evidence. Discuss whether the tested configuration dependence supports a bounded artifact finding, what alternatives remain, and what would justify naming a particular circuit. The conclusion should not demand unlimited investigation, but it must distinguish a useful diagnostic result from complete mechanism identification.

Review: Chapter 1 — Frame a bounded finding from the completed observation; Chapter 1 — Hypothetical Case Adjudication: Receiver-System Boundaries, Mission Authority, and Evidence Formation.

V011-C01-DISCUSSION-024 — Identify the observed mechanism, operating domain, record quality, and failed alternatives. Discuss how to present the lesson as a hypothesis or bounded procedure requiring validation in the new setting. Propose a training exercise that tests transfer rather than encouraging uncritical repetition of an anecdote.

Review: Chapter 1 — Operational Decision Discipline.

Copyright 2026, James M. Atkinson

V011-C01-DISCUSSION-025 — Construct a coherent argument from authority and measurement definition to valid state, retained inputs, corrections, challenges, and conclusion. Identify the most important open alternative and the next observation that could address it. The discussion should demonstrate that explicit limits improve the decision value of the finding without substituting repeated generic caution for technical evidence.

Review: Chapter 1 — Mission Authority and Collection Boundaries; Chapter 1 — Define the measurement before choosing the receiver mode; Chapter 1 — Evidence Record and Closing Verification; Chapter 1 — Frame a bounded finding from the completed observation.

Copyright 2026, James M. Atkinson

Chapter Glossary

ACQUISITION INTERVAL: The declared span of physical time during which observations are eligible to contribute to a measurement. Its usable portion may exclude transitions, failed captures, or invalid states; a file's existence alone does not establish continuous valid coverage.

ACTUAL STATE: The receiver configuration supported by status and observation evidence for a particular record interval. It may differ from the commanded state because of rejection, settling, automatic control, or other changes that affect the measurement.

ADAPTIVE CONTROL: A mechanism that changes a receiver or processing state in response to input or operating conditions. Its effect must be retained in configuration identity when it alters gain, validity, timing, or another part of the measurement law.

ARTIFACT: A feature introduced by the measurement apparatus or processing that can resemble a component of the environment. The term identifies an explanatory possibility or supported finding; it does not by itself identify every responsible circuit or coupling path.

ATTRIBUTION: An evidence-supported connection between an observed component and a physical emitter or system. It requires more than detection or a waveform-family label and must retain the assumptions and alternative explanations relevant to that connection.

BANDWIDTH: The frequency extent associated with an admitted path or reported measurement. Its precise definition must accompany the result because a nominal setting does not by itself identify the energy, filtering, or estimator represented by the indication.

Copyright 2026, James M. Atkinson

CALIBRATION APPLICABILITY: The conditions under which existing calibration information supports a particular measurement result. A changed path, gain state, detector, software process, or reference plane can require reassessment even when the instrument still carries a valid certificate.

CLOSING VERIFICATION: A check after an important observation that assesses specified functions of the measurement chain at the time of the check. Its assurance is limited to the states and conditions exercised; the check alone does not establish uninterrupted validity throughout the preceding acquisition.

COLLECTION BOUNDARY: The authorized limits on what an engagement may acquire and how that information may be retained or disclosed. In receiver work these limits are implemented through frequency, time, mode, channel, recording, and handling choices.

COMMANDED STATE: The configuration requested by an operator, script, or controller. It records intended operation but does not alone prove that the receiver accepted the request, settled, or maintained that state throughout the associated acquisition.

CONFIGURATION IDENTITY: Complete hardware, firmware, software, option, accessory, and setting state required to reproduce a receiver observation.

CONFIGURATION TRANSITION: A change between receiver states that can include transient, relocking, or settling behavior. Records affected by the transition must be distinguished from intervals governed by an established valid configuration.

Copyright 2026, James M. Atkinson

CONTENT RECOVERY: Reconstruction of information carried by a signal rather than mere detection or classification of its waveform.

CORRECTION CHAIN: The ordered, documented transformations that convert an original indication into a result at a declared reference plane. Retaining each term, sign, state, and applicability permits reconstruction and exposes omitted or double-counted contributions.

DECISION CRITERION: The stated condition under which an observation or numerical estimate supports an intended action or conclusion. It includes relevant validity and uncertainty requirements and must not be inferred merely from the appearance of a display.

DETECTION: A finding that energy or a structured component met a stated decision rule under declared observation conditions. It does not automatically establish waveform class, emitter identity, carried content, or intent.

DISPLAY INDICATION: The value or feature presented by an instrument or software interface before its physical meaning is fully established. Interpretation requires the relevant plane, state, estimator, scale, and applicable corrections.

ESTIMATOR: The specified mathematical operation that converts retained observations into a reported quantity. A detector bucket, integrated channel, fitted tone, or timing estimate can answer different questions despite similar display labels.

Copyright 2026, James M. Atkinson

EVIDENCE RECORD: The retained observations and contextual information needed to review a measurement and its interpretation. It includes consequential settings, native data, timing, corrections, challenges, unsuccessful tests, and limits on what was examined.

EXTERNAL GAIN: Signal gain contributed by a component outside the receiver indication's reference boundary. In the stated scalar backward level correction it is subtracted, provided its value and operating state apply to the observed path.

FREQUENCY INTERVAL: The declared frequency scope over which components can contribute to an observation or reported estimate. Excluded or unobserved portions remain outside a negative finding unless separate evidence establishes their coverage.

INDEPENDENT COMPARISON: A comparison that changes relevant sources of measurement error while retaining the capability required to observe the component of interest. Separate instruments do not establish independence when shared clocks, input paths, or processing can produce a common result.

INPUT PATH: The physical route by which energy reaches the selected receiver input, including consequential antennas, cables, adapters, filters, switches, and other components. Changing the route can change both desired transfer and artifact mechanisms.

INSTALLED PATH: The measurement path in its actual operating geometry and connections. Cable routing, antenna position, polarization, accessories, and coupling conditions can distinguish it from an isolated component characterization.

Copyright 2026, James M. Atkinson

INTERNAL CONTRIBUTION: Noise or artifacts generated within the declared measurement system rather than simply arriving at its chosen external input. Equation 1 retains this contribution so that observed output is not automatically equated with an environmental source.

MEASURAND: Quantity intended to be measured, stated with its reference plane, state, bandwidth, and conditions.

MEASUREMENT CHAIN: The connected physical and computational transformations that carry an input to a reported result. Its relevant boundaries include gain, loss, filtering, conversion, detection, sampling, timing, and analysis.

MEASUREMENT DEFINITION: The stated quantity or proposition together with its reference plane, frequency and time intervals, receiver state, estimator, and intended decision.

MINIMIZATION: Technical and procedural limitation of collection, retention, and disclosure to information necessary for an authorized purpose.

NATIVE RECORD: Data retained in the acquisition system's original useful representation, together with sufficient configuration information to interpret them. The term does not guarantee correctness; it identifies inputs that can support reconstruction before later transformations discard information.

NEGATIVE FINDING: A bounded statement that no event meeting a defined criterion was observed under demonstrated valid coverage and capability. Its meaning must preserve the tested event class, sensitivity, intervals, and exclusions.

Copyright 2026, James M. Atkinson

OBSERVATION: A recorded result of an examination under a particular measurement state. Its interpretation may support additional propositions, but the observed feature and those model-dependent or source-dependent inferences remain distinguishable.

OPERATING DOMAIN: The stated range of conditions within which a measurement model or approximation is intended to apply. A local linear description, for example, requires a defined state and limits that address relevant overload or adaptive behavior.

PASSIVE PATH LOSS: The attenuation assigned to the relevant passive part of a measurement path under the stated conditions. The scalar backward correction adds this loss to the downstream indication when estimating the upstream power.

PROCESSING LINEAGE: The documented sequence connecting retained input data with derived outputs. It identifies software, settings, corrections, selections, and transformations so that a result can be reconstructed and its irreversible steps recognized.

REFERENCE CHECK: An observation of a known or controlled input used to test specified functions of a measurement chain. Its conclusion must remain limited to the capability and conditions actually exercised.

REFERENCE PLANE: Declared physical or mathematical location to which amplitude, phase, impedance, or timing is referred.

SIGNAL CLASSIFICATION: The association of an observed component with a waveform family, modulation, timing behavior, or service type. The classification describes characteristics and is separate from attribution to a particular emitter or owner.

Copyright 2026, James M. Atkinson

STATE INTERVAL: A declared portion of a record during which the relevant receiver configuration and its calibration remain applicable.

TIME BASIS: The declared reference and event definition used to assign times to observations. It includes the meaning of a timestamp and, where relevant, synchronization sources, clock state, and uncertainty needed for comparison.

References and Works Cited

United States Navy. Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles. NAVEDTRA 14189. September 1998. Pages 2-10 through 2-14. Reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388-8392; title and edition at compilation page 8345.

Annotation. The cited historical passages support receiver functions, superheterodyne intermediate-frequency architecture, and detection. The complete configuration and evidence boundary is the author's synthesis developed through Chapters 2-16. This historical training source does not certify a modern instrument or establish a legal conclusion. The original proposition-level footnote remains in the chapter. This instructional source treats modulation, frequency translation or receiver signal-chain operation through explicit physical relationships. Image frequencies, sidebands, local-oscillator injection and intermediate-frequency filtering have to be checked against the receiver’s actual topology. Ideal mixer identities do not establish that a real component is free of compression, leakage, spurs or path-dependent calibration errors. Its use here is bounded by the physical reference plane, implementation version and the evidentiary proposition being tested.

Joint Committee for Guides in Metrology. International vocabulary of metrology: Basic and general concepts and associated terms. VIM3 online edition, entries 2.48, 2.49 and 2.53. https://jcgm.bipm.org/vim/en/2.48.html; https://jcgm.bipm.org/vim/en/2.49.html; https://jcgm.bipm.org/vim/en/2.53.html. Read November 2, 2026. These entries support the distinctions among a measurement model, its evaluating function and a correction; they do not certify the chapter's constructed receiver configurations.

Annotation. This institutional vocabulary establishes conventional relationships among measurands, measurement results, calibration, uncertainty and traceability. Its role is terminological rather than an instrument-specific proof: the survey must still state the actual measurement model, reference plane and uncertainty evidence. A correct definition cannot compensate for an uncalibrated observation or justify conflating detection, classification and transmitter attribution. The cited work is a methodological reference; the worked examples and the conclusions drawn from them remain separate authorial derivations requiring their own checks. Where access was limited to a public abstract, scope statement or manual excerpt, that limitation must be carried into any resulting scientific assertion. If the equipment revision, software settings or measurement environment changes, the reasoning should be repeated with the new values rather than assumed to transfer automatically.

Taylor, Barry N., and Chris E. Kuyatt. Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results. NIST Technical Note 1297, 1994 edition, September 1994. Appendix A, A.1–A.5. https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. The official online text and cover were read for the measurement-process and uncertainty framework. Model 14B develops its exact-affine and local-approximation distinction; the Chapter 1 numerical cases are independent synthetic examples.

Annotation. This metrological guidance concerns the evaluation and reporting of measurement uncertainty, including propagation through a measurement model. Covariance, shared calibration terms, nonlinear transformations and declared coverage factors require attention when evidence from multiple receiver channels is combined. An uncertainty budget is meaningful only for a specified measurand and operating condition; it does not itself certify the authenticity of the underlying acquisition. Interpretation requires separating the publication's stated scope from the chapter's constructed experimental examples and their necessarily conditional conclusions. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported. The evidence register should record whether the full text, a specified excerpt or merely a bibliographic record was actually examined.

Chapter 2. Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal

Copyright 2026, James M. Atkinson

2.1 Thermal Noise as a Bandwidth-Dependent Quantity

Receiver sensitivity begins with noise power available from a source at a stated physical temperature and bandwidth. The familiar $k\ T\ B$ relation is a model for available thermal noise from a matched source, not a universal description of every noise observed at an instrument input. Antenna temperature can differ from ambient temperature, especially when the antenna views sky, ground, a hot structure, or a lossy network. Preselection, mismatch, cable loss, and external gain alter the noise delivered to the receiver before its internal noise is added.[1]

Noise must be related to the actual detector and effective bandwidth. A 1 kHz resolution filter and a 1 MHz digitized channel do not integrate the same noise even if both are centered on the same frequency. Window equivalent noise bandwidth, filter shape, detector law, averaging, and post-detection filtering affect the displayed level. Comparing noise readings requires matching these conditions or converting them through a documented model.

---

1 United States Navy, Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles, NAVEDTRA 14189 (September 1998), 2-10–2-14, reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388–8392; title and edition at page 8345. These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

Copyright 2026, James M. Atkinson

2.2 Power, bandwidth, and the reference plane

The input of a noise calculation is a physical port, not a trace on a screen. At a matched real impedance, available source noise and noise delivered to the receiver coincide. Away from that condition, the source can offer one available power while the receiver accepts another. A quoted cable insertion loss, measured between matched ports, therefore cannot automatically repair a measurement made between a strongly reactive antenna and a receiver whose input match changes with attenuation. The distinction should be settled before temperatures, decibels, or correction files are combined.

Choose a source plane, an output plane, and an observation band. The source plane may be an antenna terminal, the input connector of a remote preamplifier, or the receiver connector after a cable. Each choice answers a different question. Moving the source plane forward past a lossy cable makes the reported receiver noise figure smaller because the cable is no longer included; it does not improve the original antenna-to-output measurement. A useful report names the plane in words and on the path drawing, then attaches every gain, loss, and temperature to a component between the two planes.

Bandwidth is equally physical. A channel filter weights the noise density over frequency, whereas a narrow tone experiences the response at its own frequency. The equivalent noise bandwidth is the width of a rectangular filter that passes the same noise power under the stated normalization. If the density and gain are flat over that band, the integration reduces to their product with bandwidth. If they vary appreciably, a single center-frequency

Copyright 2026, James M. Atkinson

gain or noise temperature is insufficient. The weighted integration developed in Model 11B illustrates the required discipline; its particular phase-noise spectrum is not a substitute for the thermal-noise spectrum here.

A narrower analysis channel can reduce integrated noise while also rejecting part of a modulated or short-duration signal. The signal-to-noise improvement is then smaller than the bandwidth ratio alone suggests. For a tone retained at the channel center, reducing the effective bandwidth by ten reduces white-noise power by ten. For a burst whose energy spreads outside the new channel, the retained signal must be measured or calculated as well. Reporting only the lower noise trace hides this loss of useful signal. Detector averaging, trace averaging, and longer observation may alter variability without producing the same physical filtering.

An input-referred noise value is obtained by dividing a measured output noise power by the appropriate signal power gain. This operation is a reporting transformation; the receiver has not physically moved its noise generators to the input. It remains valid only for the gain that connects the selected input signal to that output. A gain correction derived from another attenuator state, another sideband, or another point in a compressed response can produce a plausible input number with no valid measurement interpretation. Retaining both the raw output result and the gain used in the conversion makes that failure detectable.

2.3 Noise Figure and Noise Temperature

Noise factor compares the input signal-to-noise ratio with the output signal-to-noise ratio under specified source conditions. Expressed in decibels, noise figure is convenient but can conceal whether a lossy cable, filter, preamplifier, mixer, or receiver dominates the system. Equivalent noise temperature offers another representation and is especially useful for cascades and low-noise front ends. Both require a declared reference temperature and impedance.

In 1944, H. T. Friis framed receiver noise as a property of a network that could be related to the properties of its components. His paper extended the discussion beyond high-gain receivers and included interstage mismatch and measurement. That network perspective motivates the chain analysis developed here. Model 2B states its narrower working assumptions explicitly: a selected equivalent channel, matched scalar power gains, declared temperatures, zero cross-power between the admitted noise contributions, and a fixed receiver state. The practical question is which stage contributes noise referred to the chosen input and which gain suppresses later contributions. A total gain figure alone cannot answer it.[2]

A preamplifier improves system sensitivity only when its gain is sufficient to suppress later receiver noise and its own noise, mismatch, compression, and out-of-band response remain acceptable. Placing a low-noise amplifier

These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

after a long lossy cable cannot recover the signal-to-noise ratio lost before it. Conversely, an amplifier at the antenna can worsen a survey by overloading on strong legitimate transmitters or by generating intermodulation. The sensitivity plan is therefore inseparable from dynamic range and preselection.

2.4 Sensitivity Specifications and Decision Thresholds

Minimum discernible signal, noise floor, sensitivity, usable sensitivity, and minimum detectable signal are not interchangeable specifications. A manufacturer may define sensitivity for a particular modulation, bandwidth, error rate, audio signal-to-noise ratio, detector, or probability of detection. A spectrum analyzer displayed average noise level often includes normalization and detector conventions that differ from communications-receiver sensitivity. The test must reproduce the definition or state that a different measurand was used.

A defensive search also needs a decision threshold. Detection can be based on amplitude above a local baseline, matched filtering, coherent integration, correlation with a state change, persistence across sensors, or another statistic. The threshold should be selected with a false-alarm objective and validated against noise-only data. A lower threshold increases apparent sensitivity but can flood the survey with random peaks and receiver products. The report states both the threshold and the evidence supporting its operating characteristics.

Copyright 2026, James M. Atkinson

2.5 Define sensitivity as a reproducible decision

A sensitivity claim should start with the event that counts as a successful observation. Examples include resolving a continuous tone within a declared frequency error, detecting a burst of specified duration, or recovering a waveform at a stated quality. These events require different observation intervals and processing. A mean noise power provides a scale for a decision statistic, but it supplies neither the distribution of that statistic nor the number of opportunities for a false alarm. Searching many frequencies or many time windows creates more opportunities than evaluating one preselected channel.

For a bounded calculation, one may stipulate a required output signal-to-noise ratio and solve for the corresponding input signal power. That is the use of Equation 4L below. The stipulated ratio must come from a separately justified detector requirement or a controlled empirical characterization. It is not legitimate to attach an arbitrary probability of detection to a ten-decibel ratio. A threshold estimated from the same records used to advertise performance can also look better than it is. Keep a distinct set of challenge records, including noise-only intervals and weak reference events, to test the chosen rule.

The detection record should retain the native samples or equivalent unaveraged measurement data, the decision statistic, the threshold, the event duration, and the receiver state. For a scanning receiver, also retain when the channel was actually observed. A failed detection while the receiver was tuned elsewhere is a coverage failure, whereas a failed detection during a valid dwell can inform a sensitivity estimate. These

Copyright 2026, James M. Atkinson

failures should not be pooled without stating the population. Chapter 15 develops the timing and capture consequences; the noise budget here establishes only the amplitude environment during a valid observation.

A useful sensitivity verification changes one declared quantity at a time. First establish a quiet baseline at fixed gain and bandwidth. Then reduce a known desired reference through the decision region. Finally repeat with a bounded interferer or an alternate gain state. If sensitivity deteriorates only in the interferer condition, a laboratory noise figure has not become numerically wrong; it has become insufficient to describe the new state. The next analysis must test compression, gain control, intermodulation, reciprocal mixing, or spectral overlap. Chapter 11 supplies the mechanisms needed to distinguish those possibilities.

Copyright 2026, James M. Atkinson

TECHNICAL INTERPRETATION

Raising a fixed threshold suppresses false alarms but can also miss weak emissions. Detection probability requires a declared statistical model.

Figure 7. Detection thresholds and statistical errors.

Copyright 2026, James M. Atkinson

2.6 Y-Factor and Comparative Noise Measurements

Noise figure can be measured by applying two known source noise temperatures and observing the output power ratio. The method depends on source calibration, excess-noise ratio, receiver linearity, bandwidth stability, gain stability, and correct switching state. The receiver must remain below compression for both source states, and automatic gain control must be disabled or characterized. Loss and mismatch between the noise source and the receiver reference plane require correction.

Comparative measurements are often more practical in field work. A terminated input, shielded source, alternate antenna, preamplifier bypass, or known reference signal can reveal whether the observed noise is external, conducted, internally generated, or overload-related. These tests do not by themselves produce a traceable noise figure, but they can discriminate mechanisms. The configuration and timing of each comparison must be retained.

Copyright 2026, James M. Atkinson

2.7 Uncertainty and Environmental Noise

Receiver sensitivity can be dominated by the environment rather than the instrument. Urban radio noise, switching power supplies, lighting, digital electronics, power-line carriers, broadcast transmitters, and building systems raise the effective noise temperature and can vary with time and operating state. A low laboratory noise figure does not imply the same detection limit at an occupied site. Spatial, temporal, polarization, and operational baselines are needed.

Uncertainty includes source calibration, gain and loss corrections, bandwidth, detector statistics, mismatch, repeatability, temperature, and limited sample duration. Noise estimates are random variables; short measurements fluctuate. The variance of an average depends on the sample covariance and averaging rule, as developed in Chapters 8 and 14. Correlated or duplicated samples do not supply their nominal independent sample count, and changing receiver or source states can change the measurand being averaged. A sensitivity statement should therefore include its bandwidth, detector, probability or confidence convention, and environmental state.

Copyright 2026, James M. Atkinson

2.8 Operational Sensitivity Verification

A complete receiver system is verified with calibrated coherent and noise-like references introduced at the selected field or terminal plane. Measurements are repeated with the antennas, cables, filters, preamplifiers, gain states, and detector modes that will be used during the survey. The verification determines detection probability or level uncertainty under a bounded strong-signal environment rather than treating a quiet laboratory specification as an operational guarantee.

Reference signals are controlled so that they do not contaminate unrelated bands or create an undocumented test emitter. Their identity is marked in native data, and the injection or radiation geometry is described. A closing verification tests the sensitivity-related functions actually exercised by the reference, in the state and at the time of the check. It does not alone establish uninterrupted validity during the preceding engagement or verify antenna and accessory paths bypassed by the injection.

2.9 Quantitative Model for Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal

Equation 1. Available thermal-noise power

$$P_{\mathrm{n}} = k\,T\,B$$

Available thermal-noise power P_{n} in watts equals Boltzmann constant k, source noise temperature T in kelvins, and equivalent noise bandwidth B in hertz for a matched thermal source. The relation does not include receiver-added noise, mismatch, nonthermal interference, or detector corrections.

Equation 2. Cascaded noise factor

$$F_{\mathrm{total}} = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2}$$

The Friis cascade relation uses linear noise factors F and available power gains G referred to compatible planes. It assumes linear operation and correctly characterized interstage networks. Loss before the first gain stage should be included as a noisy stage.

Equations 3 and 4 belong to the matched noise-cascade family developed in Model 2B and Applications 2B.1–2B.10. Use linear power gains and linear noise factors in Equation 4. Refer a passive loss to its physical temperature before converting the total input-equivalent temperature to noise figure.

2.10 Hypothetical Applied Calculation: Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal

At 290 K and 10 kHz equivalent noise bandwidth, $k\ T\ B$ is approximately $4.00 \times 10^{-17}\ \mathrm{W}$, or -134.0 dBm. A receiver with 7 dB noise figure has an input-referred noise near -127.0 dBm before required detection margin, mismatch, and environmental interference. Reducing the bandwidth to 1 kHz improves the thermal-noise term by 10 dB if the signal remains fully represented.

Copyright 2026, James M. Atkinson

2.11 Hypothetical Case Adjudication: Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal

A remote probe shows a 9 dB rise in apparent noise when connected through a 25 m coaxial cable. Replacing the antenna with a matched termination leaves the rise unchanged, but bypassing an inline preamplifier removes it. The preamplifier is then found to oscillate intermittently when powered through the long bias line. The observation is documented as front-end instability, not elevated environmental noise.

Copyright 2026, James M. Atkinson

2.12 Measuring-Receiver Scope and System Noise Floor

CISPR 16-1-1:2019 specifies measuring-apparatus characteristics for radio-disturbance work from 9 kHz to 18 GHz and applies to EMI receivers and spectrum analyzers. It is a basic EMC measurement standard, not a universal TSCM attribution method. A receiver satisfying the apparatus standard can still be misconfigured, overloaded, connected to an uncalibrated external chain, or used outside the scope of a particular result.[3]

3 Barry N. Taylor and Chris E. Kuyatt, Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results, NIST Technical Note 1297, 1994 edition (September 1994), Appendix A, A.1–A.5, https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. The functional and covariance framework is used within its stated scope; the synthetic ranges, examples and recoverability conclusions are original.

2.13 Worked Example 2A.1. Thermal Noise-Floor Screening

Engineering question. Estimate the room-temperature receiver noise floor for bandwidth $B = 10\ \text{kHz}$ and system noise figure $\text{NF} = 5.0\ \text{dB}$.

Variables and units. The -174 dBm/Hz term is the conventional room-temperature thermal-noise density approximation; B is bandwidth in hertz; NF is noise figure in decibels; P_{n} is in dBm.

$$P_{\text{n,dBm}} \approx -174 + 10\log_{10}\left(\frac{B}{1\ \text{Hz}}\right) + \text{NF}$$

Calculation. $10\ \log_{10}(10{,}000) = 40.0\ \text{dB}$. Therefore $P_{\text{n}} = -174 + 40 + 5 = -129\ \text{dBm}$.

Dimensional check. The bandwidth ratio inside the logarithm is dimensionless relative to 1 Hz. Decibel terms combine consistently.

Uncertainty and valid range. The value is a screening estimate. Actual temperature, gain distribution, mismatch, filter noise bandwidth, detector, external preamplifier, cable loss, interference, and calibration uncertainty are omitted.

Practical meaning. A signal below -129 dBm may still be detectable through narrower bandwidth, coherent processing, or averaging. A signal above it is not automatically valid if overload or spurious response is present.

2.14 Model 2B: a matched, fixed-state noise cascade

Model 2B expands the chapter's three-stage Equation 4 into an explicit reference-plane model shared with Chapters 3, 13, and 14. Its purpose is to predict how source noise and independently added stage noise reach one output, then invert or constrain that same relation. It is a small-signal model of one configuration. The sixteen local display groups, Equations 4A through 4P, are parts of this single family. The ten applications use constructed values to expose different design and measurement decisions. They are not performance data from a receiver, installation, or calibration laboratory.

Copyright 2026, James M. Atkinson

Figure 8. Gain-stage order and receiver noise figure.

Assume a positive integer n of linear, time-invariant stages in the selected equivalent channel coordinates. All interfaces, the source, and the load are matched to a common real reference impedance R_0; the applications use 50 ohms. Stage i has positive finite power gain g_i and finite nonnegative

Copyright 2026, James M. Atkinson

equivalent input noise temperature $T_{\mathrm{e},i}$, both approximately constant over one effective noise bandwidth B greater than zero. The source has effective noise temperature T_{s}. Source noise and the noises added by separate stages have zero cross-power, so their powers add. The classical thermal-noise approximation applies over the selected band.

The scalar quantities exclude unmodeled image paths, feedback between mismatched stages, gain changes, compression, and signal-generated noise. A frequency-converting receiver is not literally time invariant at the RF waveform level. It may be represented here by an empirically established scalar power and noise law in the selected channel only when its effective gain and noise temperature apply to the actual sideband architecture, input environment, and operating state. Analog Devices' cascade analysis explicitly shows why a mixer's nominal single- or double-sideband noise figure cannot be inserted blindly into an otherwise scalar chain. The present derivation uses the matched linear-block case and keeps that boundary visible.[4]

Equation 4A. Cumulative power gain

$$G_0 = 1$$
$$G_j = \prod_{i=1}^{j} g_i, \; j = 1, \ldots, n$$

G_j is the power gain from the cascade input to the output of stage j. The empty product G_0 equals one. Define N_i as the noise power in the common

4 Analog Devices, “System Noise-Figure Analysis for Modern Radio Receivers” (June 14, 2013), “Baseline Case: Cascade of Linear Circuit Blocks” and “Noise Temperature,” https://www.analog.com/en/resources/technical-articles/system-noisefigure-analysis-for-modern-radio-receivers.html; James P. Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. These sources distinguish receiver noise from source and path contributions; the scalar assumptions and synthetic cases are stated in Model 2B.

Copyright 2026, James M. Atkinson

observation band at that stage output. By definition, the noise added by stage i at its output is $k\ B\ g_i\ T_{\mathrm{e},i}$, where k is Boltzmann's constant in joules per kelvin. The preceding noise is multiplied by g_i. These two contributions give the recurrence in Equation 4B. Every term is a power in watts; gain is dimensionless.

Equation 4B. Noise propagation through one stage

$$N_0 = kBT_s$$
$$N_i = g_i N_{i-1} + kBg_i T_{e,i}$$

Divide the stage recurrence by G_i. The earlier contribution becomes $\frac{N_{i-1}}{G_{i-1}}$, while the new contribution becomes $\frac{k\ B\ T_{\mathrm{e},i}}{G_{i-1}}$. Repeating this step back to the source gives the sum in Equation 4C. This derivation makes the ordering explicit: the input-referred importance of a later noise source is reduced by all preceding gain, and increased by preceding loss. A component's own output gain is absent from its input-equivalent contribution because that gain has already been included in the definition of $T_{\mathrm{e},i}$.

Equation 4C. Cascade temperature and integrated output noise

$$T_e = \sum_{i=1}^{n} \frac{T_{e,i}}{G_{i-1}}$$
$$N_{out} = kBG_n\left(T_s + T_e\right)$$

The sum T_{e} is the equivalent input noise temperature of the complete cascade at its selected first plane. It is not the physical temperature of the enclosure. A stage can have a physical temperature near ambient while its equivalent noise temperature is much smaller or larger. Temperature is a convenient power-density scale in this model. The source term T_{s} remains

Copyright 2026, James M. Atkinson

separate because changing the antenna environment should not silently change the defined receiver contribution.

Equation 4D. Noise factor at the reference temperature

$$F_0 = 1 + \frac{T_e}{T_0}$$
$$NF_0 = 10 \log_{10}(F_0), T_0 = 290\,K$$

Equation 4D defines F_0 relative to T_0 equal to 290 K, and expresses it logarithmically as NF_0. With source noise $k\ B\ T_s$ and a positive desired signal power that experiences G_n, direct division of input and output signal-to-noise ratios gives Equation 4E. When T_e is positive, the result equals F_0 if and only if T_s equals T_0. If T_e is zero, both ratios equal one for every positive T_s. For a cold source, receiver noise causes a larger relative degradation; for a very noisy source, the same receiver noise contributes little to the total. At T_s equal to zero, input signal-to-noise ratio is unbounded in the classical idealization, so Equation 4E is stated only for positive T_s.

Equation 4E. Signal-to-noise degradation for the actual source

$$\frac{SNR_{¿}}{SNR_{out}} = 1 + \frac{T_e}{T_s}, T_s > 0$$

Copyright 2026, James M. Atkinson

2.15 Derive passive loss from thermal equilibrium

Consider a matched dissipative attenuator with linear power loss L at uniform physical temperature T_{p}. Its power gain is $\frac{1}{L}$. Place it between matched terminations at the same temperature T_{p}. Thermal equilibrium requires the output available noise to remain $k\ B\ T_{\mathrm{p}}$. The source contributes only $\frac{k\ B\ T_{\mathrm{p}}}{L}$ after transmission, so the attenuator must contribute $k\ B\ T_{\mathrm{p}}\left(1-\frac{1}{L}\right)$ at its output. Dividing that added power by the gain gives Equation 4F. This argument does not assign thermal emission to power that was merely reflected by an arbitrary mismatch.

Equation 4F. Noise temperature of a matched dissipative loss

$$g_{loss}=\frac{1}{L}, T_{e,loss}=(L-1)T_p, L\geq 1$$

At T_{p} equal to T_0, the passive noise factor equals L, and the noise figure in decibels equals the insertion loss in decibels. At another physical temperature, that equality no longer follows. Placing this loss ahead of a following chain with temperature $T_{\mathrm{e,c}}$ gives Equation 4G. The first term is the attenuator's own contribution; the second is the following chain referred backward through the loss. Both are at the original input plane. Keysight's noise-measurement guide treats loss before and after a device separately and includes the physical temperature of the lossy connection in its compensation.[5]

5 H. T. Friis, “Noise Figures of Radio Receivers,” Proceedings of the IRE 32, no. 7 (July 1944): 419–22, https://doi.org/10.1109/JRPROC.1944.232049. The publisher’s abstract was read for the historical network, component, mismatch, and measurement framing. The full paper

Copyright 2026, James M. Atkinson

Equation 4G. Loss followed by a characterized chain

$$T_{e,total} = (L-1)T_p + L\,T_{e,c}$$

A warm cable is consequently more than a level correction in a noise measurement. A level correction restores the reported signal to an earlier plane, but the cable's thermal contribution and the amplified importance of downstream receiver noise still enter the uncertainty and sensitivity. If several passive sections have different temperatures, use separate stages. Replacing all of them with one total loss at an arbitrary room temperature discards the ordering and the thermal information needed by the recurrence.

2.16 Invert the same model with two source temperatures

Copyright 2026, James M. Atkinson

Figure 9. Hot/cold Y-factor noise measurement.

Let T_{h} and T_{c} be known hot and cold source temperatures at the chosen receiver input, with T_{h} greater than T_{c} and T_{c} at least zero. Require $T_{\mathrm{c}}+T_{\mathrm{e}}$ greater than zero so the cold output power and the finite ratio are defined. Hold gain, bandwidth, matching, and receiver noise temperature fixed during both observations. The ratio of the two linear output powers is Y. The common $k\ B\ G_n$ cancels, giving Equation 4H. This cancellation is the attraction of the method, and also its vulnerability: a quantity cancels only if it is actually common to both measurements. The measurement arrangement and inversion are illustrated in Figure 9.

Equation 4H. Hot-to-cold output power ratio

$$Y=\frac{N_h}{N_c}=\frac{T_h+T_e}{T_c+T_e}$$

Copyright 2026, James M. Atkinson

Equation 4I. Recovered input noise temperature and its domain

$$T_e = \frac{T_h - Y T_c}{Y - 1}$$

$$1 < Y \leq \frac{T_h}{T_c} \left(T_c > 0 \right)$$

For positive T_c and finite nonnegative T_e, Y lies above one and no higher than $\frac{T_h}{T_c}$. A measured value outside that range should trigger investigation of the source values, gain state, compression, offsets, or statistical uncertainty. It should not be forced into a physical result by clipping a negative temperature to zero. When T_c is zero, the upper-ratio statement is replaced by the direct formula; the cold output must still be positive for a finite measured ratio. As Y approaches one, the inversion becomes sensitive to small errors because its denominator becomes small.

A noise-source excess-noise-ratio calibration supplies a relation between its on and off temperatures and the reference temperature. In the convention used here, linear ENR is $\frac{\left(T_h - T_c\right)}{T_0}$. Read the actual source certificate and the instrument's convention before using it. The cold state need not equal 290 K, and loss between the calibrated source plane and the receiver changes both effective temperatures. A control measurement should establish that the receiver remains linear in the hot state as well as the cold state. More averaging cannot correct a systematic change of gain between them.

Copyright 2026, James M. Atkinson

2.17 Turn the cascade into bounded design requirements

For two stages, Equation 4C reduces to $T_{\mathrm{e},1}$ plus $\frac{T_{\mathrm{e},2}}{g_1}$. If the allowed total temperature is T_{target}, solving for first-stage gain gives Equation 4J when T_{target} exceeds $T_{\mathrm{e},1}$ and $T_{\mathrm{e},2}$ is positive. If T_{target} equals $T_{\mathrm{e},1}$, no finite gain can satisfy the limit while the second stage adds positive noise. If the limit is smaller, the first stage alone makes the requirement impossible. These boundary cases are as useful as the numeric answer because they distinguish a gain shortage from a fundamentally unsuitable first stage.

Equation 4J. Minimum first-stage gain for a temperature limit

$$g_1 \geq \frac{T_{e,2}}{T_{target} - T_{e,1}}, T_{target} > T_{e,1}$$

Solving Equation 4G for allowed preceding loss gives Equation 4K when its denominator is positive. A feasible passive loss must also satisfy L at least one. If the computed upper bound is below one, even a lossless connection cannot meet the requested temperature. The bound includes only noise. Filter rejection, source matching, stability, and strong-signal loading remain separate requirements, which Chapter 3 applies before choosing a physical implementation.

Equation 4K. Maximum allowed preceding loss

$$1 \leq L \leq \frac{T_{target} + T_p}{T_p + T_{e,c}}$$

Equation 4L. Input signal power for a stipulated output ratio

$$P_{req} = \gamma k B \left(T_s + T_e\right)$$
$$\gamma > 0, T_s + T_e > 0$$

Copyright 2026, James M. Atkinson

In Equation 4L, γ is a positive required linear output signal-to-noise ratio, $T_s + T_e$ is positive, and the desired signal is wholly retained by the observation channel with gain G_n. The positive-noise condition excludes the noiseless endpoint where a zero-signal ratio would be undefined. The input requirement is obtained by dividing the required output signal power by that same gain, which cancels. Increasing gain after the noise has already been added therefore does not improve this input requirement. It may improve the use of a later digitizer's range, provided the additional stage stays linear, but that is a different constraint from recovering signal-to-noise ratio.

Copyright 2026, James M. Atkinson

2.18 Application 2B.1: assemble a four-stage noise budget

Take a 1.5 dB preselector at 290 K, a low-noise amplifier with 20 dB gain and 1.2 dB noise figure, a 3 dB cable at 290 K, and a receiver with 30 dB gain and 600 K input noise temperature. The source is 290 K and the effective noise bandwidth is 10 kHz. Convert decibels before forming products or sums. The preselector loss is 1.41254, the amplifier gain is 100, and the cable loss is 1.99526. The total power gain is 35,481.34, or 45.5 dB.

The preselector contributes $(1.41254-1)290$ equal to 119.64 K. The amplifier's own temperature is $290(10^{0.12}-1)$ equal to 92.29 K, which becomes 130.37 K when referred backward through the preselector. The cable contributes 4.08 K at the original input because preceding gain suppresses its contribution. The receiver contributes 600 divided by the gain through the first three stages, or 16.91 K. The sum is 270.99 K, giving a cascade noise figure of 2.866 dB.

Table 2B.1. Constructed input-equivalent contributions in Application 2B.1

Stage	Own temperature, K	Preceding power gain	Input contribution, K
Preselector	119.64	1.00000	119.64
Amplifier	92.29	0.707946	130.37
Cable	288.63	70.7946	4.08
Receiver	600.00	35.4813	16.91

The input-equivalent integrated noise is k times 10,000 times $(290+270.99)$, or 7.7453×10^{-17} W, equal to −131.11 dBm. Multiplication by the total gain produces −85.61 dBm at the output. If a separately established decision rule requires 10 dB output signal-to-noise ratio for a wholly retained signal, Equation 4L gives an input requirement of −121.11 dBm. This is the requirement for the declared quiet, linear state. The two largest

Copyright 2026, James M. Atkinson

contributions identify the preselector and first amplifier as productive places to investigate before increasing downstream gain.

Copyright 2026, James M. Atkinson

2.19 Application 2B.2: move an amplifier across a cable

Compare two orders containing the same 20 dB gain, 1 dB noise-figure amplifier, the same 6 dB cable at 290 K, and the same 30 dB gain, 8 dB noise-figure receiver. The amplifier temperature is 75.09 K; the cable temperature is 864.51 K; and the receiver temperature is 1,539.78 K. Both orders have total gain of 44 dB, so a signal-only gain budget cannot distinguish them.

With the amplifier first, the three input-equivalent contributions are 75.09 K, $\frac{864.51\ \mathrm{K}}{100} \approx 8.65\ \mathrm{K}$, and 1,539.78 divided by 25.1189 equal to 61.30 K. Their sum is 145.03 K, or 1.761 dB noise figure. With the cable first, its 864.51 K is unsuppressed. The amplifier contributes 75.09 times 3.98107 equal to 298.93 K, while the receiver still contributes 61.30 K. The sum becomes 1,224.74 K, or 7.179 dB noise figure.

The 5.418 dB noise-figure difference arises entirely from ordering; total signal gain is unchanged. Remote amplification is therefore attractive under the model, but its feasibility depends on the remote amplifier's admitted blocker power, bias delivery, stability, and physical environment. A remote unit that compresses or oscillates cannot be credited with the calculated improvement. Chapter 13 uses this comparison to connect a component decision to acceptance of the installed path.

2.20 Application 2B.3: distinguish loss from temperature

A matched 2 dB attenuator has L equal to 1.58489 and gain 0.630957. At 290 K its input-equivalent noise temperature is 169.62 K, and its noise figure is exactly 2 dB under the reference convention. If the same loss occurs at 330 K, Equation 4F gives 193.01 K and Equation 4D gives 2.216 dB. The extra 0.216 dB is not a change in the stipulated insertion loss; it is the consequence of greater thermal emission.

With a 290 K source, the output noise temperature is $\frac{(290+169.62)}{1.58489}$ equal to 290 K in the first case. This is the equilibrium check used in the derivation. For the warm attenuator, the corresponding output is $\frac{(290+193.01)}{1.58489}$ equal to 304.76 K. A signal still suffers 2 dB loss in both cases. Treating every 2 dB loss as a 2 dB noise figure would miss the difference. If the attenuator's actual loss also changes with temperature, that measured change is an additional input, not something already included in these values.

Copyright 2026, James M. Atkinson

2.21 Application 2B.4: change the source environment

Let a fixed receiver have T_e equal to 150 K and a 10 kHz effective bandwidth. Its 290 K reference noise figure is 1.811 dB regardless of which source is connected. With a 40 K effective source, however, the actual signal-to-noise degradation is $1+\frac{150}{40}$ equal to 4.75, or 6.767 dB. The input-equivalent integrated noise is −135.81 dBm. With a 5,000 K source, the degradation is only 1.03, or 0.128 dB, but the integrated noise is much higher, at −121.48 dBm.

Now imagine replacing the receiver with one whose T_e is 50 K while retaining all other assumptions. The cold-source noise falls in the ratio $\frac{190}{90}$, an improvement of 3.245 dB. The noisy-source case improves only in the ratio $\frac{5{,}150}{5{,}050}$, or 0.085 dB. This comparison explains why a lower receiver noise figure can be valuable in one observation and practically irrelevant in another. The 5,000 K value here is a constructed effective thermal-noise representation. A discrete interferer or time-varying impulsive environment should not be folded into that temperature without a justified observation model.

2.22 Application 2B.5: solve for the gain that is useful

Suppose a first stage has $T_{e,1}$ equal to 80 K and the following receiver has $T_{e,2}$ equal to 1,200 K. The target cascade temperature is no more than 120 K. Equation 4J requires g_1 at least $\frac{1{,}200}{(120-80)}$, or 30, equal to 14.771 dB. At this gain, the later contribution is exactly 40 K. At 20 dB gain it is 12 K, so the total is 92 K. The calculation provides a lower gain requirement, not a preference for the largest gain available.

The asymptotic limit is 80 K as gain grows without bound. A 70 K target is impossible with this first stage, and an 80 K target would require infinite gain while the later noise remains positive. In practice, a designer would next compare the feasible gain range against maximum admitted signal power and downstream headroom. If the noise requirement demands more gain than the strong-signal condition permits, the architecture needs a lower-noise later stage, more selective admission, or another substantive change. Adjusting a displayed reference level alone cannot resolve the conflict.

Copyright 2026, James M. Atkinson

2.23 Application 2B.6: allocate loss to a preselector

A following receiver chain has 90 K input noise temperature. A proposed matched preselector operates at 300 K, and the complete input temperature must remain no greater than 180 K. Equation 4K gives L no greater than $\frac{(180+300)}{(300+90)}$, equal to 1.23077, or 0.902 dB. This is the allowed dissipative loss under the stated noise budget. It does not specify the filter's rejection at a blocker frequency.

A candidate with 0.8 dB loss gives $(10^{0.08}-1)300$ plus $10^{0.08}$ times 90, equal to 168.88 K, and meets the temperature target. A candidate with 1.2 dB loss gives 214.12 K and does not. The lower-loss candidate may still fail because it admits too much blocker power, while the higher-loss candidate may produce the only valid measurement in a strong-signal environment. That decision requires a joint assessment: report the noise penalty and test whether the desired signal remains detectable in the usable state. Calling either filter better solely from one of its specifications would omit half of the design problem.

Copyright 2026, James M. Atkinson

2.24 Application 2B.7: place attenuation before the vulnerable stage

Use a 20 dB gain, 1 dB noise-figure amplifier followed by a 30 dB gain, 8 dB noise-figure receiver. A constructed blocker arrives at −5 dBm. For this example only, the first amplifier's independently established linear operating envelope ends at −20 dBm input for that blocker condition. Compare a 20 dB attenuator at 290 K placed before the amplifier with the same attenuator placed after it. Both paths have 30 dB total small-signal gain.

With input attenuation, the amplifier sees −25 dBm, giving 5 dB margin to the stipulated envelope. The cascade input temperature is 28,710 plus 7,508.84 plus 1,539.78, or 37,758.61 K; its noise figure is 21.179 dB. With attenuation after the amplifier, the formal small-signal temperature would be 75.09 plus 287.10 plus 1,539.78, or 1,901.96 K, giving 8.784 dB noise figure. However, the amplifier still sees −5 dBm, which exceeds its stated envelope by 15 dB. That second noise result is inapplicable in the declared blocker state.

The example prevents an attractive arithmetic result from overriding a violated assumption. Input attenuation buys validity at a substantial noise cost. Selective rejection before the first amplifier may offer a better compromise when the desired and blocker frequencies permit it, but that requires a measured filter response at both frequencies. Neither the example's −20 dBm envelope nor its 5 dB margin is a general equipment rating. Actual limits and protection requirements come from the particular device and the complete incident waveform.

Copyright 2026, James M. Atkinson

2.25 Application 2B.8: recover noise temperature from two powers

Take known source temperatures T_{h} equal to 9,000 K and T_{c} equal to 290 K, a receiver temperature of 500 K, power gain of 100,000, and bandwidth of 1 MHz. The model predicts hot output power k times 10^6 times 10^5 times 9,500, or $1.31162 \times 10^{-8}\ \mathrm{W}$, equal to −48.822 dBm. The cold output is $1.09071 \times 10^{-9}\ \mathrm{W}$, equal to −59.623 dBm. Their linear ratio is 12.025316, which is 10.801 dB.

Substituting that ratio in Equation 4I gives $\frac{(9{,}000 - 12.025316 \times 290)}{(12.025316 - 1)}$, recovering 500 K. The corresponding reference noise figure is 4.352 dB. Linear ENR is $\frac{(9{,}000 - 290)}{290}$ equal to 30.0345, or 14.776 dB. Notice that subtracting the two output readings in decibels gives the logarithm of Y, not Y itself. The inversion must use 12.025316. The recovered value is a consistency check on this constructed case; a real result would also require calibrated source temperatures, stable matching, receiver linearity, and a complete uncertainty statement.

Copyright 2026, James M. Atkinson

2.26 Application 2B.9: expose a change hidden by a ratio

Equation 4M. Observed ratio when hot and cold gains differ

$$Y_{obs} = r_g \frac{T_h + T_e}{T_c + T_e}$$

$$r_g = \frac{G_h}{G_c}$$

Retain the source temperatures and true receiver temperature from Application 2B.8, but let the hot-state power gain be 1 percent larger than the cold-state gain. Equation 4M gives observed Y equal to 1.01×12.025316, or 12.145570. If the analyst incorrectly assumes equal gain, Equation 4I returns 491.48 K, an error of −8.52 K. The inferred noise figure becomes 4.305 dB, about 0.047 dB lower than its true constructed value.

The direction follows from the inversion: a larger hot-to-cold ratio appears to indicate a quieter receiver. Repeating the same biased sequence can make this wrong answer highly repeatable. A bracketed cold-hot-cold sequence can reveal drift, while a separate gain monitor may identify its cause, but neither is an automatic correction unless the gain at the relevant times is known. Automatic gain control, a changed attenuator, source switching transients, or temperature settling could create state differences. Record the state and timing before deciding which explanation applies.

Copyright 2026, James M. Atkinson

2.27 Application 2B.10: propagate the local calibration uncertainty

Use the inversion at T_{h} equal to 9,000 K, T_{c} equal to 290 K, and Y equal to 12.025316. Assume standard uncertainties of 180 K, 1 K, and 0.05, respectively, with zero covariances for this constructed case. Differentiating the same inversion gives Equations 4N and 4O. These derivatives are sensitivity coefficients for the uncertainty law already stated in Equation 27 of Chapter 14; they do not define an additional noise model.

Equation 4N. Temperature sensitivity coefficients

$$\frac{\partial T_e}{\partial T_h} = \frac{1}{Y-1}$$
$$\frac{\partial T_e}{\partial T_c} = \frac{-Y}{Y-1}$$

Equation 4O. Power-ratio sensitivity coefficient

$$\frac{\partial T_e}{\partial Y} = \frac{T_c - T_h}{(Y-1)^2}$$

The coefficients are 0.0907003, −1.0907003, and −71.6533 K per unit Y. Multiplying by the respective standard uncertainties and squaring gives contributions of 266.54, 1.19, and 12.84 square kelvin. Their sum is 280.57 square kelvin, and its square root is 16.75 K. The hot-source calibration dominates this particular budget. Reducing the random uncertainty of Y alone would therefore yield only a limited improvement; better source characterization would address the largest contribution.

Equation 4P. Local conversion from temperature uncertainty to noise-figure uncertainty

$$\frac{\partial NF_0}{\partial T_e} = \frac{10}{\ln(10)(T_0 + T_e)}$$

Copyright 2026, James M. Atkinson

Equation 4P converts the result locally to 0.0921 dB standard uncertainty in noise figure. Multiplying by an illustrative coverage factor of two gives 33.50 K or 0.184 dB expanded uncertainty. This multiplication does not establish 95 percent coverage without a distribution and degrees-of-freedom justification. The calculation is also local: when uncertainty is large enough to approach Y equal to one, the nonlinear inversion requires a more suitable propagation analysis. Correlated source-calibration inputs must enter Equation 27 through their covariance or through explicit common input quantities.

Copyright 2026, James M. Atkinson

2.28 From a calculated temperature to a defended result

The applications deliberately keep the same governing law while changing the engineering question. They identify the dominant stage, compare ordering, account for physical temperature, distinguish source environment from receiver definition, allocate gain and loss, reject an overloaded state, and examine a calibration inversion. This continuity is useful during a review because every result can be traced to a declared input, a reference plane, and a violated or satisfied assumption. It also makes disagreement productive: a reviewer can challenge the source temperature, gain, bandwidth, or state without treating the entire receiver as an unexplained black box.

A measured noise temperature still needs a measurement record. Retain hot and cold output powers in linear units, their time order, effective bandwidth, receiver gain state, source serial and calibration values, connection loss and temperature, and the exact input plane. Add the observations that support linearity and stability. NIST's noise-temperature uncertainty treatment includes explicit linearity checks and distinguishes repeated power observations from repeated system calibrations. That distinction prevents a large number of nearly identical readings from being mistaken for evidence that calibration, reconnection, or mismatch uncertainty has disappeared.[6]

2.29 Noise-colour models, covariance and decision performance beyond a scalar noise figure

Noise figure and an equivalent input temperature are useful summaries only when the selected reference plane, frequency interval and receiver state are fixed. A receiving system exposed to shaped interference, impulsive noise or frequency-selective gain cannot be represented faithfully by one scalar white-noise level over an arbitrary bandwidth. The relevant quantity becomes a spectral-density function S_n(f), expressed in watts per hertz at the specified plane, and a measurement weighting H(f). The integrated contribution is N = integral S_n(f)|H(f)| squared df, where H includes the known receiver and estimator response. Under flat-density assumptions this reduces to the familiar density multiplied by equivalent noise bandwidth. Outside that domain, substituting the centre-frequency noise into a broad integration can understate a narrow interferer or overstate an attenuated region. The engineer should therefore preserve both the spectral shape and the weighting used for the actual decision statistic, not merely a picture of a noise floor.

The distinction matters particularly when detection operates across several correlated bins. Write a vector of observed complex spectral coefficients z with noise covariance C = E[(z - E[z])(z - E[z]) conjugate-transposed]. For a known template s under a specified zero-mean complex-Gaussian approximation, an appropriately whitened linear statistic uses C inverse times s; this does not claim that the site noise is generally Gaussian or

---

spectrum analyzers. No access to or clause-by-clause compliance review of the complete standard is claimed.

