V011-C03-DISCUSSION-001. A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy. How should the team test that proposition?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy. How should the team test that proposition?” Put this particular dispute to the panel: A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy. How should the team test that proposition. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §3.2 Find the first stage that can lose validity (p. 1249)

- 02. Student A, terminology and scope: Agree the operational meanings of clean, narrow, proves and exposed, energy, proposition in “A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy. How should the team test that proposition”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and

request a specific example from the stated receiver scenario. Source: §3.2 Find the first stage that can lose validity (p. 1249)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §3.24 Low-level event survival under analogue filtering (p. 1305)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “3. Low-level event survival under analogue filtering”. Identify the first vulnerable stage and the rejection preceding it Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §3.24 Low-level event survival under analogue filtering (p. 1305)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original

trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings (p. 1276)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “3. Low-level event survival under analogue filtering”. Identify the first vulnerable stage and the rejection preceding it Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §3.24 Low-level event survival under analogue filtering (p. 1305)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Ask for the actual analog path and admitted spectrum before discussing the displayed trace Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without

changing the measurand. Source: §3.2 Find the first stage that can lose validity (p. 1249)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §3.2 Find the first stage that can lose validity (p. 1249)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §3.16 Frequency-selective headroom and the failure of scalar 'maximum input' ratings (p. 1276)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §3.2 Find the first stage that can lose validity (p. 1249)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A colleague argues that a clean narrow display proves the receiver has not been exposed to strong out-of-band energy, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §3.24 Low-level event survival under analogue filtering (p. 1305)

- 12. Student G, revised experimental answer: Address Student H’s confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving

V011-C03-DISCUSSION-004. A single filter correction is proposed for every frequency in a sweep. Under what conditions could that simplification be defensible?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A single filter correction is proposed for every frequency in a sweep. Under what conditions could that simplification be defensible?” Put this particular dispute to the panel: A single filter correction is proposed for every frequency in a sweep. Under what conditions could that simplification be defensible. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §3.3 Preselection and Filter State (p. 1251)

- 02. Student A, terminology and scope: Agree the operational meanings of single, correction, proposed and sweep, conditions, defensible in “A single filter correction is proposed for every frequency in a sweep. Under what conditions could that simplification be defensible”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §3.3 Preselection and Filter State (p. 1251)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A single filter correction is proposed for every frequency in a sweep; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Use preselection as a measured transfer function”. A flat approximation can be justified within a bounded tolerance; it is not established by one center-frequency measurement Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A single filter correction is

proposed for every frequency in a sweep; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §3.33.4 Case study 3.D4. Frequency-edge losses hidden by a centre-band calibration (p. 1334)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Use preselection as a measured transfer function”. A flat approximation can be justified within a bounded tolerance; it is not established by one center-frequency measurement Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Have participants identify the permitted amplitude error, measured passband variation, temperature and state range, and the spectrum of the desired signal Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §3.3 Preselection and Filter State (p. 1251)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving A single filter correction is proposed for every frequency in a sweep: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §3.3 Preselection and Filter State (p. 1251)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A single filter correction is proposed for every frequency in a sweep; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §3.33.4 Case study 3.D4. Frequency-edge losses hidden by a centre-band calibration (p. 1334)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A single filter correction is proposed for every frequency in a sweep: specify the altered

receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §3.3 Preselection and Filter State (p. 1251)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A single filter correction is proposed for every frequency in a sweep, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A single filter correction is proposed for every frequency in a sweep: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §3.3 Preselection and Filter State (p. 1251)

Copyright 2026, James M. Atkinson

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A single filter correction is proposed for every frequency in a sweep. Filter skirts, switched boundaries, and notches require particular scrutiny Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §3.33.4 Case study 3.D4. Frequency-edge losses hidden by a centre-band calibration (p. 1334)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A single filter correction is proposed for every frequency in a sweep, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §3.4 Use preselection as a measured transfer function (p. 1253)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A single filter correction is proposed for every frequency in a sweep. Filter skirts, switched boundaries, and notches require particular scrutiny Respond point by point to Student J.