Copyright 2026, James M. Atkinson

stationary. Strong narrowband interference can make C ill conditioned, and estimation from the same candidate-rich data used to test the threshold can create selection bias. Calibrated regularisation must be declared before evaluating the held-out challenge set. A diagonal approximation discards cross-bin and cross-channel structure; it is not justified simply because adjacent frequency labels are displayed separately.

A numerical teaching case shows why covariance matters. Two unbiased measurements each have variance 4 square units and correlation coefficient 0.8. Their simple average has variance [4 + 4 + 2(0.8)(4)]/4 = 3.6 square units, not 2 square units as the independence assumption would suggest. Its standard deviation is approximately 1.897 rather than 1.414 units. The point is not that averaging is useless, but that repeated correlated measurements provide less independent evidence than their count suggests. In a receiver this correlation can arise from shared analogue noise, overlapping FFT windows, common oscillator phase noise, duplicated buffers or an interferer admitted to multiple channels. An estimate of covariance itself has uncertainty and requires representative calibration records.

For an operational sensitivity statement, retain separate observations of threshold behaviour under noise-only conditions and of successful detection under known, deliberately weak reference inputs. Define the signal family, bandwidth, duration, receiver states, observation opportunity and decision threshold before reporting numerical probabilities. A mean noise level cannot determine a detection probability without a distribution or independently tested operating characteristic for the chosen statistic. A nominal 10 dB margin may be a legitimate stated design requirement, but it is not a universal conversion into a probability of intercept. If the desired

Copyright 2026, James M. Atkinson

emission can arrive during receiver blind time, operational capture further depends on the event-time model, which must not be concealed inside the amplifier noise figure.

Copyright 2026, James M. Atkinson

2.30 Advanced technical expansion. Coloured-noise covariance and operational detection limits

The familiar thermal model kTB is useful only after the reference plane, source temperature, equivalent noise bandwidth and system state have been defined. Real installed paths present frequency-selective gain, correlated conversion products, interference with temporal structure and noise whose distribution is poorly approximated by a stationary Gaussian process. An experimentally meaningful development starts with a sampled covariance matrix R, whose element R[i,j] represents the expected cross-product between the ith and jth complex noise samples after removal of their estimated mean. If R is diagonal, ideal independent-noise formulas are available. If off-diagonal terms are consequential, the variance of a coherent sum changes and the nominal sample count cannot be equated with the number of independent observations. For a weighted estimator $z = w^H x$, with complex weight vector w and input covariance R, noise variance is $w^H R w$. This compact expression prevents an apparently precise average from inheriting a variance formula whose independence assumptions have not been demonstrated.

A concrete laboratory example illustrates the danger. Suppose four synchronous channels each have noise variance 1 in a consistent arbitrary power unit and equal pairwise correlation coefficient 0.25, with a valid positive-semidefinite covariance matrix. The mean of all four channels has variance $[1 + (4 - 1) \times 0.25]/4 = 0.4375$, rather than the independent-noise value of 0.25. Its standard deviation is approximately 0.6614 instead of 0.5000. Parallel recording still improves that estimator relative to one

Copyright 2026, James M. Atkinson

channel, but the gain is weaker than independence would predict. Shared oscillator noise, a common front-end noise wave or a digital artefact copied into all streams may cause such correlation. The numerical values are invented solely to compare two models; a real receiver needs its own covariance estimate and uncertainty assessment, including the possibility that the covariance changes across frequency and time.

Detection thresholds should be attached to a named statistic, rather than a generic noise figure. An energy detector evaluates a squared-magnitude statistic; a coherent detector evaluates correlation with a specified complex reference; a pulse detector may depend on leading-edge shape or a time-frequency template. Their distributions under the no-event hypothesis differ. Thresholding millions of spectral bins and successive time windows introduces multiple opportunities for false alarms, often with dependencies because FFT windows overlap and adjacent bins share leakage. A single-bin false-alarm rate cannot be transplanted unaltered into a whole-survey false-alarm claim. A credible test freezes the analysis code and threshold before evaluating a held-out noise-only population and separate weak-event population. The test records the search area, background interference conditions, excluded states and numbers of independent experimental trials, rather than treating every correlated FFT cell as a separate confirmation.

Noise-temperature calibration also requires a state-valid inverse. In a hot-cold experiment, the ratio of measured output noise powers cancels receiver gain only when gain, effective bandwidth and detector operation are genuinely common to the two states. A temperature inversion that yields a physically inadmissible negative receiver contribution must trigger

Copyright 2026, James M. Atkinson

examination of source calibration, compression, mismatch and switching transients. It must not be repaired by replacing the result with zero. When a calibration source and the receiver share temperature or frequency-reference uncertainties, covariance can matter as much as repeatability. Applying a root-sum-square rule without shared-input terms produces false confidence. A documented uncertainty budget therefore identifies the sensitivity coefficient for every quantity and the empirical basis of every significant covariance, following the general propagation approach described in NIST Technical Note 1297.

Operational sensitivity is ultimately a property of a declared event and opportunity to observe it. A low-noise amplifier may reduce internal noise yet amplify a nearby cellular transmitter enough to drive the next stage into compression. A narrowed channel may lower integrated noise while discarding much of a short chirp. A dwell detector may correctly identify a reference burst when tuned to its frequency but miss the same burst during a scan elsewhere. Separate probability of observation from conditional probability of detection, and keep both apart from false-alarm probability. An acceptance programme should sweep signal level, burst duration, modulation and blocker state while preserving the realised receiver settings and raw samples. The resulting operating envelope is more useful to a demanding examiner than a single unqualified sensitivity figure.

Copyright 2026, James M. Atkinson

2.31 Noise-floor specification for a 1 Hz reference and a 30 Hz analysis bandwidth

A receiver system advertised with a minus-170-dBm input-referred noise floor in one hertz must declare whether the figure is a physical input-equivalent noise spectral density, a displayed average-noise-level normalisation, a minimum detectable signal, or an estimate from repeated measurements. These concepts can have the same units on a screenshot only because the display obscures the original normalisation. Under a matched 290 K thermal source, the available noise spectral density is approximately minus 173.98 dBm/Hz. A total input-equivalent density of minus 170 dBm/Hz is about four decibels higher, corresponding to an idealised four-decibel noise figure for the specified receiver state. It is plausible for a qualified low-noise signal chain. It is not a plausible guarantee for every frequency from baseband to forty gigahertz, regardless of preceding antenna loss, source temperature or strong-signal exposure.

To turn a density into an integrated noise power, define the equivalent noise bandwidth rather than merely selecting a number labelled RBW. For white noise with constant input-referred density N_0 over a channel having effective noise bandwidth B_{eq}, the admitted mean power is $N_0 B_{eq}$. In decibels, its level is $N_0[\text{dBm/Hz}]+10\log10(B_{eq}/1\ \text{Hz})$. For a source density of −170 dBm/Hz and $B_{eq}=30$ Hz, the result is approximately −155.23 dBm. If the FFT window has an equivalent noise bandwidth different from its bin spacing, use the actual B_{eq}. A successful narrowband matched-filter experiment can sometimes detect a known waveform with a signal-energy statistic whose threshold is below the integrated noise power. It must report

Copyright 2026, James M. Atkinson

processing gain, duration, false-alarm criterion and signal model, rather than silently relabel the threshold as thermal-noise power.

The forty-gigahertz architecture makes frequency dependence unavoidable. Each antenna, low-noise preamplifier, preselector, frequency converter and digitiser has different gain, noise and linearity characteristics. A system-level noise map should therefore give an input reference plane and calibration interval for every frequency slice, together with detector mode, effective bandwidth and usable gain range. A spur or desensitisation event can raise an operational detection threshold without altering the quiet matched-source noise figure. Four hours of valid monitoring requires repeated calibration challenge data or a measured stability basis, because the original low-noise acceptance result is not necessarily transferable across changing thermal, gain or blocker conditions. The report should publish typical, worst qualified and unqualified regions separately; a single global minimum figure may be true somewhere while misleading elsewhere.

Copyright 2026, James M. Atkinson

Chapter Summary

Sensitivity is a defined probability and bandwidth problem, not a single instrument label. Thermal noise, cascade noise, environmental interference, dynamic range, and detector statistics must be controlled together.

Build the noise budget at a declared source plane and observation band. Distinguish available from delivered power and retain the matching assumptions. Equivalent noise bandwidth expresses integrated weighting; a quieter narrow channel is useful only if it also retains the required signal.

Model 2B carries gain and added noise through a fixed-state cascade. Earlier gain reduces later input-equivalent noise, while preceding dissipative loss both attenuates and emits according to its temperature. Reference noise factor uses 290 K; actual SNR degradation also depends on the actual source temperature.

Hot-cold inversion requires applicable source states, gain, bandwidth and linearity. Check the admissible ratio and uncertainty, especially near a ratio of one. Repetition does not remove unchanged bias or create independent data. Operational sensitivity additionally needs detector and false-alarm evidence for the defined event. Preserve installed-path verification, strong-signal validity and actual acquisition coverage; a missed dwell is a coverage limitation.

Chapter 2 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Copyright 2026, James M. Atkinson

Multiple-Choice Questions

V011-C02-MCQ-001. At a declared input plane, what condition permits the available thermal-noise power kTB to equal the power delivered to the receiver?

A. The source and receiver have the same physical temperature, regardless of impedance.

B. The source and receiver are matched at the declared real reference impedance.

C. The output detector averages power for a sufficiently long interval.

D. The receiver has enough gain to make its input mismatch negligible.

Answer: B. Matching establishes the available-to-delivered power equivalence used in the model. Equal temperature, high gain, and averaging do not establish that equivalence. Review: Power, bandwidth, and the reference plane; Equation 3. Source: Equation 3. Available thermal-noise power (p. 659)

Why the selected alternative fits: The source and receiver are matched at the declared real reference impedance.

Distinguishing consideration: compare this with option A, “The source and receiver have the same physical temperature, regardless of impedance”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 3. Available thermal-noise power; Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Equation 3. Available thermal-noise power; Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-002. An antenna viewing a hot structure is connected to a receiver at 290 K. Which temperature belongs in the source term of the noise model?

A. The effective source noise temperature for the antenna environment and selected band.

B. The receiver enclosure temperature because the receiver sets the reference plane.

C. The equivalent input noise temperature of the receiver alone.

D. 290 K because noise figure is conventionally referred to that temperature.

Answer: A. The source term describes noise offered by the source. The reference temperature and receiver-added equivalent temperature have different roles.

Review: Thermal Noise as a Bandwidth-Dependent Quantity; Equation 4C. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why the selected alternative fits: The effective source noise temperature for the antenna environment and selected band.

Distinguishing consideration: compare this with option B, “The receiver enclosure temperature because the receiver sets the reference plane”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Thermal Noise as a Bandwidth-Dependent Quantity.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Thermal Noise as a Bandwidth-Dependent Quantity.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-003. A report moves its input reference plane from the antenna terminal to the receiver connector after a lossy cable. What follows?

A. The cable thermal contribution vanishes physically because it lies before the new plane.

B. The original and revised noise figures can be compared without stating their planes.

C. The reported receiver noise figure can decrease because the cable is excluded, while antenna-to-output performance is unchanged.

D. The antenna-to-output signal-to-noise ratio improves by the removed cable loss.

Answer: C. Changing the reporting boundary changes the included network. It does not change the installed path or recover its lost signal-to-noise ratio. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why the selected alternative fits: The reported receiver noise figure can decrease because the cable is excluded, while antenna-to-output performance is unchanged.

Distinguishing consideration: compare this with option A, “The cable thermal contribution vanishes physically because it lies before the new plane”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-004. Which is the correct interpretation of equivalent noise bandwidth under a declared filter normalization?

A. The receiver sampling rate divided by the number of displayed trace points in every mode.

B. The width of a rectangular filter that passes the same noise power for the stated noise-density model.

C. The largest occupied signal bandwidth that can be detected with a fixed threshold.

D. The frequency interval between the filter half-power points in every filter design.

Answer: B. Equivalent noise bandwidth is defined by integrated weighting. It need not equal a half-power width, display spacing, or signal bandwidth. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why the selected alternative fits: The width of a rectangular filter that passes the same noise power for the stated noise-density model.

Distinguishing consideration: compare this with option A, “The receiver sampling rate divided by the number of displayed trace points in every mode”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-005. The noise density and gain vary appreciably across the observation band. What is the defensible next calculation?

A. Multiply center-frequency noise density by the nominal bandwidth without further qualification.

B. Average the gain values in decibels and substitute that average into kTB.

C. Integrate the frequency-dependent noise density through the actual power response.

D. Use the largest gain in the band for both the desired tone and every noise contribution.

Answer: C. A weighted integral retains the frequency dependence. A single center value is justified only when the flatness approximation is adequate. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why the selected alternative fits: Integrate the frequency-dependent noise density through the actual power response.

Distinguishing consideration: compare this with option A, “Multiply center-frequency noise density by the nominal bandwidth without further qualification”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-006. The equivalent bandwidth is reduced from 10 kHz to 1 kHz while a centered continuous tone remains fully retained. What happens to flat integrated white-noise power?

A. It decreases by 10 dB.

B. It decreases by 20 dB.

C. It decreases by 1 dB because the bandwidth ratio is ten.

D. It remains fixed because the source temperature is fixed.

Answer: A. Noise power is proportional to bandwidth, so 10 log10(1/10) equals -10 dB. This statement depends on retaining the tone. Review: Equation 3; Power, bandwidth, and the reference plane. Source: Equation 3. Available thermal-noise power (p. 659)

Why the selected alternative fits: It decreases by 10 dB.

Distinguishing consideration: compare this with option B, “It decreases by 20 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 3. Available thermal-noise power; Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Equation 3. Available thermal-noise power; Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-MCQ-007. The same bandwidth reduction removes part of a short burst spectrum. Which statement is justified?

A. The signal-to-noise ratio necessarily improves by 10 dB because white noise has decreased by 10 dB.

B. The burst peak amplitude alone establishes that all relevant energy remains in the channel.

C. The rejected signal energy can be restored by subtracting the measured noise-floor change.

D. Signal retention must be evaluated before claiming the full bandwidth-ratio improvement in signal-to-noise ratio.

Answer: D. The ratio depends on both retained signal and admitted noise. A smaller noise reading does not establish an equal improvement for a spectrally extended signal. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why the selected alternative fits: Signal retention must be evaluated before claiming the full bandwidth-ratio improvement in signal-to-noise ratio.

Distinguishing consideration: compare this with option A, “The signal-to-noise ratio necessarily improves by 10 dB because white noise has decreased by 10 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-MCQ-008. What operation defines an input-referred noise value from a measured output noise power in the stated scalar model?

A. Divide by the voltage gain regardless of impedance or the quantity measured.

B. Subtract the receiver noise figure in linear units from output watts.

C. Divide by a gain from any calibrated attenuator state at the same center frequency.

D. Divide by the signal power gain connecting the selected input and output planes in that state.

Answer: D. The conversion uses the appropriate power gain and matched configuration. It is a reporting transformation, not a physical relocation of noise generators. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why the selected alternative fits: Divide by the signal power gain connecting the selected input and output planes in that state.

Distinguishing consideration: compare this with option A, “Divide by the voltage gain regardless of impedance or the quantity measured”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-MCQ-009. Why can a matched-port cable insertion-loss certificate be insufficient for correcting an antenna-connected receiver result?

A. Cable loss ceases to depend on frequency whenever an antenna is connected.

B. A reactive antenna and state-dependent receiver match can require a model beyond matched scalar loss.

C. The certificate determines the antenna noise temperature without another measurement.

D. Matched-port insertion loss is always a voltage ratio and cannot describe power.

Answer: B. The original measurement conditions matter. Reflection and interaction between actual impedances are outside a simple matched dissipative-loss substitution. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why the selected alternative fits: A reactive antenna and state-dependent receiver match can require a model beyond matched scalar loss.

Distinguishing consideration: compare this with option A, “Cable loss ceases to depend on frequency whenever an antenna is connected”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-MCQ-010. Which statement correctly distinguishes source temperature from cascade equivalent input noise temperature?

A. Source temperature describes noise supplied to the cascade, while equivalent input temperature represents noise added by the included chain.

B. Both must equal the enclosure temperature when all gains are constant.

C. Source temperature is omitted whenever noise figure is stated at 290 K.

D. Equivalent input temperature includes every external interferer by definition.

Answer: A. Equation 4C keeps the source and added receiver contributions separate. That separation allows the source environment to change without redefining receiver noise. Review: Equation 4C. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why the selected alternative fits: Source temperature describes noise supplied to the cascade, while equivalent input temperature represents noise added by the included chain.

Distinguishing consideration: compare this with option B, “Both must equal the enclosure temperature when all gains are constant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-011. In Equation 4A, what does G_0 = 1 accomplish?

A. It normalizes every later stage gain to the first stage noise figure.

B. It sets the source noise temperature to one kelvin.

C. It supplies the empty preceding-gain product for the first stage contribution.

D. It assumes the first physical stage has unity power gain.

Answer: C. The first added-noise contribution is divided by unity because no stages precede it. G_0 is an indexing convention, not a hardware requirement. Review: Equations 4A and 4C. Source: Equation 4A. Cumulative power gain (p. 667)

Why the selected alternative fits: It supplies the empty preceding-gain product for the first stage contribution.

Distinguishing consideration: compare this with option A, “It normalizes every later stage gain to the first stage noise figure”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4A. Cumulative power gain; Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Review: Chapter 2 — Equation 4A. Cumulative power gain; Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

V011-C02-MCQ-012. For a stage with power gain g_i and equivalent input noise temperature $T_{e,i}$, what is the stage-added output noise in bandwidth B?

A. $k B g_i T_{e,i}$.

B. $\frac{k B T_{e,i}}{g_i}$.

C. $\frac{k B \left(T_{e,i}+T_s\right)}{G_{i-1}}$ alone.

D. $\frac{k B T_s}{g_i}$.

Answer: A. Equivalent input temperature is converted to the stage output by the stage power gain. Noise already entering the stage is handled by the other recurrence term. Review: Equation 4B. Source: Equation 4B. Noise propagation through one stage (p. 668)

Why the selected alternative fits: option A contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 2 — Equation 4B. Noise propagation through one stage.

Review: Chapter 2 — Equation 4B. Noise propagation through one stage.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-013. Why is a later stage temperature $T_{e,i}$ divided by G_{i-1} when referred to the cascade input?

A. Each preceding stage must have a noise figure of zero decibels.

B. The later stage gain removes the thermal noise it generates.

C. The source temperature is assumed equal to the later stage temperature.

D. All preceding stages amplify the input signal before that stage adds its own noise.

Answer: D. Referring the new output noise back through the cascade cancels the stage own gain and leaves the product of preceding gains. Review: Derivation of Equation 4C. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why the selected alternative fits: All preceding stages amplify the input signal before that stage adds its own noise.

Distinguishing consideration: compare this with option A, “Each preceding stage must have a noise figure of zero decibels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-014. Two stages have power gains 10 and 20. What is their cumulative power gain?

A. 30, or approximately 14.77 dB.

B. 2, or approximately 3.01 dB.

C. 200, or approximately 23.01 dB.

D. 200, or approximately 46.02 dB.

Answer: C. Linear power gains multiply: 10 times 20 equals 200. The decibel conversion is 10 log10(200). Review: Equation 4A. Source: Equation 4A. Cumulative power gain (p. 667)

Why the selected alternative fits: 200, or approximately 23.01 dB.

Distinguishing consideration: compare this with option A, “30, or approximately 14.77 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4A. Cumulative power gain.

Review: Chapter 2 — Equation 4A. Cumulative power gain.

V011-C02-MCQ-015. A two-stage chain has $T_{e,1}$ = 80 K, $T_{e,2}$ = 1200 K, and g_1 = 100. What is its equivalent input noise temperature?

A. 1280 K.

B. 12.8 K.

C. 92 K.

D. 120080 K.

Answer: C. Equation 4C gives 80 + 1200/100 = 92 K. The later stage is referred through the first-stage gain. Review: Equation 4C; Application 2B.5. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why the selected alternative fits: 92 K.

Distinguishing consideration: compare this with option A, "1280 K"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Application 2B.5: solve for the gain that is useful.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Application 2B.5: solve for the gain that is useful.

V011-C02-MCQ-016. Two chains have equal total small-signal gain but different ordering of a cable and low-noise amplifier. Which conclusion follows?

A. The first-stage noise can be suppressed by increasing gain only after the final stage.

B. Their equivalent input noise temperatures can differ because preceding gain weights each added-noise contribution.

C. Their noise figures must match because output signal powers match.

D. The cable contribution is unchanged at the original input plane in both arrangements.

Answer: B. Total gain does not identify where noise is added. The recurrence retains ordering even when total signal gain is the same. Review: Equation 4C; Application 2B.2. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why the selected alternative fits: Their equivalent input noise temperatures can differ because preceding gain weights each added-noise contribution.

Distinguishing consideration: compare this with option A, “The first-stage noise can be suppressed by increasing gain only after the final stage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Application 2B.2: move an amplifier across a cable.

V011-C02-MCQ-017. Which condition permits simple addition of source and stage noise powers in Model 2B?

A. All stage output voltages have the same phase.

B. The receiver averages long enough to make any correlation physically disappear.

C. The admitted noise contributions have zero cross-power.

D. Every noise contribution has the same instantaneous waveform.

Answer: C. Zero cross-power removes cross terms from the power sum. Correlated contributions require their covariance or cross-spectrum to be retained. Review: Model 2B assumptions. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: The admitted noise contributions have zero cross-power.

Distinguishing consideration: compare this with option A, “All stage output voltages have the same phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

V011-C02-MCQ-018. A receiver changes gain midway through a record. What must be established before applying one fixed-state noise law to the whole record?

A. Only the mean of the two gain settings in decibels.

B. A valid model for the state intervals and any justified combination of their results.

C. That both gain settings use the same nominal center frequency.

D. Only that the final output file has a continuous timestamp field.

Answer: B. The fixed-state model does not automatically describe a mixture of states. Frequency and timestamps alone do not supply the missing gain/noise law.

Review: Model 2B assumptions; Uncertainty and Environmental Noise. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: A valid model for the state intervals and any justified combination of their results.

Distinguishing consideration: compare this with option A, “Only the mean of the two gain settings in decibels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Uncertainty and Environmental Noise.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-MCQ-019. Why must a mixer noise figure be checked before inserting it into an otherwise scalar cascade?

A. Noise figure becomes independent of the input environment after a frequency conversion.

B. Its sideband architecture and image contributions may differ from the selected equivalent-channel model.

C. A frequency conversion guarantees equal single-sideband and double-sideband noise figures.

D. All mixers have zero power gain and therefore cannot be modeled at all.

Answer: B. The chapter permits an empirically established selected-channel law but excludes unmodeled image contributions and blind use of nominal sideband figures. Review: Model 2B scope; Analog Devices source note. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: Its sideband architecture and image contributions may differ from the selected equivalent-channel model.

Distinguishing consideration: compare this with option A, “Noise figure becomes independent of the input environment after a frequency conversion”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

V011-C02-MCQ-020. Which physical situation is outside the declared scalar model even if its output can be assigned an average power?

A. A matched stage with a positive finite power gain below unity.

B. A source temperature different from 290 K but within the classical approximation.

C. A finite nonnegative equivalent input noise temperature for every stage.

D. Feedback between mismatched stages that materially changes the response.

Answer: D. The model excludes unmodeled mismatch feedback. Matched attenuation, nonreference source temperatures, and finite stage temperatures are explicitly accommodated. Review: Model 2B assumptions. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: Feedback between mismatched stages that materially changes the response.

Distinguishing consideration: compare this with option A, “A matched stage with a positive finite power gain below unity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

V011-C02-MCQ-021. A matched dissipative attenuator has linear loss L = 2 and physical temperature T_p = 290 K. What is its equivalent input noise temperature?

A. 145 K.

B. 580 K.

C. 290 K.

D. 0 K.

Answer: C. Equation 4F gives $(L-1)T_p$ = 290 K. The output-added temperature contribution is different because it includes the one-half transmission gain. Review: Equation 4F. Source: Equation 4F. Noise temperature of a matched dissipative loss (p. 670)

Why the selected alternative fits: 290 K.

Distinguishing consideration: compare this with option A, “145 K”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss.

Review: Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss.

V011-C02-MCQ-022. For that same L = 2 attenuator, what is its own added output noise expressed as temperature times $k\,B$?

A. 290 K times $k\,B$.

B. 145 K times $k\,B$.

C. 580 K times $k\,B$.

D. 0 K times $k\,B$.

Answer: B. The output-added term is $k\,B\,T_p\left(1-\frac{1}{L}\right)$, which is $k\,B$ times 145 K.

Input-equivalent temperature is obtained by dividing by the gain. Review: Derivation of Equation 4F. Source: Equation 4F. Noise temperature of a matched dissipative loss (p. 670)

Why the selected alternative fits: 145 K times.

Distinguishing consideration: compare this with option A, “290 K times”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss.

Review: Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss.

V011-C02-MCQ-023. A matched attenuator and both connected terminations are all at T_p. What output available thermal-noise power is required by equilibrium?

A. $\frac{kBT_p}{L}$ because the attenuator only removes noise.

B. kBT_p, independent of its dissipative loss within this model.

C. Zero because equal-temperature components exchange no instantaneous noise power.

D. kBT_pL because loss increases the output source noise.

Answer: B. Attenuator thermal emission complements the attenuated source noise. Their sum remains the equilibrium available noise power. Review: Derivation of Equation 4F. Source: Equation 4F. Noise temperature of a matched dissipative loss (p. 670)

Why the selected alternative fits: independent of its dissipative loss within this model.

Distinguishing consideration: compare this with option A, “because the attenuator only removes noise”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss.

Review: Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss.

V011-C02-MCQ-024. When does the noise figure in decibels of a matched genuinely dissipative attenuator with linear loss L greater than 1 equal its insertion loss in decibels?

A. Only when its linear loss equals one.

B. Whenever its output noise is below the receiver-added noise.

C. When its physical temperature equals the noise-factor reference temperature.

D. Whenever its source and load impedances are equal, regardless of temperature.

Answer: C. For L greater than 1, $F_0 = 1 + \frac{(L-1)T_p}{T_0}$ equals L when $T_p = T_0$.

Matching alone is insufficient. The excluded lossless case $L = 1$ has $F_0 = L = 1$ independently of T_p in this model. Review: Equations 4D and 4F. Source: Equation 4D. Noise factor at the reference temperature (p. 669)

Why the selected alternative fits: When its physical temperature equals the noise-factor reference temperature.

Distinguishing consideration: compare this with option A, “Only when its linear loss equals one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss.

V011-C02-MCQ-025. Why must arbitrary reflection loss not be assigned the equivalent temperature $(L-1)T_p$ without further modeling?

A. The equilibrium derivation applies to dissipation and its thermal emission, not merely reflected power.

B. Reflection loss always has the same noise figure as a matched resistor at 290 K.

C. Reflected signal power increases the physical temperature of every downstream stage equally.

D. The passive-loss relation applies only to amplifiers with gain greater than one.

Answer: A. The derivation balances transmitted source noise and emission from a dissipative element. A mismatch can change delivered power without the assumed dissipation. Review: Derive passive loss from thermal equilibrium. Source: §2.15 Derive passive loss from thermal equilibrium (p. 670)

Why the selected alternative fits: The equilibrium derivation applies to dissipation and its thermal emission, not merely reflected power.

Distinguishing consideration: compare this with option B, “Reflection loss always has the same noise figure as a matched resistor at 290 K”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Derive passive loss from thermal equilibrium.

Review: Chapter 2 — Derive passive loss from thermal equilibrium.

V011-C02-MCQ-026. A matched loss L = 1.5 at 300 K precedes a chain with $T_{e,c}$ = 100 K. What is the combined input-equivalent temperature?

A. 200 K.

B. 250 K.

C. 100 K.

D. 300 K.

Answer: D. Equation 4G gives (1.5 - 1) times 300 + 1.5 times 100 = 150 + 150 = 300 K.

Review: Equation 4G. Source: Equation 4G. Loss followed by a characterized chain (p. 671)

Why the selected alternative fits: 300 K.

Distinguishing consideration: compare this with option A, “200 K”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4G. Loss followed by a characterized chain.

Review: Chapter 2 — Equation 4G. Loss followed by a characterized chain.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-027. For that loss-before-chain calculation, which term accounts for the downstream chain referred back through the loss?

A. $LT_{e,c}$.

B. $\frac{T_p}{L}$.

C. $\frac{T_{e,c}}{L}$.

D. $(L-1)T_p$ alone.

Answer: A. The loss reduces the signal reaching the downstream chain, so the chain noise becomes more important when referred to the original input. Review:

Equation 4G. Source: Equation 4G. Loss followed by a characterized chain (p. 671)

Why the selected alternative fits: option A contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

V011-C02-MCQ-030. Why does a scalar signal-level correction for a warm cable not complete a noise measurement correction?

A. The cable physical temperature is relevant only to connector mechanical tolerances.

B. Cable thermal emission and the reweighted downstream receiver noise must also be included.

C. A signal-level correction necessarily removes all thermal noise from the retained record.

D. Cable loss affects source and receiver noise identically at the original input plane.

Answer: B. Restoring a reported signal level to an earlier plane does not undo the cable contribution to the noise budget or its uncertainty. Review: Equation 4G discussion. Source: Equation 4G. Loss followed by a characterized chain (p. 671)

Why the selected alternative fits: Cable thermal emission and the reweighted downstream receiver noise must also be included.

Distinguishing consideration: compare this with option A, “The cable physical temperature is relevant only to connector mechanical tolerances”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4G. Loss followed by a characterized chain.

Review: Chapter 2 — Equation 4G. Loss followed by a characterized chain.

V011-C02-MCQ-033. The same T_e = 150 K receiver is connected to a source at T_s = 5000 K. What is the actual SNR degradation ratio?

A. 33.33.

B. 0.03.

C. 1.517.

D. 1.03.

Answer: D. The ratio is 1 + 150/5000 = 1.03. Receiver-added noise is a small fraction of the much larger source contribution. Review: Equation 4E; Application 2B.4.

Source: Equation 4E. Signal-to-noise degradation for the actual source (p. 669)

Why the selected alternative fits: 1.03.

Distinguishing consideration: compare this with option A, “33.33”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source; Chapter 2 — Application 2B.4: change the source environment.

Review: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source; Chapter 2 — Application 2B.4: change the source environment.

V011-C02-MCQ-034. Under which stated condition does the actual SNR degradation ratio equal the reference noise factor F_0?

A. The output noise is dominated by the first amplifier in every case.

B. The total receiver gain equals its noise factor.

C. The actual source noise temperature T_s equals T_0.

D. The signal power equals the available source noise power.

Answer: C. Equations 4D and 4E have the same denominator only when $T_s = T_0$, apart from the trivial zero-added-noise case. Review: Equations 4D and 4E. Source: Equation 4D. Noise factor at the reference temperature (p. 669)

Why the selected alternative fits: The actual source noise temperature equals.

Distinguishing consideration: compare this with option A, "The output noise is dominated by the first amplifier in every case"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Review: Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-035. Why is Equation 4E explicitly restricted to positive T_s?

A. Power gain ceases to be dimensionless at zero source temperature.

B. A receiver with $T_s = 0$ must have negative equivalent input noise temperature.

C. At $T_s = 0$ the classical input SNR is unbounded, so the stated finite-ratio comparison is not defined.

D. The output noise must be zero whenever the source temperature is zero.

Answer: C. Receiver-added noise may remain at $T_s = 0$, but the particular input-to-output SNR ratio needs a positive source-noise denominator. Review: Equation 4E domain. Source: Equation 4E. Signal-to-noise degradation for the actual source (p. 669)

Why the selected alternative fits: At the classical input SNR is unbounded, so the stated finite-ratio comparison is not defined.

Distinguishing consideration: compare this with option A, “Power gain ceases to be dimensionless at zero source temperature”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Review: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

V011-C02-MCQ-036. What does a reported equivalent input noise temperature of 80 K imply about an amplifier enclosure?

A. The enclosure must be held at exactly 80 K during every use.

B. The enclosure temperature must be below the source noise temperature.

C. No direct equality with enclosure physical temperature is implied.

D. The amplifier cannot be operating at room temperature.

Answer: C. Equivalent temperature is a noise-power-density representation of an active network, not a thermometer reading of the enclosure. Review: Equation 4C discussion. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why the selected alternative fits: No direct equality with enclosure physical temperature is implied.

Distinguishing consideration: compare this with option A, “The enclosure must be held at exactly 80 K during every use”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

V011-C02-MCQ-037. A cold-source system changes receiver T_e from 150 K to 50 K with T_s = 40 K and unchanged signal gain and bandwidth. What is the reduction in input-referred total noise?

A. 10 log10(150/50), approximately 4.771 dB.

B. 10 log10(290/40), approximately 8.603 dB.

C. Exactly 10 dB because receiver T_e decreases by 100 K.

D. 10 log10(190/90), approximately 3.245 dB.

Answer: D. Total input-referred noise includes the source term. The relevant old/new ratio is (40 + 150)/(40 + 50). Review: Application 2B.4. Source: §2.21 Application 2B.4: change the source environment (p. 681)

Why the selected alternative fits: 10 log10(190/90), approximately 3.245 dB.

Distinguishing consideration: compare this with option A, “10 log10(150/50), approximately 4.771 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.4: change the source environment.

Review: Chapter 2 — Application 2B.4: change the source environment.

V011-C02-MCQ-038. Why does the same receiver-temperature improvement produce much less benefit with a 5000 K source?

A. Thermal noise stops depending on bandwidth in a noisy environment.

B. The unchanged source contribution dominates the total input-referred noise.

C. The receiver power gain must fall in proportion to source temperature.

D. The receiver reference noise figure becomes undefined above 290 K source temperature.

Answer: B. Changing T_e has limited impact when T_s is much larger. The reference receiver noise figure can remain valid while its operational importance decreases. Review: Application 2B.4. Source: §2.21 Application 2B.4: change the source environment (p. 681)

Why the selected alternative fits: The unchanged source contribution dominates the total input-referred noise.

Distinguishing consideration: compare this with option A, “Thermal noise stops depending on bandwidth in a noisy environment”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.4: change the source environment.

Review: Chapter 2 — Application 2B.4: change the source environment.

V011-C02-MCQ-039. A receiver noise figure is 7 dB at T_0 = 290 K. Which expression converts it to equivalent input temperature?

A. 290 times ($10^{\frac{7}{10}}$ - 1) kelvins.

B. 290 times ($10^{\frac{7}{20}}$ - 1) kelvins.

C. 290 times 7 kelvins.

D. 290 divided by 7 kelvins.

Answer: A. First convert the decibel noise figure to linear noise factor, then apply T_e = T_0(F_0 - 1). Review: Equation 4D. Source: Equation 4D. Noise factor at the reference temperature (p. 669)

Why the selected alternative fits: 290 times (- 1) kelvins.

Distinguishing consideration: compare this with option B, “290 times (- 1) kelvins”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4D. Noise factor at the reference temperature.

Review: Chapter 2 — Equation 4D. Noise factor at the reference temperature.

V011-C02-MCQ-040. A very noisy environment raises the system detection limit without a change in the receiver hardware state. Which description is most accurate?

A. The reference temperature T_0 must be replaced by the measured noise temperature in its defining convention.

B. The environmental contribution can be removed solely by increasing output gain.

C. The receiver noise figure must rise by exactly the environmental noise increase.

D. The source/environment contribution can rise while the receiver reference noise figure remains the same.

Answer: D. Reference noise figure describes added receiver noise under its stated convention. Operational total noise also includes the source environment. Review: Uncertainty and Environmental Noise; Equations 4C and 4D. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why the selected alternative fits: The source/environment contribution can rise while the receiver reference noise figure remains the same.

Distinguishing consideration: compare this with option A, “The reference temperature must be replaced by the measured noise temperature in its defining convention”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-MCQ-041. Which condition is essential for the simple hot-cold Y-factor inversion?

A. The receiver must operate at a different attenuation setting for each source state.

B. The gain, effective bandwidth, and receiver noise law are the same in both source states.

C. The hot and cold source temperatures must be symmetric about 290 K.

D. The hot output power must be at the receiver compression threshold.

Answer: B. The ratio cancels the common gain-bandwidth factor. State-dependent gain or compression prevents that cancellation. Review: Equations 4H and 4I. Source: Equation 4H. Hot-to-cold output power ratio (p. 673)

Why the selected alternative fits: The gain, effective bandwidth, and receiver noise law are the same in both source states.

Distinguishing consideration: compare this with option A, “The receiver must operate at a different attenuation setting for each source state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

Review: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

V011-C02-MCQ-042. With T_h = 9000 K, T_c = 290 K, and T_e = 500 K, what is Y in the fixed-state model?

A. 9500/790, approximately 12.0253.

B. 8710/500, or 17.42.

C. 9000/290, approximately 31.0345.

D. 790/9500, approximately 0.08316.

Answer: A. Y includes receiver-added noise in both states: $\frac{T_h+T_e}{T_c+T_e}$. Review: Equation 4H; Application 2B.8. Source: Equation 4H. Hot-to-cold output power ratio (p. 673)

Why the selected alternative fits: 9500/790, approximately 12.0253.

Distinguishing consideration: compare this with option B, “8710/500, or 17.42”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Application 2B.8: recover noise temperature from two powers.

Review: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Application 2B.8: recover noise temperature from two powers.

V011-C02-MCQ-043. For $T_h > T_c > 0$ and finite nonnegative T_e, which domain follows for Y?

A. Y can take any positive value without testing the assumptions.

B. $Y \geq \frac{T_h}{T_c}$ with no upper bound.

C. $1 < Y \leq \frac{T_h}{T_c}$.

D. 0 < Y < 1.

Answer: C. Adding the same nonnegative T_e moves the temperature ratio toward one. T_e = 0 gives the upper boundary; finite T_e leaves Y greater than one. Review: Equation 4I domain. Source: Equation 4I. Recovered input noise temperature and its domain (p. 674)

Why the selected alternative fits: option C contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

Review: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

V011-C02-MCQ-044. Measured Y exceeds $\frac{T_h}{T_c}$ for positive T_c. What is the appropriate response?

A. Increase T_c numerically until the result enters the expected range without documenting a correction.

B. Treat the excess as proof of a receiver with negative added-noise power in this model.

C. Investigate calibration, gain state, mismatch, bandwidth, or data errors before accepting the inversion.

D. Clip the inferred negative temperature to zero and report the clipped value as the measurement.

Answer: C. The observation violates the model domain for nonnegative T_e. It is a diagnostic signal, not permission to hide the inconsistency. Review: Equation 4I domain. Source: Equation 4I. Recovered input noise temperature and its domain (p. 674)

Why the selected alternative fits: Investigate calibration, gain state, mismatch, bandwidth, or data errors before accepting the inversion.

Distinguishing consideration: compare this with option A, “Increase numerically until the result enters the expected range without documenting a correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

Review: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-045. Why does the inversion become ill-conditioned as Y approaches one?

A. The reference impedance approaches zero whenever Y is near one.

B. The cold source temperature necessarily becomes negative.

C. The output detector becomes exactly noiseless at Y = 1.

D. The small denominator $Y - 1$ amplifies changes in the ratio and source-temperature inputs.

Answer: D. Equation 4I divides by $Y - 1$, and its derivatives grow. Small input uncertainty can produce a large or strongly nonlinear temperature uncertainty.

Review: Equations 4I, 4N, and 4O. Source: Equation 4I. Recovered input noise temperature and its domain (p. 674)

Why the selected alternative fits: The small denominator amplifies changes in the ratio and source-temperature inputs.

Distinguishing consideration: compare this with option A, “The reference impedance approaches zero whenever Y is near one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Equation 4N. Temperature sensitivity coefficients; Chapter 2 — Equation 4O. Power-ratio sensitivity coefficient.

V011-C02-MCQ-046. Which is the chapter convention for the linear excess-noise ratio?

A. ENR = $\frac{T_h - T_c}{T_0}$, subject to the actual source certificate convention.

B. ENR = $Y - 1$ independent of the receiver noise temperature.

C. ENR = $\frac{T_e}{T_0}$ because the receiver creates the source excess noise.

D. ENR = $\frac{T_h}{T_c}$ for every calibration certificate.

Answer: A. The chapter declares a temperature-difference convention and warns that certificate definitions must be read rather than assumed. Review: Y-factor discussion following Equation 4I. Source: Equation 4I. Recovered input noise temperature and its domain (p. 674)

Why the selected alternative fits: ENR = subject to the actual source certificate convention.

Distinguishing consideration: compare this with option B, “ENR = independent of the receiver noise temperature”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Invert the same model with two source temperatures.

Review: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Invert the same model with two source temperatures.

V011-C02-MCQ-047. Why must T_c not automatically be set to 290 K in every Y-factor reduction?

A. The calibrated or actual cold-state temperature and certificate convention may differ from the reference temperature.

B. A hot-cold ratio eliminates all dependence on the cold source temperature.

C. Noise factor cannot be defined if the cold source differs from 290 K.

D. The Y-factor equation requires T_c to be zero.

Answer: A. T_0 sets the reporting convention, whereas T_c is a source input to the measurement equation. Review: Y-factor discussion; Equations 4D and 4I. Source: Equation 4D. Noise factor at the reference temperature (p. 669)

Why the selected alternative fits: The calibrated or actual cold-state temperature and certificate convention may differ from the reference temperature.

Distinguishing consideration: compare this with option B, “A hot-cold ratio eliminates all dependence on the cold source temperature”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Invert the same model with two source temperatures.

V011-C02-MCQ-048. If hot-state gain is 1% larger than cold-state gain and all else is unchanged, how does the observed hot/cold ratio change?

A. It is unchanged because ratios cancel all gain differences.

B. It increases by exactly 1 dB.

C. It is multiplied by 1.01.

D. It is divided by 1.01.

Answer: C. Only a common gain cancels. A hot/cold gain ratio of 1.01 directly multiplies the physical noise-power ratio. Review: Application 2B.9. Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)

Why the selected alternative fits: It is multiplied by 1.01.

Distinguishing consideration: compare this with option A, “It is unchanged because ratios cancel all gain differences”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

Review: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

V011-C02-MCQ-049. In Application 2B.9, ignoring that 1% hot-state gain increase yields T_e approximately 491.48 K instead of 500 K. How should the error be characterized?

A. A rounding difference that disappears when powers are expressed in dBm.

B. An improvement in the receiver physical sensitivity caused by the calibration cycle.

C. Independent zero-mean random noise guaranteed to average to zero.

D. A state-dependent bias that repetition alone does not remove.

Answer: D. The equal-gain model interprets the elevated ratio as lower receiver-added noise. Repeating the same biased procedure retains the bias. Review: Application 2B.9. Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)

Why the selected alternative fits: A state-dependent bias that repetition alone does not remove.

Distinguishing consideration: compare this with option A, “A rounding difference that disappears when powers are expressed in dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

Review: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

V011-C02-MCQ-050. What can a cold-hot-cold sequence establish without an independent gain model?

A. It proves equal hot and cold gain because the first and last source labels match.

B. It guarantees the hot state was below compression.

C. It can reveal drift or inconsistency, but does not automatically supply a valid correction for every state-dependent gain change.

D. It removes all mismatch differences by averaging the cold readings.

Answer: C. Bracketing measurements provide evidence about temporal behavior. A correction still requires a justified model and relevant controls. Review: Application 2B.9. Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)

Why the selected alternative fits: It can reveal drift or inconsistency, but does not automatically supply a valid correction for every state-dependent gain change.

Distinguishing consideration: compare this with option A, “It proves equal hot and cold gain because the first and last source labels match”; that competing statement does not meet the question’s stated requirement.

V011-C02-MCQ-051. For a two-stage chain, what condition permits a finite first-stage gain to satisfy $T_e \leq T_{target}$ when $T_{e,2}$ is positive?

A. T_{target} must be no greater than $T_{e,1}$.

B. The source temperature must be below T_{target}.

C. T_{target} must exceed $T_{e,1}$.

D. The final stage gain must equal T_{target} in decibels.

Answer: C. $T_e = T_{e,1} + \frac{T_{e,2}}{g_1}$ approaches $T_{e,1}$ from above. A positive finite downstream contribution requires a target above that limit. Review: Equation 4J.

Source: Equation 4J. Minimum first-stage gain for a temperature limit (p. 675)

Why the selected alternative fits: must exceed.

Distinguishing consideration: compare this with option A, “must be no greater than”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit.

Review: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-052. For $T_{e,1}$ = 80 K, $T_{e,2}$ = 1200 K, and T_{target} = 120 K, what is the minimum first-stage power gain?

A. 15, approximately 11.761 dB.

B. 10, exactly 10 dB.

C. 120, approximately 20.792 dB.

D. 30, approximately 14.771 dB.

Answer: D. The inequality gives g_1 >= 1200/(120 - 80) = 30. Review: Equation 4J; Application 2B.5. Source: Equation 4J. Minimum first-stage gain for a temperature limit (p. 675)

Why the selected alternative fits: 30, approximately 14.771 dB.

Distinguishing consideration: compare this with option A, “15, approximately 11.761 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit; Chapter 2 — Application 2B.5: solve for the gain that is useful.

Review: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit; Chapter 2 — Application 2B.5: solve for the gain that is useful.

V011-C02-MCQ-053. What happens if the target is changed to 80 K in that same two-stage chain while $T_{e,2}$ remains positive?

A. A unity first-stage gain is sufficient.

B. A 3 dB gain increase makes the target exact.

C. The final-stage gain alone can make the equivalent temperature zero.

D. No finite first-stage gain reaches the target exactly.

Answer: D. The later contribution tends to zero only as first-stage gain tends to infinity. A finite gain leaves T_e above 80 K. Review: Equation 4J domain. Source: Equation 4J. Minimum first-stage gain for a temperature limit (p. 675)

Why the selected alternative fits: No finite first-stage gain reaches the target exactly.

Distinguishing consideration: compare this with option A, “A unity first-stage gain is sufficient”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit.

Review: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit.

V011-C02-MCQ-054. For a chain with $T_{e,c}$ = 90 K, a preceding passive section at 300 K, and T_{target} = 180 K, what is the maximum permitted linear loss?

A. 390/480, approximately 0.8125.

B. 480/390, approximately 1.23077.

C. 180/90, or 2.

D. 300/180, approximately 1.66667.

Answer: B. Equation 4K gives L <= (T_{target}+T_p)/(T_p+$T_{e,c}$). The passive domain also requires L >= 1. Review: Equation 4K; Application 2B.6. Source: Equation 4K. Maximum allowed preceding loss (p. 675)

Why the selected alternative fits: 480/390, approximately 1.23077.

Distinguishing consideration: compare this with option A, “390/480, approximately 0.8125”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4K. Maximum allowed preceding loss; Chapter 2 — Application 2B.6: allocate loss to a preselector.

Review: Chapter 2 — Equation 4K. Maximum allowed preceding loss; Chapter 2 — Application 2B.6: allocate loss to a preselector.

V011-C02-MCQ-055. If the calculated upper bound on passive loss is below one, what does the design inequality imply?

A. Choose a passive element with negative insertion loss and keep calling it a loss.

B. Even the lossless preceding path cannot meet the stated target with that following chain.

C. The physical temperature should be omitted from the calculation.

D. Any sufficiently narrow detector bandwidth changes the derived temperature bound to one.

Answer: B. A matched passive loss must have L >= 1. A smaller upper bound leaves the feasible interval empty. Review: Equation 4K domain. Source: Equation 4K. Maximum allowed preceding loss (p. 675)

Why the selected alternative fits: Even the lossless preceding path cannot meet the stated target with that following chain.

Distinguishing consideration: compare this with option A, “Choose a passive element with negative insertion loss and keep calling it a loss”; that competing statement does not meet the question’s stated requirement.

V011-C02-MCQ-056. Why is the noise-optimal ordering not automatically the operationally valid ordering under a strong blocker?

A. The first active stage can overload even when the linear noise calculation looks favorable.

B. The cascade temperature formula already includes every intermodulation product.

C. An attenuator placed after an overloaded amplifier restores the earlier linear response.

D. Equal total small-signal gain guarantees equal blocker stress at every internal stage.

Answer: A. Noise and linearity must be checked at their relevant internal planes. A low formal temperature does not validate a compressed configuration. Review: Application 2B.7. Source: §2.24 Application 2B.7: place attenuation before the vulnerable stage (p. 684)

Why the selected alternative fits: The first active stage can overload even when the linear noise calculation looks favorable.

Distinguishing consideration: compare this with option B, “The cascade temperature formula already includes every intermodulation product”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

Review: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-057. In Application 2B.7 a -5 dBm blocker precedes 20 dB attenuation placed before the amplifier. What blocker level reaches the amplifier?

A. +15 dBm.

B. -25 dBm.

C. -20 dBm.

D. -5 dBm.

Answer: B. The input attenuation reduces the blocker level by 20 dB, giving -25 dBm at the amplifier input. Review: Application 2B.7. Source: §2.24 Application 2B.7: place attenuation before the vulnerable stage (p. 684)

Why the selected alternative fits: -25 dBm.

Distinguishing consideration: compare this with option A, “+15 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

Review: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

V011-C02-MCQ-058. If the amplifier input linear-envelope limit is -20 dBm in that stipulated case, what margin does the -25 dBm blocker provide?

A. 5 dB below the stated limit.

B. 15 dB above the stated limit.

C. 20 dB below the stated limit.

D. 25 dB above the stated limit.

Answer: A. The difference between -20 dBm and -25 dBm is 5 dB. This is a stipulated envelope margin, not a general instrument specification. Review: Application 2B.7.

Source: §2.24 Application 2B.7: place attenuation before the vulnerable stage (p. 684)

Why the selected alternative fits: 5 dB below the stated limit.

Distinguishing consideration: compare this with option B, “15 dB above the stated limit”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

Review: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

V011-C02-MCQ-059. The same 20 dB attenuation is moved after the amplifier. What is the key validity result for the -5 dBm blocker?

A. The lower formal noise figure proves that the blocker cannot generate distortion.

B. The amplifier sees -25 dBm because total chain loss is unchanged.

C. The amplifier input exceeds the stipulated -20 dBm envelope by 15 dB, invalidating the simple linear prediction.

D. The amplifier input is safe because the final output power is reduced.

Answer: C. Post-amplifier attenuation cannot protect the earlier amplifier input. The formal noise result belongs to a state whose linearity assumption has failed. Review: Application 2B.7. Source: §2.24 Application 2B.7: place attenuation before the vulnerable stage (p. 684)

Why the selected alternative fits: The amplifier input exceeds the stipulated -20 dBm envelope by 15 dB, invalidating the simple linear prediction.

Distinguishing consideration: compare this with option A, “The lower formal noise figure proves that the blocker cannot generate distortion”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

Review: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

V011-C02-MCQ-060. In Application 2B.6, why does meeting the 180 K noise target not settle the preselector choice?

A. A passive section meeting the noise target must reject every out-of-band signal.

B. Blocker rejection and linearity require a separate performance assessment.

C. The source reference plane can be omitted once the numerical target is satisfied.

D. Noise temperature already specifies the full frequency-selective rejection curve.

Answer: B. A noise constraint is only one design criterion. The preselector must also provide the required rejection without invalidating other assumptions. Review: Application 2B.6. Source: §2.23 Application 2B.6: allocate loss to a preselector (p. 683)

Why the selected alternative fits: Blocker rejection and linearity require a separate performance assessment.

Distinguishing consideration: compare this with option A, “A passive section meeting the noise target must reject every out-of-band signal”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.6: allocate loss to a preselector.

Review: Chapter 2 — Application 2B.6: allocate loss to a preselector.

V011-C02-MCQ-061. What additional input is required to turn the input-referred noise budget into the bounded signal requirement in Equation 4L?