V011-C03-DISCUSSION-025. Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most reproducible operational result?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most reproducible operational result?” Put this particular dispute to the panel: Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most reproducible operational result. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §3.34 Synthesis: what the completed front-end record can establish (p. 1348)

- 02. Student A, terminology and scope: Agree the operational meanings of choice, best, largest and quoted, dynamic, reproducible in “Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most reproducible operational result”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a

Copyright 2026, James M. Atkinson

specific example from the stated receiver scenario. Source: §3.34 Synthesis: what the completed front-end record can establish (p. 1348)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §3.20 Laboratory decision protocol and defensible reporting (p. 1294)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “3. Laboratory decision protocol and defensible reporting”. A reproducible operational result still needs technical validity; reproducible overload is not success Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §3.20 Laboratory decision protocol and defensible reporting (p. 1294)

Copyright 2026, James M. Atkinson

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §3.22 Front-end noise spectroscopy as an instrument-state test (p. 1299)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “3. Laboratory decision protocol and defensible reporting”. A reproducible operational result still needs technical validity; reproducible overload is not success Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §3.20 Laboratory decision protocol and defensible reporting (p. 1294)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Ask participants to define the intended event and then map each quoted metric to its own conditions Put two specific questions to Student D about the

Copyright 2026, James M. Atkinson

stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §3.34 Synthesis: what the completed front-end record can establish (p. 1348)

- 08. Student D, answer to Student E: Design a discriminating experiment involving Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §3.34 Synthesis: what the completed front-end record can establish (p. 1348)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is

missing. Source: §3.22 Front-end noise spectroscopy as an instrument-state test (p. 1299)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §3.34 Synthesis: what the completed front-end record can establish (p. 1348)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §3.20 Laboratory decision protocol and defensible reporting (p. 1294)

Copyright 2026, James M. Atkinson

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §3.34 Synthesis: what the completed front-end record can establish (p. 1348)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…. Combine noise, internal loading, desired transfer, recovery, and source controls to determine the supported operating envelope Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §3.22 Front-end noise spectroscopy as an instrument-state test (p. 1299)

Copyright 2026, James M. Atkinson

- 14. Student J, Socratic challenge to Student I: For the precise observation involving Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §3.20 Laboratory decision protocol and defensible reporting (p. 1294)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for Which should decide a difficult front-end choice: the best laboratory noise figure, the largest quoted dynamic range, or the most…. Combine noise, internal loading, desired transfer, recovery, and source controls to determine the supported operating envelope Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §3.22 Front-end noise spectroscopy as an instrument-state test (p. 1299)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about Which should decide a difficult front-end

Essay Guidance

V011-C03-ESSAY-001 — Begin with output power equal to input power multiplied by each stage power gain in the valid scalar chain. Taking ten times the base-ten logarithm converts the product to a sum. A passive loss written as a positive decibel magnitude enters with a minus sign; a positive amplifier gain enters with a plus sign. Define both reference planes and compatible impedance and mismatch conventions. The desired and blocker calculations can share the component order but generally require different frequency-specific transfer values. State the fixed-state and small-signal assumptions, and explain why a successful gain calculation supplies neither a compression model nor a pulse-survival rating. Full credit requires distinguishing a logarithmic power level in dBm from a gain or loss in dB. Review: Equations 5 and 6; Find the first stage that can lose validity.

Review: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-002 — The desired level is $-92-1.2-5+16=-82.2$ dBm. The blocker level is $-8-34-5+16=-31$ dBm, giving 7 dB nominal margin below the stipulated mixer limit. Keep the two filter transfers separate and identify the mixer input as the final plane. The amplifier input blocker is -47 dBm, which must independently meet that amplifier's applicable input envelope. The calculation does not establish aggregate loading from other signals, peak-voltage stress, stability, or actual filter response at temperature. If the chain remains linear and corrections apply, subtract the net desired gain of 9.8 dB from the mixer desired level to recover -92 dBm. Do not use the 34 dB blocker rejection as the desired correction. Review: Equation 6; Use preselection as a measured transfer function.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Use preselection as a measured transfer function.