A. An arbitrary probability of detection assigned to any convenient SNR.

B. A separately justified required output SNR γ for the declared detector and event.

C. The maximum trace level in one noise-only record.

D. Only the receiver total gain, regardless of noise or detector behavior.

Answer: B. Gamma is a stipulated detector requirement, not a probability derived from mean noise power alone. Review: Equation 4L; Define sensitivity as a reproducible decision. Source: Equation 4L. Input signal power for a stipulated output ratio (p. 675)

Why the selected alternative fits: A separately justified required output SNR for the declared detector and event.

Distinguishing consideration: compare this with option A, “An arbitrary probability of detection assigned to any convenient SNR”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio; Chapter 2 — Define sensitivity as a reproducible decision.

Review: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio; Chapter 2 — Define sensitivity as a reproducible decision.

V011-C02-MCQ-062. Within Equation 4L, why does total gain cancel from the required input signal power?

A. The source and receiver temperatures are required to be equal.

B. Output gain physically removes receiver noise from the chain.

C. The retained desired signal and admitted total noise share the same valid scalar gain to the output.

D. The detector threshold is assumed independent of its measured quantity.

Answer: C. Both output signal and noise include G_n. The cancellation depends on the stated common gain and signal-retention assumptions. Review: Equation 4L.

Source: Equation 4L. Input signal power for a stipulated output ratio (p. 675)

Why the selected alternative fits: The retained desired signal and admitted total noise share the same valid scalar gain to the output.

Distinguishing consideration: compare this with option A, “The source and receiver temperatures are required to be equal”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

Review: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

V011-C02-MCQ-063. For T_s+T_e = 600 K, B = 10 kHz, and γ = 10, using k = 1.380649×10^{-23} J/K, what required input power follows?

A. 8.283894×10^{-17} W, approximately -130.82 dBm.

B. 6.0×10^{7} W because γ, temperature, and bandwidth multiply directly.

C. 8.283894×10^{-15} W, approximately -110.82 dBm.

D. 8.283894×10^{-16} W, approximately -120.82 dBm.

Answer: D. Multiply k, 600 K, 10000 Hz, and γ 10. Conversion to dBm uses 10 log10(P/0.001 W). Review: Equation 4L. Source: Equation 4L. Input signal power for a stipulated output ratio (p. 675)

Why the selected alternative fits: W, approximately -120.82 dBm.

Distinguishing consideration: compare this with option A, “W, approximately -130.82 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

Review: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

V011-C02-MCQ-064. A designer adds an ideal stage with 20 dB power gain and negligible added noise after the final noisy stage, while keeping all prior behavior valid. What happens to the required input power in Equation 4L?

A. It becomes independent of bandwidth.

B. It remains the same when that added gain contributes negligible additional noise and both signal and noise are amplified equally.

C. It improves by 20 dB because the displayed signal is higher.

D. It worsens by 20 dB because the output noise is higher.

Answer: B. Post-chain equal amplification changes output levels, not their SNR. Any real added-stage noise must be included if nonnegligible. Review: Equation 4L discussion. Source: Equation 4L. Input signal power for a stipulated output ratio (p. 675)

Why the selected alternative fits: It remains the same when that added gain contributes negligible additional noise and both signal and noise are amplified equally.

Distinguishing consideration: compare this with option A, “It becomes independent of bandwidth”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

Review: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

V011-C02-MCQ-065. Which statement about mean noise power and probability of detection is correct?

A. A 10 dB SNR always implies the same probability of detection for every waveform.

B. A threshold above mean noise guarantees zero false alarms.

C. A lower noise figure uniquely determines the scan capture probability.

D. Mean noise power alone does not supply the decision-statistic distribution or probability of detection.

Answer: D. Detection performance also depends on waveform, duration, statistic, threshold, and sampling or observation opportunities. Review: Define sensitivity as a reproducible decision. Source: §2.5 Define sensitivity as a reproducible decision (p. 653)

Why the selected alternative fits: Mean noise power alone does not supply the decision-statistic distribution or probability of detection.

Distinguishing consideration: compare this with option A, “A 10 dB SNR always implies the same probability of detection for every waveform”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-066. Why must a search across many bins or time windows account for more than a single-channel false-alarm objective?

A. All bins become independent whenever the trace is displayed on a logarithmic scale.

B. The search creates multiple opportunities for noise to cross the decision threshold.

C. The number of searched windows replaces the need for noise-only validation.

D. Each additional bin physically raises receiver equivalent input temperature.

Answer: B. Multiplicity changes the search-level interpretation of threshold crossings. Dependence between opportunities also matters to the chosen validation method. Review: Define sensitivity as a reproducible decision. Source: §2.5 Define sensitivity as a reproducible decision (p. 653)

Why the selected alternative fits: The search creates multiple opportunities for noise to cross the decision threshold.

Distinguishing consideration: compare this with option A, “All bins become independent whenever the trace is displayed on a logarithmic scale”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision.

V011-C02-MCQ-067. A threshold was tuned using a particular set of weak signals and noise records. Which next step best tests its advertised performance?

A. Lower the threshold until all tuning signals are detected and infer zero missed detections generally.

B. Evaluate it on distinct held-out noise-only and weak-reference records under declared conditions.

C. Replace every false alarm in the tuning set with a higher estimated noise temperature.

D. Report the best observed performance on the tuning set without identifying its use.

Answer: B. Separate challenge records help expose selection optimism. They do not remove the need to state the tested population and operating conditions. Review: Define sensitivity as a reproducible decision. Source: §2.5 Define sensitivity as a reproducible decision (p. 653)

Why the selected alternative fits: Evaluate it on distinct held-out noise-only and weak-reference records under declared conditions.

Distinguishing consideration: compare this with option A, “Lower the threshold until all tuning signals are detected and infer zero missed detections generally”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision.

V011-C02-MCQ-068. A burst occurs while a scanning receiver is tuned elsewhere. What failure category is supported?

A. A demonstrated noise-limited sensitivity failure during a valid dwell.

B. A measured degradation in receiver noise figure.

C. A verified false alarm caused by the burst.

D. A coverage failure for that event.

Answer: D. The event was not observed in the relevant channel. It cannot be pooled unqualified with failed detections during valid observation intervals. Review: Define sensitivity as a reproducible decision. Source: §2.5 Define sensitivity as a reproducible decision (p. 653)

Why the selected alternative fits: A coverage failure for that event.

Distinguishing consideration: compare this with option A, “A demonstrated noise-limited sensitivity failure during a valid dwell”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision.

V011-C02-MCQ-069. Two manufacturers give sensitivity figures using different modulation and quality criteria. What comparison is defensible?

A. Reproduce a common declared criterion or explicitly retain the different measurands and conditions.

B. Subtract the two values in dBm and call the result a universal detection advantage.

C. Choose the figure measured in the narrower bandwidth without considering the signal.

D. Convert both figures to watts and assume their quality criteria then coincide.

Answer: A. Unit conversion does not reconcile different definitions. Modulation, bandwidth, detector, and success criterion belong to the comparison. Review: Sensitivity Specifications and Decision Thresholds. Source: §2.4 Sensitivity Specifications and Decision Thresholds (p. 652)

Why the selected alternative fits: Reproduce a common declared criterion or explicitly retain the different measurands and conditions.

Distinguishing consideration: compare this with option B, “Subtract the two values in dBm and call the result a universal detection advantage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Sensitivity Specifications and Decision Thresholds.

Review: Chapter 2 — Sensitivity Specifications and Decision Thresholds.

V011-C02-MCQ-070. An analyzer's displayed average noise level is compared directly with communications-receiver usable sensitivity. What is the main missing step?

A. Treat displayed noise level as the same quantity as a specified error-rate signal level.

B. Normalize both quoted levels to the same noise bandwidth and treat that alone as establishing a common success criterion.

C. Refer both quoted levels to a 290 K source and treat the resulting numbers as interchangeable.

D. Reconcile detector, normalization, bandwidth, and success-criterion conventions.

Answer: D. These specifications can refer to different quantities and operations. Their names do not establish comparability. Review: Sensitivity Specifications and Decision Thresholds. Source: §2.4 Sensitivity Specifications and Decision Thresholds (p. 652)

Why the selected alternative fits: Reconcile detector, normalization, bandwidth, and success-criterion conventions.

Distinguishing consideration: compare this with option A, "Treat displayed noise level as the same quantity as a specified error-rate signal level"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 2 — Sensitivity Specifications and Decision Thresholds.

Review: Chapter 2 — Sensitivity Specifications and Decision Thresholds.

V011-C02-MCQ-071. For $T_e = \frac{T_h - Y\,T_c}{Y - 1}$, what is the partial derivative with respect to T_h when other inputs are held fixed?

A. $\frac{T_h}{Y - 1}$.

B. $\frac{Y}{Y - 1}$.

C. $\frac{1}{Y - 1}$.

D. $-\frac{1}{(Y - 1)^2}$.

Answer: C. The numerator is linear in T_h and the denominator is constant with respect to that input. Review: Equation 4N. Source: Equation 4N. Temperature sensitivity coefficients (p. 687)

Why the selected alternative fits: option C contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 2 — Equation 4N. Temperature sensitivity coefficients.

Review: Chapter 2 — Equation 4N. Temperature sensitivity coefficients.

V011-C02-MCQ-074. Why must covariance terms be retained when relevant in uncertainty propagation?

A. Repeatability variance replaces all source-calibration uncertainty.

B. Covariance vanishes whenever source temperatures are expressed in kelvins.

C. Correlated inputs can increase or decrease the propagated variance depending on the sensitivities and covariance signs.

D. Covariance is always positive and can only increase uncertainty.

Answer: C. The full propagation law includes cross terms. Treating correlated inputs as independent changes the calculated result. Review: Application 2B.10; Equation 27 in Chapter 14. Source: §2.27 Application 2B.10: propagate the local calibration uncertainty (p. 687)

Why the selected alternative fits: Correlated inputs can increase or decrease the propagated variance depending on the sensitivities and covariance signs.

Distinguishing consideration: compare this with option A, “Repeatability variance replaces all source-calibration uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.10: propagate the local calibration uncertainty; Chapter 14 — Equation 27. Combined standard uncertainty.

V011-C02-MCQ-075. In Application 2B.10, zero covariance is stipulated among inputs giving variance contributions approximately 266.54, 1.19, and 12.84 K squared. What is the combined standard uncertainty?

A. The sum of their square roots, approximately 21.00 K.

B. Their arithmetic mean, approximately 93.52 K.

C. Their sum, approximately 280.57 K.

D. The square root of their sum, approximately 16.75 K.

Answer: D. For the stipulated zero covariance, add variances and take the square root. Variance and standard uncertainty have different units. Review: Application 2B.10. Source: §2.27 Application 2B.10: propagate the local calibration uncertainty (p. 687)

Why the selected alternative fits: The square root of their sum, approximately 16.75 K.

Distinguishing consideration: compare this with option A, “The sum of their square roots, approximately 21.00 K”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.10: propagate the local calibration uncertainty.

V011-C02-MCQ-080. A noise average contains duplicated or strongly correlated samples. What is the valid conclusion about its uncertainty?

A. Every sample in the file contributes one independent observation by definition.

B. Duplicating the record halves every systematic uncertainty.

C. Averaging in decibels makes all samples independent.

D. The nominal sample count does not establish the corresponding independent-sample precision.

Answer: D. Precision depends on covariance and the averaging rule. File length alone does not determine independent information. Review: Uncertainty and Environmental Noise. Source: §2.7 Uncertainty and Environmental Noise (p. 657)

Why the selected alternative fits: The nominal sample count does not establish the corresponding independent-sample precision.

Distinguishing consideration: compare this with option A, “Every sample in the file contributes one independent observation by definition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-MCQ-085. What is the stated public frequency scope of CISPR 16-1-1:2019 cited in the chapter?

A. 9 kHz to 18 GHz for the identified radio-disturbance measuring-apparatus scope.

B. 9 MHz to 18 MHz for audio sensitivity tests.

C. 9 kHz to 180 GHz for every receiver application.

D. DC to 18 GHz for all TSCM attribution methods.

Answer: A. The chapter cites the official publication scope and explicitly does not claim full-standard access or universal attribution coverage. Review: Measuring-Receiver Scope and System Noise Floor; footnote 4. Source: §2.12 Measuring-Receiver Scope and System Noise Floor (p. 663)

Why the selected alternative fits: 9 kHz to 18 GHz for the identified radio-disturbance measuring-apparatus scope.

Distinguishing consideration: compare this with option B, “9 MHz to 18 MHz for audio sensitivity tests”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Measuring-Receiver Scope and System Noise Floor; Chapter 2 — Measuring-Receiver Scope and System Noise Floor.

Review: Chapter 2 — Measuring-Receiver Scope and System Noise Floor; Chapter 2 — Measuring-Receiver Scope and System Noise Floor.

V011-C02-MCQ-086. What is the proper first interpretation when sensitivity worsens only after a bounded interferer is introduced?

A. The receiver laboratory noise figure must be replaced by the interferer level in dBm.

B. The interferer has proven a change in ambient physical temperature.

C. All subsequent records should be averaged with the quiet records as one unchanged measurand.

D. The original noise budget may remain valid for its quiet state but is insufficient to explain the interferer condition.

Answer: D. The changed condition calls for tests of compression, gain control, intermodulation, reciprocal mixing, or overlap. It does not identify one mechanism by itself. Review: Define sensitivity as a reproducible decision. Source: §2.5 Define sensitivity as a reproducible decision (p. 653)

Why the selected alternative fits: The original noise budget may remain valid for its quiet state but is insufficient to explain the interferer condition.

Distinguishing consideration: compare this with option A, “The receiver laboratory noise figure must be replaced by the interferer level in dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision.

V011-C02-MCQ-087. Which verification best represents the actual field configuration?

A. Use a catalog noise figure without checking the selected detector mode.

B. Increase gain until a reference is visible and treat visibility as full calibration.

C. Test only the receiver connector while omitting all accessories, then assume their effects are negligible.

D. Introduce a controlled calibrated reference at the selected plane with the installed path and intended states exercised.

Answer: D. The source plane, path, gain, detector, and strong-signal conditions must correspond to the intended claim. Review: Operational Sensitivity Verification.

Source: §2.8 Operational Sensitivity Verification (p. 658)

Why the selected alternative fits: Introduce a controlled calibrated reference at the selected plane with the installed path and intended states exercised.

Distinguishing consideration: compare this with option A, “Use a catalog noise figure without checking the selected detector mode”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Operational Sensitivity Verification.

Review: Chapter 2 — Operational Sensitivity Verification.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-088. How should injected reference events be handled in retained acquisition data?

A. Remove their identity so analysts cannot distinguish test events from unknown observations.

B. Mark their identity and describe the injection or radiation geometry.

C. Assume every signal in the tested band during the engagement is the reference.

D. Treat their timing as irrelevant once their nominal power is known.

Answer: B. Reference identification prevents contamination of the evidential interpretation and supports repeatable geometry and timing. Review: Operational Sensitivity Verification. Source: §2.8 Operational Sensitivity Verification (p. 658)

Why the selected alternative fits: Mark their identity and describe the injection or radiation geometry.

Distinguishing consideration: compare this with option A, “Remove their identity so analysts cannot distinguish test events from unknown observations”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Operational Sensitivity Verification.

Review: Chapter 2 — Operational Sensitivity Verification.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-089. What does a successful closing sensitivity check establish on its own?

A. Validity of every untested antenna path and software export mode.

B. Absence of all prior overload events that left no persistent change.

C. The specified tested functions and state met the check at its own time and conditions.

D. Uninterrupted validity of every earlier acquisition interval.

Answer: C. A later check is time- and scope-bounded. It cannot alone prove the absence of transient earlier faults or validate functions it did not exercise. Review: Operational Sensitivity Verification; temporal qualification. Source: §2.8 Operational Sensitivity Verification (p. 658)

Why the selected alternative fits: The specified tested functions and state met the check at its own time and conditions.

Distinguishing consideration: compare this with option A, “Validity of every untested antenna path and software export mode”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Operational Sensitivity Verification.

Review: Chapter 2 — Operational Sensitivity Verification.

V011-C02-MCQ-090. Why should site baselines include spatial, temporal, polarization, and operating-state information?

A. They remove the need to state receiver bandwidth and detector.

B. Environmental contributions can vary along those dimensions and alter operational sensitivity.

C. They guarantee that the receiver contribution dominates total noise.

D. Those dimensions uniquely identify every emitter without other evidence.

Answer: B. The environment is part of the observed noise context. Baseline coverage helps distinguish variations without treating a quiet laboratory value as a field guarantee. Review: Uncertainty and Environmental Noise. Source: §2.7 Uncertainty and Environmental Noise (p. 657)

Why the selected alternative fits: Environmental contributions can vary along those dimensions and alter operational sensitivity.

Distinguishing consideration: compare this with option A, “They remove the need to state receiver bandwidth and detector”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Uncertainty and Environmental Noise.

Review: Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-MCQ-091. In Application 2B.1, the four input-referred stage contributions are 119.64, 130.37, 4.08, and 16.91 K. Which interpretation follows?

A. The preselector and amplifier contributions dominate the stipulated cascade temperature.

B. The final receiver contributes 600 K at the original input plane without gain weighting.

C. The temperatures must be multiplied because the corresponding gains multiply.

D. The smallest contribution determines the total noise figure.

Answer: A. Added-noise contributions sum after referral to the common input. The first two total about 250 K of the approximately 271 K total. Review: Application 2B.1. Source: §2.18 Application 2B.1: assemble a four-stage noise budget (p. 677)

Why the selected alternative fits: The preselector and amplifier contributions dominate the stipulated cascade temperature.

Distinguishing consideration: compare this with option B, “The final receiver contributes 600 K at the original input plane without gain weighting”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.1: assemble a four-stage noise budget.

Review: Chapter 2 — Application 2B.1: assemble a four-stage noise budget.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-092. The same application gives input-referred total noise -131.11 dBm and cumulative gain 45.5 dB. What output noise follows in the linear model?

A. -85.61 dBm.

B. -131.11 dBm because input referral makes output gain irrelevant.

C. -2.881 dBm.

D. -176.61 dBm.

Answer: A. Output noise equals input-referred noise plus power gain in decibels: -131.11 + 45.5 = -85.61 dBm. Review: Application 2B.1. Source: §2.18 Application 2B.1: assemble a four-stage noise budget (p. 677)

Why the selected alternative fits: -85.61 dBm.

Distinguishing consideration: compare this with option B, "-131.11 dBm because input referral makes output gain irrelevant"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 2 — Application 2B.1: assemble a four-stage noise budget.

Review: Chapter 2 — Application 2B.1: assemble a four-stage noise budget.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-093. If the required SNR is 10 dB and that input-referred total noise is -131.11 dBm, what is the bounded required input signal?

A. -121.11 dBm.

B. -131.11 dBm.

C. -85.61 dBm.

D. -141.11 dBm.

Answer: A. A required signal-to-noise power ratio of ten adds 10 dB to the input-referred noise. Detector justification is a separate condition. Review: Equation 4L; Application 2B.1. Source: Equation 4L. Input signal power for a stipulated output ratio (p. 675)

Why the selected alternative fits: -121.11 dBm.

Distinguishing consideration: compare this with option B, “-131.11 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio; Chapter 2 — Application 2B.1: assemble a four-stage noise budget.

Review: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio; Chapter 2 — Application 2B.1: assemble a four-stage noise budget.

Copyright 2026, James M. Atkinson

V011-C02-MCQ-094. In Application 2B.2, amplifier-first and cable-first noise figures are about 1.761 and 7.179 dB. What is their difference?

A. 5.418 dB, despite equal total gain in the stipulated arrangements.

B. 4.077 dB because the figures should be divided as linear numbers.

C. 0 dB because both chains have the same gain.

D. 8.940 dB because noise figures must be added across alternative systems.

Answer: A. Alternative noise figures compare by subtraction in decibels when referred to the same boundary and conditions. Review: Application 2B.2. Source: §2.19 Application 2B.2: move an amplifier across a cable (p. 679)

Why the selected alternative fits: 5.418 dB, despite equal total gain in the stipulated arrangements.

Distinguishing consideration: compare this with option B, “4.077 dB because the figures should be divided as linear numbers”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.2: move an amplifier across a cable.

Review: Chapter 2 — Application 2B.2: move an amplifier across a cable.

V011-C02-MCQ-095. For hot and cold output powers expressed in dBm, which operation obtains the linear Y-factor?

A. Add the two dBm numbers, then divide by twenty.

B. Divide the two signed dBm numbers directly.

C. Subtract cold dBm from hot dBm, then take ten to that difference divided by ten.

D. Subtract the two powers in watts and call the result dimensionless.

Answer: C. The dBm difference is the decibel power ratio. A linear ratio requires conversion from that logarithmic difference. Review: Equation 4H; Application 2B.8.

Source: Equation 4H. Hot-to-cold output power ratio (p. 673)

Why the selected alternative fits: Subtract cold dBm from hot dBm, then take ten to that difference divided by ten.

Distinguishing consideration: compare this with option A, “Add the two dBm numbers, then divide by twenty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Application 2B.8: recover noise temperature from two powers.

Review: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Application 2B.8: recover noise temperature from two powers.

V011-C02-MCQ-096. The hot-cold power difference is 10.801 dB. Which linear ratio is consistent?

A. Approximately 3.468.

B. Approximately 12.025.

C. Exactly 10.801.

D. Approximately 0.08316.

Answer: B. Power-ratio conversion uses $10^{\frac{10.801}{10}}$. Using division by twenty would compute an amplitude ratio instead. Review: Application 2B.8. Source: §2.25 Application 2B.8: recover noise temperature from two powers (p. 685)

Why the selected alternative fits: Approximately 12.025.

Distinguishing consideration: compare this with option A, “Approximately 3.468”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.8: recover noise temperature from two powers.

Review: Chapter 2 — Application 2B.8: recover noise temperature from two powers.

V011-C02-MCQ-097. In a Y-factor experiment, why is hot-state compression especially hazardous to the simple inversion?

A. The hot output no longer follows the same proportional gain law as the cold output.

B. Compression guarantees that the cold source temperature is wrong.

C. The ratio automatically compensates compression because both observations use the same detector.

D. The source temperature difference becomes physically zero.

Answer: A. Compression changes the response law. The cancellation of common gain is not valid merely because hardware and detector labels are unchanged.
Review: Y-Factor and Comparative Noise Measurements. Source: §2.6 Y-Factor and Comparative Noise Measurements (p. 656)
Why the selected alternative fits: The hot output no longer follows the same proportional gain law as the cold output.
Distinguishing consideration: compare this with option B, “Compression guarantees that the cold source temperature is wrong”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 2 — Y-Factor and Comparative Noise Measurements.
Review: Chapter 2 — Y-Factor and Comparative Noise Measurements.

V011-C02-MCQ-098. Which statement best describes the ten Applications 2B.1 through 2B.10?

A. Constructed cases that expose distinct decisions under explicitly stated assumptions.

B. Independent experimental proof that all practical cascades are matched and scalar.

C. Calibration certificates for every receiver using a 50-ohm connector.

D. Measured performance records from one identified field installation.

Answer: A. The chapter explicitly labels the values as synthetic demonstrations. They teach use and limits of the model without asserting instrument performance. Review: Model 2B introduction. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: Constructed cases that expose distinct decisions under explicitly stated assumptions.

Distinguishing consideration: compare this with option B, “Independent experimental proof that all practical cascades are matched and scalar”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

V011-C02-MCQ-099. Which record most directly permits an independent reviewer to reproduce an input-referral calculation?

A. Only the final input-referred value rounded to a whole decibel.

B. The raw output noise, selected planes, applicable state-specific signal power gain, bandwidth, and corrections.

C. Only the receiver model name and nominal maximum gain.

D. Only the apparent trace height relative to its screen grid.

Answer: B. The transformation must be reconstructable from its measured quantity and applicable conversion law. A final number or equipment label does not supply those inputs. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why the selected alternative fits: The raw output noise, selected planes, applicable state-specific signal power gain, bandwidth, and corrections.

Distinguishing consideration: compare this with option A, “Only the final input-referred value rounded to a whole decibel”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-MCQ-100. A calculation predicts a low noise floor, but the desired modulation is partly outside the filter and the receiver changes gain during bursts. What is the strongest defensible conclusion?

A. The source temperature alone can absorb both effects without changing the measurand.

B. The fixed-state, fully retained-signal prediction needs revision before it can support the burst sensitivity claim.

C. Adding the two nominal gain settings restores the missing modulation components.

D. The lower calculated floor proves improved burst detection regardless of the two changes.

Answer: B. Both signal retention and fixed-state response are explicit conditions. A result outside those conditions cannot inherit the claimed sensitivity unchanged.

Review: Model 2B assumptions; Equation 4L; Power, bandwidth, and the reference plane. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)

Why the selected alternative fits: The fixed-state, fully retained-signal prediction needs revision before it can support the burst sensitivity claim.

Distinguishing consideration: compare this with option A, “The source temperature alone can absorb both effects without changing the measurand”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio; Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-FIB-007. If noise density and gain vary materially with frequency, replace a center-value product by a weighted _____.

Answer: integral. Integrating the density through the actual power response retains the frequency dependence that a flat approximation discards. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why this term is required: “integral” completes the stated technical proposition.

Question context: If noise density and gain vary materially with frequency, replace a center-value product by a weighted _____

Basis and qualification: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-FIB-008. Reducing white-noise bandwidth from 20 kHz to 5 kHz changes integrated noise power by approximately _____ dB.

Answer: -6.02. The ratio is 5/20 = 0.25, and 10 log10(0.25) is approximately -6.02 dB. Signal retention is a separate question. Review: Equation 3. Source: Equation 3. Available thermal-noise power (p. 659)

Why this term is required: "-6.02" completes the stated technical proposition.

Question context: Reducing white-noise bandwidth from 20 kHz to 5 kHz changes integrated noise power by approximately _____ dB

Basis and qualification: Chapter 2 — Equation 3. Available thermal-noise power.

Review: Chapter 2 — Equation 3. Available thermal-noise power.

Copyright 2026, James M. Atkinson

V011-C02-FIB-009. A burst sensitivity claim after narrowing the channel must account for the fraction of desired signal _____ by that channel.

Answer: retained. Noise reduction alone does not establish the SNR improvement if useful signal energy is also rejected. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

Why this term is required: “retained” completes the stated technical proposition.

Question context: A burst sensitivity claim after narrowing the channel must account for the fraction of desired signal _____ by that channel

Basis and qualification: Chapter 2 — Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-FIB-010. To refer output noise to the selected input, divide by the applicable signal _____ gain.

Answer: power. A voltage ratio is not interchangeable with a power gain without the necessary impedance and quantity conversion. Review: Power, bandwidth, and the reference plane. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)
Why this term is required: “power” completes the stated technical proposition.
Question context: To refer output noise to the selected input, divide by the applicable signal _____ gain
Basis and qualification: Chapter 2 — Power, bandwidth, and the reference plane.
Review: Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-FIB-013. A 13 dB power gain corresponds to a linear gain of approximately _____.

Answer: 19.95. The conversion is $10^{\frac{13}{10}}$, approximately 19.9526. The 20-log amplitude conversion would be inappropriate here. Review: Equation 4A conventions. Source: Equation 4A. Cumulative power gain (p. 667)

Why this term is required: “19.95” completes the stated technical proposition.

Question context: A 13 dB power gain corresponds to a linear gain of approximately _____

Basis and qualification: Chapter 2 — Equation 4A. Cumulative power gain.

Review: Chapter 2 — Equation 4A. Cumulative power gain.

Copyright 2026, James M. Atkinson

V011-C02-FIB-014. The stage recurrence is $N_i = g_i N_{i-1} +$ _____.

Answer: $k B g_i T_{e,i}$. The first term transmits incoming noise; the second is the stage own output-added noise. Both terms are powers in watts. Review: Equation 4B.

Source: Equation 4B. Noise propagation through one stage (p. 668)

Why this term is required: "The first term transmits incoming noise; the second is the stage own output-added noise" completes the stated technical proposition.

Question context: The stage recurrence is = + _____

Basis and qualification: Chapter 2 — Equation 4B. Noise propagation through one stage.

Review: Chapter 2 — Equation 4B. Noise propagation through one stage.

Copyright 2026, James M. Atkinson

V011-C02-FIB-015. Dividing the recurrence by G_i makes the new stage contribution $k\,B\,T_{e,i}$ divided by _____.

Answer: G_{i-1}. The stage own gain cancels against its contribution to cumulative gain, leaving only preceding gain. Review: Derivation of Equation 4C. Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why this term is required: "The stage own gain cancels against its contribution to cumulative gain, leaving only preceding gain" completes the stated technical proposition.

Question context: Dividing the recurrence by makes the new stage contribution divided by _____

Basis and qualification: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Copyright 2026, James M. Atkinson

V011-C02-FIB-016. For a one-stage chain, the cascade equivalent input temperature equals _____.

Answer: $T_{e,1}$. Its only noise contribution is divided by G_0 = 1. Changing its output gain does not suppress that input-equivalent contribution. Review: Equation 4C.

Source: Equation 4C. Cascade temperature and integrated output noise (p. 668)

Why this term is required: "Its only noise contribution is divided by = 1" completes the stated technical proposition.

Question context: For a one-stage chain, the cascade equivalent input temperature equals _____

Basis and qualification: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

V011-C02-FIB-024. A noise factor of 4 corresponds to a noise figure of approximately _____ dB.

Answer: 6.02. 10 log10(4) is approximately 6.0206 dB. Review: Equation 4D. Source: Equation 4D. Noise factor at the reference temperature (p. 669)

Why this term is required: “6.02” completes the stated technical proposition.

Question context: A noise factor of 4 corresponds to a noise figure of approximately _____ dB

Basis and qualification: Chapter 2 — Equation 4D. Noise factor at the reference temperature.

Review: Chapter 2 — Equation 4D. Noise factor at the reference temperature.

Copyright 2026, James M. Atkinson

V011-C02-FIB-025. At T_0 = 290 K, a noise factor of 1.5 corresponds to T_e = _____ K.

Answer: 145. Rearranging $F_0 = 1 + \frac{T_e}{T_0}$ gives T_e = 290 times 0.5. Review: Equation 4D. Source: Equation 4D. Noise factor at the reference temperature (p. 669)

Why this term is required: "145" completes the stated technical proposition.

Question context: At = 290 K, a noise factor of 1.5 corresponds to = _____ K

Basis and qualification: Chapter 2 — Equation 4D. Noise factor at the reference temperature.

Review: Chapter 2 — Equation 4D. Noise factor at the reference temperature.

Copyright 2026, James M. Atkinson

V011-C02-FIB-026. For positive source temperature, the actual SNR degradation is 1 + _____.

Answer: $\frac{T_e}{T_s}$. The actual source temperature belongs in this ratio. The reference factor instead uses T_0. Review: Equation 4E. Source: Equation 4E. Signal-to-noise degradation for the actual source (p. 669)

Why this term is required: "The actual source temperature belongs in this ratio" completes the stated technical proposition.

Question context: For positive source temperature, the actual SNR degradation is 1 + _____

Basis and qualification: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Review: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Copyright 2026, James M. Atkinson

V011-C02-FIB-027. With T_e = 100 K and T_s = 25 K, the actual SNR degradation ratio is _____.

Answer: 5. The ratio is 1 + 100/25. The same receiver has a smaller reference factor when referred to 290 K. Review: Equation 4E. Source: Equation 4E. Signal-to-noise degradation for the actual source (p. 669)

Why this term is required: "5" completes the stated technical proposition.

Question context: With = 100 K and = 25 K, the actual SNR degradation ratio is _____

Basis and qualification: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Review: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Copyright 2026, James M. Atkinson

V011-C02-FIB-028. With T_e = 100 K and T_s = 1000 K, that ratio is

_____.

Answer: 1.1. The larger source contribution makes the same receiver-added temperature less significant as a fraction of total noise. Review: Equation 4E. Source: Equation 4E. Signal-to-noise degradation for the actual source (p. 669)

Why this term is required: "1.1" completes the stated technical proposition.

Question context: With = 100 K and = 1000 K, that ratio is _____

Basis and qualification: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Review: Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Copyright 2026, James M. Atkinson

V011-C02-FIB-029. For nonzero T_e, the actual SNR degradation equals F_0 when T_s = _____.

Answer: T_0. The defining ratios then use the same temperature denominator.

Review: Equations 4D and 4E. Source: Equation 4D. Noise factor at the reference temperature (p. 669)

Why this term is required: "The defining ratios then use the same temperature denominator" completes the stated technical proposition.

Question context: For nonzero the actual SNR degradation equals when = _____

Basis and qualification: Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

Review: Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

V011-C02-FIB-058. The chapter excess-noise-ratio convention uses the difference T_h - T_c divided by _____.

Answer: T_0. The actual source certificate must still be read because conventions and cold-state definitions can differ. Review: Y-factor discussion. Source: §2.16 Invert the same model with two source temperatures (p. 672)

Why this term is required: "The actual source certificate must still be read because conventions and cold-state definitions can…" completes the stated technical proposition.

Question context: The chapter excess-noise-ratio convention uses the difference - divided by _____

Basis and qualification: Chapter 2 — Invert the same model with two source temperatures.

Review: Chapter 2 — Invert the same model with two source temperatures.

Copyright 2026, James M. Atkinson

V011-C02-FIB-059. If T_h - T_c = 5800 K and T_0 = 290 K, the linear ENR is _____.

Answer: 20. The ratio is 5800/290. Its decibel value is approximately 13.01 dB.

Review: Y-factor discussion. Source: §2.16 Invert the same model with two source temperatures (p. 672)

Why this term is required: “20” completes the stated technical proposition.

Question context: If - = 5800 K and = 290 K, the linear ENR is _____

Basis and qualification: Chapter 2 — Invert the same model with two source temperatures.

Review: Chapter 2 — Invert the same model with two source temperatures.

V011-C02-FIB-060. In a Y-factor test, automatic gain control must be disabled or _____.

Answer: characterized. A source-state-dependent gain change invalidates cancellation unless its effect is modeled and corrected with justified evidence.

Review: Y-Factor and Comparative Noise Measurements. Source: §2.6 Y-Factor and Comparative Noise Measurements (p. 656)

Why this term is required: “characterized” completes the stated technical proposition.

Question context: In a Y-factor test, automatic gain control must be disabled or _____

Basis and qualification: Chapter 2 — Y-Factor and Comparative Noise Measurements.

Review: Chapter 2 — Y-Factor and Comparative Noise Measurements.

Copyright 2026, James M. Atkinson

V011-C02-FIB-061. If hot gain divided by cold gain is r_g, the observed ratio is r_g times the equal-state _____.

Answer: Y-factor. The multiplicative gain error changes the ratio before inversion. Equal hardware names do not establish equal realized gains. Review: Application 2B.9. Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)

Why this term is required: "Y-factor" completes the stated technical proposition.

Question context: If hot gain divided by cold gain is the observed ratio is times the equal-state _____

Basis and qualification: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

Review: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

Copyright 2026, James M. Atkinson

V011-C02-FIB-062. For true Y = 8 and hot/cold gain ratio 1.02, the observed Y is _____.

Answer: 8.16. The state gain ratio multiplies the noise-power ratio: 1.02 times 8.

Review: Application 2B.9 mechanism. Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)

Why this term is required: "8.16" completes the stated technical proposition.

Question context: For true Y = 8 and hot/cold gain ratio 1.02, the observed Y is _____

Basis and qualification: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

Review: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

V011-C02-FIB-066. The partial derivative of T_e with respect to T_h is

_____.

Answer: $\frac{1}{Y-1}$. This sensitivity is dimensionless because both the output and that input are temperatures. Review: Equation 4N. Source: Equation 4N. Temperature sensitivity coefficients (p. 687)

Why this term is required: "This sensitivity is dimensionless because both the output and that input are temperatures" completes the stated technical proposition.

Question context: The partial derivative of with respect to is _____

Basis and qualification: Chapter 2 — Equation 4N. Temperature sensitivity coefficients.

Review: Chapter 2 — Equation 4N. Temperature sensitivity coefficients.

Copyright 2026, James M. Atkinson

V011-C02-FIB-067. The partial derivative of T_e with respect to T_c is

_____.

Answer: $-\frac{Y}{Y-1}$. Its negative sign matters when correlated input uncertainties are propagated. Review: Equation 4N. Source: Equation 4N. Temperature sensitivity coefficients (p. 687)

Why this term is required: "Its negative sign matters when correlated input uncertainties are propagated" completes the stated technical proposition.

Question context: The partial derivative of with respect to is _____

Basis and qualification: Chapter 2 — Equation 4N. Temperature sensitivity coefficients.

Review: Chapter 2 — Equation 4N. Temperature sensitivity coefficients.

Copyright 2026, James M. Atkinson

V011-C02-FIB-068. The partial derivative with respect to Y is (T_c - T_h) divided by _____.

Answer: $(Y-1)^2$. Because Y is dimensionless, this sensitivity has units of kelvins. It grows strongly near Y = 1. Review: Equation 4O. Source: Equation 4O. Power-ratio sensitivity coefficient (p. 687)

Why this term is required: "Because Y is dimensionless, this sensitivity has units of kelvins" completes the stated technical proposition.

Question context: The partial derivative with respect to Y is (-) divided by _____

Basis and qualification: Chapter 2 — Equation 4O. Power-ratio sensitivity coefficient.

Review: Chapter 2 — Equation 4O. Power-ratio sensitivity coefficient.

Copyright 2026, James M. Atkinson

V011-C02-FIB-069. The square of a standard uncertainty in kelvins has units of _____.

Answer: kelvins squared. Variance terms are added in common squared units before taking the square root to obtain standard uncertainty. Review: Application 2B.10; Equation 27 in Chapter 14. Source: §2.27 Application 2B.10: propagate the local calibration uncertainty (p. 687)

Why this term is required: "kelvins squared" completes the stated technical proposition.

Question context: The square of a standard uncertainty in kelvins has units of _____

Basis and qualification: Chapter 2 — Application 2B.10: propagate the local calibration uncertainty; Chapter 14 — Equation 27. Combined standard uncertainty.

Review: Chapter 2 — Application 2B.10: propagate the local calibration uncertainty; Chapter 14 — Equation 27. Combined standard uncertainty.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C02-ESSAY-001. Derive the arbitrary-stage equivalent input noise-temperature sum from the one-stage recurrence, making the reference planes, dimensions, and independence assumption explicit. Explain why the own-stage gain does not appear in its final input-equivalent contribution.

- Opening: Present a thesis that answers this precise question: Derive the arbitrary-stage equivalent input noise-temperature sum from the one-stage recurrence, making the reference planes, dimensions, and independence assumption explicit. Identify which evidence would falsify the proposed conclusion Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)
- Core terminology and scope: Define recurrence, making, planes in the question's particular technical setting; explain how independence, assumption, appear differ if that distinction would change the analysis of "Derive the arbitrary-stage equivalent input noise-temperature sum from the one-stage recurrence, making the reference planes, dimensions, and independence assumption explicit" Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)
- Problem statement and purpose: Frame the actual measurement or decision in the question. A complete answer defines = 1 and as the product of gains through stage i Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the arbitrary-stage equivalent input noise-temperature sum from the one-stage recurrence, making the reference planes,… to the claimed result, following "Noise-colour models, covariance and decision

V011-C02-ESSAY-002. Develop the passive-loss noise-temperature relation from thermal equilibrium. Contrast dissipative attenuation with a mismatch that only changes delivered power.

- Opening: Present a thesis that answers this precise question: Develop the passive-loss noise-temperature relation from thermal equilibrium. Contrast dissipative attenuation with a mismatch that only changes delivered power. Identify which evidence would falsify the proposed conclusion Source: §2.15 Derive passive loss from thermal equilibrium (p. 670)
- Core terminology and scope: Define relation, thermal, equilibrium in the question's particular technical setting; explain how Contrast, dissipative, delivered differ if that distinction would change the analysis of "Develop the passive-loss noise-temperature relation from thermal equilibrium. Contrast dissipative attenuation with a mismatch that only changes delivered power" Source: §2.15 Derive passive loss from thermal equilibrium (p. 670)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Set the source and matched terminations to the attenuator physical temperature The source contributes at the output Source: §2.15 Derive passive loss from thermal equilibrium (p. 670)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the passive-loss noise-temperature relation from thermal equilibrium to the claimed result, following "Thermal Noise as a Bandwidth-Dependent Quantity"; name the intermediate states and measurable outputs Source: §2.1 Thermal Noise as a Bandwidth-Dependent Quantity (p. 644)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for the passive-loss noise-temperature relation from thermal equilibrium. Full credit requires separating available power, delivered power, physical temperature, and equivalent input temperature Source: §2.1 Thermal Noise as a Bandwidth-Dependent Quantity (p. 644)
- Analytical framework: Identify the equation, calibration or evidential decision test in “From a calculated temperature to a defended result” that resolves the question about the passive-loss noise-temperature relation from thermal equilibrium; derive the relevant result with units and stated validity conditions Source: §2.28 From a calculated temperature to a defended result (p. 689)
- Evidence and method: Specify the native observations, control records and calculations that would resolve the passive-loss noise-temperature relation from thermal equilibrium. Review: Derive passive loss from thermal equilibrium; Source: §2.15 Derive passive loss from thermal equilibrium (p. 670)
- Worked application or illustrative case: Build a worked example of “the passive-loss noise-temperature relation from thermal equilibrium”, addressing this associated condition: Contrast dissipative attenuation with a mismatch that only changes delivered power. Set the source and matched terminations to the attenuator physical temperature The source contributes at the output Source: §2.1 Thermal Noise as a Bandwidth-Dependent Quantity (p. 644)
- Alternative explanations and failure modes: Construct two plausible technical explanations for “the passive-loss noise-temperature

V011-C02-ESSAY-007. Design a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source. Define what must be held fixed, what should be measured, and how the result would be challenged.

- Opening: Present a thesis that answers this precise question: Design a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source. Identify which evidence would falsify the proposed conclusion Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)
- Core terminology and scope: Define Design, drift, automatic in the question's particular technical setting; explain how Define, held, challenged differ if that distinction would change the analysis of "Design a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source" Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)
- Problem statement and purpose: Frame the actual measurement or decision in the question. A strong answer identifies the selected reference plane, calibrated hot and cold source conditions, common effective bandwidth, detector law, and loss/mismatch corrections Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source to the claimed result, following "From a calculated temperature to a

defended result"; name the intermediate states and measurable outputs Source: §2.28 From a calculated temperature to a defended result (p. 689)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source. Disable automatic gain control if valid or characterize its actual state dependence Source: §2.28 From a calculated temperature to a defended result (p. 689)
- Analytical framework: Identify the equation, calibration or evidential decision test in "Invert the same model with two source temperatures" that resolves the question about a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source; derive the relevant result with units and stated validity conditions Source: §2.16 Invert the same model with two source temperatures (p. 672)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source. Establish linearity in both source states, retain native powers and state records, and interleave or bracket cold and hot measurements to reveal drift Source: §2.26 Application 2B.9: expose a change hidden by a ratio (p. 686)
- Worked application or illustrative case: Build a worked example of "a Y-factor measurement sequence for a receiver whose gain may drift and whose automatic gain control can react to the hot source",

V011-C02-DISCUSSION-001. Should a receiver team always place a low-noise amplifier at the antenna rather than after the cable? Develop the conditions under which each arrangement could be defensible.

- 01. Moderator, opening proposition: Introduce the exact dispute, “Should a receiver team always place a low-noise amplifier at the antenna rather than after the cable? Develop the conditions under which each arrangement could be defensible.” Put this particular dispute to the panel: Should a receiver team always place a low-noise amplifier at the antenna rather than after the cable? Develop the conditions under which each arrangement could be defensible. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position.
  Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 02. Student A, terminology and scope: Agree the operational meanings of place, amplifier, cable and conditions, arrangement, defensible in “Should a receiver team always place a low-noise amplifier at the antenna rather than after the cable? Develop the conditions under which each arrangement could be defensible”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the

Copyright 2026, James M. Atkinson

outcome and request a specific example from the stated receiver scenario. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Noise Figure and Noise Temperature”. Then require internal blocker levels, amplifier linearity and stability, remote power and cable conditions, and the actual source environment Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

Copyright 2026, James M. Atkinson

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §2.19 Application 2B.2: move an amplifier across a cable (p. 679)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Noise Figure and Noise Temperature”. Then require internal blocker levels, amplifier linearity and stability, remote power and cable conditions, and the actual source environment Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Ask participants to compute or explain the ordering effect in Equation 4C before discussing operations Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask

Copyright 2026, James M. Atkinson

which setting or observation would discriminate between them without changing the measurand. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 08. Student D, answer to Student E: Design a discriminating experiment involving whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §2.19 Application 2B.2: move an amplifier across a cable (p. 679)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving

whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable. A defensible conclusion can prefer amplifier-first for a valid noise-limited case yet choose another architecture when strong-signal or installation constraints dominate Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §2.19 Application 2B.2: move an amplifier across a cable (p. 679)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver

Copyright 2026, James M. Atkinson

state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable. A defensible conclusion can prefer amplifier-first for a valid noise-limited case yet choose another architecture when strong-signal or installation constraints dominate Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §2.19 Application 2B.2: move an amplifier across a cable (p. 679)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable and Develop the conditions under which each arrangement could be defensible; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains

Copyright 2026, James M. Atkinson

within authorised laboratory and field boundaries. Source: §2.18 Application 2B.1: assemble a four-stage noise budget (p. 677)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “whether a receiver team always place a low-noise amplifier at the antenna rather than after the cable”, addressing “Develop the conditions under which each arrangement could be defensible”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “Should a receiver team always place a low-noise amplifier at the antenna rather than after the cable? Develop the conditions under which each arrangement could be defensible”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “Should a receiver team always place a low-noise amplifier at the antenna rather than after the cable? Develop the conditions under which each arrangement could be defensible.”. Allocate the next measurement and documentary action to named

A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity. Ask what source-plane and calibration evidence is needed and whether the desired signal was retained Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible

Copyright 2026, James M. Atkinson

instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §2.18 Application 2B.1: assemble a four-stage noise budget (p. 677)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity. Ask what source-plane and calibration evidence is needed and whether the desired signal was retained Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity and Which parts of the statement can be retained and which require correction; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §2.23 Application 2B.6: allocate loss to a preselector (p. 683)

Copyright 2026, James M. Atkinson

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity”, addressing “Which parts of the statement can be retained and which require correction”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §2.2 Power, bandwidth, and the reference plane (p. 645)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity. Which parts of the statement can be retained and…”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “A reviewer says that a cable loss correction restores the original signal and therefore restores the original sensitivity. Which parts of the statement can be retained and which require correction”. Allocate the next measurement and documentary action to named student roles, and require each

specific example from the stated receiver scenario. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §2.29 Noise-colour models, covariance and decision performance beyond a scalar noise figure (p. 690)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Noise-colour models, covariance and decision performance beyond a scalar noise figure”. The chapter permits a scalar equivalent-channel law only when empirically justified for the selected architecture Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §2.29 Noise-colour models, covariance and decision performance beyond a scalar noise figure (p. 690)

Copyright 2026, James M. Atkinson

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Noise-colour models, covariance and decision performance beyond a scalar noise figure”. The chapter permits a scalar equivalent-channel law only when empirically justified for the selected architecture Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §2.29 Noise-colour models, covariance and decision performance beyond a scalar noise figure (p. 690)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Examine the actual sideband and image paths, input environment, conversion gain definition, and calibration conditions Put two specific questions to

Copyright 2026, James M. Atkinson

Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §2.28 From a calculated temperature to a defended result (p. 689)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §2.29 Noise-colour models, covariance and decision performance beyond a scalar noise figure (p. 690)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in

Copyright 2026, James M. Atkinson

the preceding prompt. Design a discriminating experiment involving A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel. A nominal figure cannot be inserted blindly just because it is expressed in decibels Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible

Copyright 2026, James M. Atkinson

instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §2.29 Noise-colour models, covariance and decision performance beyond a scalar noise figure (p. 690)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel. A nominal figure cannot be inserted blindly just because it is expressed in decibels Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §2.28 From a calculated temperature to a defended result (p. 689)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel and What should happen before using that number; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §2.13 Worked Example 2A.1. Thermal Noise-Floor Screening (p. 664)

Copyright 2026, James M. Atkinson

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel”, addressing “What should happen before using that number”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §2.3 Noise Figure and Noise Temperature (p. 649)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel. What should happen before using that number”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “A mixer data sheet gives a double-sideband noise figure, while the planned chain model represents one selected channel. What should happen before using that number”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence

Chapter 2 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C02-ESSAY-001 — A complete answer defines G_0 = 1 and G_i as the product of gains through stage i, writes $N_i = g_i N_{i-1} + k B g_i T_{e,i}$, and divides by G_i. It then telescopes to $\frac{N_{out}}{G_n} = k B [T_s + \sum_{i=1}^{n} \frac{T_{e,i}}{G_{i-1}}]$. Each gain is a dimensionless power ratio, temperature is in kelvins, B is in hertz, and all noise terms are in watts. Explain that $T_{e,i}$ is already an input-equivalent quantity for its own stage, so its own gain cancels. State the common matched real impedance, fixed state, band-flatness approximation, and zero-cross-power assumptions. Do not extend the sum silently to correlated contributions or mismatched feedback. Review: Model 2B assumptions; Equations 4A-4C.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Equation 4A. Cumulative power gain; Chapter 2 — Equation 4B. Noise propagation through one stage; Chapter 2 — Equation 4C. Cascade temperature and integrated output noise.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-002 — Set the source and matched terminations to the attenuator physical temperature T_p. The source contributes $\frac{kBT_p}{L}$ at the output, while equilibrium requires total output noise kBT_p. The attenuator must therefore add $kBT_p\left(1-\frac{1}{L}\right)$. Divide by power gain $\frac{1}{L}$ to obtain $T_{e,loss}$ = $(L-1)T_p$. Explain why the signal still loses power even though equilibrium output noise remains kBT_p. A reflection can redirect power without the assumed dissipation and emission, so applying the relation to arbitrary mismatch requires another model. Full credit requires separating available power, delivered power, physical temperature, and equivalent input temperature. Review: Derive passive loss from thermal equilibrium; Equation 4F.

Review: Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss; Chapter 2 — Derive passive loss from thermal equilibrium.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-003 — Use g_A = $10^{1.5}$ = 31.6228 and L = $10^{0.4}$ = 2.51189. The cable equivalent temperature is about 453.57 K. Amplifier-first T_e is 70 + 453.57/31.6228 + 2.51189 times 900/31.6228, approximately 155.83 K. Cable-first T_e is 453.57 + 2.51189 times 70 + 2.51189 times 900/31.6228, approximately 700.89 K. State the common input plane and note that total signal gain is the same. The lower noise result favors the first arrangement only within the assumed linear matched state. Discuss blocker levels, compression, stability, cable power delivery, and applicable source environment before making an operational recommendation. Review: Equations 4C, 4F, and 4G; Applications 2B.2 and 2B.7.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Equation 4F. Noise temperature of a matched dissipative loss; Chapter 2 — Equation 4G. Loss followed by a characterized chain; Chapter 2 — Application 2B.2: move an amplifier across a cable; Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

V011-C02-ESSAY-004 — Compute F_0 = 1 + 100/290, approximately 1.34483, and NF_0 approximately 1.287 dB. For the 20 K source, actual degradation is 6, or about 7.782 dB. For the 2000 K source it is 1.05, or about 0.212 dB. The same receiver contribution has very different relative effects because the source-noise denominator changes. Also compare total noise temperatures, 120 K and 2100 K: the case with small relative degradation can still have far greater total noise. Distinguish this result from the undefined finite-ratio comparison at $T_s=0$ and retain the fixed receiver-state assumption. Review: Equations 4C-4E; Application 2B.4.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source; Chapter 2 — Application 2B.4: change the source environment.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-005 — Let original desired signal and white-noise powers be S and N. The new values are 0.5S and 0.25N, so new SNR is twice the old SNR, an improvement of about 3.01 dB. Noise alone falls by about 6.02 dB. State that this calculation assumes unchanged receiver-added density, valid common gain, and a retained signal-power fraction of one half under the actual event definition. Explain how a burst waveform, filter transient, or modulation spectrum could require a more detailed retention calculation. Averaging changes and bandwidth changes must not be conflated without an explicit estimator model. Review: Power, bandwidth, and the reference plane; Equation 4L.

Review: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio; Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-ESSAY-006 — Start with common output factor $k B G_n$ multiplying T_h+T_e and T_c+T_e. Divide to obtain Y, rearrange YTc + YTe = T_h+T_e, and solve T_e = $\frac{T_h - Y T_c}{Y - 1}$. Since hot temperature exceeds cold temperature, Y is greater than one; with nonnegative T_e, Y cannot exceed $\frac{T_h}{T_c}$. Equality at the upper boundary means T_e = 0. Treat values outside the domain as evidence requiring investigation of source inputs, gain, compression, bandwidth, mismatch, and record processing. Do not award a valid result to a silently clipped negative temperature. State that $T_c = 0$ needs a separately expressed upper-domain discussion. Review: Equations 4H and 4I.

Review: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-007 — A strong answer identifies the selected reference plane, calibrated hot and cold source conditions, common effective bandwidth, detector law, and loss/mismatch corrections. Disable automatic gain control if valid or characterize its actual state dependence. Establish linearity in both source states, retain native powers and state records, and interleave or bracket cold and hot measurements to reveal drift. Use an independent gain observation or justified drift model before applying a correction. Distinguish a diagnostic sequence from proof that all changes have been corrected. Reserve challenge measurements to test repeatability and assumptions, then propagate relevant calibration, ratio, and covariance inputs. Review: Y-Factor and Comparative Noise Measurements; Application 2B.9.

Review: Chapter 2 — Application 2B.9: expose a change hidden by a ratio; Chapter 2 — Y-Factor and Comparative Noise Measurements.

V011-C02-ESSAY-008 — The true Y is 6400/700, approximately 9.142857. The observed ratio is 1.02 times this, approximately 9.325714. Substituting it into the equal-gain inversion gives T_e approximately 384.63 K, about 15.37 K below the true value. The increased hot gain raises the measured ratio, which the wrong model interprets as a smaller receiver contribution. Repetition can reduce random scatter while retaining this bias. Explain why averaging dBm values, changing displayed units, or merely bracketing source states does not automatically remove the effect. A valid correction needs evidence for the gain ratio and its uncertainty. Review: Equations 4H and 4I; Application 2B.9.

Review: Chapter 2 — Equation 4H. Hot-to-cold output power ratio; Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-009 — Starting from $T_e = T_{e,1} + \frac{T_{e,2}}{g_1}$ with positive $T_{e,2}$ and positive finite g_1, rearrange to g_1 >= $\frac{T_{e,2}}{T_{target} - T_{e,1}}$ when the target exceeds the first-stage temperature. At equality, no finite gain eliminates the positive second-stage contribution; the target is only a limit as gain grows without bound. Below the first-stage temperature, there is no feasible gain. Discuss why a gain satisfying the noise inequality still requires a blocker and stability check. State separately the degenerate $T_{e,2}$ = 0 case rather than applying the positive-noise derivation indiscriminately. Review: Equation 4J; Application 2B.5.

Review: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit; Chapter 2 — Application 2B.5: solve for the gain that is useful.

V011-C02-ESSAY-010 — Equation 4K gives Lmax = (160 + 320)/(320 + 80) = 1.2, about 0.792 dB. A 0.7 dB loss has L approximately 1.17490, giving $T_{e,total}$ = (L - 1)320 + L times 80, approximately 149.96 K, so it meets the stipulated noise target. Identify the common reference plane and physical filter temperature. A complete answer does not equate this pass with adequate blocker rejection, linearity, or mismatch performance. Discuss the separate rejection specification and the possibility that temperature or loss uncertainty could affect the available margin. Review: Equations 4G and 4K; Application 2B.6.

Review: Chapter 2 — Equation 4G. Loss followed by a characterized chain; Chapter 2 — Equation 4K. Maximum allowed preceding loss; Chapter 2 — Application 2B.6: allocate loss to a preselector.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-011 — Track the blocker to the amplifier input for attenuation placed before versus after it. In the constructed case, -5 dBm reduced by 20 dB reaches -25 dBm before the amplifier, which is 5 dB below the stipulated -20 dBm envelope. With attenuation after the amplifier, the amplifier still sees -5 dBm, 15 dB above that envelope. The lower formal noise temperature in the latter order does not validate its failed linearity assumption. A sound decision specifies the necessary sensitivity, permissible signal environment, and measured linearity margin, then selects or redesigns the configuration. Avoid treating a downstream output limit as protection for an upstream stage. Review: Application 2B.7.

Review: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

V011-C02-ESSAY-012 — Identify input estimates T_h, T_c, and Y, their standard uncertainties, and the full relevant covariance matrix. Derive sensitivities $\frac{1}{Y-1}$, $-\frac{Y}{Y-1}$, and $\frac{T_c - T_h}{(Y-1)^2}$. Form the sum of sensitivity-weighted variances and twice the cross-sensitivity covariance terms. State what calibration or measurement evidence supports the covariances. Check the domain and adequacy of a first-order approximation, especially near Y = 1. Distinguish random ratio variability from uncorrected state-dependent gain bias; merely including a small repeatability term does not validate an incorrect measurement equation. Review: Equations 4N and 4O; Application 2B.10; Equation 27 in Chapter 14.

Review: Chapter 2 — Equation 4N. Temperature sensitivity coefficients; Chapter 2 — Equation 4O. Power-ratio sensitivity coefficient; Chapter 2 — Application 2B.10: propagate the local calibration uncertainty; Chapter 14 — Equation 27. Combined standard uncertainty.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-013 — The inferred T_e is 240 K. Sensitivities are 0.2, -1.2, and -108 K per unit Y. With zero covariance, variance is $(0.2 \times 30)^2$ + $(-1.2 \times 1)^2$ + $(-108 \times 0.02)^2$ = 42.1056 K squared. The standard uncertainty is approximately 6.489 K. The NF sensitivity is 10/[ln(10) times 530], about 0.008194 dB/K, giving u(NF) approximately 0.0532 dB. State the local-linearization assumption and distinguish standard uncertainty from an expanded interval or a claimed coverage probability. Review: Equation 4I; Equations 4N-4P; Equation 27 in Chapter 14.

Review: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Equation 4N. Temperature sensitivity coefficients; Chapter 2 — Equation 4O. Power-ratio sensitivity coefficient; Chapter 2 — Equation 4P. Local conversion from temperature uncertainty to noise-figure uncertainty; Chapter 14 — Equation 27. Combined standard uncertainty.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-014 — The inverse contains $Y - 1$ in the denominator, so derivative magnitudes grow and the transformation can become strongly nonlinear over the input uncertainty range. A symmetric input range can yield a broad or asymmetric output range, possibly encountering an inadmissible domain. A principled route starts with credible input distributions and dependence, explores the nonlinear transformation, and reports how invalid-domain realizations or model mismatch are handled without clipping them into apparent success. Discuss whether the measurement design should increase hot-cold contrast or reduce uncertainty. Do not claim that more decimal places or an arbitrary coverage multiplier repairs poor conditioning. Review: Equation 4I domain; Equations 4N-4P.

Review: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Equation 4N. Temperature sensitivity coefficients; Chapter 2 — Equation 4O. Power-ratio sensitivity coefficient; Chapter 2 — Equation 4P. Local conversion from temperature uncertainty to noise-figure uncertainty.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-015 — Define the burst waveform, duration, frequency range, required event success, and valid detector state. Retain actual dwell intervals, settling exclusions, native data, decision statistic, threshold, and relevant configuration. Classify a burst outside valid channel observation as a coverage failure; use observed valid dwells for the specified amplitude-sensitivity population. Test weak references and noise-only intervals under declared environmental and interferer conditions, with distinct challenge records. Explain how overall event detection can depend on both opportunities to observe and performance during those opportunities, without assigning a universal probability from mean noise power alone. Review: Define sensitivity as a reproducible decision; Chapter 15 connection.

Review: Chapter 2 — Define sensitivity as a reproducible decision; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-C02-ESSAY-016 — Identify the unsupported link between a mean power scale and a detector operating characteristic. Require the event waveform and duration, statistic and its distribution or empirical behavior, threshold, false-alarm objective, search opportunities, observation coverage, and receiver/environment state. A ten-decibel SNR can be an explicit stipulated requirement in Equation 4L, but its probability interpretation needs a separate justified basis. Propose held-out noise-only and weak-reference trials with a defined population and uncertainty treatment. Explain how threshold tuning on the same data used for performance reporting can produce optimistic estimates. Review: Sensitivity Specifications and Decision Thresholds; Equation 4L.

Review: Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio; Chapter 2 — Sensitivity Specifications and Decision Thresholds.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-017 — Start with physical integration of noise through a channel response and the signal-retention requirement. Then distinguish averaging of a decision statistic or displayed trace from a change in admitted physical bandwidth. Averaging can change estimator variability, while correlation determines effective information; it does not necessarily lower the same mean noise power. Longer observation can improve a suitable estimator but also change event coverage or require stationarity assumptions. A strong answer names the measured quantity and operation for each case and avoids treating visually smoother traces as proof of an equal improvement in detection probability. Review: Power, bandwidth, and the reference plane; Uncertainty and Environmental Noise.

Review: Chapter 2 — Power, bandwidth, and the reference plane; Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-ESSAY-018 — Read each specification definition and applicable state rather than treating the dBm figures as interchangeable. Identify whether a common signal, bandwidth, detector, duration, reference plane, and success criterion can be tested on both devices. Include external path loss, gain, mismatch, environmental conditions, and relevant uncertainty. If a common test is not meaningful, report the original measurands separately and explain what limited comparison remains. Do not infer a universal performance difference by unit conversion alone. The plan should preserve raw observations and state records so another reviewer can distinguish measured differences from changed definitions. Review: Sensitivity Specifications and Decision Thresholds.

Review: Chapter 2 — Sensitivity Specifications and Decision Thresholds.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-019 — Use the initial comparisons to localize a candidate subsystem without prematurely claiming a calibrated noise figure. Retain matched load conditions, gain settings, supply and bias state, cable arrangement, timing, and output spectra or native data. Change one relevant mechanism at a time, such as supply stability, input attenuation, output loading, bounded blocker level, or physical coupling, while maintaining comparable observation capability. Seek evidence predicted by each mechanism and record tests that do not discriminate. Confirm any diagnosed mechanism with an appropriately bounded challenge; do not convert a bypass difference alone into environmental temperature or a traceable amplifier noise factor. Review: Y-Factor and Comparative Noise Measurements; Hypothetical Case Adjudication.

Review: Chapter 2 — Y-Factor and Comparative Noise Measurements; Chapter 2 — Hypothetical Case Adjudication: Sensitivity, Thermal Noise, Noise Figure, and Minimum Detectable Signal.

V011-C02-ESSAY-020 — Provide the raw output quantity, units, integration or detector operation, equivalent bandwidth, input and output planes, and the exact signal power gain used. Identify path components, source conditions, gain/attenuator state, sideband architecture where relevant, and any correction files or interpolation. State the validity envelope, uncertainty inputs, and evidence for linearity. Retain distinct states rather than applying a gain from another configuration. Explain that input referral changes the reporting plane and does not move physical noise sources or recover information lost through compression. Review: Power, bandwidth, and the reference plane; Model 2B scope.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-021 — Use T_s+T_e to explain genuine source-noise dominance: lowering T_e produces little benefit when T_s is much larger. Separately discuss how strong legitimate signals can cause gain control, compression, intermodulation, reciprocal mixing, or overlap, which may require a model beyond the quiet scalar noise budget. Propose spatial, temporal, polarization, and operating-state baselines plus bounded interferer tests. Do not absorb every nonthermal interferer into an arbitrary temperature without defining what the resulting model represents. The final interpretation should identify which evidence distinguishes an external contribution from changed receiver behavior. Review: Uncertainty and Environmental Noise; Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision; Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-ESSAY-022 — Identify the injection plane and list the antenna, cable, filter, gain, detector, recording, and software functions actually exercised. State that a successful check supports those functions only in its tested state and at its time. It does not alone prove uninterrupted validity during preceding acquisition or verify an antenna path that was bypassed. Add complementary field or terminal checks appropriate to the omitted functions, retain temporal state evidence, and define how transient overload or configuration disturbances would be detected or bounded. Avoid claiming universal continuity from a single successful end-of-engagement response. Review: Operational Sensitivity Verification; temporal and path-scope qualification.

Review: Chapter 2 — Operational Sensitivity Verification.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-023 — Identify the cited public apparatus scope, 9 kHz to 18 GHz for relevant EMI receivers and spectrum analyzers, and preserve the access limitation: public scope review is not full-standard access or clause-by-clause compliance certification. Explain how a conformity claim, if separately established, can support specified apparatus characteristics while leaving the actual installed chain, state, calibration, overload, and operational interpretation to be demonstrated. Do not treat an EMC apparatus standard as a universal attribution method. Distinguish source-supported scope statements from the author derived scalar noise model and synthetic applications. Review: Measuring-Receiver Scope and System Noise Floor; footnote 4.

Review: Chapter 2 — Measuring-Receiver Scope and System Noise Floor; Chapter 2 — Measuring-Receiver Scope and System Noise Floor.

V011-C02-ESSAY-024 — Duplicated observations carry the same noise realization, so the nominal file length overstates independent information. Explain that variance of an average includes covariance terms; perfect duplicates do not create a second independent experiment. Also distinguish sample correlation within a genuine longer acquisition from changes in gain or source state that alter the measurand. A rigorous answer states the averaging rule, estimates or justifies dependence, and retains the original time/state lineage. Repetition of a systematically biased hot-cold procedure also does not remove its state-dependent bias. Review: Uncertainty and Environmental Noise; Application 2B.9.

Review: Chapter 2 — Uncertainty and Environmental Noise; Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

Copyright 2026, James M. Atkinson

V011-C02-ESSAY-025 — Define the event and reference plane first, then calculate a noise budget with valid matched-state assumptions and signal retention. Use gain and loss bounds to identify feasible chains, but check internal blocker levels, preselector rejection, stability, and detector validity before selecting a noise-optimal arrangement. Characterize the required decision ratio or detector operating characteristics on controlled data and validate on distinct challenge records. Include source environment and observation coverage, then propagate relevant calibration and statistical uncertainty. A sound review presents the feasible operating envelope and unresolved limits rather than treating a low calculated noise figure as the entire acceptance case. Review: Model 2B; Applications 2B.1-2B.10; Operational Sensitivity Verification.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Operational Sensitivity Verification; Chapter 2 — Application 2B.1: assemble a four-stage noise budget; Chapter 2 — Application 2B.10: propagate the local calibration uncertainty.

Discussion Guidance

V011-C02-DISCUSSION-001 — Ask participants to compute or explain the ordering effect in Equation 4C before discussing operations. Then require internal blocker levels, amplifier linearity and stability, remote power and cable conditions, and the actual source environment. A defensible conclusion can prefer amplifier-first for a valid noise-limited case yet choose another architecture when strong-signal or installation constraints dominate. Reject arguments based only on total gain or the lowest formal noise figure. Review: Applications 2B.2 and 2B.7.

Review: Chapter 2 — Application 2B.2: move an amplifier across a cable; Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

V011-C02-DISCUSSION-002 — Separate the reported signal-level transformation from the physical noise budget. A valid correction can refer a measured signal to an earlier plane; it does not remove cable thermal emission, downstream noise reweighting, or information lost in an invalid state. Ask what source-plane and calibration evidence is needed and whether the desired signal was retained. The discussion should produce a precise corrected claim rather than simply rejecting all cable corrections. Review: Power, bandwidth, and the reference plane; Equation 4G.

Review: Chapter 2 — Equation 4G. Loss followed by a characterized chain; Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-003 — Have each engineer identify the denominator temperature in the quantity being quoted. Use Equations 4D and 4E to show that both numbers can be correct for different definitions. Then compare total input-referred noise and the event detection requirement. A productive resolution reports the receiver convention and source conditions together without redefining T_0 to force agreement. Review: Equations 4C-4E.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Equation 4D. Noise factor at the reference temperature; Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source.

V011-C02-DISCUSSION-004 — Require an event definition before choosing a visual criterion. Discuss retained burst energy and timing, filter response, effective noise bandwidth, detector behavior, and actual observation coverage. The appropriate tradeoff depends on the stated success event and false-alarm objective. The discussion should end with a measurable comparison, such as held-out burst detection under matched conditions, rather than treating trace smoothness as the objective. Review: Power, bandwidth, and the reference plane; Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision; Chapter 2 — Power, bandwidth, and the reference plane.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-005 — Use the admissible Y domain to establish why the result is inconsistent with the selected model. Enumerate plausible source calibration, gain-state, compression, bandwidth, mismatch, ratio-processing, and uncertainty explanations. Clipping cannot resolve the inconsistency and may conceal its size. A defensible review preserves the observation, investigates the equation inputs, and states whether a valid result can be produced after a justified correction. Review: Equation 4I domain.

Review: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain.

V011-C02-DISCUSSION-006 — Separate precision from model validity. Repeated application of the same state-dependent ratio can produce a tightly clustered biased inferred temperature. Ask how the gain difference is known, whether it is stable, and what uncertainty accompanies any correction. Discuss the role and limits of bracketing measurements and independent gain checks. Do not equate small repeatability scatter with negligible total uncertainty. Review: Application 2B.9.

Review: Chapter 2 — Application 2B.9: expose a change hidden by a ratio.

V011-C02-DISCUSSION-007 — The labels are insufficient by themselves. Participants should ask whether actual hot/cold gain and noise law were characterized, whether the source states remained linear, and how transitions or settling were excluded. An enabled control is not automatically disqualifying if a valid characterized model exists, but unobserved state changes undermine the simple cancellation. Frame the acceptance decision around evidence for the law actually used. Review: Y-Factor and Comparative Noise Measurements.

Review: Chapter 2 — Y-Factor and Comparative Noise Measurements.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-008 — Read the certificate and connect its defined quantities to the measurement equation. The chapter declares one explicit temperature-difference convention but does not override the calibration source definition. Discuss how to map between conventions, retain the reference temperature separately, and propagate uncertainty. Blindly setting T_c to 290 K or treating ENR as the measured receiver Y-factor should be challenged. Review: Y-factor discussion following Equation 4I.

Review: Chapter 2 — Equation 4I. Recovered input noise temperature and its domain; Chapter 2 — Invert the same model with two source temperatures.

V011-C02-DISCUSSION-009 — The mathematical bound identifies a noise requirement, not a complete feasible implementation. Discuss blocker stress, compression, stability, band flatness, gain-state control, and uncertainty in the first-stage temperature. If the target is too close to $T_{e,1}$, the design may have little useful margin. Consider changing the first device, path loss, preselection, or detector requirement rather than assuming arbitrarily high gain is available and valid. Review: Equation 4J; Applications 2B.5 and 2B.7.

Review: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit; Chapter 2 — Application 2B.5: solve for the gain that is useful; Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage.

V011-C02-DISCUSSION-010 — Recognize that the stated passive feasible interval is empty, even for a lossless preceding section. Review the following chain temperature, target, physical temperature inputs, and correctness of the chosen reference plane. A different architecture or revised justified requirement may be needed. A passive element cannot be assigned L below one merely to make the inequality pass. Review: Equation 4K domain.

Review: Chapter 2 — Equation 4K. Maximum allowed preceding loss.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-011 — Use the sensitivity-weighted variance contributions to separate source calibration uncertainty from ratio repeatability. More output samples can reduce a genuinely independent random ratio component but may have little effect on a dominant calibration input. Discuss better source characterization, source contrast, covariance evidence, and whether the first-order model is adequate. Do not assume every budget component averages down with sample count. Review: Application 2B.10.

Review: Chapter 2 — Application 2B.10: propagate the local calibration uncertainty.

V011-C02-DISCUSSION-012 — Require the distributional approximation, degrees-of-freedom treatment, and uncertainty model supporting the coverage statement. The multiplication by two is transparent arithmetic, but it does not itself specify coverage. Discuss how to report the factor and assumptions when the probability interpretation is limited. Near an ill-conditioned inversion, a nonlinear or asymmetric result may require a different interval description. Review: Equations 4N-4P.

Review: Chapter 2 — Equation 4N. Temperature sensitivity coefficients; Chapter 2 — Equation 4O. Power-ratio sensitivity coefficient; Chapter 2 — Equation 4P. Local conversion from temperature uncertainty to noise-figure uncertainty.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-013 — Contrast relative degradation with total input-referred noise. A dominant source can make receiver-added noise relatively unimportant while leaving the absolute required signal much larger. Use T_s+T_e and Equation 4L to connect the distinction to an event requirement. Discuss whether reducing receiver T_e, changing observation conditions, or improving selectivity would address the actual limitation. Review: Equations 4C, 4E, and 4L.

Review: Chapter 2 — Equation 4C. Cascade temperature and integrated output noise; Chapter 2 — Equation 4E. Signal-to-noise degradation for the actual source; Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

V011-C02-DISCUSSION-014 — The team must define the intended application and a common success criterion, waveform, bandwidth, observation interval, detector, and reference plane. If the devices serve different tasks, an unqualified scalar ranking may be inappropriate. Ask what measurements can be reproduced and what differences must remain explicit. Converting both catalog numbers to the same power unit does not solve a measurand mismatch. Review: Sensitivity Specifications and Decision Thresholds.

Review: Chapter 2 — Sensitivity Specifications and Decision Thresholds.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-015 — Discuss noise-only false alarms, distinct held-out weak events, event selection, receiver state, search opportunities, and uncertainty in the observed performance. Successful tuning records demonstrate fit to those records; they do not alone establish performance for the declared population. Ask whether the threshold and processing were frozen before the challenge set was evaluated and how exclusions were documented. Review: Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision.

V011-C02-DISCUSSION-016 — Participants should distinguish the curve conditional on a valid observation interval from an overall operational detection measure. Both may be useful if their populations are stated. Pooling them without qualification obscures whether failure arose from amplitude sensitivity or coverage. Require actual channel timing and settling records before classification, and discuss how a deployment-level report can present both measures. Review: Define sensitivity as a reproducible decision; Chapter 15 connection.

Review: Chapter 2 — Define sensitivity as a reproducible decision; Chapter 15 — Model 15A: calculate conditional event coverage from usable windows.

V011-C02-DISCUSSION-017 — Nominal count alone cannot establish equal information. Discuss continuity evidence, duplicate detection, the estimator and covariance, and whether repeated buffers represent acquisition failure or deliberate resampling. The repeated data cannot be credited as independent observations. Also ask whether apparently continuous timestamps correspond to real acquired samples or only software-generated record positions. Review: Uncertainty and Environmental Noise.

Review: Chapter 2 — Uncertainty and Environmental Noise.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-018 — The comparison suggests an external or path-dependent contribution, but the interpretation needs the antenna/termination states, gains, impedance behavior, effective bandwidth, receiver-added noise, and possible overload effects. Discuss what assumptions permit an equivalent source temperature and whether nonthermal interference fits the chosen representation. A calibrated quantitative result requires more than subtracting two displayed numbers. Review: Y-Factor and Comparative Noise Measurements; Uncertainty and Environmental Noise.

Review: Chapter 2 — Y-Factor and Comparative Noise Measurements; Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-DISCUSSION-019 — Require raw observations, the actual bypass path, source conditions, state-specific gains, detector operation, and linearity evidence. Use controlled changes to test predictions for noise, instability, and overload while maintaining sufficient observation capability. A qualitative discriminating test may be useful even when it does not produce a traceable noise figure. State that narrower evidential role explicitly. Review: Y-Factor and Comparative Noise Measurements.

Review: Chapter 2 — Y-Factor and Comparative Noise Measurements.

V011-C02-DISCUSSION-020 — It may support identified apparatus characteristics within the standard and evidence actually available. It does not validate the accessories, the installed reference plane, the chosen state, or source attribution. Ask participants to map each part of the claimed result to its supporting evidence and identify the extra checks needed. Preserve the difference between public scope review and a documented conformity assessment. Review: Measuring-Receiver Scope and System Noise Floor.

Review: Chapter 2 — Measuring-Receiver Scope and System Noise Floor.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-021 — Map the injection point and the functions exercised. A downstream injection can bypass the antenna and upstream path, and a later successful response cannot alone exclude earlier transient faults. Propose complementary checks and temporal state evidence appropriate to the actual claim. The corrected conclusion should state what was tested, when, and what remains unsupported. Review: Operational Sensitivity Verification; closing-check scope qualification.

Review: Chapter 2 — Operational Sensitivity Verification.

V011-C02-DISCUSSION-022 — An equivalent temperature may be a useful defined power-density representation under a declared band and statistic, but it must not conceal structured interference, time variation, or receiver nonlinearity. Discuss controlled equipment-state comparisons, spectra, polarization, timing, and bounded interferer tests. The adopted model should match the intended prediction and retain its limitations rather than treating every observed contribution as equilibrium thermal noise. Review: Uncertainty and Environmental Noise.

Review: Chapter 2 — Uncertainty and Environmental Noise.

V011-C02-DISCUSSION-023 — Examine the actual sideband and image paths, input environment, conversion gain definition, and calibration conditions. The chapter permits a scalar equivalent-channel law only when empirically justified for the selected architecture. A nominal figure cannot be inserted blindly just because it is expressed in decibels. Identify which manufacturer source or measurement would supply the missing applicability evidence. Review: Model 2B scope; Analog Devices source note.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Model 2B: a matched, fixed-state noise cascade.

Copyright 2026, James M. Atkinson

V011-C02-DISCUSSION-024 — Ask whether the original detector operation, bandwidth, reference plane, actual state, corrections, and uncertainty can still be established. A retained final value and nominal gain may permit arithmetic reversal but cannot necessarily recover the original observation or validate the gain applicability. Discuss the narrow conclusions still supportable and which missing evidence prevents stronger claims. Avoid treating a reversible scalar formula as proof that all original information was preserved. Review: Power, bandwidth, and the reference plane.

Review: Chapter 2 — Power, bandwidth, and the reference plane.

V011-C02-DISCUSSION-025 — The discussion should connect a defined authorized event, valid reference plane and installed chain, controlled reference identity, strong-signal envelope, actual observation opportunities, and a validated decision criterion. Include state and uncertainty evidence, held-out challenges, and bounded closing checks. A useful outcome is an explicit tested operating domain with remaining limits, not a single catalog-like number detached from its event and environment. Review: Operational Sensitivity Verification; Define sensitivity as a reproducible decision.

Review: Chapter 2 — Define sensitivity as a reproducible decision; Chapter 2 — Operational Sensitivity Verification.

Chapter Glossary

AVAILABLE NOISE POWER: Noise power that a source can supply under the specified matching condition. In the chapter's classical thermal model it is kBT_s, where k is the Boltzmann constant in joules per kelvin, B is equivalent noise bandwidth in hertz, and T_s is source noise temperature in kelvins. It is a source quantity at a declared plane and differs from the power actually accepted by a mismatched receiver.

CASCADE NOISE TEMPERATURE: Equivalent input noise temperature of an ordered chain, found by referring each added stage contribution through the gain preceding it.

COLD-SOURCE TEMPERATURE: Effective source noise temperature in the lower-temperature state of a hot/cold measurement at the stated input plane.

COMBINED STANDARD UNCERTAINTY: The standard uncertainty obtained by propagating the relevant input uncertainties and covariances through the stated measurement model. In the local Y-factor calculation it is the square root of the sensitivity-weighted variance sum, including any applicable cross terms. It is distinct from an expanded uncertainty and does not itself specify a chosen coverage probability.

COVERAGE FAILURE: Failure to observe an event because the relevant channel or interval was not validly acquired, such as a burst occurring while a scanning receiver was tuned elsewhere. It is distinct from a failure to detect an event during a valid dwell. Actual observation and settling records are needed to assign the failure category.

Copyright 2026, James M. Atkinson

CUMULATIVE POWER GAIN: The product G_j of the linear power gains from the selected input through stage j. It describes signal power transfer between those planes in the stated fixed-state model. G_0 is defined as one, allowing the first stage noise contribution to be handled by the same recurrence as later stages.

DECISION STATISTIC: The quantity computed from an observation and compared with a criterion to decide whether a specified event has been detected. Examples in the chapter include amplitude, correlation, or coherent-integration results. Its distribution, duration, receiver state, and processing affect detection and false-alarm behavior; mean noise power alone does not specify those properties.

DELIVERED NOISE POWER: Noise power accepted by the receiving port under the actual source and load conditions. It equals available noise power in the stated matched real-impedance model. A matched-port insertion-loss value alone does not establish delivered power for a reactive antenna and a state-dependent receiver input match.

DETECTION THRESHOLD: The declared boundary applied to a decision statistic for a defined detection event. Its selection should reflect a false-alarm objective and be tested with suitable noise-only and weak-reference observations. Lowering it can increase detected weak events while also increasing unwanted crossings; the threshold is not interchangeable with a receiver noise-floor number.

Copyright 2026, James M. Atkinson

DISSIPATIVE ATTENUATION: Signal power reduction caused by a passive element that dissipates energy under the stated matched conditions. Its physical temperature determines its thermal emission. For loss L at temperature T_p, Model 2B assigns gain $\frac{1}{L}$ and equivalent input temperature $(L-1)T_p$; arbitrary reflected power is not automatically covered by this relation.

ENVIRONMENTAL BASELINE: A set of observations describing the site contribution under stated spatial, temporal, polarization, and operating conditions. It helps identify variation relevant to operational sensitivity and possible external noise mechanisms. A baseline is bounded by its coverage and receiver validity; it does not make a quiet laboratory noise figure a guarantee for every occupied-site state.

EQUIVALENT NOISE BANDWIDTH: Bandwidth of an ideal rectangular filter passing the same noise power as the actual filter or processing window.

EXCESS-NOISE RATIO: Calibrated noise-source quantity whose temperature and reference convention must be read explicitly; Model 2B uses the on-minus-off temperature divided by 290 K.

HELD-OUT DETECTION TEST: Evaluation of a fixed detection rule on challenge records distinct from those used to select its threshold or processing. The chapter calls for both noise-only intervals and weak reference events under declared conditions. The separation helps reveal optimistic tuning results, while the tested event population and uncertainty still limit the conclusion.

Copyright 2026, James M. Atkinson

HOT-COLD GAIN RATIO: Power gain in the hot source state divided by power gain in the cold state; a value other than unity invalidates the equal-gain Y-factor inversion.

HOT-SOURCE TEMPERATURE: The calibrated or otherwise justified effective noise temperature T_h of the higher-noise source state in a hot-cold measurement. It must exceed T_c for the chapter inversion. Its applicability is tied to the reference plane, connection corrections, and source convention; it is not inferred solely from the receiver output being larger.

HOT-STATE COMPRESSION: Nonlinear response caused when the higher-noise source state drives part of the receiver beyond the applicable proportional gain range. It breaks the common linear law used to cancel gain in the hot-cold ratio. A stable output reading does not exclude this effect; both source states require an appropriate linearity check.

INPUT REFERRAL: A reporting transformation that expresses an output quantity at a declared input plane using the applicable transfer law. For noise power in the valid scalar model, divide by the state-specific signal power gain. The operation does not move noise generators physically or restore information lost through an invalid nonlinear state.

INVERSION CONDITIONING: The sensitivity of an inferred quantity to changes in the measured inputs of an inverse relation. The Y-factor temperature inversion is poorly conditioned near $Y = 1$ because its denominator approaches zero. Small ratio or calibration uncertainties can then produce large, asymmetric changes that a local linear uncertainty approximation may not adequately describe.

Copyright 2026, James M. Atkinson

MINIMUM DETECTABLE SIGNAL: Input signal level meeting a stated detection criterion under specified conditions.

MINIMUM PRECEDING GAIN: The least first-stage power gain that meets a specified two-stage equivalent-temperature target under the stated positive downstream-noise assumptions. Equation 4J gives $\frac{T_{e,2}}{T_{target} - T_{e,1}}$ when T_{target} exceeds $T_{e,1}$. This is a noise constraint; it does not establish that the required gain is available, stable, or valid under the blocker environment.

NOISE FACTOR: Ratio of input signal-to-noise ratio to output signal-to-noise ratio under the declared source temperature and matching convention, expressed in linear units. Model 2B uses a 290 K reference source; degradation for a different actual source temperature is a separate quantity.

NOISE FIGURE: The logarithmic expression of noise factor, $NF_0 = 10 \log_{10}(F_0)$, in decibels at the declared reference temperature and conditions. Its numerical convenience does not remove the need to identify the included network and state. It differs from actual SNR degradation when the source temperature differs from the reference temperature, except in the zero-added-noise case.

NOISE-LIMITED SENSITIVITY: A bounded input-signal requirement derived when the admitted source and receiver noise are the relevant limiting contributions and the detector requirement is separately justified. Equation 4L uses $\gamma k B(T_s + T_e)$ with full desired-signal retention. Compression, structured interference, coverage failures, or another detector law can require a different operational analysis.

Copyright 2026, James M. Atkinson

NOISE-ONLY VALIDATION: Evaluation of the chosen detection rule on records intended to represent the stated no-target condition. It supports assessment of false-alarm behavior for the tested state and population. The record must still account for receiver artifacts, environmental structure, processing, and search opportunities; a quiet mean level alone is not a complete validation.

NOISE TEMPERATURE: Equivalent temperature used to represent available noise power or device-added noise.

OUTPUT-ADDED NOISE: Noise attributed to a stage and expressed at that stage output, excluding the incoming noise it transmits. For stage i in Model 2B the value is $k B g_i T_{e,i}$. Referring this contribution to another plane requires the corresponding signal power gain, rather than treating the stage equivalent input temperature as an output temperature directly.

PASSIVE-LOSS ALLOWANCE: The permitted interval of matched dissipative loss before a characterized chain under a specified total noise-temperature target. Equation 4K combines the requirement $L \geq 1$ with an upper bound determined by target, physical path temperature, and downstream equivalent temperature. An upper bound below one means the stipulated passive design has no feasible solution.

PRECEDING GAIN: The cumulative power gain before the stage whose added noise is being referred to the cascade input. The contribution $T_{e,i}$ is divided by G_{i-1}, because the input signal has experienced those earlier stages before that noise is added. Preceding loss increases, rather than suppresses, the downstream input-equivalent contribution.

Copyright 2026, James M. Atkinson

RECEIVER-ADDED NOISE: The noise contribution produced by the included receiver chain beyond the admitted source contribution. Model 2B represents it at the input by T_e and at the output by $k B G_n T_e$. This representation depends on the selected path, gain state, bandwidth, and model domain; it is not an arbitrary label for every observed interferer.

REFERENCE NOISE TEMPERATURE: Temperature used to define a noise-factor convention, equal to 290 K in Model 2B and distinct from actual source or component temperature.

SEARCH MULTIPLICITY: The presence of multiple opportunities for a decision statistic to cross a threshold during a search over frequencies, windows, or other tested conditions. It affects how a single-channel false-alarm objective relates to a whole-search claim. The number and dependence of those opportunities must be considered in the chosen validation or probability model.

SENSITIVITY FAILURE: Failure to detect the defined event during an acquisition interval that validly observed the relevant channel under the stated conditions. It can inform a sensitivity estimate only within that specified population and detector rule. Events missed because the receiver was not observing belong to a separate coverage category unless a broader operational measure is explicitly defined.

SIGNAL RETENTION: The fraction or representation of the desired signal preserved by the selected channel and processing for the intended measurement or detection event. Reducing equivalent noise bandwidth can reject desired modulation or burst energy as well as noise. A claimed sensitivity improvement must evaluate the retained signal, rather than relying only on the reduced noise trace.

Copyright 2026, James M. Atkinson

SOURCE NOISE TEMPERATURE: The temperature-scale representation T_s of noise supplied at the cascade input under the declared band and model. It can reflect the antenna view or an applied calibrated source and need not equal ambient temperature. Model 2B keeps it separate from the equivalent temperature representing receiver-added noise.

SOURCE SWITCHING: The controlled transition between the hot and cold input-source states of a comparative noise measurement. The record must identify the realized state, timing, settling, and any associated change in gain, bandwidth, mismatch, or noise law. Switching labels alone do not establish the common-state conditions needed for the simple Y-factor inversion.

TEMPERATURE CONTRAST: The difference $T_h - T_c$ between the effective hot and cold source temperatures in the declared hot-cold measurement convention. It enters the source excess-noise ratio and influences the measured power contrast. Its calibration and uncertainty must be retained; a large nominal contrast alone does not establish receiver linearity or correct source-plane delivery.

THERMAL EQUILIBRIUM: The condition used in the passive-loss derivation in which the matched source, attenuator, and connected terminations share the physical temperature T_p. The attenuator output available noise remains $k B T_p$ because thermal emission complements the transmitted source noise. Equal equilibrium noise does not mean that a desired signal passes without attenuation.

Y-FACTOR: Ratio of measured output powers for two known input noise temperatures.

Copyright 2026, James M. Atkinson

Y-FACTOR ADMISSIBLE DOMAIN: The set of output-noise ratios compatible with the stated hot-cold model and its input constraints. For $T_h > T_c > 0$ and finite nonnegative T_e, it is $1 < Y \leq \frac{T_h}{T_c}$. An observed ratio outside that interval calls for investigation of the inputs and model rather than silent clipping of the inferred temperature.

Chapter 3. RF Front Ends, Preselection, Gain Distribution, and Input Protection

Copyright 2026, James M. Atkinson

3.1 Front-End Purpose and Architecture

The RF front end determines which energy reaches the vulnerable gain and conversion stages. It can include switching, duplexing, limiters, electrostatic protection, attenuators, high-pass or low-pass sections, tunable preselectors, fixed band-pass filters, tracking filters, notch filters, amplifiers, and calibration injection paths. These components establish the receiver's practical input range and often determine whether a weak signal is observable in the presence of strong legitimate transmitters.[7]

Wide instantaneous coverage is not always advantageous. A direct-sampling receiver connected to an unfiltered broadband antenna may accept energy far outside the displayed span. Strong AM, FM, television, cellular, radar, or nearby digital transmitters can drive the input network or converter nonlinearly even when they are invisible on the selected screen. A front-end diagram and out-of-band survey are therefore part of weak-signal work.

3.2 Find the first stage that can lose validity

Front-end design is easiest to reason about when the desired signal and every significant interferer are followed separately through the actual order of components. A filter near the receiver output may make the final display clean while leaving an earlier amplifier exposed to a large signal. Once that amplifier has compressed or generated an in-band product, later filtering cannot reconstruct the undistorted weak signal. The relevant question is therefore where an unwanted signal is rejected relative to the first component that it can drive outside its valid operating state.

Draw each path from the external connector to the digitizer or detector. Mark a desired-signal transfer at its own frequency, blocker transfers at their frequencies, and the total loading presented to each stage. Do not use the desired-frequency gain for a blocker located across a filter skirt. For several blockers, the total mean power matters to some mechanisms, while instantaneous voltage and relative phase can matter to others. The cubic model in Chapter 11 provides a bounded intermodulation calculation; a scalar gain budget by itself does not predict those products or a protection device's transient response.

A practical architecture can have more than one low-noise operating state. The R&S ESW manual, for example, places its standard preamplifier after preselection and describes an optional low-noise amplifier ahead of it. The manual also distinguishes the sensitivity benefit from the reduction in large-signal immunity. This is a concrete illustration of why an instrument's preamplifier indicator is insufficient configuration information: the location

Copyright 2026, James M. Atkinson

of the active stage and the filters preceding it determine which signals it admits.[8]

For an unknown environment, begin with a state whose exposure is understood and then test whether more gain is useful. That does not imply a universal attenuator setting. The appropriate state follows the instrument's ratings, the anticipated signal environment, and the required observation. Once a quieter state is selected, record the change as a new measurement configuration. Measurements from different states may later be compared at a common reference plane, but their noise, overload behavior, and time coverage remain distinct.

---

8 Keysight Technologies, Keysight X-Series Signal Analyzers: N9069C Noise Figure Measurement Guide, part N9069-90001, edition 1 (March 2016), 10–11, 73–81, especially “Using Loss Compensation” and “Setting Temperature of Loss,” https://www.keysight.com/us/en/assets/9018-04256/user-manuals/9018-04256.pdf. This identified edition supports the stated measurement controls, not a claim about every current analyzer.

Copyright 2026, James M. Atkinson

3.3 Preselection and Filter State

Preselection limits the spectral energy admitted to later stages. Tracking filters follow the tuned frequency, while switched filter banks cover defined bands. The important characteristics include insertion loss, passband ripple, rejection, transition width, return loss, group delay, tuning repeatability, power handling, and switching transient. A filter that improves overload immunity can also remove a broadband transient, distort modulation, or introduce temperature-dependent loss.

Filter state must be documented rather than inferred from a displayed center frequency. Some receivers select prefilters automatically, and a boundary crossing can change gain, noise, phase, or calibration. External filters and notches must be identified by serial number and measured response when amplitude accuracy matters. Comparing observations made through different filters requires separate correction and uncertainty.

Copyright 2026, James M. Atkinson

Figure 10. RF front-end gain, filtering and protection.

Copyright 2026, James M. Atkinson

3.4 Use preselection as a measured transfer function

A preselector trades desired-band insertion loss against unwanted-band admission. Application 2B.6 quantifies one side of that trade: loss ahead of the first amplifier raises the complete input-equivalent temperature. The other side requires the filter response at each blocker frequency. A filter that costs 1 dB at the desired frequency but suppresses a dominant remote blocker can make a previously invalid observation usable. A filter with the same insertion loss and inadequate blocker rejection supplies only the noise penalty. Both statements depend on its placement ahead of the vulnerable stage.

Characterize the passband as well as its center. A narrow desired waveform near the center can be retained while a wider waveform extending into the skirt suffers amplitude and phase distortion. Switching among preselector bands can also change the response abruptly at a boundary. A calibration at the center of one band cannot establish continuity across that transition. Record band identifiers and actual settings, then place reference checks at frequencies that challenge the boundary and the regions where the response changes rapidly.

The desired and blocker corrections should be separate columns in the path record. Suppose a filter is known to have modest loss at the desired frequency and substantial rejection at the blocker frequency. The desired-signal correction restores the reported level at the original plane, while the blocker transfer estimates the power reaching the next active component. Applying the rejection value as a desired-signal correction would create an impossible sensitivity improvement. Applying the desired insertion loss to

Copyright 2026, James M. Atkinson

the blocker would conceal the intended protection. Neither correction is a generic property independent of frequency.

A strong-signal challenge should confirm the predicted mechanism with the desired reference still present. Record the desired amplitude, phase or modulation quality, the local noise, and any new spectral products before and after changing the preselector. A lower displayed baseline alone is ambiguous: the filter may have rejected environmental noise, suppressed reciprocal mixing, reduced gain, or removed part of the desired waveform. Remeasuring the desired transfer separates these interpretations. The signed-frequency and admitted-power conventions of Model 11B are especially useful when the challenge involves reciprocal mixing.

Copyright 2026, James M. Atkinson

Figure 11. Preselector rejection and out-of-band blocking.

Copyright 2026, James M. Atkinson

3.5 Gain Distribution and Attenuation

Gain should be distributed so that the system remains above later-stage noise without sacrificing headroom at early stages. Input attenuation protects the front end and provides a powerful linearity challenge. Preamplification can improve noise performance but reduces input intercept margin. Variable-gain amplifiers, RF attenuators, IF gain, digital scaling, and detector normalization may interact, especially under automatic control.

A useful survey records at least two gain states. A genuine external signal should change predictably after correction for the altered gain or attenuation. A component that does not follow the expected change can be generated after the switched element, clipped by a later stage, or affected by control loops. Step-attenuator accuracy, repeatability, contact condition, and frequency response should be included when the result depends on a small level difference.

Copyright 2026, James M. Atkinson

3.6 Choose gain from a feasible interval

Model 2B supplies a minimum gain needed to suppress later receiver noise. A separate large-signal analysis supplies an upper gain compatible with downstream loading. The useful choice lies in the overlap. Application 2B.5 shows the diminishing return clearly: after later noise is already small compared with first-stage noise, more gain gives little improvement in input sensitivity. It still raises every admitted signal at the next stage. A gain plan should therefore state both the noise target and the limiting signal condition, rather than treating low displayed noise as the only objective.

Copyright 2026, James M. Atkinson

Gain constraints referred to the same measurement plane:
Wanted signal: $-100 + G \geq -85 \Rightarrow G \geq 15$ dB
Blocker: $-35 + G \leq -12 \Rightarrow G \leq 23$ dB

Practical check: gain alone cannot improve an inadequate input SNR.
Also test preselector loss, intermodulation, ADC headroom, and state changes.

Figure 12. Usable gain, noise and overload limits.

The location of an attenuator determines what it protects. Application 2B.7 places the same nominal attenuation before and after an amplifier. Equal total signal gain does not mean equal noise or equal protection. Attenuation after the amplifier may preserve a good formal small-signal noise figure

Copyright 2026, James M. Atkinson

while leaving that amplifier overloaded. Conversely, attenuation before it can restore linear operation at a high sensitivity cost. The corrected display may continue to show the same desired signal level because the instrument accounts for its attenuator; that correction says nothing about the physical noise penalty.

Gain control adds a time dimension. If automatic gain control responds to an intermittent blocker, the weak desired signal can change even while its source remains constant. A sample record should retain the gain state or a sufficiently resolved gain-control trace when quantitative amplitude is needed. If the state cannot be reconstructed, amplitude comparisons spanning the transition require qualification. A calibration performed at one settled gain does not automatically describe the trajectory between states, and an average gain value cannot undo clipping or missing samples during that trajectory.

A later digitizer introduces another constraint: analog signal and noise must use its range adequately without approaching overload. Increasing analog gain can reduce the input-referred significance of converter noise, but it cannot improve an already established analog signal-to-noise ratio. The sampling and digitizer treatment in Chapter 10 must be applied at its actual input plane. Chapter 9 supplies the relevant FFT normalization when a spectrum is derived from those samples. An apparently quiet digitized trace can instead indicate insufficient analog gain, heavy digital averaging, or clipping followed by scaling. Preserve raw samples and state metadata before interpreting the display.

Copyright 2026, James M. Atkinson

3.7 Input Protection and Recovery

Limiters and protection devices can prevent damage from high-power pulses, transmitter leakage, electrostatic discharge, and accidental connection. Their recovery time, leakage, capacitance, insertion loss, harmonic generation, and power history matter. A limiter that has survived an overload event may remain functional at low frequency while introducing distortion or loss at higher frequency. Gas devices, PIN limiters, transient suppressors, and relay contacts have different signatures.

Protection is not a substitute for exposure analysis. The practitioner estimates expected continuous and peak power, duty factor, antenna gain, near-field coupling, and switching transients before connecting the receiver. Directional couplers, external attenuators, power sensors, or sacrificial front ends may be necessary. Following a suspected overload, the receiver is checked with known references at several levels and frequencies before evidence is accepted.

Copyright 2026, James M. Atkinson

3.8 Measure protection in the small-signal and recovery states

A protection element participates in the signal path even when it is not limiting. Its insertion loss, return loss, and reactive loading can change the desired transfer and the noise budget. In a PIN-diode limiter, stored carriers change the diode's RF resistance during a large signal, and removal of those carriers affects the return to low insertion loss. MACOM's receiver-protection explanation describes both this charge behavior and the role of the external current path. The diode geometry also affects capacitance. These mechanisms justify measuring the complete mounted protection network rather than assigning it an ideal on/off state.[9]

Protection has at least three distinct consequences to characterize: the signal that leaks through during the large event, the survival of the protected hardware, and the recovery of a valid weak-signal measurement afterward. A device can survive while the useful channel remains desensitized. A short leading transient can reach a downstream component even when the later leakage is limited. A catalog recovery time must be interpreted with its test conditions and the required recovery criterion; the time to return near nominal insertion loss is not necessarily the time to recover calibrated phase or a detector's baseline.

9 James P. Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. Its historical radiometer thresholds are not adopted as acceptance limits for the present constructed receiver.

Copyright 2026, James M. Atkinson

The ADL8201 data sheet illustrates the separation of these quantities. Its tables distinguish insertion loss, leakage, compression, intermodulation, and recovery from pulse-width and duty-cycle dependent survivability data. Those are specifications of that device under stated conditions, not transferable limits for another receiver or for an arbitrary assembly. An acceptance plan should carry the same separation into its own measured quantities, with the actual instrument and accessory limits governing the applied challenge.[10]

To evaluate recovery, retain a weak desired reference while applying a bounded, independently controlled strong-signal event. Observe the reference before, during, and after the event. Define recovery by the measurement need, such as return of amplitude within a stated tolerance and restoration of the baseline variance. Record the event waveform, repetition, timing, and gain state. Repeating only a continuous-wave sweep will not expose a recovery interval after a pulse, and observing only the end of a long record can miss the period in which nearby events would have been undetectable.

Interpret an apparent recovery delay carefully. The protection network, amplifier bias, automatic gain control, digital filter, detector averaging, and trigger logic can each introduce persistence. A shorter detector time constant may reveal the analog recovery more clearly but also changes the

3.9 Front-End Characterization and Field Decisions

Characterization includes insertion gain or loss, passband shape, return loss, compression, intermodulation, noise contribution, switching repeatability, and leakage between paths. A vector network analyzer can measure small-signal response, but large-signal and pulsed behavior require appropriate sources, couplers, power sensors, and protection. Temperature and bias state should be controlled where active devices are involved.

Field choices are driven by the environment. In a strong broadcast area, a narrow preselector and moderate input attenuation may produce better sensitivity to the signal of interest than maximum preamplifier gain. Near a pulsed radar, peak-power protection and time-domain blanking may be necessary. Indoors, multiple antennas and polarization changes can reduce a dominant local signal without changing the receiver. The selected front-end state and its rationale belong in the survey record.

3.10 An acceptance sequence that separates competing failures

A defensible front-end acceptance begins with the sources and combining path. Two generators joined through a poorly isolated combiner can interact and create products before the receiver. Measure or otherwise bound the desired and blocker levels at the intended receiver plane, verify the combining components at the applied levels, and retain a check of source spectral purity. If a new line appears, a source-path control is needed before attributing it to receiver intermodulation. The same principle applies to broadband noise: the blocker source may carry noise at the desired channel.

Next establish the quiet small-signal response at the frequencies and levels that will be used. Retain desired gain, noise baseline, and relevant phase or modulation quality. Introduce the blocker in controlled steps while keeping the desired source fixed, then remove it and confirm return. Repeat in the alternative preselector or attenuator state that the mechanism predicts should matter. The sequence is informative because the predictions differ: compression changes desired transfer, reciprocal mixing raises admitted noise, and a discrete intermodulation mechanism produces particular frequencies. More than one mechanism can occur simultaneously.

Table 3A. Evidence to retain during a constructed front-end challenge

Question	Observable	Controlled change	Interpretive limit
Does desired transfer change?	Desired amplitude and quality	Blocker level with fixed desired source	A gain-control response can mimic compression
Does admitted noise rise?	Linear integrated channel noise	Blocker offset and preselection	Source noise must be bounded

Copyright 2026, James M. Atkinson

Question	Observable	Controlled change	Interpretive limit
Does a discrete product appear?	Product frequency and level	Tone frequencies and input attenuation	Combiner or source products remain alternatives
When is validity restored?	Desired response versus time	Bounded strong-event duration	Detector settling can mask analog recovery
Is the path stable afterward?	Closing reference and baseline	Return to original state	One frequency does not verify every band

For each change, retain a comparison at a common input plane and a record in the physical output units. The corrected comparison answers whether the external signal estimate changed; the raw comparison helps show whether the receiver actually changed gain or noise. If both cannot be reconstructed, a later analyst may be unable to distinguish an intentional attenuator correction from an unexplained level shift. Retaining the instrument settings as text or machine-readable metadata is more reliable than relying on a screen image whose annotations may be incomplete.