V011-C03-ESSAY-003 — Each blocker has approximately 0.015849 mW mean power. Their sum is approximately 0.031698 mW, or -14.99 dBm. The increase relative to either individual blocker is about 3.01 dB. State the observation interval and cross-term assumption that make this mean-power addition appropriate. Instantaneous voltage depends on the component waveforms, impedance, timing, and relative phase; crest behavior cannot be inferred solely from the mean-power sum. A scalar gain budget also omits nonlinear products and protection dynamics. A complete acceptance argument therefore compares the appropriate aggregate mean, peak, and individual-tone conditions with the actual stage limits, using compatible quantities rather than treating one dBm number as every type of stress. Review: Find the first stage that can lose validity; Equation 6.

Review: Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-004 — The downstream temperature allowance is 40 K, so the first-stage linear power gain must be at least $\frac{1200}{40}=30$, approximately 14.77 dB. The blocker condition permits no more than 19 dB gain. The feasible interval is therefore approximately 14.77 to 19 dB, under the stated model. Of the available settings, 15 dB lies inside it; 10 dB fails the noise target and 20 dB exceeds the downstream blocker bound. At 15 dB the gain is approximately 31.6228, giving total equivalent temperature about 112.95 K and a blocker level of -27 dBm. The latter has 4 dB margin to the stipulated limit. Check the first amplifier's own exposure, stability, source matching, signal retention, and uncertainty before treating this scalar feasible choice as an accepted configuration. Review: Choose gain from a feasible interval; Model 2B Equation 4J; Equation 6.

Review: Chapter 2 — Model 2B: a matched, fixed-state noise cascade; Chapter 2 — Equation 4J. Minimum first-stage gain for a temperature limit; Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-005 — Show that the intersection is empty: a 21 dB compromise violates both original bounds. Identify the mechanism behind each bound before proposing changes. Better blocker rejection before the limiting path can relax the loading bound if the desired transfer and preceding-loss noise penalty remain acceptable. A lower-noise downstream stage, lower first-stage equivalent temperature, or a different gain distribution can relax the noise constraint. Greater downstream linear range may change the loading bound but cannot repair an earlier overloaded stage. A revised sensitivity target requires an application-based justification rather than an arbitrary numerical relaxation. Recompute the interval and validate the selected physical state, including frequency response and relevant uncertainty. The result should be a supported new design or an explicit infeasibility finding. Review: Choose gain from a feasible interval; Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function; Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-006 — With attenuation before the amplifier, its input blocker is -19 dBm, 4 dB below the stated validity limit. The final small-signal prediction is +1 dBm. With attenuation after the amplifier, the amplifier sees -7 dBm, 8 dB above its stated valid input limit; the same +1 dBm end-to-end prediction is therefore not justified by the small-signal model. Do not report that invalid prediction as measured performance. Explain that attenuation placement also changes input-referred noise through the cascade relation. The valid arrangement still needs a check that the amplifier output and downstream components tolerate the resulting level and that the attenuator's own rating applies. Equal nominal net gain describes neither equal noise nor equal internal validity. Review: Gain Distribution and Attenuation; Application 2B.7; Equation 6.

Review: Chapter 2 — Application 2B.7: place attenuation before the vulnerable stage; Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Gain Distribution and Attenuation.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-007 — Identify the actual band identifiers and switching rule, then use reference frequencies on both sides of the boundary and within the region where response changes rapidly. Keep the desired reference plane, source level, processing bandwidth, and detector convention controlled. Retain raw response and corrected response, relevant phase or modulation quality, noise, and the realized filter state. Repeat tuning across the boundary in both directions to reveal hysteresis or state-selection differences where relevant. A center-frequency calibration from one band cannot establish continuity. Associate each correction with its own state and uncertainty, and distinguish a physical response change from a correction-table discontinuity. Test the occupied bandwidth of the intended waveform, not only a single tone at the nominal tuning frequency. Review: Preselection and Filter State; Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function; Chapter 3 — Preselection and Filter State.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-008 — The desired-to-noise ratio improves by 2 dB because desired power changes by -4 dB while noise changes by -6 dB. Equivalently, divide the desired retention factor by the noise retention factor. This arithmetic assumes the quantities are comparable integrated powers at a common plane and that the detector law remains applicable. It does not establish preservation of waveform phase, burst onset, group delay, or enough observation time. A burst claim needs the actual signal spectrum, temporal filter response, success criterion, and relevant false-alarm condition. Retain desired-reference measurements before and after the filter and account for any changed processing bandwidth. Do not report the full 6 dB baseline reduction as a 6 dB sensitivity improvement. Review: Use preselection as a measured transfer function; Chapter 2 signal-retention relation.