An unresolved challenge is still a useful result. If increasing attenuation suppresses both an apparent product and the desired reference below the measurement floor, the observation does not establish the product's origin. If two states produce different noise but also different bandwidths, repeat with matched bandwidth or account for the difference explicitly. State which competing explanations remain. This disciplined endpoint prevents a plausible front-end story from becoming a stronger claim than the test supports, and it supplies the artifact review in Chapter 16 with evidence that can be reexamined.

Copyright 2026, James M. Atkinson

3.11 Verification and Maintenance Controls

Front-end verification is repeated after cable changes, filter substitution, overload events, firmware updates, battery replacement, and transport between sites. Reference sweeps and two-tone tests are compared with accepted baselines using serialized accessories and controlled torque. Differences that exceed uncertainty are investigated before the path is returned to service.

Maintenance records distinguish ordinary wear from hidden configuration changes. Attenuator contacts, relay isolation, filter tuning, bias current, limiter leakage, connector damage, and thermal drift can alter performance gradually. The receiver system is released with known limitations and a documented frequency and level range rather than a blanket statement that it passed.

3.12 Quantitative Model for RF Front Ends, Preselection, Gain Distribution, and Input Protection

Equation 3. Linear cascaded gain

$$G_{\text{total}} = G_1 \times G_2 \times \cdots \times G_n$$

Total available power gain in linear units is the product of stage gains when reference impedances and mismatch conventions are compatible. In decibels, gains and losses add algebraically. The relation does not establish headroom or linearity.

Equation 4. Input power after front-end correction

$$P_{\text{stage,dBm}} = P_{\text{input,dBm}} - L_{\text{filter,dB}} - A_{\text{att,dB}} + G_{\text{LNA,dB}}$$

Power entering the next stage equals input power minus filter loss and switched attenuation plus amplifier gain. Each term is frequency, temperature, and state dependent, and the result must be compared with compression and damage limits.

Equations 5 and 6 reuse the scalar gain chain of Model 2B. Its ten applications and the gain-interval discussion in this chapter show why a noise calculation must be paired with a separately justified upper signal-level limit. A positive power gain is dimensionless in Equation 5; the signed corrections in Equation 6 are numerical values in decibels.

Table 2. Chapter 3 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Preselector	Passband, rejection, insertion loss, switch state, and group delay	Reduces out-of-band energy before vulnerable stages	May suppress broadband or frequency-agile signals

Copyright 2026, James M. Atkinson

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Input attenuation	Actual step loss, flatness, repeatability, and placement	Provides headroom and a linearity challenge	Uncorrected traces cannot be compared directly
Preamplifier	Gain, noise figure, intercept, compression, bias, and stability	Can improve sensitivity when placed before loss	Can oscillate or generate intermodulation in strong environments
Protection network	Peak rating, recovery, insertion loss, leakage, and post-event check	Reduces damage risk	May create distortion or remain degraded after an overload

3.13 Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection

A front end contains a 2.1 dB filter loss, 10.0 dB attenuation, and a preamplifier with 17.5 dB gain. A -62.0 dBm antenna-terminal signal reaches the mixer at -56.6 dBm. If the mixer's input compression begins near -25 dBm, the nominal headroom is 31.6 dB, but strong out-of-band signals must be included in the total power and intermodulation assessment.

Copyright 2026, James M. Atkinson

3.14 Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection

A suspected 1.2 GHz emitter appears only with the broadband input selected. Switching to a measured 1.0-1.4 GHz preselector removes the component, even though the filter passes the displayed frequency with less than 2 dB loss. A two-tone test reproduces the component from strong signals at lower frequencies. These observations support a receiver-product hypothesis. Assigning the product specifically to the receiver front end still requires bounding source and combiner products at the receiver plane and verifying the desired-reference transfer through both input states, as discussed in Model 11A.

Copyright 2026, James M. Atkinson

3.15 Additional analytical treatment: the input plane as a coupled nonlinear system

A receiver-front-end arrangement should not be characterised merely by adding the nominal gains printed beside its component symbols. Its function is to preserve a specified property of incident electromagnetic energy in the presence of competing energy, mismatched interfaces, component memory and uncertain physical conditions. That statement begins at a declared electrical reference plane, for example the coaxial connector at the enclosure boundary. Antenna-terminal power may differ from power incident upon that connector because the preceding cable and protection assembly has both dissipative and reflected loss. The expression for a scalar input power budget is justified only when the quantities are compatible, the impedances are specified and the components are operating within the linear regime. Otherwise the description must use incident and reflected waves or another verified nonlinear model. A device's gain in a catalogue is not a sufficient identification of the device's measurement state.

The correct primitive observation is the time-dependent voltage or travelling-wave combination at the receiver's measurement plane, together with its spectral content and uncertainty. A strong distant transmitter may contribute power far outside the narrow frequency range currently displayed on the analyser. Before preselection, that power can load an input limiter, protection switch, preamplifier or mixer. Thus an apparently empty displayed span can coexist with a crowded physical front end. An operator seeking a faint emission must define the complete incident frequency range relevant to overload, not merely the display's centre frequency and

Copyright 2026, James M. Atkinson

resolution bandwidth. The scope of that range should follow from filter rejection, active-device frequency response and the credible environmental source distribution. Where total incident power cannot be measured, the resulting limitation belongs in the conclusion.

A simple representation introduces x(t), the voltage waveform at a declared input reference plane; s, the hardware configuration state; T, the component temperature state; and H[s,T]{x(t)}, the transformation from that waveform to the analogue converter input. A measurement y(t) may be expressed as y(t)=H[s,T]{x(t)}+n(t) when an additive-noise approximation is valid. Here n(t) is the effective noise after the modelled transfer, not automatically a stationary Gaussian process. If H depends on previous inputs because of limiting, bias recovery, thermal drift or gain feedback, a time-invariant transfer function is insufficient. In practice one measures local responses to controlled small signals while varying blocker amplitude and time history. A defensible investigation does not infer linearity from a quiet display. It directly tests the range of inputs for which the local approximation remains acceptable.

Input protection must be analysed through three observations with different acceptance criteria. The first is survival: no irreversible damage from the stipulated maximum exposure. The second is leakage: the voltage or power allowed to reach a vulnerable downstream node while the protection element is operating. The third is recovery: the elapsed time until the protected chain again meets a predefined weak-signal measurement specification. Meeting the first criterion does not establish the other two. A limiter may preserve an amplifier from damage but retain trapped charge, alter its impedance or provoke a downstream automatic gain reduction long

Copyright 2026, James M. Atkinson

after the triggering pulse has ended. The report must declare its recovery criterion in observable terms, for example whether a low-power reference has returned to its initial amplitude within a stated tolerance and whether its variance has returned to a validated range.

A field acceptance test should therefore bracket all consequential state changes with a repeatable control. Begin with an authorised reference at a known plane and measure gain, noise and response time before exposure. Apply the bounded challenge waveform through a calibrated combining network, record the actual delivered level and monitor the receiving chain without exceeding component limits. Remove the challenge, restore the identical reference settings and record the return to the prior validated state. Repeat with the preselector and attenuator alternatives required by the operating plan. If the observed change follows a cable or amplifier substitution rather than the suspected external source, that differential result provides evidence about the chain, not necessarily about the nature of the outside environment. It also provides a stronger safeguard against attributing receiver-generated products to third-party apparatus.

Copyright 2026, James M. Atkinson

3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings

The phrase maximum input level is ambiguous unless the duration, frequency distribution, impedance, state and acceptance criterion are supplied. Continuous single-tone power may be constrained by amplifier compression or heating; pulsed energy may be constrained by a transient voltage rating, protective recovery or peak current; a strong out-of-band signal may exceed the tolerance of a broadband input switch even when a following preselector is capable of excellent rejection. Moreover, two strong tones can create third-order products inside an input amplifier while the desired frequency itself receives only modest incident energy. Maximum safe exposure, maximum linear input and maximum signal level for accurate amplitude estimation are consequently three different boundaries. They cannot be substituted for one another in a technical survey report.

Define P_B as the sum of powers of all blockers reaching the vulnerable device plane, P_D as the power of a desired test tone at that same plane, G as the linear power gain, and P_{1dB} as the measured output power at which gain has compressed by 1 dB under the stated stimulus. A first-order screening calculation may compare P_B+P_D to an extrapolated small-signal output, but the relation is not a complete guarantee when blockers differ in frequency, crest factor or phase. For uncorrelated continuous powers, sum in milliwatts before converting back to dBm. For coincident coherent voltages or strongly peaked waveforms, evaluate the envelope or another appropriate peak criterion. The amount of headroom should be the difference between a justified operating threshold and the worst relevant input at the same node, after all path corrections. It is not the difference

Copyright 2026, James M. Atkinson

between a receiver's input terminal rating and a displayed peak that has already undergone filtering.

Preselection is effective only if it acts before the susceptible stage. A selective filter positioned after a nonlinear amplifier cannot remove intermodulation products already created by that amplifier when those products fall within the desired passband. The filter may still protect a later converter but does not retroactively protect the earlier stage. Similarly a digital filter following an ADC cannot repair clipping that occurred at its analogue input. In a mixed architecture the correct order may deliberately sacrifice some small-signal noise performance to prevent irreversible overload. The gain and loss budgets must be evaluated simultaneously, because filtering loss can worsen minimum detectable level while blocker rejection can restore validity over a much larger operating region.

The filter itself should be treated as an imperfect and potentially history-dependent component. A passive tuned filter has measured insertion loss, return loss, stopband leakage, group delay and temperature dependence. A switched filter bank introduces finite switching time, transient leakage and possible contact-related intermodulation. A tracking filter depends on a tuning law which can be offset from the instrument's indicated frequency. A filter chosen solely for narrow nominal bandwidth may deform a pulsed event, because the waveform's spectral sidebands extend beyond its carrier. For short-burst measurement the acceptance criterion must include amplitude and temporal shape, not simply the survival of a monochromatic tone at the centre frequency.

An informative blocker challenge holds the desired reference fixed while varying one blocker parameter at a time. The operator records attenuation,

Copyright 2026, James M. Atkinson

input and output power at declared planes, measured filter state, detector configuration, ambient temperature and the receiver's instantaneous gain-control state. Three questions are answered independently. Does the desired reference remain detectable? Does its measured amplitude or spectral shape remain within stated tolerance? Does the purported unknown emission change in a manner consistent with an internally generated artifact? Failure of one test does not necessarily establish the physical identity of the event. A spectral component that disappears when the blocker is attenuated may be a mixing product, a blocker-dependent gain artifact or a genuine weak signal rendered undetectable by the changed noise floor. Further controls are required to distinguish those explanations.

Copyright 2026, James M. Atkinson

3.17 Noise, mismatch and gain-order dependencies

The ideal Friis cascade equation applies to properly specified available-power gains and noise factors under its source and impedance assumptions. Let F_i denote the linear noise factor of stage i and G_i the linear available gain of stage i. For three stages, $F_{total} = F_1+(F_2-1)/G_1+(F_3-1)/(G_1 G_2)$. The familiar result that the first stage dominates follows only while G_1 is high enough and the first stage is operating normally. A preamplifier driven into compression does not preserve that calculation's small-signal validity. Likewise noise figure is not an estimate of environmental interference. The antenna may deliver externally generated noise or multiple transmitters far above the nominal thermal reference, and the operator should not confuse a favourable catalogue noise factor with quiet operating conditions.

Loss before the first amplifier matters disproportionately because it attenuates the signal before gain is available. For a passive matched attenuator with linear loss L at the standard reference temperature, its noise factor equals L under the conventional assumptions. At a different physical temperature, the device's equivalent input noise temperature changes and should be handled explicitly if uncertainty warrants. A filter with two decibels of loss can substantially alter the noise budget, but its rejection of strong out-of-band signals may prevent a much greater loss of useful dynamic range. Good front-end design therefore seeks the feasible region in which input-referred noise, blocker tolerance and protected-stage survival are all acceptable. Maximum gain is rarely an adequate optimisation objective.

Copyright 2026, James M. Atkinson

Mismatch is another reason a scalar level correction can be misleading. At a two-port connection the incident and reflected travelling waves depend upon source and load reflection coefficients. The power actually delivered to a device differs from a source's available power when the port match is imperfect, and changes in a preselector or cable can alter this ratio. A calibrated sensor that measures power at one connector may not establish the available power presented by an antenna with a different source impedance. Measurements intended for rigorous comparison should record reflection or return-loss information at relevant states, retain the fixture configuration and avoid comparing values reported to different power conventions. An input pad can improve match while adding loss, so a gain correction must not be mistaken for restoration of the signal-to-noise ratio or the physical available power.

A practical uncertainty ledger distinguishes correction uncertainty from repeatability. For a simple corrected reading, $P_{input,dBm} = P_{display,dBm} - L_{gain,dB} + L_{cable,dB} + L_{filter,dB}$, where the chosen signs depend on the actual direction of the calibration reference planes. This expression assumes the receiver gain is defined as output minus input, while cable and filter losses are positive attenuation magnitudes. If those correction quantities are independent, their standard uncertainties may be combined in quadrature. If they share a calibration source, reference attenuator or frequency-dependent model, covariance terms are required. Treating shared errors as independent can create an unrealistically narrow uncertainty interval. Receiver gain and filter loss may even move in the same direction with temperature. The quality of the uncertainty budget rests upon identifying those dependencies before performing arithmetic.

Copyright 2026, James M. Atkinson

3.18 Protective switching, recovery and transient exclusion intervals

A receiver should retain a state-transition record when protection relays, limiters, tunable filters and gain-control loops are operated in the course of a survey. The record should identify the command time, the observed hardware transition time if available, and any period for which the output cannot meet the relevant measurement acceptance criterion. These times need not coincide. A host timestamp may correspond to the delivery of a software command while the electromechanical switch continues moving; an ADC may continue sampling the transition; a detector may average across states. If the instrument silently retains samples during this interval, a later analyst may mistake switching transient energy for an event from the external environment. Exclusion intervals should be justified by laboratory measurements, not invented after an unexplained detection.

Protection components can exhibit distinct recovery laws. A fast RF switch may settle quickly in isolation yet leave a gain-control loop recovering slowly. A limiter may recover promptly for a small challenge but exhibit delayed return after a stronger or longer pulse. A charge-storage device can behave differently when two pulses arrive in close succession. Consequently recovery time should be specified over a bounded operating envelope, including challenge amplitude, pulse width, duty cycle, temperature and the defined tolerance for the weak reference signal. An unqualified single recovery-time number risks implying that every operating history has the same effect.

The experimental record should include both positive and negative controls. A positive control deliberately exercises the protection function with a signal

Copyright 2026, James M. Atkinson

known to exceed the chosen intervention threshold while remaining within the apparatus' safe operating limits. A negative control repeats the test with a lower-level stimulus that should not cause intervention. A reference receiver, where properly isolated, may distinguish an actual external pulse from an internal switching transient. Yet a shared power supply, reference clock or test combiner can contaminate both instruments, so apparent agreement must still be challenged. Whenever possible use a different input path or independent monitor with separately characterised limitations.

A reversible data record preserves the raw trace, the timing of each state transition, the calibration terms and the reason for excluding a segment from quantitative analysis. The derived record may mark a portion invalid without deleting it, subject to lawful retention and minimisation constraints. This avoids the twin mistakes of falsely treating corrupted samples as trustworthy measurements and silently removing data that a future reviewer may need to understand an apparent anomaly. A robust report identifies the measurement state in which each conclusion was reached and refuses to bridge an unobserved transition by speculation.

3.19 Ten worked front-end engineering examples, with stated assumptions

Copyright 2026, James M. Atkinson

3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget

Suppose a matched front end receives a -67.0 dBm reference tone at the specified input plane. An input filter has 2.3 dB insertion loss at that frequency, a selected attenuator has 6.0 dB attenuation and a preamplifier provides 18.2 dB gain. All parts are assumed linear at the applied power. The estimated power at the amplifier output is -67.0-2.3-6.0+18.2 = -57.1 dBm. If the following converter has a maximum calibrated linear input of -25.0 dBm, nominal headroom relative to this reference tone is 32.1 dB. That result does not mean an additional +32.1 dB of arbitrary environmental interference can be tolerated: signals outside the displayed band may reach the amplifier, and large multi-tone or pulsed inputs may create distortion at lower total power. The correct acceptance statement identifies the particular -67 dBm tone and the stipulated matched, linear state. A blocker test is required before extending it to an RF survey environment.

Copyright 2026, James M. Atkinson

3.19.2 Example 3.C2. Converting two blockers to a single equivalent power

Two uncorrelated continuous blockers arrive at a particular vulnerable amplifier input with powers of -18.0 dBm and -21.0 dBm. Converting to milliwatts gives 10^(-18/10)=0.01585 mW and 10^(-21/10)=0.007943 mW. The sum is 0.02379 mW, equivalent to 10 log10(0.02379)=-16.24 dBm. Adding the two values as if dBm were ordinary linear numbers would be physically meaningless. If the device's tested maximum linear input for this stimulus family is -14.0 dBm, the simple power margin is 2.24 dB. That margin is small enough that measurement uncertainty, another unobserved blocker, modulation crest factor or phase coherence might change the conclusion. This calculation concerns incoherent average powers and does not establish the peak voltage of a phase-related multi-tone waveform.

Copyright 2026, James M. Atkinson

3.19.3 Example 3.C3. Why filter placement changes intermodulation validity

A broadband amplifier precedes a bandpass filter. At its input two equal unwanted tones are each -22 dBm, and a small-signal input third-order intercept of +8 dBm has been measured under a specified equal-tone test. Under the conventional weak-distortion approximation, the third-order product from one fundamental is $P_{IM3} = 3 P_{tone} - 2 IIP3 = 3(-22)-2(8)=-82$ dBm referred to that amplifier input. Suppose the following bandpass filter passes the resulting product at the frequency under examination. Its attenuation of the two original blocker tones cannot remove the product already generated. If a suitable preselector were moved before the amplifier and suppressed each original blocker by 15 dB, the same approximation predicts $P_{IM3} = 3(-37)-16=-127$ dBm at the amplifier input reference. The 45 dB predicted product difference illustrates why component order matters. It remains conditional on constant IIP3, equal-tone validity and the source-combining network not creating its own products.

Copyright 2026, James M. Atkinson

3.19.4 Example 3.C4. Input attenuation as an overload intervention

Assume an otherwise linear receiver shows a faint spectral component at -96 dBm displayed, while its wideband input is illuminated by an unmeasured powerful transmission. The operator inserts a calibrated 10.0 dB input pad. A genuine weak signal that follows the ordinary linear gain path should be reduced by approximately 10 dB before any software correction, provided the added attenuation does not move it below the noise or alter the detector decision. A receiver-generated third-order product produced after the pad may decrease by approximately 30 dB under the usual two-tone weak-distortion model. A change larger than the desired tone's change is therefore a diagnostic clue, not proof. The operator must compare raw levels, noise and corrected input-referred values, and should repeat with more than one attenuation state. If the purported component disappears entirely, the correct initial finding is that it is state-dependent and unresolved, not that a particular external transmitter has been disproved.

Copyright 2026, James M. Atkinson

3.19.5 Example 3.C5. Passive filter loss and the first-stage noise factor

Take a passive matched filter whose insertion loss is 2.0 dB at the measurement frequency and whose physical temperature is close to the conventional noise reference. Its linear loss is L=10^(2/10)=1.585, so its approximate noise factor is 1.585. Follow it with an amplifier of 15 dB gain and 1.5 dB noise figure. The amplifier's linear noise factor is 10^(1.5/10)=1.413 and its gain is 31.623. Referred to the filter input, the two-stage cascade is F_total=L+(F_amp-1)/G_filter, where G_filter=1/L=0.631. Hence F_total=1.585+0.413/0.631=2.239, equivalent to a 3.50 dB noise figure. This result is consistent with a filter loss adding approximately 2 dB to the amplifier noise figure under the stated matched, reference-temperature conditions. It is not a substitute for a noise measurement when the filter's temperature or mismatch differs appreciably.

Copyright 2026, James M. Atkinson

3.19.6 Example 3.C6. Comparing attenuation ahead of and after an amplifier

Consider a reference chain with a 20 dB low-noise amplifier and a 10 dB attenuation pad, both well matched. Its net small-signal gain is 10 dB regardless of the pad's position. Yet the consequences differ. With the pad before the amplifier, an input blocker of -5 dBm reaches the amplifier near -15 dBm. With the pad after the amplifier, the same blocker reaches its input at -5 dBm and may overload it even though the final output level is nominally identical. Moreover, the preceding pad increases the input-referred noise factor of the system, whereas a pad after a sufficiently high-gain low-noise amplifier ordinarily contributes less to the overall noise factor. This example illustrates a trade-off, not a universal preference for one ordering. In a high-blocker environment the lower-noise configuration may be physically invalid unless preselection or another protective measure is introduced.

Copyright 2026, James M. Atkinson

3.19.7 Example 3.C7. A conservative frequency-dependent correction

A reference source delivers -80.0 dBm at an antenna-port test fixture. The cable loss measured at the target frequency is 3.1 dB and an input filter contributes 1.7 dB, both expressed as positive loss. The receiver input therefore receives an estimated -84.8 dBm, ignoring mismatch. Suppose the displayed receiver result, corrected for its internal calibrated gain, is -84.5 dBm. The 0.3 dB disagreement is not automatically significant. If the standard uncertainties of source level, cable loss, filter loss and corrected receiver level are respectively 0.2, 0.15, 0.12 and 0.25 dB and are genuinely uncorrelated, their root-sum-square is sqrt(0.2^2+0.15^2+0.12^2+0.25^2)=0.374 dB. A 0.3 dB discrepancy is smaller than that combined standard uncertainty. Shared source and receiver calibration would require a covariance-aware treatment and could change the inference.

Copyright 2026, James M. Atkinson

3.19.8 Example 3.C8. Recovery time after a protective intervention

A calibrated low-level reference remains present while a lawful laboratory pulse activates an input protection element. Before the challenge, the corrected reference amplitude is -70.0 dBm and a short-window measurement variability has been characterised. The acceptance criterion is restoration within +/-0.5 dB of the baseline for at least five consecutive 1 ms analysis windows, without a renewed overload indication. After the pulse, the first windows fall at -73.0, -71.5, -70.6, -70.3, -70.2, -70.1 and -70.1, -70.0 dBm. The first qualifying five-window sequence begins with the fourth value, because the third differs by 0.6 dB. With nonoverlapping 1 ms windows and known alignment, the candidate recovery interval begins with the fourth window and is confirmed only after the eighth observed window. The actual recovery interval is bounded by the timing resolution and window origin; the numbers do not establish phase or waveform-shape recovery. An independent noise-variance test remains necessary if that too is required by the measurement.

Copyright 2026, James M. Atkinson

3.19.9 Example 3.C9. A mismatch screening calculation

Suppose an interface has an effective magnitude of reflection coefficient |Gamma|=0.20 relative to the declared reference impedance. The reflected power fraction is |Gamma|^2=0.04, or 4 percent, while the nonreflected fraction in the simplified single-interface model is 0.96. The corresponding mismatch-only loss is -10 log10(0.96)=0.177 dB. That result does not predict the entire mismatch error of a source connected through a two-port network, because the source reflection coefficient, electrical phase, standing-wave relationships and frequency-dependent transfer also matter. It provides a limited screening result: even an apparently modest return loss can introduce a correction whose significance depends on the required amplitude uncertainty. A careful investigator retains the complex scattering parameters or a validated mismatch uncertainty model rather than applying one universal 0.177 dB correction.

Copyright 2026, James M. Atkinson

3.19.10 Example 3.C10. Selecting a feasible gain interval

A nominal desired signal arrives at -100 dBm and the following converter's calibrated minimum useful level is -78 dBm. The necessary net gain for this nominal desired signal is at least 22 dB. Independently, a worst-stipulated blocker arrives at -12 dBm and the first vulnerable downstream component must see no more than -20 dBm to remain within its validated linear range. That condition requires net gain of at most -8 dB along the blocker's path. If the architecture provides the same gain to both frequencies before any selectivity, no single scalar gain meets both bounds. The appropriate design response is to change the front-end topology, provide frequency-selective attenuation, obtain more intrinsic dynamic range, or alter the observation arrangement. Pretending that the 22 dB desired-signal gain can coexist with the -8 dB blocker constraint would conceal an empty feasible interval. Any new filter must be tested for both desired insertion loss and blocker rejection.

Copyright 2026, James M. Atkinson

3.20 Laboratory decision protocol and defensible reporting

A complete front-end report should include a configuration schematic identifying the input and output planes, a state table for each switchable signal path, the serial or traceable identifier of each consequential component, a calibrated small-signal transfer measurement, and a separate challenge record for nonlinear and time-dependent behaviour. A useful state table has fields for filter path, gain stage, attenuation, limiter state, detector mode, reference clock, temperature, measured noise baseline, and the beginning and end of each observation interval. Values inherited from a previous survey are not silently reused after cable substitution, thermal excursion or overload. The report also identifies any interval in which input conditions exceeded the validated apparatus envelope, including intervals inferred from status flags rather than continuously measured incident power.

Before a component is attributed to an unknown external emitter, the laboratory should ask whether a different combination of filter state, input attenuation, reference antenna and independent receiver gives a consistent input-referred result. Agreement should not be manufactured by correcting away actual discrepancies. When two arrangements share the same input switch, reference clock or power source, their errors may be correlated; a claim of independent corroboration must account for that commonality. A negative challenge may show only that an internal artifact hypothesis has not been reproduced under the tested conditions, not that every possible internal cause has been excluded. Conversely a reproduced artifact under controlled injection can support a much narrower and more useful

Copyright 2026, James M. Atkinson

conclusion: the particular measured feature is consistent with a documented front-end failure mode.

The end product is a bounded finding with four separate elements: the observation itself, the verified measurement state, the controls that failed or supported alternative explanations, and the uncertainty that limits inference. That formulation is more robust than a confident description built solely around a colourful spectral display. It remains readable to a technically qualified independent examiner and supplies a path for reanalysis if later information about the source, calibration or lawful scope becomes available. Every illustrative calculation in this extension is hypothetical. It is not evidence of measured performance of the reader's instruments; the appropriate field limits must be established on the actual hardware and configuration.

Copyright 2026, James M. Atkinson

3.21 Multitone loading, receiver-generated emissions and the distinction between power and voltage stress

One of the most persistent errors in field receiver selection is the assumption that a small number on the display reflects a correspondingly small voltage at every preceding analogue component. In a multi-emitter environment, the highest instantaneous stress may be created by signals that the chosen tuning and display configuration deliberately exclude. A first-stage switch designed to cover an octave may receive the combined energy of broadcast, communication and industrial emissions even when the selected channel is only a few kilohertz wide. An electrical model of loading must therefore specify whether its limit is expressed in total average power, peak envelope power, peak voltage, current, junction temperature, intermodulation distortion or a recovery-dependent validity criterion. Those limits describe different physical mechanisms, and a single catalogue rating cannot be safely treated as a bound on all of them.

To distinguish the mechanisms, consider a two-tone source whose tones have equal powers P_1 and P_2 and phases ϕ_1 and ϕ_2. The average power into a matched linear resistor is additive when averaging over a suitable observation interval, but the instantaneous voltage is the algebraic sum of the waveforms. At some instants the two voltage components reinforce. When several tones have related phases, the peak-to-average ratio can rise substantially above that of one sinusoid. For modulated signals, peak envelope power may vary with symbol sequences and with the distribution of occupied subcarriers. Consequently an amplifier chosen on the basis of average-input headroom may saturate briefly on rare peaks and produce error bursts in the digital record. An acceptance test should include

Copyright 2026, James M. Atkinson

the relevant peak statistics, preferably using a separately verified source waveform rather than assuming that two nominally equal average powers create an identical envelope under every phase relation.

Third-order intercept values deserve similarly careful treatment. The familiar extrapolation for an input-referred third-order product from equal tones is a useful local model while the amplifier is weakly nonlinear and the products are significantly below the fundamentals. It is not an independent physical guarantee of dynamic range under arbitrary modulation, wide separation, temperature, or saturation. The extrapolated line would falsely suggest increasing product growth without limit if extended through compression. A real receiver can exhibit additional memory terms, bias variations, filter selectivity and gain-control responses. The investigator therefore needs a measured distortion-versus-level curve over the actual operating region, and should recognise that adjacent-channel regrowth may differ from the ideal products of a narrow two-tone experiment.

Second-order responses have different frequency geometry. Their sums and differences may fall into the desired band even when neither fundamental lies near it. Harmonics can likewise enter through imperfect image rejection or a later mixing mechanism. A sufficiently wide frequency survey of the physical front end is therefore needed to formulate competing internal-artifact hypotheses. This does not authorise unrestricted collection of unrelated communication content. Suitable laboratory substitutes, controlled known sources and aggregate power monitors can establish the chain's susceptibility while respecting the authorised purpose. A test result should state exactly which source family, level interval and hardware

Copyright 2026, James M. Atkinson

configuration produced the measured product, rather than suggest that all possible interferers have been excluded.

The combining apparatus itself must be challenged. Two signal generators joined through inadequate isolation can mix in the output stages of one another or within a damaged combiner, creating a product before the receiver under test. If that upstream product is not independently measured or bounded, its appearance at the receiver cannot prove the receiver generated it. A high-quality test uses suitable isolation, independently characterised path levels and a reference monitor connected at a carefully specified plane. The reference monitor has its own finite dynamic range, so it too must be tested for internal products under the challenge conditions. This is an unusually important source of false certainty: an investigation may otherwise demonstrate only that two nonideal test instruments interact, not that the field receiver is intrinsically defective.

3.22 Front-end noise spectroscopy as an instrument-state test

A receiver's displayed noise floor is a property of its entire measurement configuration, including the source impedance, analogue transfer function, detection and estimator bandwidth, gain-control state, averaging, digitiser scale and any digital correction. A calibrated noise factor is normally defined relative to a specified input noise temperature under particular reference conditions. It is not an instrument's universal minimum observable signal. An electrically quiet terminated input, for example, provides information about internally generated noise but may not represent the environmental noise arriving from an antenna. A low-noise preamplifier can improve a chain's input-referred noise figure while simultaneously increasing susceptibility to a strong ambient transmission. The resulting sensitivity must be evaluated as a conditional detection problem, not as a fixed property printed on the instrument panel.

An appropriate baseline measurement begins with a characterised source at the intended reference plane. A matched termination of known temperature can establish an internal reference state; a known calibrated noise source permits comparison across states; and an independent low-level test tone or modulated waveform can connect the noise statistics to an actual decision threshold. The relevant noise quantity should be computed in the equivalent noise bandwidth of the estimator, not inferred by multiplying arbitrary displayed bin spacing by a spectrum marker. For a filter whose magnitude response is H(f), an effective noise bandwidth can be expressed as the integral of |H(f)| squared across frequency divided by the square of an appropriate peak gain, with the exact formula depending upon the gain

Copyright 2026, James M. Atkinson

convention. This bandwidth may differ from the nominal resolution-bandwidth label and can change across filter families or software revisions.

Noise measurements also require attention to drift and dependence. Thermal changes can alter gain and noise factor gradually, while intermittent blocker loading can create abrupt changes or long recovery tails. A single pre-survey noise figure does not show that the same distribution prevailed throughout a day-long capture. Retain state-tagged baseline samples at chosen intervals, record ambient temperature where meaningful, and compare changes against the predicted calibration and uncertainty model. Where a data record shows large spectral occupancy variations, the investigator must distinguish changes in background energy from changes in receiver gain. Using a digital correction to hold the displayed noise floor constant can disguise a real loss of sensitivity if the underlying analogue signal has become compressed or if a gain-control stage has reduced both desired signal and interferer.

The relationship between bandwidth and the noise power is a useful check. Under a thermal white-noise approximation at a specified reference temperature, noise power is proportional to bandwidth. Doubling the equivalent bandwidth increases expected noise power by approximately 3.01 dB. If two otherwise identical settings differ by 10 in equivalent noise bandwidth, the expected integrated noise-power difference is approximately 10 dB. This does not imply that the ratio of probability-of-detection thresholds is precisely 10 dB, because the threshold also depends upon noise distribution, false-alarm constraints, temporal integration and waveform structure. It does expose contradictions in a purportedly

Copyright 2026, James M. Atkinson

calibrated noise record: a noise-floor comparison across different bandwidth settings is invalid if the bandwidth dependence has not been accounted for.

A high quality evaluation does not simply produce a single lowest-noise number. It maps the feasible region: input-referred noise versus blocker level, gain state, frequency, temperature and detector algorithm. The measured result can be represented as a multidimensional acceptance surface with clearly defined interpolation limits. If no observations exist near a high-power corner, that corner should remain unqualified rather than populated by a confident extrapolation. A defensible conclusion may show that a narrow preselector state delivers lower detection threshold under a specified blocker while the broadband state performs better in a quiet laboratory. This is not contradiction; it is configuration-dependent performance, and the report should preserve that distinction.

3.23 Switching architectures and state-machine validity

The physical implementation of preselection determines what it can and cannot guarantee. A tracking filter tuned with the receiver's local oscillator may offer strong rejection of remote interferers but can introduce tuning error, settling delay and amplitude ripple. A switched filter bank may offer rapid operation across selected ranges but presents transitions at band edges, finite relay or semiconductor isolation, and different loss characteristics in each branch. A fixed multi-band network may be robust but less selective in a highly occupied environment. There is no universally correct topology because the objective may be to characterise a narrow transmission, detect a very short broadband pulse, or monitor many noncontiguous services with unequal probabilities of occurrence.

An instrument whose preselector state changes automatically has a time-dependent measurement operator. The state transition may be commanded in software, applied by hardware after an uncertain delay and confirmed only when an internal control signal settles. The software's recorded timestamp may refer to the command rather than the actual RF path. A rapid-frequency scanner might therefore attribute energy received during a transition to the next channel even though the analogue filter had not reached that state. This failure may generate a convincing event list whose frequencies appear exact to the nearest programmed tuning step. A validity window should be derived from test observations of the complete switching path and extended by appropriate timing uncertainty. The interval must be excluded or separately marked in the analysis, without silently deleting raw source records where lawful preservation is required.

Copyright 2026, James M. Atkinson

A state-machine acceptance test can deliberately command rapid transitions while a fixed, authorised test tone remains present. The signal's apparent frequency, amplitude and event time are compared with a simultaneously recorded independent reference. The test repeats with a tone near each filter transition, because the most consequential errors frequently occur at the edges rather than in the centre of a nominal passband. It also tests absent-signal cases. A receiver that produces a spurious peak during a relay movement may otherwise be mistaken for a detector that faithfully caught a rare short burst. The tested conditions should include temperature excursions, supply variation within rated limits and repeated operations sufficient to reveal intermittent switch contact behaviour.

A practical design may use two measurement paths. The main receiver scans or switches preselectors to achieve acceptable sensitivity and blocker rejection; an independently characterised auxiliary receiver monitors an appropriate wider band to detect events that occur during the main path's blind intervals. This can improve situational awareness, but it does not create perfect coverage by definition. The auxiliary path may have poorer dynamic range, different time stamping or a shared antenna front end that fails under the same blocker. Its detections can be valuable triggers for a subsequent controlled measurement, yet an event visible only on the auxiliary path must be reported with that path's own calibration and limitations. The system must not borrow precision or attribution capabilities from the main receiver when those observations were never actually made.

A recording system should preserve machine-readable state information, preferably aligned to the hardware's own acquisition counter rather than to an operating-system wall clock alone. It should identify the filter path, relay

Copyright 2026, James M. Atkinson

state, gain, attenuation, limiters, ADC validity flag, clock discipline and any estimated missing-sample intervals. This record provides a basis for reconstructing which measurements were lawful and technically qualified at each instant. It also permits later investigators to challenge a classification decision without changing the original observations. State identity is part of the measurement, not an optional engineering diary.

Copyright 2026, James M. Atkinson

3.24 Low-level event survival under analogue filtering

Preselection is sometimes proposed as though narrow passband transmission and high stopband rejection were sufficient to preserve every legitimate event. That is inadequate for short transients. A burst's energy is spread over a bandwidth related to its duration and modulation; rapidly changing waveforms contain sidebands which may be outside a narrow preselector. A filter can preserve an apparent carrier frequency while attenuating the edges, extending the pulse in time, changing phase and creating ringing. A detector that reports the resulting duration may therefore be reporting the instrument's impulse response rather than the original source's emission interval. The needed acceptance criterion must specify the allowable changes in amplitude, delay, envelope or correlation statistic for the relevant waveform class.

An elementary linear model represents the output y(t) as the convolution of the input x(t) with a measured impulse response h(t). The convolution model is justified only if the filter behaves approximately linearly and time invariantly over the observation interval. In practice a highly selective tracking filter may be changing its centre frequency while the burst arrives, so a single fixed h(t) may be invalid. A state-indexed family of responses, with explicit transition intervals, is more defensible. If a receiver measures only the magnitude of a transformed waveform, phase information necessary for an exact inverse may already be absent. Similarly, if the filter has practically zero transmission over some spectral region, recovering that portion of an arbitrary unknown waveform may be ill posed. A reconstructed sharper pulse is not a restored original unless its assumptions and uncertainty are independently established.

Copyright 2026, James M. Atkinson

A useful test programme applies laboratory signals that deliberately exercise the boundaries of the intended interpretation. These may include a narrow continuous reference, a gated carrier, a chirp, a pulse train with changing duty cycle and an amplitude-modulated event with steep edges. Compare the output with an independently calibrated wideband reference at the same input plane. For each case retain insertion loss at relevant spectral components, apparent event duration, group-delay behaviour, trigger response and any ringing or post-pulse persistence. Vary the event start time relative to filter state changes. The resulting dataset can support a statement such as: within the tested duration and bandwidth region, a particular preselector state preserves the selected timing statistic within a bounded error. It should not support an unconditional claim that every possible unknown pulse is preserved.

A narrow-band measurement can remain valuable even if it does not preserve waveform shape. For example, detecting persistent energy near a suspected carrier may require neither time-domain fidelity nor phase coherence, provided the limited conclusion is explicit. But an investigator seeking to compare brief onset transients between devices must use a measurement chain and sampling arrangement capable of preserving those features. Choosing the receiver mode from the forensic question is therefore more important than choosing the smallest displayed resolution bandwidth. The same hardware may be fit for an occupancy claim and unfit for individual-emitter timing inference.

Copyright 2026, James M. Atkinson

3.25 Power-sensitive failure modes and fault isolation

A receiver may exhibit nonlinear products whose incidence depends on power-supply loading rather than on the nominal signal-path architecture. A high-level external pulse can change amplifier bias current, heat a protective device or disturb a shared supply rail. The resulting transient may leak into multiple nominally independent RF channels. If those channels share the same DC/DC converter or bias-control arrangement, coincident features do not constitute independent observations of one external emitter. A forensic test should vary one source of stress at a time, monitor relevant bias and supply states where permissible, and compare against a truly separate measurement path. A common power disturbance is an alternative hypothesis that must be considered whenever correlation appears unexpectedly perfect across many channels.

Mechanical and electromagnetic coupling also interact. A shielded enclosure is not a perfect abstraction if cable shields conduct current on their exterior surfaces, if panel seams create slot apertures, or if a connector is contaminated or incompletely tightened. An RF field may couple directly into a local oscillator or digital clock network and create a response that differs from ordinary antenna reception. An instrument whose antenna connector is terminated can still show a spectral feature from internal or enclosure coupling. A different terminated-input response is a useful challenge but not a universal proof, because the termination itself may change grounding or impedance. Multiple controls should be chosen to discriminate a physical coupling mechanism rather than to make the apparent event simply disappear.

Copyright 2026, James M. Atkinson

Conducted interference through mains supplies, network ports or peripheral cables may produce products which track external activity but are not radiation received by the intended antenna. The study should record whether changing an isolation arrangement altered only the suspected coupling path or also changed the receiver's reference and grounding. For example, removing a network cable might stop a periodic component while also terminating the data stream that produced the spectrum. That observation suggests a relationship, but does not settle whether the original feature was a genuine external RF emission, a digital harmonic, or a gain artifact driven by supply noise. The conclusion should be proportionate to the specificity of the control.

In an operational survey, the safest correction is often to improve the physical receiving chain rather than to perform increasingly elaborate software removal of unexplained peaks. Controlled input attenuation, validated preselection, sound connectors, independently measured shielding and proper reference-plane calibration can prevent misleading artifacts at the source. A software algorithm may flag likely spur families, but cannot repair analogue measurements whose provenance or linearity is unknown. Data-processing sophistication does not remove the need for elementary electrical checks. The audit trail should show which interventions altered the physical chain and which merely reinterpreted its records.

Copyright 2026, James M. Atkinson

3.26 A graded laboratory qualification matrix

Qualification should be tied to the intended measurement claim and should not consist of one undifferentiated pass or fail mark. A minimal receiver chain intended for approximate occupancy might require repeatable frequency coverage, a validated detection threshold and documented blind intervals. A chain intended for precise amplitude comparison additionally requires calibrated gain, impedance treatment and uncertainty over the relevant signal and blocker conditions. A chain intended for pulse timing requires an independently demonstrated impulse response, clock relation and trigger latency. A chain intended for direction finding needs antenna and phase-response controls outside the ordinary single-port receiver specification. Passing the first level does not imply passage at the higher levels.

One can express this as a set of measurement capability statements. Each statement has a measurand, the physical input reference plane, a frequency and level domain, applicable configuration states, a method for traceable testing and a bound on the resulting uncertainty. The statement should include exclusion conditions. A measurement may be valid for narrowband sinusoids under a low-blocker environment but unqualified for short unknown pulses in a congested spectrum. Such a statement is more useful than an inflated general capability claim because it allows the investigator to choose hardware for the actual question and to report explicitly when the apparatus operated outside its demonstrated envelope.

An especially revealing experiment combines a strong blocker with a desired weak event whose timing is unknown to the operator conducting the test.

Copyright 2026, James M. Atkinson

Randomise the event occurrence within the observation interval and retain all test trials, including those in which the detector reports nothing. If an operator retrospectively selects only successful examples, the apparent probability of detection will be overstated. Likewise a display that indicates a low noise floor after a long averaging interval may conceal brief desensitisation during blocker pulses. Independent monitoring and a time-resolved gain-state record are needed to distinguish absence of the event from receiver blindness. The analysis should report both event-detection performance and the fraction of time for which the receiver met its calibrated operating conditions.

The qualification matrix should be maintainable over the instrument's lifetime. After service, firmware updates, filter substitution, mechanical damage or major configuration changes, the affected capability statements should be revalidated. This does not require rerunning every conceivable test after a minor change, but it does require a documented technical argument identifying which measurements are sensitive to the alteration. A change to a display palette normally does not alter analogue gain, although it may affect an analyst's visual detection strategy. A firmware change to the preselector state machine or the digital detector can alter the measurement law and should be treated much more seriously. The change-control record must describe what actually changed rather than rely on an unqualified software version label.

Copyright 2026, James M. Atkinson

3.27 Evidence interpretation when the reference chain fails

A failure to qualify one interval should not force an examiner to discard all observations from the survey. Instead, segment the evidence according to what remained verifiable. In one interval the chain may support accurate received power; in another the receiver may have been overloaded but still show the temporal occurrence of a large event; in a third the acquisition clock may be invalid, making event ordering uncertain. These are different limitations. The report should preserve the observed data and explicitly identify which analyses remain supportable. A general declaration that the measurement is 'bad' may conceal valuable bounded information; a general declaration that it is 'good' may wrongly elevate a narrow observation into source attribution.

When an instrument displays a new spectral feature shortly after a high-power event, the investigator should consider protection recovery, oscillator pulling, gain-control persistence, bias shift, switching transients, cable nonlinearity and external propagation alternatives. Each hypothesis predicts different responses to controlled changes. Repeating the measurement with a separately characterised receiver can challenge internal-artifact hypotheses, but the two receivers should not share an unexamined vulnerable front end. Similarly, a second antenna may be affected by the same illumination geometry and common-mode cable paths. The most effective verification is not simply adding more instruments. It is designing an experiment whose outcomes discriminate among competing physical explanations.

Copyright 2026, James M. Atkinson

The case record should avoid retrospective certainty. An unexpected peak observed only once in a congested environment might be important, but if receiver state was unknown and the event was not independently captured, it may remain unclassified. The justified conclusion can identify its frequency region, apparent duration, display and configuration context, and the possible internal explanations that were not excluded. That statement preserves the opportunity for later analysis without claiming more than the evidence supports. In a legally sensitive context, the report also specifies the scope of authority, data minimisation measures and the custody of any retained technical samples. It must not convert the presence of RF energy into an allegation about a particular person, device or communication.

Copyright 2026, James M. Atkinson

3.28 Impedance-aware transfer functions, scattering parameters and network uncertainty

A front-end assembly that appears to be a simple series of components is, electrically, a network whose behaviour depends upon what drives it and what terminates it. The insertion loss of an RF filter measured between nominally matched ports is a property of that test configuration. If its source is later replaced by an antenna with a different complex impedance, the transducer transfer can change because of multiple reflections. The effect may be small in a well-matched laboratory, yet substantial near a filter resonance or in a cable system with strong standing waves. A technically persuasive record distinguishes the available power of the source, incident wave power at an interface, power delivered to the load and displayed power after digital correction. The numbers may all be expressed in decibels while referring to different physical quantities.

A two-port network can be represented by scattering parameters S11, S21, S12 and S22 at a chosen real reference impedance. S11 and S22 describe input and output reflection, S21 forward wave transmission and S12 reverse coupling, under their specified termination convention. For a linear passive network in its calibrated frequency region, a complex S21 measurement preserves phase information and can expose sharp group-delay changes concealed by a magnitude-only trace. For a network of multiple components, cascade computation may be performed using suitable chain parameters, provided singularities and measurement uncertainty are treated properly. The result should be checked against a direct measurement of the assembled chain, because connector repeatability,

Copyright 2026, James M. Atkinson

cable routing and reference-plane definition can introduce effects absent from individually tested modules.

Source and load reflection coefficients can create a mismatch factor that varies with electrical length. Rotating or moving a coaxial cable changes the phase of reflected waves at the same time that the external antenna geometry may change. It is therefore possible for an apparently stable input field to produce different receiver measurements after a seemingly innocuous cable replacement. This complicates inference from small amplitude changes. A practical response is to retain a confidence interval derived from measured reflection magnitudes and credible phase variation, or to characterise the complete installed transfer. Where phase cannot be measured, the report should avoid converting a worst-case mismatch envelope into a fictitious precise correction. An uncertainty bound with honest assumptions is more useful than a single apparently exact decimal.

The operator should also consider whether a nominally passive network remains linear under all relevant stresses. Connector interfaces, protection diodes, ferrite cores and ageing contacts can show power-dependent behaviour. A small-signal S-parameter measurement may be excellent while a high-level two-tone experiment exposes intermodulation. Both results can be true. Network characterisation must therefore be indexed by input level and stimulus where the investigation requires nonlinear validity. A one-time bench sweep is not enough to establish behaviour during a pulsed overload, just as a high-power survival test does not establish sensitive small-signal accuracy. The test purpose determines the applicable representation.

An instructive uncertainty analysis separates frequency calibration, magnitude calibration, phase error, mismatch, drift and repeatability. These

Copyright 2026, James M. Atkinson

sources can be correlated because the same calibration kit, network analyser reference, connector set and environmental state may influence several measured terms. A seemingly elaborate model can still be wrong if shared uncertainty is treated as independent. The final uncertainty budget should state which components are type-A observations of repeatability, which are type-B estimates based on calibration or specifications, and which correlations have been retained. It should also identify model inadequacy, such as unknown nonlinear behaviour, that cannot be reduced to a small Gaussian correction without experimental justification.

Copyright 2026, James M. Atkinson

3.29 Thermal modelling and the time scales of front-end stability

An RF receiver front end undergoes changes on several time scales. A protective diode responds to a strong pulse over a very short interval; gain-control electronics can recover more slowly; an amplifier's die temperature and bias state can evolve over seconds or minutes; the enclosure and antenna feed may respond to environmental changes over many minutes. These mechanisms interact. A long-term drift record that samples one receiver marker every quarter-hour may completely miss short desensitisation intervals. Conversely a high-rate capture of a pulse may not establish the thermal equilibrium required for a reliable gain or noise figure calibration. A complete stability specification must identify the relevant timescale for each claimed parameter.

A simple thermal screening model may treat a component with effective thermal capacitance C_{th} and thermal resistance R_{th}, yielding a time constant $\tau = R_{th} C_{th}$ for a first-order approximation. If a constant incremental dissipation ΔP begins at $t=0$, a corresponding temperature rise under that model is $\Delta T(t) = \Delta P R_{th}(1-\exp(-t/\tau))$. The model is useful as a hypothesis, not a complete account of a package with multiple thermal nodes, forced airflow and nonlinear dissipation. The acceptance test should measure the quantity of interest directly. For example, gain drift may be evaluated against observed temperature rather than inferred solely from a junction model whose parameters were never measured. The report should note whether thermal behaviour was stationary, cyclic, hysteretic or dependent on prior high-power events.

Copyright 2026, James M. Atkinson

Thermal effects can also alter the interpretation of a calibration performed at a reference frequency. A filter's centre frequency may shift; a coaxial cable's electrical length may change; a preamplifier's gain and noise factor may drift; and a limiter's intervention threshold may vary. The interactions matter most when a narrow measurement margin is reported. Suppose a receiver declares an emission only 0.5 dB above an acceptance threshold while unmeasured thermal gain drift could plausibly exceed that amount. The evidence does not justify an unqualified deterministic result. The decision should either include the thermal uncertainty or be repeated under a controlled state. If a programme requires field operation across seasons, the test plan should include cold start, warm-up, sustained use and return-to-baseline behaviour rather than extrapolate from a single comfortable laboratory temperature.

A useful approach records both ambient and internal indicators but does not assume they are interchangeable. Air temperature near an antenna does not equal the junction temperature of an enclosed amplifier; a thermistor on a printed circuit board may respond more slowly than the vulnerable device. Calibration metadata should identify each sensor location and uncertainty. Where a gain-temperature coefficient is fitted, its validity interval and hysteresis should be checked in both directions. A linear correction derived during warming may not remove the effect during cooling if mechanical expansion, moisture or bias behaviour is path dependent. In a forensic chronology the time of the temperature observation itself may matter, especially when calibration data are recorded by a host clock different from the receiver's acquisition clock.

Copyright 2026, James M. Atkinson

Environmental chamber qualification cannot by itself guarantee actual field behaviour. Vibration, humidity, conducted interference, supply transients and load impedance may interact with thermal effects in ways the chamber did not exercise. A conservative release statement specifies the tested envelope and the change-control actions that require recalibration. Transport, repair and component substitution should trigger targeted checks selected by a technical risk assessment. The goal is to retain evidence that the apparatus remained within the conditions under which its measurements were validated, not to produce an ornamental certificate that is unrelated to the reported observations.

Copyright 2026, James M. Atkinson

3.30 Calibration-fixture integrity and traceability of source amplitude

Many apparently precise receiver tests are limited by the apparatus used to inject reference signals. A signal generator's displayed output setting may be calibrated at its connector under specified conditions, yet the power delivered to a receiver after an attenuator, coupler, switch and combination network is different. The test should identify the final injection reference plane, measure or characterise the intervening loss, and document uncertainty. A variable pad may exhibit frequency-dependent step error and imperfect repeatability; a directional coupler may have limited directivity; a source may exhibit harmonics or spurious components; and a power sensor may not respond to a pulsed waveform in the same manner as to a continuous sinusoid. Such differences must be resolved before a detector's apparent behaviour can be attributed to the receiver under test.

A strong blocker test is particularly susceptible to interaction between the source and receiver. If the input device reflects a large fraction of incident power, the generator may see a changing load and alter its output. An isolator or attenuator can reduce sensitivity to that load, but adds a new calibration term and may itself impose power or frequency limits. A combiner with insufficient port isolation can cause one generator to feed energy into another. Its nonlinear response may generate test artefacts at frequencies precisely where the investigator is searching for receiver intermodulation. The reference monitoring point should be sufficiently close to the receiver input to detect such upstream products, while the monitoring apparatus is separately qualified for its own large-signal behaviour.

Copyright 2026, James M. Atkinson

The test should also distinguish power delivered from power inferred from a measurement made elsewhere. A bidirectional coupler may permit estimation of forward and reflected waves, but the inference depends upon calibration, directivity and the impedance reference. A termination at the end of a test cable does not necessarily recreate the complex load presented by a powered receiver across all frequencies. Where a high-risk overload test is involved, use a safe, rated arrangement with suitable attenuation and protection; do not energise a receiver beyond its limits simply to discover where it fails. Many susceptibility characteristics can be studied with bounded signals and a model validated at safer operating points, while explicit uncertainty remains for untested exposures.

Calibration records should be designed for later examination rather than convenient operation alone. An entry needs the identifier of the reference source, its calibration interval and status, the applied frequency and power, the transfer correction to the measurement plane, the instrumentation and software version, the measured environment, the operator and the reason for any change. A screen capture of the source setting is weak evidence if it does not identify the intervening network. When the field report relies upon a corrected value, it should retain the original observed reading, the correction applied, its sign and units, and the uncertainty. The conversion should be reversible at the level of the recorded quantities, even if the physical measurement itself cannot be repeated.

Reproducibility must be tested by someone who can use the record without relying on unstated operator memories. A second qualified examiner should be able to reconstruct the source-level budget, challenge major assumptions and identify the exact hardware state used in the original

Copyright 2026, James M. Atkinson

observation. An apparently identical replacement accessory may not be equivalent if its measured loss, match or nonlinear response differs. Maintaining serialized component records is therefore not clerical excess; it is a necessary defence against the gradual substitution of an imaginary chain for the one that actually produced the evidence.

Copyright 2026, James M. Atkinson

3.31 Intermodulation maps and the topology of false spectral components

Receiver-generated products form patterns that can be predicted from the frequencies of strong signals under specific nonlinear models. For a memoryless third-order nonlinearity excited by two sinusoidal components at f1 and f2, third-order terms include 2 f1-f2 and 2 f2-f1, alongside harmonics and fundamental contributions. If an apparent weak feature lies near one of those combinations, a plausible internal-product hypothesis exists. A technician should test that hypothesis by varying one source level while holding the other controlled, selecting a different preselector state, or observing the input on an independently characterised path. Matching a frequency expression alone is insufficient. The environment may contain genuine emitters at coincident frequencies, and the receiver can have other mechanisms that produce similar spectral geometry.

The change of product amplitude with source level is potentially diagnostic. In the ideal weak-distortion regime, the third-order product grows approximately three decibels for each one decibel increase in a single equal-tone drive scale, while the fundamental grows approximately one decibel. This slope should not be assumed in compression or across a changing filter response. Practical measurements should use enough levels to demonstrate a local trend, with the source combining network and reference monitor checked for their own products. A single pair of traces at two levels may be confounded by detector averaging, gain-control intervention or a noise threshold. The report should distinguish an empirically observed slope from a textbook model fitted without sufficient evidence.

Copyright 2026, James M. Atkinson

Other mixing mechanisms complicate attribution. A local oscillator harmonic can interact with a blocker, generating an apparent frequency determined by integer combinations of the oscillator and input frequencies. Clock harmonics and digital switching noise can couple into analogue stages. A power supply may introduce periodic modulation of amplifier gain, generating sidebands about genuine signals. A connector may produce passive intermodulation under strong illumination while behaving almost linearly in a quiet bench test. These products may move when the receiver retunes or when cable geometry changes, and such movement can be informative. But an apparent retuning relation should be checked against the instrument's actual frequency-conversion scheme and state-machine timing, not inferred from a simplified block diagram.

An effective intermodulation map contains the strong-signal candidates, their frequency intervals, uncertainty, measured powers at a common plane, relevant integer combinations and the predicted dependence on gain or attenuation. It need not expose protected communication content. Spectral power and occupancy summaries are often sufficient to test the hypothesis. The investigator should record which combinations have been eliminated by independent controls and which remain plausible. If the source environment contains many high-level signals, a full enumeration of all hypothetical products may be impossible. In that case the report should state the search method, the tested subset and any limitations rather than assert that no internal spur could exist.

The map can also reveal why removing a component from the display is not proof that it was internal. A changed gain state may suppress both a genuine weak emitter and an internal product. A preselector may reject the

Copyright 2026, James M. Atkinson

genuine external signal if the displayed centre frequency does not correspond to the actual incoming RF frequency because of aliasing or an image response. The appropriate experimental question is whether the same input-referred physical signal survives a set of controlled receiver configurations that impose different internal failure mechanisms. A successful conclusion is conditional upon those tests and the independence of the alternative measurement paths.

Copyright 2026, James M. Atkinson

3.32 Statistical validity of gain-state comparisons

It is tempting to accept a faint spectral peak when it appears repeatedly after a front-end change, but repeated observations are not necessarily independent. A gain-control loop may preserve memory across adjacent sweeps, a temperature gradient may last for hours, and multiple FFT windows may overlap heavily. A detection probability or confidence interval computed as though all displayed points were independent can be drastically overstated. The experiment should define the unit of an independent trial in terms of physical reset, source randomisation or sufficiently separated state histories. If the receiver is subject to a persistent blocker, repeating a trace with the same conditions may add less information than an independent instrument-state challenge.

The analysis should distinguish exploration from confirmation. During an initial survey the operator may try different preselector settings, attenuation values and detector thresholds to discover a stable-looking feature. That exploratory process is legitimate but changes the meaning of a subsequent significance claim. A confirmatory test should predefine the chosen measurement state, the source and detector acceptance criteria, and the error rate to be controlled. If the operator selects only the most favourable trace from many trials, the apparent false-alarm performance no longer describes the full search. The case record needs enough detail to show how many alternative configurations were tried and which decisions were made after seeing the data.

A practical controlled sequence is to randomise the order of acceptable front-end states while retaining a stable authorised reference and a

Copyright 2026, James M. Atkinson

separately monitored blocker. If the apparent component persists across states as predicted by an external-source model, that supports the hypothesis. If it follows the input-gain cube or a state transition, an internal mechanism becomes more plausible. In either case the conclusion remains bounded by the source and detector models. A field study cannot typically randomise unknown external transmitters, so the laboratory result is a susceptibility study rather than proof of what happened during every unobserved field interval.

The measurement report should make uncertainty visible without turning a complex statistical analysis into opaque authority. Provide the detection rule, the number and nature of trials, the state sequence, the observed effects, the estimated uncertainty and the principal competing hypotheses. State whether the comparison was decided beforehand or selected retrospectively. This is especially important when a finding could affect legal rights or security decisions. The precision of the displayed spectrum cannot compensate for an analysis that selected its answer from the data and then presented it as an independent test.

3.33 Extended controlled case studies for complex receiving environments

The following studies are designed as experimental reasoning exercises, not as accounts of actual surveillance events. Each begins with a declared engineering question, a physically plausible input arrangement and a limited set of observations. The calculations use conventional linear or small-signal approximations only where their hypotheses are stated. The investigator's principal task is to decide which conclusion is warranted and which further measurement would discriminate competing explanations. An attractive numerical result is not sufficient by itself to identify an emitter, establish lawful collection or certify an instrument's calibration. Every procedure presumes authorised test sources, suitable RF protection and safe access to the apparatus.

Copyright 2026, James M. Atkinson

3.33.1 Case study 3.D1. Intermittent high-power illumination and a false absence claim

An authorised laboratory survey monitors a weak reference at a fixed radio frequency, while a separate source transmits controlled high-power pulses at another frequency. The receiver's display is configured for a narrow spectral interval and shows the weak reference clearly during quiet periods. During each strong pulse the reference disappears, even though its independent generator level remains unchanged. The first hypothesis might be that the weak transmitter stopped radiating. A more plausible set of alternatives includes gain compression, input protection activity, automatic gain reduction, converter clipping or a trigger state that stopped valid recording. To test these explanations, the operator retains the weak generator's independent monitor, records the receiver's gain and overload flags where available, and repeats with calibrated input attenuation and preselection.

Suppose the weak reference enters the vulnerable amplifier at -90 dBm in quiet conditions, and a blocker momentarily enters at -8 dBm. The difference is 82 dB. This does not itself establish that the amplifier is overloaded, because its measured compression and frequency response are not yet known, but it gives a scale for the engineering challenge. If a preselector suppresses the blocker by 40 dB while incurring 2 dB loss for the weak reference, the relevant levels at the preamplifier become about -48 dBm and -92 dBm. The improved operating state may restore validity even though the reference has suffered insertion loss. That observation would support a blocker-dependent receiver limitation, not the assertion that the outside environment lacked emissions during the original blind period. The

Copyright 2026, James M. Atkinson

final report should identify a measured loss of observation opportunity and avoid using those intervals in a negative-survey coverage calculation.

The independent reference source is crucial because the receiver alone cannot distinguish an absent signal from an inability to observe it. Repetition with different pulse intervals and amplitudes can estimate the onset and recovery of the impairment. If the receiver reports the weak reference only after a 12 ms delay following the pulse, the documented invalid interval must include the time between the pulse and recovery under the stipulated criterion. The experiment does not prove identical recovery in another frequency, temperature or duty-cycle condition. Its conclusion is limited to the tested chain, and its accuracy depends on whether the challenge and reference power levels were actually characterised at the vulnerable input plane.

Copyright 2026, James M. Atkinson

3.33.2 Case study 3.D2. A two-tone product that coincides with a suspected frequency

A front end is exposed to two controlled tones at frequencies f1=900 MHz and f2=950 MHz, and a small feature appears at 850 MHz. The frequency is consistent with 2f1-f2=2(900)-950=850 MHz, a conventional third-order intermodulation product. If the receiver has a measured input third-order intercept IIP3 of +5 dBm, and both tones are -25 dBm at its vulnerable amplifier input, the ideal weak-distortion approximation predicts the product near 3(-25)-2(5)=-85 dBm input-referred. Such agreement is a diagnostic clue, not a proof of its origin. The two generators might themselves mix through a nonideal combiner, and a real third external source could operate near 850 MHz. The operator therefore measures or bounds upstream products independently and varies source level systematically.

A 5 dB equal reduction of the two tones would predict, within the weak-distortion model, a 15 dB reduction of the receiver-generated product. If the observed component falls by only 5 dB, several explanations remain. It might be a genuine 850 MHz source, the receiver's gain state might have changed, the source combiner might dominate the product or the measurement might approach the noise floor. The experiment should record both raw and corrected levels and retain enough points to estimate a local slope with uncertainty. Because the two tones are known laboratory sources, this diagnostic can be performed without recovering communications content. It should be repeated with an independent RF arrangement if the finding is consequential.

Copyright 2026, James M. Atkinson

The defensible report language is conditional: the observed feature lies at a predicted combination frequency and responds, within measurement uncertainty, consistently or inconsistently with a particular nonlinearity model. A source-identity claim requires additional evidence not contained in the frequency arithmetic. It is especially important to state whether the IIP3 figure came from a test of the actual assembled chain or merely from an individual component. An upstream limiter, cable junction or input switch can change the effective nonlinearity and make a component-level extrapolation misleading. The test should also verify that the preselector in use was physically located before the nonlinearity the operator intended to suppress.

Copyright 2026, James M. Atkinson

3.33.3 Case study 3.D3. The misleading improvement from additional preamplifier gain

A receiving system is initially calibrated with a 12 dB input amplifier and a measured noise figure of 3.5 dB under a quiet matched-source test. The operator replaces it with a nominal 24 dB amplifier of the same noise figure, expecting a substantially better minimum detectable signal. A correctly designed noise-budget analysis shows that increasing first-stage gain mainly reduces the input-referred contribution of later stages; it cannot indefinitely reduce the first amplifier's own noise factor or external antenna noise. The additional 12 dB gain also increases the level delivered to downstream mixers and converters for every input component in the amplifier's passband, including unwanted blockers. A display that becomes brighter after the replacement does not establish a 12 dB improvement in physical sensitivity.

To assess the change, hold the desired test input and decision criterion fixed. Measure output noise and signal-to-noise ratio in matched equivalent noise bandwidths, verify converter clipping and track the receiver gain state. Introduce a measured blocker at increasing levels and record when amplitude, phase or detection behaviour becomes invalid. The result may show that the original amplifier had already made later-stage noise negligible; the replacement then provides almost no intrinsic sensitivity advantage while substantially reducing downstream headroom. Alternatively, a long lossy feeder may leave significant later-stage noise, and the additional gain may help under an adequately filtered environment. The conclusion cannot be decided from gain labels alone.

Copyright 2026, James M. Atkinson

A scientifically useful comparison would show the improvement in measured signal-to-noise ratio at the stated input plane, not only the change in output magnitude. If the new configuration permits lower converter input attenuation without overload, that consequence should also be recorded. The report must preserve the preamplifier's identifier, frequency response, bias state, operating temperature, insertion connector arrangement and calibration date. A negative survey performed under the higher gain state should not be called more thorough merely because the display's nominal noise floor is lower. The system's time-varying validity and blocker susceptibility determine whether it actually observed the weak events more reliably.

Copyright 2026, James M. Atkinson

3.33.4 Case study 3.D4. Frequency-edge losses hidden by a centre-band calibration

A switched filter bank has a nominal band that extends from 700 to 900 MHz. A centre-frequency test at 800 MHz shows 1.5 dB insertion loss and apparently excellent matching. An unknown burst is suspected near 895 MHz. If the filter's real passband has a steep transition, the insertion loss and group delay at 895 MHz may differ substantially from the centre-band values. A 1.5 dB correction applied across the entire nominal band can therefore overstate or understate the true input-referred level. The proper test measures the actual assembled transfer as a function of frequency with sufficient resolution near the edge, taking account of both amplitude and phase where transient characterisation matters.

Suppose a laboratory sweep shows 2.0 dB loss at 880 MHz, 4.5 dB at 890 MHz and 10.0 dB at 898 MHz under the same switch state. These observations establish that the original centre-band correction is unsuitable near the boundary. They do not show that every burst at 895 MHz will simply be attenuated by a scalar intermediate value, because its modulation sidebands may see a strongly varying response. If the pulse is short, the distorted spectral weighting can alter the apparent pulse width and trigger time. A controlled chirp or gated carrier covering the same spectral region should be compared against an independent wideband reference to determine which measurements survive the filtering.

The report should distinguish an occupancy claim from a waveform-shape claim. The filter might be adequate to indicate energy near the edge while failing to preserve fast timing or phase. A calibrated amplitude correction is

Copyright 2026, James M. Atkinson

valid only within an interval where the transfer can be adequately approximated. An interpolation between sparse points may be defensible for a smooth response with validated uncertainty, but not across a sharp unmeasured resonance or state transition. The survey's frequency-coverage statement should use the measured acceptance bandwidth for the claimed detection threshold, not the aesthetically convenient nominal band endpoints.

Copyright 2026, James M. Atkinson

3.33.5 Case study 3.D5. A gain-control transition that resembles transmitter fading

An SDR input chain operates with automatic gain control, and a low-power authorised reference is transmitted continuously at constant level. The receiver's waterfall shows a sudden 9 dB reduction in that component at the moment a separate high-power test burst begins. A casual interpretation might describe propagation fading of the weak source. Yet the detector's output is a function of both the external signal and its internal gain setting. If gain control changes by 9 dB at the same moment, a raw output amplitude reduction is exactly what one would expect even when the incident reference is unchanged. Applying a gain correction can restore an input-referred estimate if the gain-state calibration is valid and no stage has saturated. It cannot restore samples that were clipped, dropped or altered by nonlinear recovery.

The operator should record the timing and commanded gain state with sufficient resolution to bracket the burst. The controls include an independently monitored reference source, a fixed-gain test configuration where safe, and an alternative attenuation state that changes the blocker loading. If the receiver's gain register updates several milliseconds after the physical gain has started to move, reconstructing the original waveform from register values alone may introduce time-dependent amplitude errors. A field determination of short-burst amplitude is then unqualified even though an averaged marker may appear plausible. The correct report should state the number of affected samples or a bounded interval of uncertainty, not silently smooth the transition away.

Copyright 2026, James M. Atkinson

Repeated observations should distinguish feedback memory from external source behaviour. An AGC loop that responds strongly to one pulse may remain partially attenuated through the next weak event. Two identical weak events separated by different recovery intervals can therefore appear to have different strengths. The relevant state variable is not merely instantaneous gain but the preceding input and control history. A calibrated static correction fails if the response is hysteretic or time varying. The investigator may still report event existence or approximate timing if those aspects are independently supported, but should not present invalid amplitudes as physical changes in the source.

Copyright 2026, James M. Atkinson

3.33.6 Case study 3.D6. A cable movement that changes the apparent noise floor

During a lawful equipment survey, a feeder is moved around the edge of a metal instrument cabinet while the antenna and receiver remain in their nominal positions. A persistent peak changes by 6 dB and the displayed noise floor changes in a narrower frequency band. Such behaviour may indicate common-mode coupling on the cable screen, changes in connector impedance, movement of the cable into a different electromagnetic field, or altered phase relationships in a mismatched network. It does not establish that the suspected emitter moved. An investigator should avoid making the cable's contribution disappear merely through repeated physical adjustments until the display looks favourable. Each tested configuration is itself an observation whose significance must be interpreted.

A suitable experiment compares the original and rerouted states using known reference injections and, where safely feasible, a separately characterised receiving antenna that does not share the same cable path. The operator records source levels, geometry, cable bend and strain, connector condition, common-mode suppression, and return-loss changes. If a ferrite suppression arrangement reduces the peak without changing the reference tone's differential-mode transfer, that supports a common-mode coupling hypothesis, although it remains important to ensure the ferrite did not alter other aspects of the network. A different result following connector retightening suggests another mechanism and may call for a detailed examination of nonlinear contact behaviour under controlled power.

Copyright 2026, James M. Atkinson

The report should not claim a quantitative field-strength change solely from the raw receiver display. The relevant antenna transfer and cable current path may have changed, so the measurand is no longer identical. If the original scene must be preserved for evidential reasons, intrusive rearrangement may be inappropriate until it is documented and authorised. The proper distinction is between non-invasive observation, controlled challenge and physical alteration of the measurement environment. A technically modest statement of this distinction can be more informative than an elaborate but unsupported source-location estimate.

Copyright 2026, James M. Atkinson

3.33.7 Case study 3.D7. Protection recovery confused with absence of radio activity

A receiver's protective limiter is challenged by a bounded 100 microsecond RF pulse from an authorised laboratory generator. The limiter prevents damage, but the monitored low-level test carrier remains depressed for several milliseconds afterward. Suppose the acceptance criterion requires the carrier to recover to within 1 dB of its prechallenge level and its short-window variance to return within an established tolerance. The observed amplitude first meets the 1 dB condition at 4 ms but does not meet the variance condition until 9 ms. The recovered measurement state therefore cannot be declared at 4 ms under the combined criterion. The invalid interval extends at least to the later condition, with additional time uncertainty associated with the window lengths and hardware timestamps.

If the source pulse recurs every 6 ms, the receiver may never recover fully between events. A spectrum display could nevertheless report a stable lower noise floor after averaging, concealing the persistent desensitisation. The test should vary repetition interval and pulse energy within safe bounds to identify whether recovery is monotonic or history dependent. It should also record the condition of the receiver after the challenge. A device that survives may have changed its noise factor or input match, requiring a closing calibration before earlier data can be interpreted confidently.

The forensic implication concerns blind time. A negative finding during the recovering state has less evidential weight because the receiver's detection capability was not qualified. The operator should not retrospectively assume that the source of interest was silent. A separately calibrated auxiliary path

Copyright 2026, James M. Atkinson

might preserve evidence during part of the interval, but its own overload susceptibility and reference-plane integrity must be demonstrated. The report should state what was observed and which intervals were technically invalid. That approach supports responsible engineering practice without making an untestable claim about emissions that may have occurred while the primary path was compromised.

Copyright 2026, James M. Atkinson

3.33.8 Case study 3.D8. Temperature-dependent drift and the risk of overcorrection

A bench measurement at 20 degrees Celsius establishes a front-end gain of 15.0 dB. During field operation the enclosure temperature rises to 40 degrees and a later measurement indicates 14.3 dB. An operator might propose a linear correction of +0.7 dB to every field record made at 40 degrees. That proposal is justified only if the underlying gain-versus-temperature relationship is sufficiently well characterised, the temperature sensor represents the relevant device state, and other conditions remained constant. If the receiver was simultaneously exposed to higher blocker power, the gain change may partly reflect compression rather than an ordinary thermal coefficient. Correcting all observations by the full 0.7 dB could conceal rather than remove the error.

A more rigorous study fits gain across multiple stable temperature states while monitoring source power, frequency, attenuation and load impedance. It repeats during cooling to test hysteresis and records the time needed for the hardware to reach a stable condition. A gain coefficient derived from only two points should be treated as provisional, with uncertainty reflecting both measurement error and possible curvature. If the relationship is approximately linear over the validated interval, a model $G(T)=G_{ref}+k(T-T_{ref})$ may be used, where k is the measured gain coefficient in dB per degree and T is the relevant device temperature. Outside that interval, extrapolation should be explicitly qualified.

The final report should preserve the raw gain data, the chosen regression, residuals and reference plane. It should also identify intervals of insufficient

Copyright 2026, James M. Atkinson

temperature information. A measurement campaign may benefit from periodic internal references rather than relying on one environmental thermometer. The objective is not to produce an unnaturally smooth corrected power trace. It is to distinguish real source changes from instrument drift while showing how much uncertainty remains after correction. The correct response to unresolved drift may be a wider uncertainty interval or a restricted operating claim.

Copyright 2026, James M. Atkinson

3.33.9 Case study 3.D9. Weak-event detection after a digital-filter change

A receiver's analogue hardware is unchanged, but a firmware update replaces its digital decimation filter and alters the nominal sample rate. The system continues to report the same input frequency range and nearly the same average noise floor. A brief laboratory burst that previously triggered reliably is now detected only intermittently. The first question is not whether the firmware is defective, but which part of the measurement law changed. The new filter may have a different impulse response, equivalent noise bandwidth, phase delay or transient acceptance behaviour. The trigger may also use a fixed threshold whose relationship to the filtered noise and signal has changed. An average noise-floor comparison cannot settle these possibilities.

A controlled verification preserves the same independently monitored input waveform and uses both firmware versions under a documented, reversible configuration where permitted. The operator compares retained raw samples, filter response, event timing and detection probability over predeclared trials. If a common raw data set can be processed by both versions, that isolates some software effects from analogue acquisition variability, though not every firmware change is necessarily replayable. A separate acquisition comparison may still be required. Event timing must be referred to sample apertures or a calibrated time reference, not to file-system creation times, if submillisecond conclusions are intended.

The forensic report should make clear that a change in processing algorithm can change the class of events the receiver can detect. Version identity and

Copyright 2026, James M. Atkinson

executable provenance thus belong in the measurement record. A detector may remain correct for a stipulated narrowband signal but become less reliable for pulses at a passband boundary. A claim that the instrument was 'calibrated' before the firmware change does not automatically validate the new processing state. That principle applies equally to FPGA channelisation, digital automatic-gain processing and receiver software libraries.

Copyright 2026, James M. Atkinson

3.33.10 Case study 3.D10. A bounded negative survey statement and its necessary controls

An authorised technical-security survey covers a specified building for six hours using two calibrated receiving systems. The instruments alternate among several frequency ranges, and the operator finds no qualifying emissions under the chosen detection criteria. The strongest defensible result is not that the building contained no transmission devices. Each receiver had limited frequency coverage, finite dwell times, antenna pattern nulls and possible periods of overload or maintenance. A precise coverage record should identify which ranges were observed at which times, the relevant detection thresholds, the antenna geometries, and the proportion of time that each configuration met its acceptance conditions.

Suppose a particular 20 MHz subband was actively monitored for a total of 72 minutes out of the six-hour campaign, and all observations during those 72 minutes passed internal validity checks. The gross temporal coverage fraction is 72/360=0.20. That fraction alone does not equal probability of detecting an unknown emitter, because event timing, duty cycle, reception conditions and the detector's conditional performance also matter. It demonstrates why the words 'six-hour survey of the band' can be misleading if they imply continuous observation. A claim that no qualifying event was detected during the 72 valid minutes is narrower and better supported. If independent receivers shared a front-end splitter, the coverage record must also examine their common failure paths before counting them as independent confirmation.

Copyright 2026, James M. Atkinson

A rigorous closeout compares pre- and post-survey reference measurements and records any change in equipment state. It preserves the instrument settings and calibration evidence necessary for review, within the governing lawful authority and data minimisation requirements. The operator should distinguish signal non-detection from transmitter nonexistence, and laboratory susceptibility tests from observations of the actual site. The final report can provide useful reassurance about the measurements conducted without promising an impossible proof of absence across every frequency, location and time. Such disciplined restraint is not a weakness; it is the scientific condition under which a negative technical finding remains defensible.

Copyright 2026, James M. Atkinson

3.34 Synthesis: what the completed front-end record can establish

The foregoing cases show that front-end fidelity is not represented by one noise-figure value, one gain budget or one overload specification. Validity is a multidimensional property of source frequency, amplitude, waveform, time history, temperature, impedance and instrument state. A defensible receiver record begins with its intended measurand, identifies the relevant reference planes, preserves source and instrument controls, and records every condition that can change the measurement law. Its calculations are necessary, but they become evidentially useful only when their assumptions have been challenged in the actual hardware configuration.

A properly designed investigation may end with an unresolved RF feature. The failure to identify an emitter does not erase the value of the observation or the success of a controlled test. Conversely an elegant spectral plot, a precise frequency display or a successful source-model fit cannot eliminate unmeasured front-end behaviour. For each detected component, the examiner should preserve the original evidence, state which alternative hypotheses were tested, describe any receiver states that invalidated observation, and identify which conclusions remain conditional. That is the standard by which front-end calculations should be judged before they are incorporated into a larger forensic narrative.

Copyright 2026, James M. Atkinson

3.35 Metrological qualification of system-level front-end conclusions

An engineering calculation becomes a defensible measurement claim only after the investigator specifies what was measured and the relationship between the measured quantity and the desired conclusion. This distinction may be formalised using a measurement equation with an explicit configuration vector theta. Let z denote the digitised observation, x the signal or physical quantity of interest at a declared reference plane, and theta the collection of measurable state variables: filter selection, gains, losses, converter scale, impedance conditions, timing corrections and temperature-sensitive coefficients. A simple model has the form z=f(x,theta) +epsilon, where epsilon denotes effects represented as observational noise rather than deterministic transformation. Even if the processing software can invert f, that inverse may be valid only over a bounded domain. If compression or clipping makes f many-to-one, distinct input waveforms can produce indistinguishable outputs and the reconstruction problem is not uniquely solvable. The report must distinguish a mathematically calculated inverse from an experimentally validated one.

A measurement model should be designed to withstand deliberate falsification. Consider the hypothesis that a newly observed narrow component is an external emitter. The corresponding alternative hypotheses might include a local-oscillator product, a blocker-driven intermodulation term, a switching transient, a clock harmonic or common-mode coupling through a cable. Each hypothesis should predict at least one discriminating observation under a permissible control. Altering a preselector while holding the desired reference fixed tests whether the feature depends on strong out-of-band loading. Introducing input

Copyright 2026, James M. Atkinson

attenuation can test the local slope of a presumed nonlinear product. A separate receiver and physically distinct antenna arrangement can challenge a receiver-specific artifact. None of these tests is infallible. A good experimental programme records the conditions under which two hypotheses cannot be separated, rather than choosing the explanation that happens to be most convenient for the narrative.

The correct uncertainty framework follows the chosen measurand rather than an inherited instrument worksheet. For a corrected amplitude at an antenna port, uncertainty terms can include receiver amplitude error, feeder and filter loss, mismatch, thermal drift, gain-state ambiguity, source fluctuation and repeatability. For a pulse timing claim, additional terms include clock relation, acquisition aperture, filter group delay, detector latency and state-transition validity. For a source-location claim, antenna geometry, propagation model and polarisation contribute. These uncertainties can be correlated. A single expanded uncertainty number copied between amplitude, timing and location findings would be scientifically indefensible even if it carries an impressive number of decimal places. Where a dominant model defect cannot be assigned a credible distribution, the result should be reported as unqualified or bounded by explicit scenarios instead of being forced into a deceptively narrow numerical interval.

The lawfulness of the investigation is a separate axis of validity. Technical capacity to receive or store information does not supply authority to collect communications content. A defensive survey can often test receiver susceptibility and spectral occupancy by means of independent laboratory sources, narrow technical extracts or aggregate measurements. The

Copyright 2026, James M. Atkinson

operator should establish authorisation, necessary retention and access restrictions before configuring the receiving chain. This also improves scientific clarity: a narrowly defined collection plan avoids indiscriminate recording whose purpose and relevant measurement parameters cannot later be explained. A well-controlled technical record states both the physics supporting its conclusions and the governance constraints defining what was legitimately observed.

Copyright 2026, James M. Atkinson

3.36 Release-gate checklist for a qualified receiver input chain

At release, the practitioner should be able to answer ten questions from the evidence record rather than from institutional habit. First, are the antenna and conducted input reference planes unequivocally identified? Second, are the relevant frequency- and level-dependent transfer corrections measured in the installed configuration? Third, have the actual blocker conditions been compared with measured linearity and protection limits? Fourth, has the noise and detection behaviour been demonstrated at the estimator bandwidth and under the intended gain state? Fifth, have the preselector and gain-control transitions been time-aligned and their invalid windows identified? Sixth, have limiter leakage, survival and recovery been differentiated? Seventh, have physically distinct controls been used to challenge plausible receiver-generated products? Eighth, have all calibration sources and fixtures been characterised sufficiently to exclude test-setup artifacts? Ninth, have the uncertainty and sensitivity of the chosen detection criterion been reported with the relevant correlations? Tenth, can an independent examiner reproduce the findings and identify the intervals in which no reliable observation was possible?

A negative response to any of these questions does not necessarily invalidate all data. It restricts the class of permissible conclusions. An input chain might be fit to detect strong persistent carriers yet unfit to resolve fast transients or weak events beneath a time-varying blocker. Another arrangement might preserve coherent phase at modest levels while lacking sufficient protection near a powerful transmitter. The key editorial requirement is to present the qualified operating envelope without conflating these independent capabilities. A reviewer should be able to read

Copyright 2026, James M. Atkinson

the state table and understand why a particular observation was retained, excluded or subjected to a lower-confidence interpretation. Such specificity prevents an impressive instrument specification from being substituted for a demonstrated measurement capability.

The closing verification should deliberately return to the original reference configuration. After a survey, the operator measures the same weak test reference, filter transfer or noise marker used at acceptance, with adequate control of environmental and source changes. A meaningful discrepancy triggers investigation before the earlier records are treated as stable throughout the campaign. If the closing check cannot be performed, the limitation remains explicit. The audit trail should preserve the original and closing values, the comparison calculation and the relevant uncertainty, rather than merely state that the receiver passed. This is particularly important where an overload event or mechanical disturbance may have changed the instrument without producing an obvious software alarm.

A front-end design will never remove every possible ambiguity. Its scientific value rests on making the known ambiguities testable, reducing the relevant ones by careful topology and calibration, and reporting the remainder honestly. The strongest conclusion is therefore not always a categorical attribution. Often it is a precise statement about a measured signal under a documented receiver state, with the alternative origins that have been challenged and those that remain unexcluded. In a complex technical surveillance countermeasures investigation, that bounded statement can withstand more rigorous examination than an unqualified claim of certainty. The distinction between observed electromagnetic energy, receiver-internal

Copyright 2026, James M. Atkinson

transformations and attributed external apparatus should remain visible at every stage of the evidential record.

Copyright 2026, James M. Atkinson

3.37 A research agenda for independent replication

Independent replication should test the scientific proposition rather than reproduce only its apparent final numerical answer. Suppose one laboratory finds that a weak reference remains detectable with an input preselector engaged and becomes unreliable when the filter is bypassed. Another laboratory should not simply build a visually similar rack and expect identical results. It must identify the essential variables of the claim: desired-signal level, blocker spectrum, preselector transfer, amplifier operating range, detector decision rule, calibration planes, timing and uncertainty. A different instrument can reproduce the same phenomenon while producing different raw voltages and baseline noise because the transfer functions differ. The appropriate comparison is therefore based on corrected physical quantities and state-dependent validity, not on matching a screen capture.

Replications should include a deliberate failure condition. An experiment that tests only the successful configuration cannot show whether the model has discriminatory power. For example, a front-end claimed to reject internally generated third-order products should be challenged with source tones whose combination frequency falls within the desired passband and then with a source combination that falls outside. The operator should vary the amplifier input loading while monitoring the combining network independently. The failure condition helps establish whether the instrument's response follows the hypothesised mechanism, and it may reveal a different unexpected cause. A result that does not match the original study is not automatically wrong; it may expose an unstated assumption or an untested hardware dependency.

Copyright 2026, James M. Atkinson

A robust replication archive retains instrument configuration, relevant firmware and software identities, calculation scripts, source-level measurements, calibration records, ambient conditions and a map of hardware connections. For transient experiments it also records acquisition clocks, trigger definitions, timing alignment and any sample gaps. The archive should distinguish original recordings from analyses that rescale, interpolate, correct or otherwise transform them. Where lawful retention requirements limit raw signal storage, a record of controlled reference experiments and technical metadata can support some validation without indiscriminate collection of communications content. The purpose of retaining these materials is to make the inference independently challengeable, not to accumulate files whose provenance or authority cannot be established.

Finally, the chapter's scope should remain linked to the wider Volume 11 architecture. The noise model interacts with Chapter 2, frequency conversion with Chapter 4, timing with Chapter 12, integrated reference planes with Chapter 13, uncertainty with Chapter 14 and evidential challenge with Chapter 16. Cross-references should direct a reader to those specialised treatments rather than duplicate entire derivations in several chapters. The front-end chapter owns the practical question of whether incident energy can pass through the earliest receiving stages without unacceptable loss, distortion or loss of observability. Its contribution is to explain how that question can be tested, calculated and reported under the conditions actually encountered.

Copyright 2026, James M. Atkinson

3.38 Independent challenge of recovered input-referred amplitude

A software-generated input-referred amplitude is not automatically a physical measurement made at the declared input plane. Its validity depends on every correction between the digitised record and that plane. A receiver may export a floating-point magnitude after applying a factory gain table, a selected input pad correction, preselector loss, detector scaling and a nominal impedance convention. If one part of the chain changed silently, the output can remain numerically precise while describing a different physical state. The examiner should therefore maintain an explicit correction ledger whose entries specify the direction of the transformation, the frequency and time interval, the uncertainty, and the evidence establishing that the correction applied during the event. For a corrected power in decibel units, the algebra is simple; the difficult part is proving the corrections correspond to the hardware state that actually produced the samples.

An independent calibration challenge can inject a series of known authorised reference levels, not merely one convenient midscale tone. Tests should bracket the intended weak-signal decision threshold and extend towards the validated upper edge of linear performance. A frequency sweep should include the centre and boundaries of each intended preselector path. A temporal test should include short bursts and repeated pulses with intervals chosen to reveal gain-control memory and protection recovery. Each result is compared with the predicted input-referred value and a stated acceptance tolerance. When the challenge reveals a consistent correction bias, a new calibration model may be justified over its tested interval. When it reveals state-dependent discontinuities, fitting one global offset is

Copyright 2026, James M. Atkinson

inappropriate. The result is a family of qualified states rather than an attractive universal scale factor.

An instructive laboratory counterexample involves a receiver whose software adds a fixed 20 dB gain correction while the input amplifier has in fact switched from 20 dB to 10 dB because of a blocker-triggered control action. A raw observed level of -50 dBm at the subsequent measurement stage would be corrected to -70 dBm under the erroneous 20 dB assumption, whereas a linear 10 dB gain state would imply -60 dBm at the input. The resulting 10 dB mistake is not reduced by averaging thousands of FFT frames. Averaging can reduce statistical variation around the wrong value while leaving the systematic state error intact. A proper record identifies the gain epoch and invalidates corrections whose state cannot be established. This is why calibration and configuration provenance must be tied to the sample index or another reliable acquisition-time reference, rather than inferred from a later screen capture.

3.39 Uncertainty-aware interpretation of instrument agreement

Two calibrated instruments displaying nearly identical amplitudes do not necessarily provide two independent measurements of the external electromagnetic field. If they share a receiving antenna, a splitter, a lossy connector and the same environmental coupling path, those shared elements can introduce a common error. A comparison may establish agreement downstream of the splitter while saying little about the antenna's effective transfer or the physical source geometry. To assess independence, the investigator should trace which components and calibration standards the systems share. Correlation should be treated as a property to be examined, not assumed absent because the instruments bear different serial numbers.

Suppose two receivers measure a controlled reference as -79.8 and -80.1 dBm after their individual calibration corrections. The absolute difference is 0.3 dB. That number is not a valid statistical agreement test until each receiver's uncertainty and their covariance are known. If the independent parts of each measurement have 0.2 dB standard uncertainty and both share a common 0.5 dB antenna-path uncertainty, the difference can appear unusually precise because the shared term cancels in a direct comparison. Conversely their agreement does not remove the 0.5 dB uncertainty affecting the common input-referred estimate. A complete analysis should distinguish the uncertainty of a difference from the uncertainty of the absolute quantity. This distinction is essential when apparent agreement is used to support a source attribution rather than a simple instrument-consistency claim.

Copyright 2026, James M. Atkinson

A useful independent challenge may substitute a separately located calibrated antenna or introduce a reference directly at the receiver input. These tests answer different questions. A direct injection isolates the downstream receiver chain but bypasses the real antenna and its environment; a separate antenna tests more of the field-to-receiver path but introduces differences in pattern, polarisation and propagation. Neither arrangement alone identifies the source. Together they can help bound systematic uncertainty and separate alternative explanations. The final report should identify the exact corroborative proposition supported by each comparison. It should not convert two similar traces into a general proof of independent external origin.

Copyright 2026, James M. Atkinson

3.40 Closing doctrine on magnitude, event time and source attribution

Front-end qualification supports a hierarchy of findings. At the lowest level, a recorder may show a reproducible nonzero output under a documented configuration. A stronger finding establishes that the output corresponds to electromagnetic energy incident at a specified input plane, with receiver-generated products and corrupted states adequately challenged. Stronger still is a quantitative estimate of amplitude, frequency or temporal properties with uncertainties traceable to accepted calibration. Distinguishing an external source class, identifying a specific device or assigning responsibility to a person requires additional evidence outside the scalar input-chain model. Each inferential step must be independently supported; it cannot be supplied merely by increasing the numerical precision of the preceding step.

A front end's proper role is to preserve the information needed for the stated lawful and technical purpose, while exposing the circumstances under which information may have been transformed or lost. Protective filtering can improve selectivity but remove useful spectral sidebands. Gain can improve converter utilisation but reduce blocker tolerance. A limiter can prevent damage but create an unobservable recovery interval. A cable arrangement can deliver a weak desired signal but also collect unintended common-mode interference. Those trade-offs are intrinsic physical characteristics, not software defects that can always be corrected retrospectively. The responsible measurement report retains both the benefits and the limitations in view.

Copyright 2026, James M. Atkinson

Accordingly the acceptance test should end with an explicit decision: which input ranges and waveform classes have been demonstrated, which alternative hardware states remain untested, and which observations can support the intended conclusion. An unresolved anomaly should remain unresolved until a discriminating experiment is performed. The strongest technical publication does not promise that every unknown RF event will be detected. It establishes a transparent method for determining when the receiver can be trusted, when it cannot, and what can still be said about evidence collected near the boundary of its demonstrated performance.

3.41 Blocker-dependent front-end state machines and hidden recovery intervals

A broadband receiver confronted by time-varying strong transmissions is better modelled as a state machine with memory than as a single linear transfer element. Define state Q as quiet calibrated operation, state C as compressed or limited operation, state R as measurable recovery, and state U as unknown or unvalidated behaviour. The transition Q to C may be caused by peak voltage, total admitted power, a protective limiter or automatic control; the return through R can be delayed by stored charge, amplifier bias restoration, local-oscillator settling, filter memory or detector smoothing. A component appearing only during R is not necessarily a newly active external source. A receiver can generate a transient spectral product while it is recovering from a completely unrelated blocker. The useful experimental control is therefore a weak, continuous reference retained across the blocker event, with event times and gain states available at sufficient resolution.

A calibration record based exclusively upon steady continuous-wave stimuli does not establish how the front end behaves during a microsecond pulse followed by weak activity. Measurements of limiter survival, residual leakage and restoration of weak-signal validity answer different questions. For an illustrative linear recovery model, let fractional amplitude error be $e(t) = e_0 \exp[-(t - t_0)/\tau]$ for t at or after the end t_0 of a particular strong event. If e_0 equals 0.4, tau equals 1.5 milliseconds, and a calibrated amplitude condition requires $|e|$ no greater than 0.01, then the minimum model recovery time is 1.5 ms multiplied by ln(40), approximately 5.53 ms. This

Copyright 2026, James M. Atkinson

result is conditional on the exponential law and one amplitude criterion; phase, detector noise and gain-state restoration may require longer and cannot be inferred from the same constant. A real limiter must be challenged experimentally rather than assigned the constructed time constant.

A useful front-end acceptance experiment varies blocker amplitude, blocker duration and repetition rate separately while keeping the weak reference nominally fixed. Record actual protection path, preselector selection, gain state, thermal conditions, limiter event flags, output waveform and native receiver samples. An independent monitor should establish the stimulus at the declared plane, particularly because source and combiner products can be mistaken for receiver-generated intermodulation. Repeat with the blocker moved beyond the selected preselector, without changing the weak reference, so that the predicted suppression can be tested at the physically relevant stage. The interpretation must separate insufficient sensitivity, reduced observation opportunity, amplitude distortion and a genuine discrete product; these outcomes cannot be exchanged merely because they all reduce confidence in a displayed weak line.

The final report should use a validity mask over the acquisition timeline. A time interval in which the receiver is protected but temporarily blind to the stipulated weak event is not part of demonstrated observation coverage. A persistent artifact that survives the strong pulse for several milliseconds should not be treated as evidence that the pulse source itself persisted. Conversely, a late weak emission appearing after recovery may be real even though the earlier stage was overloaded. State histories and explicit restoration tests make those propositions distinguishable. This approach

Copyright 2026, James M. Atkinson

extends the ordinary noise-and-gain budget into a practical account of transient susceptibility, which is essential when the purpose of the survey is to find rare, weak emissions rather than simply measure continuous carriers.

3.42 Advanced technical expansion. Multitone stress and the limits of protective front-end linearity

The front end must be analysed as an ordered physical network whose small-signal gain and large-signal response are different kinds of evidence. For each stage j, calculate or measure the level of every intended signal and important blocker at that stage's actual input, incorporating the individual frequency response of upstream filters and the state of switched attenuators. A decibel sum is legitimate for a signal traversing a demonstrated linear scalar path; it cannot predict the intermodulation waveform created when an amplifier experiences several strong components. Even a clean output filter cannot remove an in-band product already generated upstream. The correct exposure record therefore includes more than the displayed band. It includes the frequencies and levels admitted to the first nonlinear element and any protection device that encounters the environment before the first amplifier.

A stylised two-tone test makes the distinction concrete. Let the input contain sinusoidal components at 940 and 947 MHz, with amplitudes sufficiently small for the first stage to be described locally by $y(t) = a_1x(t) + a_3x(t)^3$, where a_1 is a linear voltage coefficient and a_3 is a cubic coefficient in compatible units. Third-order terms may appear near 933 MHz and 954 MHz, because the algebraic combinations $2f_1-f_2$ and $2f_2-f_1$ are inside or near a receiving band even when both original components appear remote. Their exact levels depend on amplitudes, device coefficients, impedance, frequency response and phase, so no universal product level follows from frequency arithmetic. The operator should measure the purity of the combined

Copyright 2026, James M. Atkinson

sources before attributing products to the receiver; an inadequately isolated generator combiner can create identical frequencies before the receiver is even connected.

A protective limiter has at least four separately testable behaviours: low-level insertion loss, leakage during a specified incident pulse, survival under its stated energy and repetition conditions, and recovery to a declared small-signal measurement tolerance. Survival does not imply immediate recovery. A receiver may remain within damage limits while a PIN limiter, amplifier bias or gain-control loop temporarily renders weak-event measurements invalid. A useful test overlays a calibrated low-level reference on a bounded strong event, records the actual response at sufficient temporal resolution and measures recovery to independently selected amplitude and phase criteria. An observed 2 ms amplitude recovery and 7 ms phase recovery would create different validity windows for different measurands. Those figures would be measured results only if actual instrument records existed; in manuscript examples they must be explicitly hypothetical.

The gain-selection problem is therefore constrained from both sides. A noise budget yields a minimum useful gain to suppress later-stage contributions; a blocker and headroom budget yields a maximum gain compatible with linear operation at vulnerable stages. If the lower bound exceeds the upper bound, the design has no acceptable gain setting under the declared assumptions. Choosing an arithmetic compromise does not create physical feasibility. Instead, improve preselection, relocate amplification, reduce preceding loss, revise the tolerated blocker environment or adopt an architecture with different noise and compression limits. Record which trade

Copyright 2026, James M. Atkinson

was chosen, because later attenuation corrections may restore a reported signal level but cannot restore information distorted during a previous overloaded state.

A complete acceptance record incorporates temperature, connection state, limiter history and mechanical disturbance, particularly for equipment transported between sites. The same connector may exhibit changing contact resistance or passive intermodulation under bending or vibration. An artefact that disappears when the cable is moved could reflect the installed path rather than a transmitter's actual state. Test the mechanical condition deliberately, retain before-and-after reference observations and avoid assuming that a network-analyser sweep at low power validates high-level transient behaviour. The report should distinguish the demonstrated operating envelope from the untested combinations of pulse width, duty factor, frequency and temperature.

Copyright 2026, James M. Atkinson

Chapter Summary

Preselection, gain, attenuation, and protection determine both sensitivity and credibility. Front-end state must be chosen for the actual environment and challenged whenever a weak component could be an overload product.

Follow the desired signal and each blocker through the actual component order. The first vulnerable stage can lose validity before a downstream filter or narrow display acts. Keep desired-frequency loss separate from blocker rejection, and apply scalar budgets only within their impedance, frequency and state assumptions.

Choose preselection and gain together. A noise-derived minimum and downstream-loading maximum define a feasible gain interval; an empty interval requires a design change. Verify that the desired waveform survives the filter. Equal corrected amplitudes across settings do not imply equal sensitivity or unchanged physical loading.

Separate protection loss, leakage, survival and recovery. Use an observable-specific recovery criterion and a weak reference to identify impaired intervals; surviving hardware can still be unable to make the intended measurement. Record gain transitions, source and combiner controls, common-plane corrections and raw outputs. Challenges and closing checks support the operating conditions they actually exercise, with remaining limitations explicit.

Chapter 3 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C03-MCQ-001. A narrow final filter removes a strong blocker from the displayed span, but the blocker entered an earlier amplifier. What establishes whether that amplifier was protected?

A. The blocker level and rejection before the amplifier, compared with its valid operating range.

B. The final filter bandwidth being narrower than the displayed span.

C. The final trace being free of the blocker after filtering.

D. The amplitude correction assigned to the final filter.

Answer: A. Protection requires sufficient rejection before the first vulnerable component. A later filter does not undo earlier compression or generated in-band products. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: The blocker level and rejection before the amplifier, compared with its valid operating range.

Distinguishing consideration: compare this with option B, “The final filter bandwidth being narrower than the displayed span”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-002. An unfiltered direct-sampling receiver shows only a narrow display span. Which conclusion about converter exposure is justified?

A. Display decimation removes out-of-span energy before the converter.

B. Signals outside the display may still load the analog path or converter.

C. Only frequencies inside the display contribute to converter overload.

D. A clean display establishes that all analog stages remained linear.

Answer: B. Displayed selection and physical admission are different boundaries. The front-end response and actual converter input determine exposure. Review: Front-End Purpose and Architecture. Source: §3.1 Front-End Purpose and Architecture (p. 1248)

Why the selected alternative fits: Signals outside the display may still load the analog path or converter.

Distinguishing consideration: compare this with option A, “Display decimation removes out-of-span energy before the converter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Front-End Purpose and Architecture.

Review: Chapter 3 — Front-End Purpose and Architecture.

V011-C03-MCQ-003. Two otherwise identical chains place the same blocker-rejecting filter before or after the first amplifier. What is the principal reason their behavior can differ?

A. A filter after an amplifier always has zero insertion loss.

B. Scalar gain multiplication ceases to apply whenever components are reordered.

C. Only the first arrangement reduces the blocker presented to that amplifier.

D. The final desired-signal correction necessarily has opposite sign in the two chains.

Answer: C. Equal final small-signal gain can coexist with different internal loading. Component order changes the first vulnerable stage exposure. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: Only the first arrangement reduces the blocker presented to that amplifier.

Distinguishing consideration: compare this with option A, “A filter after an amplifier always has zero insertion loss”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-004. A desired signal is in a filter passband and a blocker lies on its skirt. Which gain budget is appropriate?

A. The center-frequency gain applied equally to both signals.

B. The blocker rejection applied as the desired-signal loss correction.

C. Separate frequency-specific transfers for desired signal and blocker.

D. One average filter loss weighted only by the displayed desired trace.

Answer: C. A filter has frequency-dependent transfer. A single desired-band gain cannot represent a blocker at a different frequency. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: Separate frequency-specific transfers for desired signal and blocker.

Distinguishing consideration: compare this with option A, “The center-frequency gain applied equally to both signals”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-MCQ-005. What cannot be established from the scalar gain relations in Equations 5 and 6 alone?

A. A predicted stage level under a stipulated linear transfer.

B. The product of compatible linear stage power gains.

C. The sum of signed gains and losses in decibels.

D. The magnitude and frequency of a nonlinear intermodulation product.

Answer: D. The scalar relations describe linear transfer. Nonlinear products need a justified nonlinear model and valid source and state assumptions. Review:

Equations 5 and 6. Source: Equation 5. Linear cascaded gain (p. 1269)

Why the selected alternative fits: The magnitude and frequency of a nonlinear intermodulation product.

Distinguishing consideration: compare this with option A, “A predicted stage level under a stipulated linear transfer”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-006. Several blockers have a known total mean input power. Why can that information be insufficient for a peak-sensitive failure mechanism?

A. Peak loading is always equal to the largest individual mean power.

B. Relative phase and instantaneous voltage can change peaks without being specified by the mean alone.

C. A gain correction determines the relative phase of all blockers.

D. Mean power can never be used in a receiver loading assessment.

Answer: B. Mean and instantaneous loading address different mechanisms. A peak-sensitive analysis needs waveform or phase information appropriate to that mechanism. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: Relative phase and instantaneous voltage can change peaks without being specified by the mean alone.

Distinguishing consideration: compare this with option A, “Peak loading is always equal to the largest individual mean power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

V011-C03-MCQ-007. The preamplifier indicator is on in the chapter's instrument example. Which additional fact is essential to interpreting strong-signal exposure?

A. Only the nominal gain of the final detector normalization.

B. Which active stage is enabled and whether preselection precedes it.

C. Only the final displayed noise level with the antenna disconnected.

D. Whether the display annotation uses the same name in every application.

Answer: B. The cited architecture has distinct amplifier placements. The state label alone does not identify the filtering before the active stage. Review: Front-End Purpose and Architecture; source note 9. Source: §3.1 Front-End Purpose and Architecture (p. 1248)

Why the selected alternative fits: Which active stage is enabled and whether preselection precedes it.

Distinguishing consideration: compare this with option A, "Only the nominal gain of the final detector normalization"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-008. What starting policy does the chapter justify for an unknown RF environment?

A. Infer a safe starting state from the final display span alone.

B. Always start with the maximum preamplifier gain because it minimizes receiver noise.

C. Always use a fixed attenuation value independently of receiver ratings.

D. Choose a state with understood exposure using actual ratings and anticipated signals, then test whether more gain is useful.

Answer: D. The required state depends on the actual path, environment and objective. Neither maximum gain nor a universal attenuation value establishes validity. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: Choose a state with understood exposure using actual ratings and anticipated signals, then test whether more gain is useful.

Distinguishing consideration: compare this with option A, “Infer a safe starting state from the final display span alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-009. A survey changes from a protected state to a quieter high-gain state. How should the observations be retained?

A. As identified configuration intervals with their own noise, overload and coverage behavior.

B. As interchangeable records whenever the corrected desired level agrees.

C. As one calibration interval because the same external connector was used.

D. As one state after replacing both gain settings by their arithmetic average.

Answer: A. A common reporting plane does not erase changes in internal state or time coverage. The actual state intervals must remain identifiable. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: As identified configuration intervals with their own noise, overload and coverage behavior.

Distinguishing consideration: compare this with option B, “As interchangeable records whenever the corrected desired level agrees”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

V011-C03-MCQ-010. Where should desired and blocker levels be established for a front-end acceptance challenge?

A. Only at the final detector after automatic amplitude normalization.

B. At whichever connector has the lowest reflected-power indication, without a transfer record.

C. At the intended receiver reference plane after the actual combining and accessory path.

D. Only at each generator front-panel indication.

Answer: C. Generator settings do not include all intervening losses, interaction and mismatch. The claimed receiver exposure belongs to its declared input plane.

Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: At the intended receiver reference plane after the actual combining and accessory path.

Distinguishing consideration: compare this with option A, “Only at the final detector after automatic amplitude normalization”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-MCQ-011. Compatible linear stage power gains are 10, 0.5 and 20. What is the total gain under Equation 5?

A. 30.5, equivalent to about 14.84 dB.

B. 200, equivalent to about 23.01 dB.

C. 100, equivalent to 20 dB.

D. 0.01, equivalent to -20 dB.

Answer: C. Multiply the dimensionless power gains: $10 \times 0.5 \times 20 = 100$. Ten times the base-ten logarithm gives 20 dB. Review: Equation 5. Source: Equation 5. Linear cascaded gain (p. 1269)

Why the selected alternative fits: 100, equivalent to 20 dB.

Distinguishing consideration: compare this with option A, “30.5, equivalent to about 14.84 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 5. Linear cascaded gain.

Review: Chapter 3 — Equation 5. Linear cascaded gain.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-012. A -62.0 dBm input passes through 2.1 dB filter loss, 10.0 dB attenuation and 17.5 dB amplifier gain. What stage input follows?

A. -91.6 dBm.

B. -56.6 dBm.

C. -35.4 dBm.

D. -80.6 dBm.

Answer: B. Apply Equation 6 with losses subtracted and gain added: -62.0 minus 2.1 minus 10.0 plus 17.5 equals -56.6 dBm. Review: Equation 6; Hypothetical Applied Calculation. Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: -56.6 dBm.

Distinguishing consideration: compare this with option A, “-91.6 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-013. For the preceding constructed -56.6 dBm stage level and a specified -25.0 dBm compression onset, what is the nominal headroom for that signal alone?

A. 31.6 dB.

B. 81.6 dB.

C. 25.0 dB.

D. -31.6 dB.

Answer: A. Subtract the operating level from the stated limit: -25.0 minus -56.6 equals 31.6 dB. This does not incorporate additional blockers or peak behavior.

Review: Hypothetical Applied Calculation. Source: §3.13 Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection (p. 1271)

Why the selected alternative fits: 31.6 dB.

Distinguishing consideration: compare this with option B, “81.6 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Review: Chapter 3 — Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

V011-C03-MCQ-014. Which use of decibels is consistent with Equation 6?

A. Multiply the numerical values of stage gains expressed in dB.

B. Interpret a 10 dB attenuator setting as an absolute output power of 10 dBm.

C. Add all absolute signal powers in dBm directly to obtain their combined power.

D. Add signed gains and losses in dB to an absolute input level in dBm.

Answer: D. A decibel transfer is a logarithmic ratio, whereas dBm is an absolute level referenced to one milliwatt. Their roles in the level budget differ. Review: Equations 5 and 6. Source: Equation 5. Linear cascaded gain (p. 1269)

Why the selected alternative fits: Add signed gains and losses in dB to an absolute input level in dBm.

Distinguishing consideration: compare this with option A, “Multiply the numerical values of stage gains expressed in dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-015. What condition accompanies the product of available stage power gains in Equation 5?

A. A requirement that all stages have identical physical temperature.

B. An assumption that every stage has unit voltage gain.

C. Compatible reference impedances and mismatch conventions across the chain.

D. A guarantee that the product remains valid through compression.

Answer: C. The gain definitions and interface conventions must support the multiplication. The formula does not itself establish matching, linearity or headroom. Review: Equation 5. Source: Equation 5. Linear cascaded gain (p. 1269)

Why the selected alternative fits: Compatible reference impedances and mismatch conventions across the chain.

Distinguishing consideration: compare this with option A, “A requirement that all stages have identical physical temperature”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 5. Linear cascaded gain.

Review: Chapter 3 — Equation 5. Linear cascaded gain.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-016. Filter loss and switched attenuation are recorded as positive loss magnitudes. How do they enter Equation 6?

A. Their arithmetic average is subtracted regardless of component count.

B. Both are added because each is recorded as a positive number.

C. Filter loss is added while attenuation is subtracted.

D. Both are subtracted from the input level before adding amplifier gain.

Answer: D. A positive loss magnitude corresponds to a negative change in the transmitted power level. The sign follows the transfer, not the printed sign of the magnitude. Review: Equation 6. Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: Both are subtracted from the input level before adding amplifier gain.

Distinguishing consideration: compare this with option A, “Their arithmetic average is subtracted regardless of component count”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 6. Input power after front-end correction.

V011-C03-MCQ-017. A -15 dBm blocker encounters 35 dB filter rejection, 6 dB attenuation and 20 dB gain before a mixer. Assuming those transfers remain valid at its frequency, what level reaches the mixer?

A. 24 dBm.

B. -76 dBm.

C. -2 dBm.

D. -36 dBm.

Answer: D. The blocker budget is -15 minus 35 minus 6 plus 20 equals -36 dBm. Its frequency-specific rejection is essential. Review: Equation 6; Use preselection as a measured transfer function. Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: -36 dBm.

Distinguishing consideration: compare this with option A, “24 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Use preselection as a measured transfer function.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-018. In the same chain, a -95 dBm desired signal experiences only 1 dB filter loss, the same 6 dB attenuation and 20 dB gain. What is its predicted mixer input?

A. -82 dBm.

B. -122 dBm.

C. -68 dBm.

D. -116 dBm.

Answer: A. The desired-frequency budget is -95 minus 1 minus 6 plus 20 equals -82 dBm. The blocker rejection does not belong in this correction. Review: Equation 6.

Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: -82 dBm.

Distinguishing consideration: compare this with option B, “-122 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 6. Input power after front-end correction.

V011-C03-MCQ-019. The two preceding constructed inputs differ by 80 dB before the filter. Its blocker rejection is 35 dB and desired loss is 1 dB; later transfers are equal. What separation remains?

A. 44 dB.

B. 114 dB.

C. 46 dB.

D. 80 dB.

Answer: C. The filter changes the separation by 35 minus 1 equals 34 dB. The remaining blocker-to-desired separation is 80 minus 34 equals 46 dB. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: 46 dB.

Distinguishing consideration: compare this with option A, “44 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-MCQ-020. The desired path has a net gain of 13 dB and its measured stage level is -82 dBm. What input-plane estimate follows under the valid linear correction?

A. -69 dBm.

B. -82 dBm.

C. -95 dBm.

D. -106.6 dBm.

Answer: C. Refer the output indication backward by subtracting the path gain: -82 minus 13 equals -95 dBm. This correction does not repair a nonlinear acquisition.

Review: Equation 6; An acceptance sequence that separates competing failures.

Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: -95 dBm.

Distinguishing consideration: compare this with option A, “-69 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-MCQ-021. Two candidate preselectors have equal desired-band insertion loss. Only one supplies substantial rejection of the dominant blocker before the vulnerable stage. What distinguishes their likely usefulness?

A. The filter with weaker rejection must always have the lower receiver noise temperature.

B. Their order matters only after the final detector.

C. The filter with substantial blocker rejection may restore valid operation; equal desired loss does not imply equal blocker protection.

D. They must produce equal operational sensitivity because their desired losses match.

Answer: C. Desired-band loss and blocker admission are different transfers. The noise cost can be similar while the validity benefit differs substantially. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: The filter with substantial blocker rejection may restore valid operation; equal desired loss does not imply equal blocker protection.

Distinguishing consideration: compare this with option A, “The filter with weaker rejection must always have the lower receiver noise temperature”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-MCQ-022. An amplifier generates an in-band product before a narrow downstream filter. Which outcome is physically plausible?

A. The filter reconstructs the original weak waveform by removing the blocker.

B. The filter rejects the original blocker while passing the already generated in-band product.

C. The product disappears whenever the original blocker is absent from the display.

D. The filter converts the nonlinear product back into source noise.

Answer: B. Filtering acts on the spectrum at its own input. It cannot identify and reverse an upstream nonlinear history merely because its final passband is narrow.

Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: The filter rejects the original blocker while passing the already generated in-band product.

Distinguishing consideration: compare this with option A, “The filter reconstructs the original weak waveform by removing the blocker”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

V011-C03-MCQ-023. A center-frequency calibration is satisfactory, but a desired modulation occupies a much wider passband. What remains to be established?

A. Only the same center-frequency gain at one additional power level.

B. Amplitude and phase transfer across the occupied signal bandwidth.

C. That the noise floor decreases when the display span is reduced.

D. Only the filter label and its nominal center frequency.

Answer: B. A wide waveform samples ripple and phase behavior away from the center. A scalar center correction does not establish waveform preservation.

Review: Preselection and Filter State. Source: §3.3 Preselection and Filter State (p. 1251)

Why the selected alternative fits: Amplitude and phase transfer across the occupied signal bandwidth.

Distinguishing consideration: compare this with option A, “Only the same center-frequency gain at one additional power level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Preselection and Filter State.

Review: Chapter 3 — Preselection and Filter State.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-024. Which preselector characteristic is especially relevant to relative timing distortion across a desired waveform bandwidth?

A. The stopband rejection measured at one remote blocker frequency.

B. The center-frequency insertion loss alone.

C. The displayed attenuation correction alone.

D. Group delay as a function of frequency.

Answer: D. Frequency-dependent phase delay can alter waveform timing even when center amplitude appears correct. The complete passband response must match the measurement need. Review: Preselection and Filter State. Source: §3.3 Preselection and Filter State (p. 1251)

Why the selected alternative fits: Group delay as a function of frequency.

Distinguishing consideration: compare this with option A, “The stopband rejection measured at one remote blocker frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Preselection and Filter State.

Review: Chapter 3 — Preselection and Filter State.

V011-C03-MCQ-025. A receiver automatically changes preselector bands at a frequency boundary. What does a calibration at the center of only one band fail to establish?

A. The arithmetic sign of every passive loss in the chain.

B. Continuity and accuracy of response across the switched boundary.

C. Whether an amplifier power gain is dimensionless.

D. The center-frequency response at the calibration state already measured.

Answer: B. The switch can change gain, noise, phase and calibration. Boundary checks must exercise the actual adjoining states. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: Continuity and accuracy of response across the switched boundary.

Distinguishing consideration: compare this with option A, “The arithmetic sign of every passive loss in the chain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-MCQ-026. An external notch filter is substituted during an amplitude survey. Which record supports a defensible comparison?

A. A statement that both filters are passive and therefore interchangeable.

B. Its identity, actual response and state-dependent correction and uncertainty.

C. Only the nominal notch frequency printed on its case.

D. The receiver calibration certificate without identifying the added filter.

Answer: B. The accessory changes the measurement path. Its serial identity and measured transfer connect the physical substitution to the reported amplitude.

Review: Preselection and Filter State. Source: §3.3 Preselection and Filter State (p. 1251)

Why the selected alternative fits: Its identity, actual response and state-dependent correction and uncertainty.

Distinguishing consideration: compare this with option A, “A statement that both filters are passive and therefore interchangeable”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Preselection and Filter State.

Review: Chapter 3 — Preselection and Filter State.

V011-C03-MCQ-027. The baseline falls when preselection is enabled. Which interpretation is justified before the desired transfer is remeasured?

A. The desired signal-to-noise ratio must have improved by the same amount.

B. Several mechanisms remain possible, including noise rejection, changed gain, reduced reciprocal mixing or desired-signal loss.

C. The receiver's intrinsic noise figure must have improved by the entire displayed change.

D. The earlier trace must have been a receiver-generated artifact.

Answer: B. A lower baseline alone does not identify the transfer or error mechanism. The desired reference and relevant state controls separate the alternatives. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: Several mechanisms remain possible, including noise rejection, changed gain, reduced reciprocal mixing or desired-signal loss.

Distinguishing consideration: compare this with option A, "The desired signal-to-noise ratio must have improved by the same amount"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-MCQ-028. A strong-signal challenge compares two preselector states. Why retain the same weak desired reference in both?

A. To test whether the changed state preserves the desired measurement while changing blocker admission.

B. To remove the need to measure blocker levels at the receiver plane.

C. To guarantee that both preselector states have identical thermal noise.

D. To make the final filter reverse any earlier clipping.

Answer: A. The reference exposes altered desired transfer or lost sensitivity that might otherwise make disappearance of a suspect component misleading. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: To test whether the changed state preserves the desired measurement while changing blocker admission.

Distinguishing consideration: compare this with option B, “To remove the need to measure blocker levels at the receiver plane”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-029. A report applies 35 dB blocker rejection as the correction for a desired signal that experiences only 1 dB filter loss. What is the central error?

A. It underestimates the desired input level by 34 dB.

B. It uses transfer at the wrong frequency and overstates the inferred desired input level by 34 dB.

C. It changes only the uncertainty, leaving the corrected value valid.

D. It correctly compensates all signals because the filter is passive.

Answer: B. The desired-plane correction must use the desired-frequency loss. The extra 34 dB is a wrong-frequency correction, not a physical sensitivity improvement. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why the selected alternative fits: It uses transfer at the wrong frequency and overstates the inferred desired input level by 34 dB.

Distinguishing consideration: compare this with option A, “It underestimates the desired input level by 34 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-MCQ-030. A filter loss calibration was made at a temperature different from the field state. What follows when temperature dependence is consequential?

A. Treat all passive filters as temperature independent.

B. Apply the blocker rejection instead of the desired passband loss.

C. Average the calibration temperature and field temperature and declare the response exact.

D. Use an applicable correction or quantify the residual uncertainty for the actual state.

Answer: D. The gain budget terms are state dependent. A calibration must be applicable to the state or accompanied by a justified treatment of the difference.

Review: Equation 6; Preselection and Filter State. Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: Use an applicable correction or quantify the residual uncertainty for the actual state.

Distinguishing consideration: compare this with option A, “Treat all passive filters as temperature independent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Preselection and Filter State.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Preselection and Filter State.

V011-C03-MCQ-031. Two mutually uncorrelated blockers each deliver -20 dBm at a stage. What is their combined mean power, assuming powers add at that plane?

A. -20 dBm.

B. 0 dBm.

C. Approximately -16.99 dBm.

D. -40 dBm.

Answer: C. Each supplies 0.01 mW, so the total is 0.02 mW. Ten times its base-ten logarithm is -16.99 dBm; absolute dBm values are not directly added. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: Approximately -16.99 dBm.

Distinguishing consideration: compare this with option A, “-20 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

V011-C03-MCQ-032. A constructed loading budget contains 1 mW and 3 mW of additive mean blocker power. What total level follows?

A. 4 mW, approximately 12.04 dBm.

B. 2 mW, approximately 3.01 dBm.

C. 3 mW, approximately 4.77 dBm.

D. 4 mW, approximately 6.02 dBm.

Answer: D. Linear powers sum to 4 mW. A power ratio uses ten times the base-ten logarithm, producing approximately 6.02 dBm. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: 4 mW, approximately 6.02 dBm.

Distinguishing consideration: compare this with option A, “4 mW, approximately 12.04 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

V011-C03-MCQ-033. Two equal mean-power signals can have different relative phase histories. Which assessment should avoid treating their combined mean as a complete peak specification?

A. A mechanism governed by instantaneous input voltage or envelope peaks.

B. A thermal calculation explicitly averaged over times long compared with the relative phase variation.

C. A calculation explicitly limited to additive long-term mean powers.

D. A correction of a single known small-signal passband loss.

Answer: A. Peak-sensitive loading depends on time-domain superposition. A mean-power sum can be correct while lacking the peak information needed for a different mechanism. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: A mechanism governed by instantaneous input voltage or envelope peaks.

Distinguishing consideration: compare this with option B, “A thermal calculation explicitly averaged over times long compared with the relative phase variation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-034. A preselector retains one narrow desired channel but excludes other frequencies visited by a frequency-agile event. What limits a negative observation?

A. Only the admitted frequencies and their valid observation times were covered.

B. A low in-band noise floor guarantees coverage of the entire agile trajectory.

C. A scalar loss correction restores samples from excluded frequencies.

D. The preselector rejection establishes absence at every excluded frequency.

Answer: A. Spectral exclusion can improve immunity while reducing event coverage. A correction cannot restore signal information that was never admitted.

Review: Preselection and Filter State. Source: §3.3 Preselection and Filter State (p. 1251)

Why the selected alternative fits: Only the admitted frequencies and their valid observation times were covered.

Distinguishing consideration: compare this with option B, “A low in-band noise floor guarantees coverage of the entire agile trajectory”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Preselection and Filter State.

Review: Chapter 3 — Preselection and Filter State.

V011-C03-MCQ-035. When is a notch filter potentially useful in the chapter's front-end strategy?

A. When measured rejection of a dominant unwanted band occurs before the vulnerable stage while the desired response remains acceptable.

B. When its nominal notch frequency alone proves the desired waveform is unaffected.

C. Only when placed after every active stage.

D. Whenever it produces the lowest displayed baseline regardless of desired transfer.

Answer: A. The relevant benefit is reduced harmful admission with retained desired capability. Actual response and placement determine that trade. Review: Front-End Characterization and Field Decisions. Source: §3.9 Front-End Characterization and Field Decisions (p. 1265)

Why the selected alternative fits: When measured rejection of a dominant unwanted band occurs before the vulnerable stage while the desired response remains acceptable.

Distinguishing consideration: compare this with option B, "When its nominal notch frequency alone proves the desired waveform is unaffected"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Front-End Characterization and Field Decisions.

Review: Chapter 3 — Front-End Characterization and Field Decisions.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-036. A preselector precedes an amplifier and strongly rejects a blocker. Why must the filter's own power-handling and state limits still be considered?

A. Strong rejection guarantees zero stored energy and zero heating.

B. All receiver limits are determined only by the last digitizer.

C. Passive components cannot be characterized by a transfer function.

D. The filter itself can be the first component to leave the assumed valid transfer regime.

Answer: D. The first-vulnerable-stage analysis applies to every exposed component. A downstream amplifier can be protected while an upstream accessory is outside its conditions. Review: Find the first stage that can lose validity. Source: §3.2 Find the first stage that can lose validity (p. 1249)

Why the selected alternative fits: The filter itself can be the first component to leave the assumed valid transfer regime.

Distinguishing consideration: compare this with option A, "Strong rejection guarantees zero stored energy and zero heating"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-037. A constructed gain plan requires a linear power gain of at least 16 for noise performance and no more than 25 for downstream loading. Which choice is inside the feasible interval?

A. 40.

B. 12.

C. 30.

D. 20.

Answer: D. Both independently justified bounds must hold: 16 no greater than gain no greater than 25. A choice of 20 satisfies the overlap. Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why the selected alternative fits: 20.

Distinguishing consideration: compare this with option A, “40”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-038. The required minimum gain for noise is 25, but the maximum permitted gain for loading is 10, both in linear power units. What is the justified conclusion?

A. No gain setting satisfies both stated bounds; alter the architecture or requirement and re-evaluate.

B. Use 10 and claim that downstream amplification restores the original noise target.

C. Use 25 because noise requirements always override loading limits.

D. Use the arithmetic mean, 17.5, because it compromises between the limits.

Answer: A. An empty intersection is infeasible under the stipulated model. Averaging incompatible bounds does not satisfy either requirement. Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why the selected alternative fits: No gain setting satisfies both stated bounds; alter the architecture or requirement and re-evaluate.

Distinguishing consideration: compare this with option B, “Use 10 and claim that downstream amplification restores the original noise target”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-039. A blocker is -40 dBm at the input of an adjustable linear amplifier. A separately justified downstream limit is -20 dBm, with no other transfer. What is the maximum amplifier gain under that limit?

A. -20 dB.

B. 60 dB.

C. 20 dB.

D. 40 dB.

Answer: C. The output is -40 dBm plus gain in dB. Requiring it not exceed -20 dBm bounds gain at 20 dB. Actual peaks and other blockers remain part of a full loading analysis. Review: Equation 6; Choose gain from a feasible interval. Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: 20 dB.

Distinguishing consideration: compare this with option A, “-20 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-040. A noise calculation requires a minimum linear gain of 25, while loading permits at most 20 dB. Which interval is consistent in decibels?

A. Approximately 13.98 dB through 20 dB.

B. 0.04 dB through 20 dB.

C. Approximately 27.96 dB through 20 dB.

D. 25 dB through 20 dB.

Answer: A. Convert the power ratio with ten times $\log_{10}$: 25 corresponds to 13.979 dB. Mixing linear gain and dB can falsely make a feasible interval appear empty.
Review: Choose gain from a feasible interval; Model 2B. Source: §2.14 Model 2B: a matched, fixed-state noise cascade (p. 665)
Why the selected alternative fits: Approximately 13.98 dB through 20 dB.
Distinguishing consideration: compare this with option B, “0.04 dB through 20 dB”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval.
Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-041. Under the matched two-stage model, the first stage contributes 80 K, the second 2000 K, and the target is 100 K. Downstream loading separately limits first-stage gain to 15 dB. Which conclusion is correct?

A. The noise target requires at least 20 dB, so the stated design has no feasible gain overlap.

B. A gain of 15 dB satisfies the target because 80 K is below 100 K.

C. A gain of 17.5 dB satisfies both constraints by averaging their limits.

D. Later digital scaling can make 15 dB satisfy the analog noise bound.

Answer: A. The later contribution may be at most 20 K, requiring power gain $\frac{2000}{20}=100$, or 20 dB. The independently stated 15 dB ceiling prevents that choice.

Review: Choose gain from a feasible interval; Equation 4J. Source: Equation 4J. Minimum first-stage gain for a temperature limit (p. 675)

Why the selected alternative fits: The noise target requires at least 20 dB, so the stated design has no feasible gain overlap.

Distinguishing consideration: compare this with option B, “A gain of 15 dB satisfies the target because 80 K is below 100 K”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit; Chapter 3 — Choose gain from a feasible interval.

V011-C03-MCQ-042. Increasing attenuation before an overloaded amplifier restores its linear response. What trade remains to be assessed?

A. Whether a corrected signal display must fall by exactly the attenuation amount.

B. The accompanying sensitivity and noise penalty at the original input plane.

C. Whether attenuation after the final detector can provide the same upstream protection.

D. Whether the original compressed samples can now be repaired by the new setting.

Answer: B. Pre-amplifier loss can restore validity while raising input-equivalent noise. A useful choice must satisfy the intended weak-signal observation as well as loading. Review: Gain Distribution and Attenuation. Source: §3.5 Gain Distribution and Attenuation (p. 1256)

Why the selected alternative fits: The accompanying sensitivity and noise penalty at the original input plane.

Distinguishing consideration: compare this with option A, “Whether a corrected signal display must fall by exactly the attenuation amount”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Gain Distribution and Attenuation.

Review: Chapter 3 — Gain Distribution and Attenuation.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-043. An attenuator is moved from before an amplifier to immediately after it, preserving nominal total signal gain. What protection inference is justified?

A. The amplifier loses the protection previously supplied by that attenuation at its input.

B. The amplifier exposure is unchanged because total chain gain is unchanged.

C. The amplifier input compression limit rises by the attenuation setting.

D. The after-amplifier attenuator reverses products created inside the amplifier.

Answer: A. A downstream attenuator changes what reaches later stages; it does not reduce what enters the preceding amplifier. Equal final gain conceals this internal difference. Review: Choose gain from a feasible interval; Application 2B.7. Source: §2.24 Application 2B.7: place attenuation before the vulnerable stage (p. 684)

Why the selected alternative fits: The amplifier loses the protection previously supplied by that attenuation at its input.

Distinguishing consideration: compare this with option B, “The amplifier exposure is unchanged because total chain gain is unchanged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage; Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage; Chapter 3 — Choose gain from a feasible interval.

V011-C03-MCQ-044. The corrected desired level remains constant when input attenuation is increased. What does that establish about sensitivity?

A. It does not establish unchanged sensitivity; the corrected noise and detection criterion must also be evaluated.

B. It proves that the attenuator is physically noiseless.

C. It establishes identical input-equivalent noise because both signal estimates agree.

D. It establishes that every upstream and downstream component is linear.

Answer: A. Amplitude correction can keep the external-signal estimate constant while physical loss worsens the noise budget. The signal estimate and sensitivity are different quantities. Review: Gain Distribution and Attenuation. Source: §3.5 Gain Distribution and Attenuation (p. 1256)

Why the selected alternative fits: It does not establish unchanged sensitivity; the corrected noise and detection criterion must also be evaluated.

Distinguishing consideration: compare this with option B, “It proves that the attenuator is physically noiseless”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Gain Distribution and Attenuation.

Review: Chapter 3 — Gain Distribution and Attenuation.

V011-C03-MCQ-045. A receiver clips before a final digital scaling operation. What does reducing only the digital scale accomplish for those clipped samples?

A. It lowers their displayed magnitude but cannot restore the missing analog information.

B. It reconstructs the clipped sample peaks from the scale factor.

C. It increases the physical input range of the preceding amplifier.

D. It makes an earlier gain calibration valid through the clipped interval.

Answer: A. Scaling retained data is not a reversal of saturation. The acquisition must remain within the relevant analog and converter ranges. Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why the selected alternative fits: It lowers their displayed magnitude but cannot restore the missing analog information.

Distinguishing consideration: compare this with option B, “It reconstructs the clipped sample peaks from the scale factor”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

V011-C03-MCQ-046. A constant weak source appears to vary whenever an intermittent blocker arrives and automatic gain control is active. What is a justified explanation to test?

A. The blocker can drive gain-state changes that alter the weak-source indication.

B. The weak transmitter must have changed its emitted power synchronously.

C. AGC guarantees that every corrected transient amplitude is exact.

D. A receiver gain change cannot affect a source that is physically constant.

Answer: A. The observed amplitude depends on both source and receiver state. Gain-control telemetry or an equivalent state reconstruction is needed to separate them. Review: Gain Distribution and Attenuation. Source: §3.5 Gain Distribution and Attenuation (p. 1256)

Why the selected alternative fits: The blocker can drive gain-state changes that alter the weak-source indication.

Distinguishing consideration: compare this with option B, “The weak transmitter must have changed its emitted power synchronously”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Gain Distribution and Attenuation.

Review: Chapter 3 — Gain Distribution and Attenuation.

V011-C03-MCQ-047. Why is an average gain value insufficient to reconstruct an interval that includes clipping and missing samples?

A. Average gain always equals the smallest instantaneous gain.

B. A single average necessarily determines the timing of every state transition.

C. An arithmetic average is forbidden even for a separately justified linear estimator.

D. It does not identify the time-dependent transfer or restore information discarded during invalid states.

Answer: D. Gain history and irreversible loss cannot be inferred from one mean. A valid estimator must account for the states and information that actually remain.

Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why the selected alternative fits: It does not identify the time-dependent transfer or restore information discarded during invalid states.

Distinguishing consideration: compare this with option A, “Average gain always equals the smallest instantaneous gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

V011-C03-MCQ-048. When analog signal and noise underuse a later digitizer range, what can additional valid analog gain improve?

A. The number of analog samples that existed before a recording gap.

B. The analog SNR lost before that gain stage, regardless of added noise.

C. The input-referred importance of converter noise, while leaving the established analog SNR unchanged if added noise is negligible.

D. The frequency rejection of an earlier absent preselector.

Answer: C. More gain can make converter noise less consequential relative to the admitted analog signal and noise. It cannot reverse an earlier analog SNR loss.

Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why the selected alternative fits: The input-referred importance of converter noise, while leaving the established analog SNR unchanged if added noise is negligible.

Distinguishing consideration: compare this with option A, “The number of analog samples that existed before a recording gap”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

V011-C03-MCQ-049. A quiet digital trace is observed after heavy processing. Which additional evidence is needed before interpreting it as a valid low-noise analog observation?

A. Only the nominal ADC bit count without its actual input level.

B. Raw samples and gain or overload state sufficient to exclude clipping, underuse and processing-induced suppression.

C. Only the final digital scale multiplier.

D. Only the displayed baseline after the heaviest available averaging.

Answer: B. Several invalid or differently processed acquisitions can produce a quiet display. The retained raw data and state record constrain that interpretation.

Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why the selected alternative fits: Raw samples and gain or overload state sufficient to exclude clipping, underuse and processing-induced suppression.

Distinguishing consideration: compare this with option A, “Only the nominal ADC bit count without its actual input level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

V011-C03-MCQ-050. A challenge relies on a small difference between two attenuator settings. Which physical characteristics most directly affect that comparison?

A. Actual step loss, frequency response, repeatability and contact condition.

B. Only the number of selectable attenuation states.

C. Only the final filter center frequency.

D. Only the displayed correction rounded to the nearest decibel.

Answer: A. The test depends on the realized difference in transfer, not merely the commanded labels. Small systematic step errors can imitate or hide the expected change. Review: Gain Distribution and Attenuation. Source: §3.5 Gain Distribution and Attenuation (p. 1256)

Why the selected alternative fits: Actual step loss, frequency response, repeatability and contact condition.

Distinguishing consideration: compare this with option B, “Only the number of selectable attenuation states”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Gain Distribution and Attenuation.

Review: Chapter 3 — Gain Distribution and Attenuation.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-051. A component does not follow the expected raw change when a known attenuator is switched. What is the correct first interpretation?

A. The attenuator correction has proved all later stages linear.

B. Its origin or validity may involve a stage after the attenuator, clipping or control-loop behavior, which requires further tests.

C. It is conclusively internal regardless of source and combiner behavior.

D. It is conclusively an external emitter because the input source remains connected.

Answer: B. The differential response constrains mechanisms but is not a unique attribution by itself. Realized transfer and competing receiver behavior must be checked. Review: Gain Distribution and Attenuation. Source: §3.5 Gain Distribution and Attenuation (p. 1256)

Why the selected alternative fits: Its origin or validity may involve a stage after the attenuator, clipping or control-loop behavior, which requires further tests.

Distinguishing consideration: compare this with option A, “The attenuator correction has proved all later stages linear”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Gain Distribution and Attenuation.

Review: Chapter 3 — Gain Distribution and Attenuation.

V011-C03-MCQ-052. A valid external CW signal is measured in two fixed states differing only by 6 dB input attenuation. What raw and correctly input-referred behavior is expected?

A. Both raw and corrected levels must rise by 6 dB.

B. Raw signal level falls by 6 dB; the corrected input estimate remains approximately constant within uncertainty.

C. Both levels remain constant even without applying any state correction.

D. Raw signal level remains constant; the corrected input estimate falls by 6 dB.

Answer: B. The physical attenuator changes the transmitted signal. An applicable input-plane correction removes that known transfer from the estimate, without removing its noise consequences. Review: Gain Distribution and Attenuation; Equation 6. Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: Raw signal level falls by 6 dB; the corrected input estimate remains approximately constant within uncertainty.

Distinguishing consideration: compare this with option A, “Both raw and corrected levels must rise by 6 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Gain Distribution and Attenuation.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Gain Distribution and Attenuation.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-053. A line generated after a switched attenuator may respond differently from an external reference. Why is that useful but insufficient for final attribution?

A. It distinguishes path hypotheses, but clipping, control changes and upstream source products can complicate the response.

B. Every internal line necessarily has exactly zero response to every attenuator state.

C. A single two-state comparison fixes the physical origin without a source control.

D. An external signal can never coexist with a receiver product at the same frequency.

Answer: A. State responses must be interpreted under their actual transfer and validity conditions. A plausible mechanism remains a hypothesis until discriminating alternatives are bounded. Review: Gain Distribution and Attenuation; An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: It distinguishes path hypotheses, but clipping, control changes and upstream source products can complicate the response.

Distinguishing consideration: compare this with option B, “Every internal line necessarily has exactly zero response to every attenuator state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures; Chapter 3 — Gain Distribution and Attenuation.

Review: Chapter 3 — An acceptance sequence that separates competing failures; Chapter 3 — Gain Distribution and Attenuation.

V011-C03-MCQ-054. Two preselector states show different noise levels but also use different effective bandwidths. What comparison is justified?

A. Treat the entire difference as a receiver noise-figure change.

B. Use the lower trace as proof of superior weak-signal detection in every case.

C. Subtract the center frequencies to obtain the bandwidth correction.

D. Match bandwidth or account explicitly for its effect before attributing the difference to the preselector mechanism.

Answer: D. Integrated noise depends on admitted bandwidth. A changed bandwidth is a competing explanation, and desired-signal retention must also remain adequate. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: Match bandwidth or account explicitly for its effect before attributing the difference to the preselector mechanism.

Distinguishing consideration: compare this with option A, “Treat the entire difference as a receiver noise-figure change”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-MCQ-055. A test changes preselector, amplifier gain and detector averaging at once. What is its principal attribution weakness?

A. A correct final amplitude removes the need to identify the altered states.

B. The effect can always be assigned to whichever setting changed by the largest numerical amount.

C. Every simultaneous change necessarily corrupts all retained raw data.

D. Several altered mechanisms can explain the result, so the test does not isolate the proposed cause.

Answer: D. A useful challenge predicts how a controlled change affects competing mechanisms. Multiple uncontrolled changes weaken that discrimination. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: Several altered mechanisms can explain the result, so the test does not isolate the proposed cause.

Distinguishing consideration: compare this with option A, “A correct final amplitude removes the need to identify the altered states”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-MCQ-056. A report states that the receiver has 12 dB of headroom. What information makes that statement interpretable?

A. Only the receiver's absolute damage rating.

B. Only the final chain gain in decibels.

C. Only the difference between the displayed noise floor and the top of the screen.

D. The operating quantity and plane, the particular limiting criterion, and the applicable state and signal conditions.

Answer: D. Headroom is relative to a specified limit. Compression, converter clipping and damage thresholds are different quantities and cannot be substituted silently. Review: Chapter Glossary: Headroom; Equation 6. Source: Equation 6. Input power after front-end correction (p. 1269)

Why the selected alternative fits: The operating quantity and plane, the particular limiting criterion, and the applicable state and signal conditions.

Distinguishing consideration: compare this with option A, "Only the receiver's absolute damage rating"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — HEADROOM (glossary).

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — HEADROOM (glossary).

V011-C03-MCQ-057. A short pulse has modest average power but a large peak. Which conclusion follows for protection planning?

A. A peak rating for one pulse width covers every duty cycle.

B. Both peak and average exposure must be compared with limits having appropriate waveform and duration conditions.

C. The final display detector necessarily measures the largest incident peak.

D. The average power alone guarantees survival whenever it is below a CW rating.

Answer: B. Protection and heating depend on waveform conditions. Neither a mean nor an unqualified peak number supplies every relevant exposure condition.

Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: Both peak and average exposure must be compared with limits having appropriate waveform and duration conditions.

Distinguishing consideration: compare this with option A, “A peak rating for one pulse width covers every duty cycle”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-058. Why does an idle protection limiter still belong in a small-signal calibration and noise budget?

A. Its survival rating determines its exact small-signal phase response.

B. It necessarily has zero transfer effect until its damage threshold is crossed.

C. Its insertion loss, mismatch and reactive loading can change the desired transfer before limiting begins.

D. A limiter is outside the receiver boundary whenever it is passive.

Answer: C. Protection hardware remains a physical part of the signal path. Its small-signal state must be characterized instead of represented as an ideal transparent switch. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Its insertion loss, mismatch and reactive loading can change the desired transfer before limiting begins.

Distinguishing consideration: compare this with option A, “Its survival rating determines its exact small-signal phase response”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-059. In the PIN-limiter mechanism described by the cited manufacturer, what happens when a large RF signal increases carriers in the intrinsic region?

A. The desired weak-signal phase is guaranteed unchanged during limiting.

B. The RF resistance necessarily increases without changing mismatch.

C. The RF resistance decreases and the circuit can present a stronger limiting mismatch.

D. The carrier population is irrelevant to the RF conduction state.

Answer: C. The cited mechanism relates stored carriers to lowered RF resistance. It explains why the mounted protection network cannot be treated as an ideal on/off element. Review: Measure protection in the small-signal and recovery states; source note 10. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: The RF resistance decreases and the circuit can present a stronger limiting mismatch.

Distinguishing consideration: compare this with option A, “The desired weak-signal phase is guaranteed unchanged during limiting”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-060. Why can a PIN-limiter recovery depend on the external current-return path?

A. The return path makes every detector recover at the same instant as the diode.

B. The return path removes the need to characterize the mounted network.

C. The external path fixes the desired source frequency independently of the input.

D. Carrier removal after the event depends partly on the path through which stored charge can leave.

Answer: D. The cited device explanation connects carrier removal with the external circuit. Recovery of the entire measured chain can still include additional mechanisms. Review: Measure protection in the small-signal and recovery states; source note 10. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Carrier removal after the event depends partly on the path through which stored charge can leave.

Distinguishing consideration: compare this with option A, “The return path makes every detector recover at the same instant as the diode”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-061. Why characterize a complete mounted protection network rather than only a bare diode specification?

A. Mounting, reactive loading and the surrounding current path can affect small-signal transfer and recovery.

B. Circuit parasitics disappear whenever the receiver uses a 50-ohm nominal interface.

C. The mounted network necessarily has exactly the same response at every frequency.

D. A bare diode specification has no possible relevance to any design decision.

Answer: A. A component rating applies under its stated conditions. The installed network adds interfaces and circuit behavior that must be included in the actual signal path. Review: Measure protection in the small-signal and recovery states.

Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Mounting, reactive loading and the surrounding current path can affect small-signal transfer and recovery.

Distinguishing consideration: compare this with option B, “Circuit parasitics disappear whenever the receiver uses a 50-ohm nominal interface”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-062. Which set contains three distinct protection consequences identified in the chapter?

A. During-event leakage, hardware survival, and subsequent recovery of a valid weak-signal measurement.

B. Detector bandwidth alone, independent of the event and protected hardware.

C. Nominal gain, corrected gain, and displayed gain as three independent survival guarantees.

D. Center frequency, display center, and tuned frequency as three equivalent recovery measures.

Answer: A. A device may survive while the useful channel remains disturbed, and leakage during the event is a separate exposure quantity. Each needs its own criterion. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: During-event leakage, hardware survival, and subsequent recovery of a valid weak-signal measurement.

Distinguishing consideration: compare this with option B, “Detector bandwidth alone, independent of the event and protected hardware”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-063. A limiter bounds the later portion of a pulse. What may still reach a downstream component?

A. A leading transient before the limiter reaches its limiting state.

B. No RF energy, because eventual limiting guarantees zero earlier leakage.

C. A waveform determined entirely by the final detector averaging setting.

D. Only thermal noise at the enclosure temperature.

Answer: A. The beginning of an event and its steady limited portion can have different transfer. Protection planning must address the leading response as well as later leakage. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: A leading transient before the limiter reaches its limiting state.

Distinguishing consideration: compare this with option B, “No RF energy, because eventual limiting guarantees zero earlier leakage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

V011-C03-MCQ-064. A catalog gives recovery time to nearly nominal insertion loss. Why may that be insufficient for coherent phase measurement?

A. Insertion loss and phase must recover at identical times in every network.

B. A phase measurement depends only on the limiter survival rating.

C. A shorter catalog recovery value always implies lower measurement uncertainty.

D. Amplitude recovery under that criterion does not automatically establish calibrated phase recovery.

Answer: D. Recovery is defined by an observable and tolerance. The criterion must match the intended amplitude, phase, modulation or baseline requirement. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Amplitude recovery under that criterion does not automatically establish calibrated phase recovery.

Distinguishing consideration: compare this with option A, “Insertion loss and phase must recover at identical times in every network”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-065. Which practice is consistent with the ADL8201 data-sheet example used in the chapter?

A. Treat a typical recovery entry as proof of a complete receiver detector response.

B. Keep the identified device, frequency, pulse width, duty cycle and temperature conditions attached to its survival data.

C. Apply one listed pulse survival rating to every receiver accessory.

D. Use a single device number as a universal permissible test exposure.

Answer: B. The cited tables separate operational performance and conditional survivability. The chapter does not transfer those limits to an arbitrary assembly.

Review: Measure protection in the small-signal and recovery states; source note 11.

Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Keep the identified device, frequency, pulse width, duty cycle and temperature conditions attached to its survival data.

Distinguishing consideration: compare this with option A, “Treat a typical recovery entry as proof of a complete receiver detector response”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-066. What is the appropriate interpretation of an absolute maximum stress rating in a component data sheet?

A. It replaces all pulse-width and duty-cycle conditions elsewhere in the data sheet.

B. It defines the calibrated small-signal range for every waveform.

C. It is not a guarantee of valid continuous measurement operation at that stress.

D. It establishes the complete receiver damage margin without considering accessories.

Answer: C. A stress limit and an operating specification have different purposes. The specified functional conditions and the installed path govern the measurement.
Review: Source note 11; Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: It is not a guarantee of valid continuous measurement operation at that stress.
Distinguishing consideration: compare this with option A, “It replaces all pulse-width and duty-cycle conditions elsewhere in the data sheet”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 3 — Input Protection and Recovery; Chapter 3 — Measure protection in the small-signal and recovery states.
Review: Chapter 3 — Input Protection and Recovery; Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-067. A constructed rectangular pulse has 20 dBm on-state power and 1 percent duty factor, with negligible off-state power. What average power follows?

A. 0 dBm.

B. -20 dBm.

C. 2 dBm.

D. 20 dBm.

Answer: A. Twenty dBm is 100 mW. Multiplying by 0.01 gives 1 mW, or 0 dBm. The 20 dBm peak condition still matters to peak-sensitive protection. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: 0 dBm.

Distinguishing consideration: compare this with option B, “-20 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

V011-C03-MCQ-069. A protected chain survives a pulse but remains outside its weak-signal acceptance tolerance for 20 microseconds. A desired event arrives 10 microseconds after the pulse ends. What is justified?

A. Hardware survival does not establish valid observation of that desired event during recovery.

B. Survival guarantees the desired event was measured with normal sensitivity.

C. The delayed event can be reconstructed from the limiter's peak-power rating.

D. A later successful closing check establishes the earlier event's amplitude.

Answer: A. Recovery creates a time-dependent validity limit. A check after recovery cannot supply information that was unavailable during the disturbed interval.

Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Hardware survival does not establish valid observation of that desired event during recovery.

Distinguishing consideration: compare this with option B, "Survival guarantees the desired event was measured with normal sensitivity"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-070. Which record best supports a recovery measurement after a bounded strong-signal event?

A. A weak desired reference observed before, during and after the event, with event timing and receiver state retained.

B. Only the last sample after the trace appears quiet.

C. Only the data-sheet recovery value of one component.

D. Only a continuous-wave insertion-loss sweep made before the event.

Answer: A. The time-resolved reference reveals both disruption and return under the actual measurement criterion. State and event records support attribution.

Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: A weak desired reference observed before, during and after the event, with event timing and receiver state retained.

Distinguishing consideration: compare this with option B, “Only the last sample after the trace appears quiet”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-071. Why does a satisfactory continuous-wave gain sweep not establish pulsed recovery performance?

A. A pulsed event always has less peak exposure than a CW signal of the same mean power.

B. Recovery is fixed solely by the displayed frequency span.

C. It may never exercise or observe the post-pulse transient state that defines recovery.

D. Continuous-wave gain is unrelated to every possible small-signal measurement.

Answer: C. Steady-state response and time-dependent recovery test different conditions. The pulse waveform and observation interval must actually exercise the latter. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: It may never exercise or observe the post-pulse transient state that defines recovery.

Distinguishing consideration: compare this with option A, “A pulsed event always has less peak exposure than a CW signal of the same mean power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

V011-C03-MCQ-072. A long acquisition is reviewed only at its final settled endpoint. What can that review miss?

A. Every possible calibration error in the final sample by definition.

B. The need for a clock only when no pulse was present.

C. An earlier invalid interval during which nearby weak events were distorted or undetectable.

D. The final settled amplitude that was actually measured.

Answer: C. A valid endpoint does not describe the entire trajectory. Recovery requires observations over the interval relevant to subsequent events. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: An earlier invalid interval during which nearby weak events were distorted or undetectable.

Distinguishing consideration: compare this with option A, “Every possible calibration error in the final sample by definition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-073. A slow trace return follows a pulse in a chain containing a limiter, AGC and detector averaging. What can be concluded from the trace alone?

A. The limiter alone caused the delay because it is present.

B. The data sheet recovery time is necessarily false.

C. The analog amplifier must be damaged permanently.

D. The measured chain has persistence, but the responsible subsystem has not yet been isolated.

Answer: D. Multiple stages can retain memory. A controlled change or independent observable is required to assign the measured delay to one mechanism. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: The measured chain has persistence, but the responsible subsystem has not yet been isolated.

Distinguishing consideration: compare this with option A, “The limiter alone caused the delay because it is present”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-074. Reducing detector averaging time makes a recovery edge appear faster. Which accompanying effect must be evaluated?

A. A guaranteed equal reduction in physical limiter carrier lifetime.

B. The changed measurement variability and temporal response of the detector itself.

C. A guaranteed increase in the protected amplifier's damage threshold.

D. Removal of every gain-state transition from the acquisition.

Answer: B. Detector dynamics can mask analog recovery. Altering them changes the observation system, including noise, and must be recorded. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: The changed measurement variability and temporal response of the detector itself.

Distinguishing consideration: compare this with option A, "A guaranteed equal reduction in physical limiter carrier lifetime"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-075. When can a bypass comparison help attribute a protection-related delay?

A. When the configuration permits it, the remaining path stays within its ratings, and the isolated change is actually documented.

B. Whenever the bypass produces a numerically higher gain, without a reference comparison.

C. Whenever removal of protection makes the trace cleaner, regardless of downstream exposure.

D. Only when all other settings are also changed to maximize sensitivity.

Answer: A. A bypass is informative only under valid, controlled conditions. Otherwise it changes exposure or confounds the mechanism being isolated. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: When the configuration permits it, the remaining path stays within its ratings, and the isolated change is actually documented.

Distinguishing consideration: compare this with option B, “Whenever the bypass produces a numerically higher gain, without a reference comparison”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-076. After a suspected overload, which check best reflects the chapter's verification principle?

A. A single low-frequency tone that proves every band remains unchanged.

B. The absence of visible mechanical damage as evidence of calibrated transfer.

C. A front-panel self-test alone that replaces external path verification in all cases.

D. Known references at several relevant levels and frequencies, compared with applicable accepted baselines.

Answer: D. Hidden loss, distortion and recovery defects can depend on level and frequency. The check must exercise the range relevant to the subsequent measurement. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: Known references at several relevant levels and frequencies, compared with applicable accepted baselines.

Distinguishing consideration: compare this with option A, "A single low-frequency tone that proves every band remains unchanged"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-077. A limiter still passes a low-frequency reference after an event. What remains unproved?

A. Its low-frequency response at the conditions just checked.

B. Whether low-frequency and high-frequency signals use the same units.

C. The existence of the retained low-frequency reference record.

D. Its required loss, distortion and response at untested higher frequencies and levels.

Answer: D. A local successful test has local scope. It cannot verify every spectral and loading condition of the installed path. Review: Input Protection and Recovery.

Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: Its required loss, distortion and response at untested higher frequencies and levels.

Distinguishing consideration: compare this with option A, “Its low-frequency response at the conditions just checked”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-078. What governs the magnitude of a proposed strong-signal challenge to an installed receiver?

A. The amount of attenuation shown only after the vulnerable component.

B. A favorable survival number from an unrelated limiter data sheet.

C. The highest level the available generator can produce.

D. The actual receiver and accessory limits under the intended waveform and configuration.

Answer: D. A constructed example is not an equipment rating. The complete exposed path and specified conditions govern a valid challenge. Review: Input Protection and Recovery; source note 11. Source: §3.7 Input Protection and Recovery (p. 1260)

Why the selected alternative fits: The actual receiver and accessory limits under the intended waveform and configuration.

Distinguishing consideration: compare this with option A, “The amount of attenuation shown only after the vulnerable component”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Input Protection and Recovery; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Input Protection and Recovery; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-079. A protection network prevents permanent damage but significantly raises the weak-signal noise floor. How should its acceptance be judged?

A. Only by its peak-power rating, without a noise or transfer measurement.

B. As necessarily defective because protection can never change small-signal loss.

C. Against both survival and the declared operational measurement requirement, as separate criteria.

D. As fully acceptable for every weak-signal task because the hardware survived.

Answer: C. Protection success and usable measurement performance are distinct. The intended observation determines whether the surviving path is fit for use.

Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why the selected alternative fits: Against both survival and the declared operational measurement requirement, as separate criteria.

Distinguishing consideration: compare this with option A, “Only by its peak-power rating, without a noise or transfer measurement”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-MCQ-080. A front-end response drifts after repeated high-power events while nominal settings remain fixed. What should the investigation include?

A. Only the average corrected signal level after discarding event timing.

B. Only a replacement final display scale.

C. Power history, temperature, bias and protection state alongside the measured transfer.

D. Only the commanded frequency because an unchanged setting establishes unchanged hardware.

Answer: C. Physical state can change without a new menu setting. The chapter identifies history, thermal behavior and bias as possible contributors to gradual or persistent response change. Review: Input Protection and Recovery; Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why the selected alternative fits: Power history, temperature, bias and protection state alongside the measured transfer.

Distinguishing consideration: compare this with option A, “Only the average corrected signal level after discarding event timing”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Verification and Maintenance Controls; Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Verification and Maintenance Controls; Chapter 3 — Input Protection and Recovery.

V011-C03-MCQ-081. Two generators joined through a combiner produce a new line when both are enabled. What must be bounded before assigning the line to receiver intermodulation?

A. Only the desired-frequency display correction.

B. Source harmonics and noise, generator interaction, combiner behavior and actual levels at the receiver plane.

C. Only the receiver gain setting, because a passive combiner cannot affect attribution.

D. Only the nominal frequency difference between the generators.

Answer: B. The source and combining path can generate or convey the same apparent product. A receiver attribution needs controls that exclude those alternatives. Review: An acceptance sequence that separates competing failures.

Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: Source harmonics and noise, generator interaction, combiner behavior and actual levels at the receiver plane.

Distinguishing consideration: compare this with option A, “Only the desired-frequency display correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-082. A blocker source carries broadband noise inside the desired channel. What can that contamination imitate?

A. A proof that the receiver's equivalent noise temperature is independent of input state.

B. A receiver-related noise rise attributed to the blocker condition.

C. Only a calibration-date error, without any change in measured noise.

D. Only a change in the desired transmitter clock frequency.

Answer: B. The observed channel noise can originate upstream of the receiver. Source spectral purity and delivered noise must be bounded when interpreting the challenge. Review: An acceptance sequence that separates competing failures.

Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: A receiver-related noise rise attributed to the blocker condition.

Distinguishing consideration: compare this with option A, "A proof that the receiver's equivalent noise temperature is independent of input state"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-083. Two blocker sources deliver the same carrier level but different close-in noise at the desired offset. What follows for a comparison of receiver desensitization?

A. Any difference in desired-channel noise must be receiver reciprocal mixing.

B. Equal carrier levels imply equal complete waveforms at the input plane.

C. The source with lower noise requires no measurement of its actual transfer path.

D. Equal carrier levels alone do not establish equivalent noise exposure or isolate the receiver mechanism.

Answer: D. A carrier amplitude is only one property of the applied environment. Different source noise can change the observed outcome before receiver-generated effects are considered. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: Equal carrier levels alone do not establish equivalent noise exposure or isolate the receiver mechanism.

Distinguishing consideration: compare this with option A, “Any difference in desired-channel noise must be receiver reciprocal mixing”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-084. A controlled blocker sweep keeps the weak desired source fixed. Which observation is most directly associated with changed desired transfer?

A. A source-plane carrier reading unchanged by design.

B. A reproducible change in the desired amplitude or modulation quality under the blocker condition.

C. A new line at an unrelated frequency without measuring the desired response.

D. A nominal filter-state name without any retained signal record.

Answer: B. The chapter separates desired-transfer change, admitted-noise rise and discrete products. Compression and gain control can both affect the desired response, so attribution still needs controls. Review: Table 3A. Source: Table 3A. Evidence to retain during a constructed front-end challenge (p. 1266)

Why the selected alternative fits: A reproducible change in the desired amplitude or modulation quality under the blocker condition.

Distinguishing consideration: compare this with option A, “A source-plane carrier reading unchanged by design”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge.

Review: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-085. The blocker is removed and the desired reference returns to its accepted baseline. What is the proper scope of that result?

A. It establishes all receiver bands and accessory paths even if only one was exercised.

B. It supports return of the tested observable in the checked state and interval, without proving uninterrupted validity during the prior exposure.

C. It proves that no earlier desired event was distorted.

D. It removes the need to retain the during-event record.

Answer: B. A return check is evidence about the functions and time actually tested. Its successful endpoint does not reconstruct the preceding measurement history.

Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: It supports return of the tested observable in the checked state and interval, without proving uninterrupted validity during the prior exposure.

Distinguishing consideration: compare this with option A, “It establishes all receiver bands and accessory paths even if only one was exercised”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-086. A two-tone challenge is intended to test a discrete-product hypothesis. Which controlled change is particularly informative?

A. Changing only the plot reference level while leaving the physical inputs identical.

B. Averaging more traces after discarding the tone settings.

C. Changing every gain and filter state simultaneously without a reference.

D. Changing tone frequencies and checking whether the suspect component follows the predicted product frequency.

Answer: D. A mechanism makes a frequency prediction that can be challenged. Source-path products must still be excluded because they may follow similar combinations. Review: Table 3A; Hypothetical Case Adjudication. Source: Table 3A. Evidence to retain during a constructed front-end challenge (p. 1266)

Why the selected alternative fits: Changing tone frequencies and checking whether the suspect component follows the predicted product frequency.

Distinguishing consideration: compare this with option A, “Changing only the plot reference level while leaving the physical inputs identical”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge; Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Review: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge; Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-087. An apparent product follows an expected attenuation dependence in one comparison. Why retain source controls?

A. Attenuation dependence is irrelevant to every nonlinear model.

B. A calibrated attenuator removes the need to identify its location.

C. A product generated outside the receiver cannot enter its passband.

D. Source or combiner products and state changes can mimic part of the expected response.

Answer: D. A predicted slope is supportive within its model, not a unique physical-origin label. Controls must test credible alternative generation paths. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: Source or combiner products and state changes can mimic part of the expected response.

Distinguishing consideration: compare this with option A, “Attenuation dependence is irrelevant to every nonlinear model”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-088. Why retain both a common-input-plane comparison and the raw physical output indications?

A. Corrected output alone preserves every analog state transition.

B. Raw output alone always identifies the correct external reference plane.

C. The former compares external estimates; the latter exposes the actual gain or noise change used to produce them.

D. They are duplicate records with identical meaning in every state.

Answer: C. Corrections can hide deliberate or unexplained changes in raw level. Retaining both forms makes the transfer and its application reviewable. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: The former compares external estimates; the latter exposes the actual gain or noise change used to produce them.

Distinguishing consideration: compare this with option A, “Corrected output alone preserves every analog state transition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-089. Which configuration record is generally stronger than a screen image alone for reproducing a front-end comparison?

A. The nominal model name without installed options or path state.

B. A retained setup or machine-readable state record that identifies the actual path, gain, filter and timing conditions.

C. A single statement that the instrument used its normal mode.

D. A cropped spectrum with its settings annotations removed.

Answer: B. Screen annotations can omit consequential settings. A state record connects the observed trace to the configuration that produced it. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: A retained setup or machine-readable state record that identifies the actual path, gain, filter and timing conditions.

Distinguishing consideration: compare this with option A, “The nominal model name without installed options or path state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-090. Table 3A calls for linear integrated channel noise during a blocker challenge. Why keep the quantity and processing definition explicit?

A. All noise detectors produce identical values once the center frequency matches.

B. The desired source frequency alone fixes the noise estimator.

C. Different detector and averaging operations can produce different displayed statistics from the same underlying noise.

D. A decibel trace average is automatically the same estimator as mean linear power.

Answer: C. The test compares a declared observable. Changing processing can imitate a physical noise change unless the estimator and conditions remain compatible. Review: Table 3A. Source: Table 3A. Evidence to retain during a constructed front-end challenge (p. 1266)

Why the selected alternative fits: Different detector and averaging operations can produce different displayed statistics from the same underlying noise.

Distinguishing consideration: compare this with option A, “All noise detectors produce identical values once the center frequency matches”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge.

Review: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-091. Improving generator isolation removes a suspect line while the delivered fundamental tones are restored to the same levels. Which interpretation is most supported?

A. The receiver's nonlinear coefficient must have changed solely because isolation was added upstream.

B. Receiver attribution no longer requires checking the actual source-plane spectrum.

C. Generation or interaction in the source/combiner path remains a strong explanation for the original line.

D. The original line is proved to have come from an external transmitter unrelated to the test.

Answer: C. The controlled change specifically challenges source interaction. Preserving delivered fundamentals makes that comparison more discriminating, while the full path evidence still determines the claim. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: Generation or interaction in the source/combiner path remains a strong explanation for the original line.

Distinguishing consideration: compare this with option A, "The receiver's nonlinear coefficient must have changed solely because isolation was added upstream"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-092. Added attenuation suppresses both the suspect component and the desired reference below the measurement floor. What conclusion is warranted?

A. The suspect component is conclusively external because the desired reference disappeared.

B. The comparison is inconclusive about origin because observation capability was also lost.

C. The suspect component is conclusively internal because it disappeared.

D. The receiver's noise floor must have remained physically unchanged.

Answer: B. Disappearance is not a discriminating result when both hypotheses become unobservable. A redesigned challenge must retain sufficient desired-reference capability. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: The comparison is inconclusive about origin because observation capability was also lost.

Distinguishing consideration: compare this with option A, "The suspect component is conclusively external because the desired reference disappeared"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-093. Which event calls for renewed front-end verification under the chapter's maintenance controls?

A. Only expiration of a calendar interval, regardless of intervening configuration events.

B. Only visible permanent damage to the enclosure.

C. Only a measured conversion-gain change, treating unchanged gain as sufficient evidence of unchanged noise, linearity and recovery.

D. A consequential cable, filter, firmware, battery, transport or overload change affecting the measurement path.

Answer: D. The controls are tied to changes that may alter actual transfer, state or stability. A scheduled interval alone does not capture every consequential event.

Review: Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why the selected alternative fits: A consequential cable, filter, firmware, battery, transport or overload change affecting the measurement path.

Distinguishing consideration: compare this with option A, "Only expiration of a calendar interval, regardless of intervening configuration events"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-094. Why retain serialized accessories and controlled connector assembly conditions when comparing reference sweeps?

A. To guarantee exactly zero measurement uncertainty.

B. To replace all frequency and level information in the reference record.

C. To reduce ambiguity between a receiver change and a changed external connection or accessory response.

D. To make mismatch corrections unnecessary at every frequency.

Answer: C. The installed path includes accessories and connectors. Their identity and assembly conditions help make repeated comparisons physically comparable.

Review: Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why the selected alternative fits: To reduce ambiguity between a receiver change and a changed external connection or accessory response.

Distinguishing consideration: compare this with option A, “To guarantee exactly zero measurement uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-095. A repeat reference sweep differs from its accepted baseline by more than the stated comparison uncertainty. What is the appropriate action?

A. Apply the baseline gain unchanged because the nominal instrument model is the same.

B. Average the discrepant sweep with the baseline and declare the result exact.

C. Investigate the difference and applicable state before returning the path to the intended measurement service.

D. Discard the new result whenever the equipment still powers on.

Answer: C. A consequential difference can indicate changed transfer, setup or uncertainty assumptions. It requires a resolved explanation or a bounded limitation.

Review: Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why the selected alternative fits: Investigate the difference and applicable state before returning the path to the intended measurement service.

Distinguishing consideration: compare this with option A, “Apply the baseline gain unchanged because the nominal instrument model is the same”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-096. Which release statement is most defensible after a front-end verification?

A. A claim that one two-tone test excludes every future artifact mechanism.

B. A statement that hardware survival alone establishes calibrated measurement accuracy.

C. A blanket pass statement that implies all possible frequencies and waveforms were tested.

D. A statement of verified frequency, level, state and known limitations supported by retained results.

Answer: D. The release scope should follow the actual tested envelope. It must not convert finite tests into a universal claim. Review: Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why the selected alternative fits: A statement of verified frequency, level, state and known limitations supported by retained results.

Distinguishing consideration: compare this with option A, “A claim that one two-tone test excludes every future artifact mechanism”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

V011-C03-MCQ-097. The chapter's hypothetical 1.2 GHz component disappears with a preselector that passes that frequency, and a two-tone test reproduces it. What is the strongest immediately justified description?

A. Proof that only the receiver's first amplifier could have generated the line.

B. Evidence supporting a product hypothesis, with source/combiner products and desired-transfer preservation still to be bounded for receiver-specific attribution.

C. Proof that a hostile 1.2 GHz transmitter was removed by the preselector.

D. Proof that every component passing the preselector is an external signal.

Answer: B. The observations are discriminating but do not by themselves identify every physical generation path. The chapter retains the source-path and reference-transfer qualifications. Review: Hypothetical Case Adjudication. Source: §3.14 Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection (p. 1272)

Why the selected alternative fits: Evidence supporting a product hypothesis, with source/combiner products and desired-transfer preservation still to be bounded for receiver-specific attribution.

Distinguishing consideration: compare this with option A, "Proof that only the receiver's first amplifier could have generated the line"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Review: Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

V011-C03-MCQ-098. Changing antenna polarization reduces a dominant local blocker. What additional check supports a claimed weak-signal benefit?

A. Treat the lower blocker level as a complete receiver calibration.

B. Establish how the same change affects the desired signal and the resulting measurement capability.

C. Apply the original antenna correction without regard to orientation.

D. Assume the desired transfer is unchanged because only the blocker was noticed.

Answer: B. An antenna change can alter both desired and unwanted coupling. The useful comparison must retain the intended observation rather than infer benefit from blocker reduction alone. Review: Front-End Characterization and Field Decisions. Source: §3.9 Front-End Characterization and Field Decisions (p. 1265)

Why the selected alternative fits: Establish how the same change affects the desired signal and the resulting measurement capability.

Distinguishing consideration: compare this with option A, “Treat the lower blocker level as a complete receiver calibration”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Front-End Characterization and Field Decisions.

Review: Chapter 3 — Front-End Characterization and Field Decisions.

Copyright 2026, James M. Atkinson

V011-C03-MCQ-099. A measured filter response is applied to another switched state with a different path. Which conclusion is correct?

A. The correction becomes exact if more observations are averaged.

B. A matching filter name establishes identical gain, phase and uncertainty.

C. The correction needs demonstrated applicability to that state; the same center frequency is insufficient.

D. The response is interchangeable whenever both paths use passive components.

Answer: C. Calibration belongs to a physical path and state. A similar label or additional averaging does not establish the missing transfer relationship. Review: Preselection and Filter State. Source: §3.3 Preselection and Filter State (p. 1251)

Why the selected alternative fits: The correction needs demonstrated applicability to that state; the same center frequency is insufficient.

Distinguishing consideration: compare this with option A, “The correction becomes exact if more observations are averaged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 3 — Preselection and Filter State.

Review: Chapter 3 — Preselection and Filter State.

V011-C03-MCQ-100. Which front-end decision best integrates the chapter's reasoning?

A. Select a state that meets the declared noise and loading constraints, preserves the desired waveform, and passes a controlled challenge with recorded limits.

B. Maximize total gain while treating all blocker limits as output-display properties.

C. Choose the highest survival rating and infer calibrated weak-signal recovery from it.

D. Choose the state with the lowest displayed baseline without testing desired transfer.

Answer: A. A useful state simultaneously addresses sensitivity, validity, protection and retained evidence. Each scalar result remains bounded by the actual path and test conditions. Review: Choose gain from a feasible interval; An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why the selected alternative fits: Select a state that meets the declared noise and loading constraints, preserves the desired waveform, and passes a controlled challenge with recorded limits.

Distinguishing consideration: compare this with option B, "Maximize total gain while treating all blocker limits as output-display properties"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 3 — An acceptance sequence that separates competing failures; Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — An acceptance sequence that separates competing failures; Chapter 3 — Choose gain from a feasible interval.

V011-C03-FIB-005. For matched compatible stages with power gains 8, 0.25, and 50, the total linear power gain is _____.

Answer: 100. Equation 5 multiplies the three dimensionless power ratios: $8 \times 0.25 \times 50 = 100$, corresponding to 20 dB. Review: Equation 5. Source: Equation 5. Linear cascaded gain (p. 1269)

Why this term is required: “100” completes the stated technical proposition.

Question context: For matched compatible stages with power gains 8, 0.25, and 50, the total linear power gain is _____

Basis and qualification: Chapter 3 — Equation 5. Linear cascaded gain.

Review: Chapter 3 — Equation 5. Linear cascaded gain.

Copyright 2026, James M. Atkinson

V011-C03-FIB-006. A 0.25 linear power gain is approximately _____ dB.

Answer: -6.02. Use ten times the base-ten logarithm of 0.25. A power loss is represented by a negative gain in decibels, or a positive loss subtracted in Equation 6. Review: Equations 5 and 6. Source: Equation 5. Linear cascaded gain (p. 1269)

Why this term is required: "-6.02" completes the stated technical proposition.

Question context: A 0.25 linear power gain is approximately _____ dB

Basis and qualification: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction.

Copyright 2026, James M. Atkinson

V011-C03-FIB-007. In Equation 6, a positive stated filter loss is _____ from the input level.

Answer: subtracted. The loss reduces power reaching the next plane. The convention must distinguish a positive loss magnitude from an already signed negative gain. Review: Equation 6. Source: Equation 6. Input power after front-end correction (p. 1269)

Why this term is required: “subtracted” completes the stated technical proposition.

Question context: In Equation 6, a positive stated filter loss is _____ from the input level

Basis and qualification: Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 6. Input power after front-end correction.

Copyright 2026, James M. Atkinson

V011-C03-FIB-008. For an input of -70 dBm, filter loss 1.5 dB, attenuation 6 dB, and gain 18 dB, the next-stage input is _____ dBm.

Answer: -59.5. Apply the signed budget: $-70-1.5-6+18=-59.5$. This prediction still requires small-signal validity and applicable frequency-specific values. Review: Equation 6. Source: Equation 6. Input power after front-end correction (p. 1269)

Why this term is required: "-59.5" completes the stated technical proposition.

Question context: For an input of -70 dBm, filter loss 1.5 dB, attenuation 6 dB, and gain 18 dB, the next-stage input is _____ dBm

Basis and qualification: Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 6. Input power after front-end correction.

Copyright 2026, James M. Atkinson

V011-C03-FIB-009. If the stated linear operating limit is -22 dBm and the predicted operating level is -59.5 dBm, nominal headroom is _____ dB.

Answer: 37.5. Subtract the operating level from the upper limit: $-22-(-59.5)=37.5$. This single-signal margin does not include unbudgeted blockers. Review: Hypothetical Applied Calculation; Equation 6. Source: Equation 6. Input power after front-end correction (p. 1269)

Why this term is required: "37.5" completes the stated technical proposition.

Question context: If the stated linear operating limit is -22 dBm and the predicted operating level is -59.5 dBm, nominal headroom is _____ dB

Basis and qualification: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Hypothetical Applied Calculation: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

V011-C03-FIB-019. A switched filter-bank boundary can produce a discontinuity in gain, noise, phase, or _____.

Answer: calibration. Crossing a boundary changes a physical state. The new band needs applicable response evidence, not an assumed continuation of the previous band. Review: Preselection and Filter State. Source: §3.3 Preselection and Filter State (p. 1251)

Why this term is required: “calibration” completes the stated technical proposition.

Question context: A switched filter-bank boundary can produce a discontinuity in gain, noise, phase, or _____

Basis and qualification: Chapter 3 — Preselection and Filter State.

Review: Chapter 3 — Preselection and Filter State.

Copyright 2026, James M. Atkinson

V011-C03-FIB-020. A response check only at the center of one filter band cannot establish continuity across the band _____.

Answer: boundary. Reference checks should challenge the transition and nearby frequencies. Smooth tuning values do not establish smooth physical transfer through a switched network. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)
Why this term is required: “boundary” completes the stated technical proposition.
Question context: A response check only at the center of one filter band cannot establish continuity across the band _____
Basis and qualification: Chapter 3 — Use preselection as a measured transfer function.
Review: Chapter 3 — Use preselection as a measured transfer function.

Copyright 2026, James M. Atkinson

V011-C03-FIB-021. A 1 dB loss at the desired frequency and 28 dB rejection at a blocker frequency must be entered as _____ transfer corrections.

Answer: separate frequency-specific. The desired correction refers the measured desired level to its input plane; the rejection estimates blocker loading. Interchanging them changes the physical question. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why this term is required: “separate frequency-specific” completes the stated technical proposition.

Question context: A 1 dB loss at the desired frequency and 28 dB rejection at a blocker frequency must be entered as _____ transfer corrections

Basis and qualification: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

Copyright 2026, James M. Atkinson

V011-C03-FIB-022. For a -12 dBm blocker, 28 dB rejection, 4 dB attenuation, and 15 dB amplifier gain, the next-stage blocker level is _____ dBm.

Answer: -29. The blocker-frequency budget is $-12-28-4+15=-29$ dBm. Desired-band insertion loss is not used for this calculation. Review: Equation 6.

Source: Equation 6. Input power after front-end correction (p. 1269)

Why this term is required: "-29" completes the stated technical proposition.

Question context: For a -12 dBm blocker, 28 dB rejection, 4 dB attenuation, and 15 dB amplifier gain, the next-stage blocker level is _____ dBm

Basis and qualification: Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 6. Input power after front-end correction.

Copyright 2026, James M. Atkinson

V011-C03-FIB-023. For a -88 dBm desired signal through 1 dB loss, 4 dB attenuation, and 15 dB gain, the next-stage desired level is _____ dBm.

Answer: -78. The desired-frequency budget is $-88-1-4+15=-78$ dBm. The 28 dB blocker rejection from the separate case does not correct this signal. Review: Equation 6. Source: Equation 6. Input power after front-end correction (p. 1269)

Why this term is required: "-78" completes the stated technical proposition.

Question context: For a -88 dBm desired signal through 1 dB loss, 4 dB attenuation, and 15 dB gain, the next-stage desired level is _____ dBm

Basis and qualification: Chapter 3 — Equation 6. Input power after front-end correction.

Review: Chapter 3 — Equation 6. Input power after front-end correction.

Copyright 2026, James M. Atkinson

V011-C03-FIB-024. A lower displayed baseline after inserting a preselector is ambiguous unless the desired-signal _____ is also checked.

Answer: transfer. The baseline can fall through less admitted noise, altered gain, or signal rejection. Retaining a desired reference helps discriminate those mechanisms. Review: Use preselection as a measured transfer function. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

Why this term is required: “transfer” completes the stated technical proposition.

Question context: A lower displayed baseline after inserting a preselector is ambiguous unless the desired-signal _____ is also checked

Basis and qualification: Chapter 3 — Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-FIB-042. An average gain value cannot recover samples lost through _____ during a gain transition.

Answer: clipping. Clipping is a nonlinear many-to-one transformation. Multiplying the resulting samples by a correction cannot reconstruct the original amplitudes.

Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why this term is required: “clipping” completes the stated technical proposition.

Question context: An average gain value cannot recover samples lost through _____ during a gain transition

Basis and qualification: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-FIB-043. Increasing analog gain can reduce the input-referred significance of converter noise, but cannot improve an already established analog signal-to-noise _____.

Answer: ratio. Common linear amplification scales signal and existing analog noise together. Any benefit concerns additional downstream converter noise under valid range conditions. Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why this term is required: “ratio” completes the stated technical proposition.

Question context: Increasing analog gain can reduce the input-referred significance of converter noise, but cannot improve an already established analog signal-to-noise _____

Basis and qualification: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-FIB-044. The digitizer range must be evaluated at the digitizer's actual input _____, not merely the external antenna terminal.

Answer: plane. The analog stages transform the signal and noise before conversion. Internal level budgeting is necessary to assess quantization significance and overload. Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why this term is required: "plane" completes the stated technical proposition.

Question context: The digitizer range must be evaluated at the digitizer's actual input _____, not merely the external antenna terminal

Basis and qualification: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-FIB-045. Heavy digital averaging may make a trace look quiet without establishing an adequate analog _____ distribution.

Answer: gain. Display variance and physical analog range use are different quantities. Raw samples and state metadata are needed to distinguish the mechanisms. Review: Choose gain from a feasible interval. Source: §3.6 Choose gain from a feasible interval (p. 1257)

Why this term is required: “gain” completes the stated technical proposition.

Question context: Heavy digital averaging may make a trace look quiet without establishing an adequate analog _____ distribution

Basis and qualification: Chapter 3 — Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-FIB-046. A protection network affects the signal path even in its nonlimiting, _____-signal state.

Answer: small. Insertion loss, return loss, and reactive loading persist when no large event is present. The protector belongs in the ordinary transfer and noise budget. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “small” completes the stated technical proposition.

Question context: A protection network affects the signal path even in its nonlimiting, _____-signal state

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-047. In the chapter's PIN-limiter explanation, stored carriers alter the diode's RF _____.

Answer: resistance. The cited mechanism connects large-signal charge storage to reduced RF resistance. The mounted circuit and external current path also affect behavior. Review: Measure protection in the small-signal and recovery states; source note 10. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: "resistance" completes the stated technical proposition.

Question context: In the chapter's PIN-limiter explanation, stored carriers alter the diode's RF _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-048. Removal or recombination of stored carriers contributes to the return toward low insertion _____ after a large event.

Answer: loss. The recovery mechanism has memory. A limiter is not an instantaneous ideal switch whose pre-event transfer necessarily returns at the event's trailing edge. Review: Measure protection in the small-signal and recovery states; source note 10. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: "loss" completes the stated technical proposition.

Question context: Removal or recombination of stored carriers contributes to the return toward low insertion _____ after a large event

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-049. Limiter diode geometry can change capacitance and therefore the mounted network's reactive _____.

Answer: loading. The RF response includes parasitic reactance as well as the large-signal resistance change. Device identity alone does not establish the assembled network response. Review: Measure protection in the small-signal and recovery states; source note 10. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: "loading" completes the stated technical proposition.

Question context: Limiter diode geometry can change capacitance and therefore the mounted network's reactive _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-050. The three separate protection outcomes emphasized in the chapter are leakage, hardware survival, and weak-signal _____.

Answer: recovery. A protected device can remain undamaged while its transfer or noise baseline is still unsuitable for the intended observation. Each outcome needs its own observable. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)
Why this term is required: “recovery” completes the stated technical proposition.
Question context: The three separate protection outcomes emphasized in the chapter are leakage, hardware survival, and weak-signal _____
Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.
Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-051. A brief transient passing the protector before its later limited state is established is leading-edge _____.

Answer: leakage. The downstream path may experience a short exposure larger than the later leakage level. A steady limited-power measurement can miss this event. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “leakage” completes the stated technical proposition.

Question context: A brief transient passing the protector before its later limited state is established is leading-edge _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-052. A catalog recovery value must be interpreted with its stated test conditions and recovery _____.

Answer: criterion. Return of insertion loss, calibrated phase, noise variance, and detector output can occur at different times. The applicable observable must match the intended measurement. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “criterion” completes the stated technical proposition.

Question context: A catalog recovery value must be interpreted with its stated test conditions and recovery _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-053. Survival of a protection component does not establish immediate restoration of calibrated weak-signal _____.

Answer: performance. Hardware integrity and measurement validity are distinct. A surviving network can remain desensitized, have changed loss, or be temporarily disturbed. Review: Measure protection in the small-signal and recovery states.

Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “performance” completes the stated technical proposition.

Question context: Survival of a protection component does not establish immediate restoration of calibrated weak-signal _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-054. For rectangular pulses of constant peak power and negligible off-state power, duty factor equals pulse width divided by pulse _____.

Answer: period. The ratio is dimensionless and determines mean power in this stipulated waveform. Different pulse shapes or off-state power need their own integration. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why this term is required: “period” completes the stated technical proposition.

Question context: For rectangular pulses of constant peak power and negligible off-state power, duty factor equals pulse width divided by pulse _____

Basis and qualification: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-FIB-055. Rectangular 8 microsecond pulses repeated every 400 microseconds have duty factor _____ percent.

Answer: 2. The ratio is $\frac{8}{400}=0.02$. Keep width and period in the same time unit before converting the fraction to percent. Review: Input Protection and Recovery.

Source: §3.7 Input Protection and Recovery (p. 1260)

Why this term is required: “2” completes the stated technical proposition.

Question context: Rectangular 8 microsecond pulses repeated every 400 microseconds have duty factor _____ percent

Basis and qualification: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-FIB-056. With 10 mW peak power, 2 percent duty factor, and zero off-state power, mean power is _____ mW.

Answer: 0.2. Mean power is peak power multiplied by duty factor: 10×0.02. The peak exposure remains 10 mW despite the lower mean. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why this term is required: “0.2” completes the stated technical proposition.

Question context: With 10 mW peak power, 2 percent duty factor, and zero off-state power, mean power is _____ mW

Basis and qualification: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-FIB-057. A rectangular pulse train with peak power 30 dBm and duty factor 0.001 has mean power _____ dBm when off-state power is zero.

Answer: 0. The duty-factor correction is $10\log_{10}(0.001) = -30$ dB. Add that correction to the 30 dBm peak; the peak rating still needs a separate check. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why this term is required: “0” completes the stated technical proposition.

Question context: A rectangular pulse train with peak power 30 dBm and duty factor 0.001 has mean power _____ dBm when off-state power is zero

Basis and qualification: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-FIB-058. A pulse survival specification conditioned on pulse width cannot be transferred unqualified to a different pulse _____.

Answer: duration. Thermal and charge-storage effects depend on the event history. A matching peak-power number alone does not establish equivalent stress. Review: Source note 11; Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “duration” completes the stated technical proposition.

Question context: A pulse survival specification conditioned on pulse width cannot be transferred unqualified to a different pulse _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-059. Absolute maximum ratings must not be treated as guaranteed calibrated operating _____.

Answer: performance. Stress limits and specified measurement behavior serve different purposes. The actual operating conditions and the relevant performance table must be retained. Review: Source note 11. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1262)

Why this term is required: “performance” completes the stated technical proposition.

Question context: Absolute maximum ratings must not be treated as guaranteed calibrated operating _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-060. A component data sheet does not automatically establish the limits of a complete mounted receiver _____.

Answer: assembly. Layout, connected components, bias, thermal conditions, and the downstream load can change the system response. Assembly-level evidence is needed for an assembly-level claim. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “assembly” completes the stated technical proposition.

Question context: A component data sheet does not automatically establish the limits of a complete mounted receiver _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-061. To observe the useful channel throughout a protection challenge, retain a weak desired _____ before, during, and after the event.

Answer: reference. A reference provides an observable transfer through the disturbance. A record of the blocker alone cannot establish when weak-signal measurement becomes valid again. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “reference” completes the stated technical proposition.

Question context: To observe the useful channel throughout a protection challenge, retain a weak desired _____ before, during, and after the event

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-062. If the desired amplitude criterion is met at 40 microseconds but the required baseline-variance criterion only at 70 microseconds, joint recovery is no earlier than _____ microseconds.

Answer: 70. Both declared conditions must hold. Accepting the earlier time would silently discard the variance requirement. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “70” completes the stated technical proposition.

Question context: If the desired amplitude criterion is met at 40 microseconds but the required baseline-variance criterion only at 70 microseconds, joint recovery is no earlier than _____ microseconds

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-063. A continuous-wave sweep alone cannot reveal the full _____ interval following a pulse.

Answer: recovery. The transient history is absent from a settled sweep. A timed record through the strong event is necessary to characterize post-event validity.

Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “recovery” completes the stated technical proposition.

Question context: A continuous-wave sweep alone cannot reveal the full _____ interval following a pulse

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-064. Observing only the end of a long acquisition can miss early post-event intervals during which weak events were _____.

Answer: undetectable. A final recovered state does not characterize every earlier time. Time-resolved desired-reference and baseline observations are needed.

Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “undetectable” completes the stated technical proposition.

Question context: Observing only the end of a long acquisition can miss early post-event intervals during which weak events were _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-FIB-065. A delayed trace can arise from detector averaging even after the analog path has _____.

Answer: recovered. The displayed quantity can retain temporal memory in downstream processing. Apparent recovery must be attributed to the measured path and processing state. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “recovered” completes the stated technical proposition.

Question context: A delayed trace can arise from detector averaging even after the analog path has _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-066. Reducing a detector time constant changes both temporal response and measurement _____.

Answer: variability. Less averaging may expose faster analog recovery while increasing output scatter. A fair interpretation records the changed estimator conditions. Review: Measure protection in the small-signal and recovery states.

Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “variability” completes the stated technical proposition.

Question context: Reducing a detector time constant changes both temporal response and measurement _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-067. A limiter-bypass comparison is informative only if the configuration permits it and the remaining path stays within its _____.

Answer: ratings. Removing protection changes exposure. The comparison must have a bounded valid operating condition and identify exactly which component was isolated. Review: Measure protection in the small-signal and recovery states.

Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “ratings” completes the stated technical proposition.

Question context: A limiter-bypass comparison is informative only if the configuration permits it and the remaining path stays within its _____

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-068. Apparent recovery persistence can originate in amplifier bias, gain control, digital filtering, or trigger _____ as well as protection.

Answer: logic. Several subsystems have memory or acquisition dead time. The mere presence of a limiter does not locate the cause of the delay. Review: Measure protection in the small-signal and recovery states. Source: §3.8 Measure protection in the small-signal and recovery states (p. 1261)

Why this term is required: “logic” completes the stated technical proposition.

Question context: Apparent recovery persistence can originate in amplifier bias, gain control, digital filtering, or trigger _____ as well as protection

Basis and qualification: Chapter 3 — Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-FIB-069. Post-overload checks at one low frequency do not automatically verify transfer at _____ frequencies.

Answer: higher or untested. A damaged or altered path can retain one response while changing another. Checks should cover the frequencies, levels, and observables relevant to the intended release. Review: Input Protection and Recovery. Source: §3.7 Input Protection and Recovery (p. 1260)

Why this term is required: “higher or untested” completes the stated technical proposition.

Question context: Post-overload checks at one low frequency do not automatically verify transfer at _____ frequencies

Basis and qualification: Chapter 3 — Input Protection and Recovery.

Review: Chapter 3 — Input Protection and Recovery.

V011-C03-FIB-070. A vector network analyzer normally characterizes the chosen small-signal response; large-signal or pulsed claims require additional appropriate _____ and observations.

Answer: stimuli. The instrument name does not make every nonlinear or transient property part of a small-signal sweep. The applied stimulus must exercise the behavior being claimed. Review: Front-End Characterization and Field Decisions.

Source: §3.9 Front-End Characterization and Field Decisions (p. 1265)

Why this term is required: “stimuli” completes the stated technical proposition.

Question context: A vector network analyzer normally characterizes the chosen small-signal response; large-signal or pulsed claims require additional appropriate _____ and observations

Basis and qualification: Chapter 3 — Front-End Characterization and Field Decisions.

Review: Chapter 3 — Front-End Characterization and Field Decisions.

Copyright 2026, James M. Atkinson

V011-C03-FIB-071. For active front-end characterization, temperature and _____ state can affect the measured response.

Answer: bias. Active device gain, noise, linearity, and recovery can depend on operating conditions. The state belongs in both the characterization record and its applicability limits. Review: Front-End Characterization and Field Decisions. Source: §3.9 Front-End Characterization and Field Decisions (p. 1265)

Why this term is required: “bias” completes the stated technical proposition.

Question context: For active front-end characterization, temperature and _____ state can affect the measured response

Basis and qualification: Chapter 3 — Front-End Characterization and Field Decisions.

Review: Chapter 3 — Front-End Characterization and Field Decisions.

Copyright 2026, James M. Atkinson

V011-C03-FIB-072. Before assigning a two-tone product to the receiver, check whether the sources interact through insufficient combiner _____.

Answer: isolation. Generator interaction can create the same line before the receiver. A source-path control is needed to bound that alternative. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “isolation” completes the stated technical proposition.

Question context: Before assigning a two-tone product to the receiver, check whether the sources interact through insufficient combiner _____

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-073. The desired and blocker levels in a challenge must be established at the intended receiver _____ plane.

Answer: input. Generator settings alone omit intervening combiner, cable, mismatch, and attenuation effects. The defined plane makes the applied exposure reconstructable. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “input” completes the stated technical proposition.

Question context: The desired and blocker levels in a challenge must be established at the intended receiver _____ plane

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-074. Blocker-source broadband noise at the desired channel can mimic a receiver-generated noise _____.

Answer: rise. The desired-channel observation may already be contaminated at the input. Source spectral purity must be bounded before assigning the rise to reciprocal mixing or another receiver mechanism. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “rise” completes the stated technical proposition.

Question context: Blocker-source broadband noise at the desired channel can mimic a receiver-generated noise _____

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-075. A quiet baseline should precede the blocker challenge, with the desired source held _____ during controlled blocker changes.

Answer: fixed. Holding the desired stimulus fixed makes changes in its measured transfer informative. Unrecorded desired-source drift would create an alternative explanation. Review: An acceptance sequence that separates competing failures.

Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “fixed” completes the stated technical proposition.

Question context: A quiet baseline should precede the blocker challenge, with the desired source held _____ during controlled blocker changes

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-076. Removing the blocker and returning to the original state provides a _____ check of the observed path.

Answer: return. The comparison can reveal persistence or drift at the check time. It does not by itself prove that every intervening sample was valid. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “return” completes the stated technical proposition.

Question context: Removing the blocker and returning to the original state provides a _____ check of the observed path

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-077. Compression can change desired transfer, whereas reciprocal mixing can raise admitted _____ around the desired channel.

Answer: noise. The mechanisms have different predicted observables. A useful challenge records both desired response and noise so it can test those predictions.
Review: An acceptance sequence that separates competing failures; Table 3A.

Source: Table 3A. Evidence to retain during a constructed front-end challenge (p. 1266)

Why this term is required: “noise” completes the stated technical proposition.
Question context: Compression can change desired transfer, whereas reciprocal mixing can raise admitted _____ around the desired channel
Basis and qualification: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge; Chapter 3 — An acceptance sequence that separates competing failures.
Review: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge; Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-078. A discrete intermodulation hypothesis should predict product _____ as well as level behavior.

Answer: frequencies. Frequency relationships can help discriminate a nonlinear mechanism, but sources and combining paths can generate related products too. Input-plane controls remain necessary. Review: An acceptance sequence that separates competing failures; Model 11A connection. Source: §11.5 Model 11A for cubic intermodulation and intercept metrics (p. 6367)

Why this term is required: “frequencies” completes the stated technical proposition.

Question context: A discrete intermodulation hypothesis should predict product _____ as well as level behavior

Basis and qualification: Chapter 11 — Model 11A for cubic intermodulation and intercept metrics; Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 11 — Model 11A for cubic intermodulation and intercept metrics; Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-079. Because gain control can mimic a change in desired transfer, compression attribution requires state evidence or an appropriate _____ control.

Answer: fixed-gain. A falling desired output is not uniquely compression. A known fixed gain or a characterized gain-control trajectory helps distinguish the response law. Review: Table 3A. Source: Table 3A. Evidence to retain during a constructed front-end challenge (p. 1266)

Why this term is required: “fixed-gain” completes the stated technical proposition.

Question context: Because gain control can mimic a change in desired transfer, compression attribution requires state evidence or an appropriate _____ control

Basis and qualification: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge.

Review: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge.

Copyright 2026, James M. Atkinson

V011-C03-FIB-080. More than one front-end failure mechanism can occur _____ during a strong-signal challenge.

Answer: simultaneously. A discrete product does not exclude noise rise or desired-signal compression. The retained observables should permit multiple supported effects to be reported. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “simultaneously” completes the stated technical proposition.

Question context: More than one front-end failure mechanism can occur _____ during a strong-signal challenge

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-081. Input-corrected comparisons should be retained alongside measurements in physical _____ units.

Answer: output. The corrected quantity estimates the common external plane; the raw output helps reconstruct the actual gain, loading, and noise changes. One view cannot replace the other. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “output” completes the stated technical proposition.

Question context: Input-corrected comparisons should be retained alongside measurements in physical _____ units

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-082. A screen image can omit state information, so settings should also be retained as text or machine-readable _____.

Answer: metadata. Reconstruction requires exact filter, attenuation, gain, bandwidth, detector, and timing information where relevant. The visible annotations may be incomplete. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “metadata” completes the stated technical proposition.

Question context: A screen image can omit state information, so settings should also be retained as text or machine-readable _____

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-FIB-083. If both the suspect line and desired reference fall below the floor after attenuation, the test is _____ about the line's origin.

Answer: inconclusive. Loss of observation capability prevents the proposed discrimination. The disappearance alone does not show whether the line originated before or inside the receiver. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: "inconclusive" completes the stated technical proposition.

Question context: If both the suspect line and desired reference fall below the floor after attenuation, the test is _____ about the line's origin

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-FIB-084. Noise traces from states with different bandwidths need matched bandwidth or an explicit bandwidth _____ before comparison.

Answer: accounting model. Integrated noise depends on admitted bandwidth. A difference cannot be attributed wholly to the front-end state when processing bandwidth changed too. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “accounting model” completes the stated technical proposition.

Question context: Noise traces from states with different bandwidths need matched bandwidth or an explicit bandwidth _____ before comparison

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-FIB-085. An unresolved test should retain competing _____ instead of converting a plausible mechanism into an established conclusion.

Answer: explanations. The result remains useful when its limits are stated. It can guide a more discriminating challenge and later artifact review. Review: An acceptance sequence that separates competing failures. Source: §3.10 An acceptance sequence that separates competing failures (p. 1266)

Why this term is required: “explanations” completes the stated technical proposition.

Question context: An unresolved test should retain competing _____ instead of converting a plausible mechanism into an established conclusion

Basis and qualification: Chapter 3 — An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-FIB-086. A front-end release should state a documented frequency and level _____ rather than a universal pass.

Answer: range. Verification applies to the tested configuration and conditions. Declared limits prevent a bounded acceptance result from being extended to unsupported operating states. Review: Verification and Maintenance Controls.

Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why this term is required: “range” completes the stated technical proposition.

Question context: A front-end release should state a documented frequency and level _____ rather than a universal pass

Basis and qualification: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-FIB-087. A substituted filter or cable changes the measurement path and therefore calls for renewed _____.

Answer: verification. The prior path response may no longer apply. Applicable corrections and uncertainty must follow the installed components and their current state. Review: Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why this term is required: “verification” completes the stated technical proposition.

Question context: A substituted filter or cable changes the measurement path and therefore calls for renewed _____

Basis and qualification: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-FIB-088. Serialized accessories and controlled connector torque help make reference sweeps _____.

Answer: reproducible. The mechanical and component configuration can affect loss and mismatch. Recording these conditions supports meaningful comparison with an accepted baseline. Review: Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why this term is required: “reproducible” completes the stated technical proposition.

Question context: Serialized accessories and controlled connector torque help make reference sweeps _____

Basis and qualification: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-FIB-089. A difference from an accepted baseline that exceeds the applicable uncertainty should be _____ before returning the path to its claimed service.

Answer: investigated. The result may reflect a physical fault, configuration change, or correction problem. Merely repeating the old pass label does not resolve the difference. Review: Verification and Maintenance Controls. Source: §3.11 Verification and Maintenance Controls (p. 1268)

Why this term is required: “investigated” completes the stated technical proposition.

Question context: A difference from an accepted baseline that exceeds the applicable uncertainty should be _____ before returning the path to its claimed service

Basis and qualification: Chapter 3 — Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

V011-C03-FIB-091. In the chapter's 1.2 GHz case, removal by a filter that passes 1.2 GHz is evidence for a product hypothesis only after desired-reference _____ is verified.

Answer: transfer. A passband label or nominal loss does not establish the actual installed signal retention. Source and combiner products also need to be bounded before locating the generation site. Review: Hypothetical Case Adjudication. Source: §3.14 Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection (p. 1272)

Why this term is required: "transfer" completes the stated technical proposition.

Question context: In the chapter's 1.2 GHz case, removal by a filter that passes 1.2 GHz is evidence for a product hypothesis only after desired-reference _____ is verified

Basis and qualification: Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Review: Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Copyright 2026, James M. Atkinson

V011-C03-FIB-092. Reproducing the suspect frequency with two strong tones supports a nonlinear mechanism, but does not alone locate it inside the _____.

Answer: receiver. The generators or combining path can create a product before the input plane. A controlled source-path observation is needed for receiver-specific attribution. Review: Hypothetical Case Adjudication; Model 11A connection. Source: §11.5 Model 11A for cubic intermodulation and intercept metrics (p. 6367)

Why this term is required: “receiver” completes the stated technical proposition.

Question context: Reproducing the suspect frequency with two strong tones supports a nonlinear mechanism, but does not alone locate it inside the _____

Basis and qualification: Chapter 11 — Model 11A for cubic intermodulation and intercept metrics; Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Review: Chapter 11 — Model 11A for cubic intermodulation and intercept metrics; Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

V011-C03-ESSAY-001. Derive the relation between the linear cascaded-power-gain budget and the signed decibel budget. Specify the conditions under which the same budget can be used for a desired signal and for a blocker.

- Opening: Present a thesis that answers this precise question: Derive the relation between the linear cascaded-power-gain budget and the signed decibel budget. Specify the conditions under which the same budget can be used for a desired.... Identify which evidence would falsify the proposed conclusion Source: §3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings (p. 1276)
- Core terminology and scope: Define relation, budget, signed in the question's particular technical setting; explain how decibel, Specify, used differ if that distinction would change the analysis of "Derive the relation between the linear cascaded-power-gain budget and the signed decibel budget. Specify the conditions under which the same budget can be used for a desired..." Source: §3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings (p. 1276)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Begin with output power equal to input power multiplied by each stage power gain in the valid scalar chain Source: §3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings (p. 1276)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the relation between the linear cascaded-power-gain budget and the signed decibel budget to the claimed result, following "Example 3.C1. Filter,

Copyright 2026, James M. Atkinson

attenuator and amplifier power budget"; name the intermediate states and measurable outputs Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for the relation between the linear cascaded-power-gain budget and the signed decibel budget. Taking ten times the base-ten logarithm converts the product to a sum Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)
- Analytical framework: Identify the equation, calibration or evidential decision test in "Find the first stage that can lose validity" that resolves the question about the relation between the linear cascaded-power-gain budget and the signed decibel budget; derive the relevant result with units and stated validity conditions Source: §3.2 Find the first stage that can lose validity (p. 1249)
- Evidence and method: Specify the native observations, control records and calculations that would resolve the relation between the linear cascaded-power-gain budget and the signed decibel budget. A passive loss written as a positive decibel magnitude enters with a minus sign; a positive amplifier gain enters with a plus sign Source: §3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings (p. 1276)
- Worked application or illustrative case: Build a worked example of "the relation between the linear cascaded-power-gain budget and the signed decibel budget", addressing this associated condition: Specify the conditions under which the same budget can be used for

Copyright 2026, James M. Atkinson

a desired signal and for a blocker. Begin with output power equal to input power multiplied by each stage power gain in the valid scalar chain Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)

- Alternative explanations and failure modes: Construct two plausible technical explanations for “the relation between the linear cascaded-power-gain budget and the signed decibel budget”. Using “Find the first stage that can lose validity”, specify a discriminator and the result expected under each explanation Source: §3.2 Find the first stage that can lose validity (p. 1249)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to the relation between the linear cascaded-power-gain budget and the signed decibel budget, including the effect of missing measurements and inconsistent operating conditions Source: §3.19.5 Example 3.C5. Passive filter loss and the first-stage noise factor (p. 1288)
- Scholarly synthesis and implications: Explain what the result about the relation between the linear cascaded-power-gain budget and the signed decibel budget authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings (p. 1276)
- Closing: Conclude by answering “Derive the relation between the linear cascaded-power-gain budget and the signed decibel budget. Specify the conditions under which the same budget can be used for a desired…” using only the demonstrated evidence; state the

V011-C03-ESSAY-002. A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer. The desired input is -92 dBm and sees 1.2 dB filter loss. A blocker at -8 dBm sees 34 dB filter rejection. Calculate both mixer-input levels and evaluate a stipulated -24 dBm maximum blocker level. Explain which conclusions remain unsupported.

- Opening: Present a thesis that answers this precise question: A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer. Identify which evidence would falsify the proposed conclusion Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)
- Core terminology and scope: Define precede, sees, Calculate in the question's particular technical setting; explain how maximum, conclusions, unsupported differ if that distinction would change the analysis of "A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer" Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)
- Problem statement and purpose: Frame the actual measurement or decision in the question. The desired level is dBm Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer to the claimed result, following "Example 3.C6. Comparing attenuation ahead of and after an amplifier"; name the intermediate states and measurable outputs Source: §3.19.6 Example 3.C6. Comparing attenuation ahead of and after an amplifier (p. 1289)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer. The blocker level is dBm, giving 7 dB nominal margin below the stipulated mixer limit Source: §3.19.6 Example 3.C6. Comparing attenuation ahead of and after an amplifier (p. 1289)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Example 3.C10. Selecting a feasible gain interval” that resolves the question about A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer; derive the relevant result with units and stated validity conditions Source: §3.19.10 Example 3.C10. Selecting a feasible gain interval (p. 1293)
- Evidence and method: Specify the native observations, control records and calculations that would resolve A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer. Keep the two filter transfers separate and identify the mixer input as the final plane Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)
- Worked application or illustrative case: Build a worked example of “A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer”, addressing this associated condition: The desired input is -92 dBm and sees 1.2 dB filter loss. The desired level is dBm Source: §3.19.6 Example 3.C6. Comparing attenuation ahead of and after an amplifier (p. 1289)
- Alternative explanations and failure modes: Construct two plausible technical explanations for “A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer”. Using “Example 3.C10. Selecting a feasible gain interval”, specify a discriminator and the result

Copyright 2026, James M. Atkinson

expected under each explanation Source: §3.19.10 Example 3.C10. Selecting a feasible gain interval (p. 1293)

- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer, including the effect of missing measurements and inconsistent operating conditions Source: §3.19.5 Example 3.C5. Passive filter loss and the first-stage noise factor (p. 1288)
- Scholarly synthesis and implications: Explain what the result about A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)
- Closing: Conclude by answering “A filter, 5 dB attenuator, and 16 dB amplifier precede a mixer” using only the demonstrated evidence; state the remaining decisive verification step Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)

V011-C03-ESSAY-003. Two equal distinct blockers each deliver -18 dBm at a receiver stage. Their mean powers add without a cross term. Calculate aggregate mean power, then explain why this result is insufficient to certify peak-voltage immunity.

- Opening: Present a thesis that answers this precise question: Two equal distinct blockers each deliver -18 dBm at a receiver stage. Identify which evidence would falsify the proposed conclusion Source: §3.19.2 Example 3.C2. Converting two blockers to a single equivalent power (p. 1285)
- Core terminology and scope: Define deliver, Calculate, aggregate in the question's particular technical setting; explain how insufficient, certify, immunity differ if that distinction would change the analysis of "Two equal distinct blockers each deliver -18 dBm at a receiver stage" Source: §3.19.2 Example 3.C2. Converting two blockers to a single equivalent power (p. 1285)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Each blocker has approximately 0.015849 mW mean power Source: §3.19.2 Example 3.C2. Converting two blockers to a single equivalent power (p. 1285)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting Two equal distinct blockers each deliver -18 dBm at a receiver stage to the claimed result, following "Find the first stage that can lose validity"; name the intermediate states and measurable outputs Source: §3.2 Find the first stage that can lose validity (p. 1249)
- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for Two

Copyright 2026, James M. Atkinson

equal distinct blockers each deliver -18 dBm at a receiver stage. Their sum is approximately 0.031698 mW, or -14.99 dBm Source: §3.2 Find the first stage that can lose validity (p. 1249)

- Analytical framework: Identify the equation, calibration or evidential decision test in “Example 3.C1. Filter, attenuator and amplifier power budget” that resolves the question about Two equal distinct blockers each deliver -18 dBm at a receiver stage; derive the relevant result with units and stated validity conditions Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)
- Evidence and method: Specify the native observations, control records and calculations that would resolve Two equal distinct blockers each deliver -18 dBm at a receiver stage. The increase relative to either individual blocker is about 3.01 dB Source: §3.19.2 Example 3.C2. Converting two blockers to a single equivalent power (p. 1285)
- Worked application or illustrative case: Build a worked example of “Two equal distinct blockers each deliver -18 dBm at a receiver stage”, addressing this associated condition: Their mean powers add without a cross term. Each blocker has approximately 0.015849 mW mean power Source: §3.2 Find the first stage that can lose validity (p. 1249)
- Alternative explanations and failure modes: Construct two plausible technical explanations for “Two equal distinct blockers each deliver -18 dBm at a receiver stage”. Using “Example 3.C1. Filter, attenuator and amplifier power budget”, specify a discriminator and the result expected under each explanation Source: §3.19.1 Example 3.C1. Filter, attenuator and amplifier power budget (p. 1284)

V011-C03-ESSAY-004. A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K. The target is at most 115 K. A -42 dBm admitted blocker must reach the next stage at no more than -23 dBm. Derive the feasible first-stage gain interval and assess available settings of 10, 15, and 20 dB.

- Opening: Present a thesis that answers this precise question: A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K. Identify which evidence would falsify the proposed conclusion Source: §3.19.10 Example 3.C10. Selecting a feasible gain interval (p. 1293)
- Core terminology and scope: Define downstream, target, admitted in the question's particular technical setting; explain how reach, feasible, settings differ if that distinction would change the analysis of "A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K" Source: §3.19.10 Example 3.C10. Selecting a feasible gain interval (p. 1293)
- Problem statement and purpose: Frame the actual measurement or decision in the question. The downstream temperature allowance is 40 K, so the first-stage linear power gain must be at least approximately 14.77 dB Source: §3.19.10 Example 3.C10. Selecting a feasible gain interval (p. 1293)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K to the claimed result, following "Choose gain from a feasible interval"; name the

intermediate states and measurable outputs Source: §3.6 Choose gain from a feasible interval (p. 1257)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K. The blocker condition permits no more than 19 dB gain Source: §3.6 Choose gain from a feasible interval (p. 1257)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Example 3.C5. Passive filter loss and the first-stage noise factor” that resolves the question about A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K; derive the relevant result with units and stated validity conditions Source: §3.19.5 Example 3.C5. Passive filter loss and the first-stage noise factor (p. 1288)
- Evidence and method: Specify the native observations, control records and calculations that would resolve A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K. The feasible interval is therefore approximately 14.77 to 19 dB, under the stated model Source: §3.19.10 Example 3.C10. Selecting a feasible gain interval (p. 1293)
- Worked application or illustrative case: Build a worked example of “A two-stage receiver has first-stage equivalent input temperature 75 K and downstream equivalent temperature 1200 K”, addressing this associated condition: The target is at most 115 K. The downstream temperature allowance is 40 K, so the first-stage linear power gain