Review: Chapter 3 — Use preselection as a measured transfer function; Chapter 2 — Equation 4L. Input signal power for a stipulated output ratio.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-009 — Retain native samples or physical detector output with acquisition timing, gain-state telemetry or a sufficiently resolved gain-control trace, filter and attenuator states, and the fixed desired-reference identity. Align the state trajectory with the affected data and characterize the transfer for the states and transitions used. Compare a permitted fixed-gain challenge or an independently characterized control response to discriminate source change from automatic gain action. A mean gain can conceal short compression, clipped samples, settling, or gaps; those losses are not invertible by one scalar correction. State which intervals remain quantitatively usable, which have qualified amplitude, and which cannot support the intended claim. A calibration at one settled gain does not establish the transition law. Review: Choose gain from a feasible interval; Gain Distribution and Attenuation.

Review: Chapter 3 — Choose gain from a feasible interval; Chapter 3 — Gain Distribution and Attenuation.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-010 — Map the desired signal, admitted noise, and strongest relevant event to the actual converter input. In the valid linear region, common analog gain does not improve the SNR already present before that gain. It can reduce the converter-added contribution when referred back to the external input. The useful gain is bounded above by converter range and earlier-stage linearity, and below by the acceptable downstream contribution. Preserve the relevant waveform peaks rather than budgeting only mean power. Keep raw sample scaling and the gain state so later FFT normalization is interpretable. Explain why a digitally rescaled or heavily averaged quiet trace does not prove appropriate range use, and why clipped samples cannot be restored by gain metadata. Review: Choose gain from a feasible interval; Chapter 10 digitizer connection; Chapter 9 normalization connection.

Review: Chapter 3 — Choose gain from a feasible interval; Chapter 10 — Quantization, Clipping, and Converter Performance; Chapter 10 — Quantization margin and channel bandwidth; Chapter 9 — Windowed DFT normalization: line amplitude, noise density, and finite-record energy.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-011 — First quantify what reaches the downstream path during the event, including any leading transient and later leakage under the actual source and load conditions. Second establish hardware survival using the applicable conditioned limits and post-event functional evidence; absence of obvious damage is not every performance test. Third measure recovery of the desired weak-signal observables, such as amplitude, phase, modulation quality, and baseline variance within stated tolerances. Retain a weak reference throughout a bounded event and record timing, waveform, duty factor, gain state, and processing. Explain that each criterion can pass at a different time or stress level. Device data-sheet values are conditional evidence for that device and cannot be transferred as receiver-assembly ratings. Review: Measure protection in the small-signal and recovery states; source note 11.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-012 — The duty factor is $\frac{6}{300}=0.02$, or 2 percent. Mean power is $50\times0.02=1$ mW, which is 0 dBm; peak power is approximately 16.99 dBm. The mean may inform some thermal questions, but it does not replace the peak, pulse-width, repetition, leading-edge leakage, or recovery conditions relevant to the device and assembly. State the rectangular-waveform and zero-off-state assumptions explicitly. A different pulse shape requires time integration. Apply the actual component and accessory ratings to the proposed challenge and retain the waveform delivered at the receiver plane. Do not infer a universal safe pulse test merely because the average power is modest. Review: Input Protection and Recovery; Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Input Protection and Recovery.

V011-C03-ESSAY-013 — If all three criteria are required and remain satisfied thereafter under the declared observation rule, recovery is no earlier than 85 microseconds after the defined event time origin. State whether the origin is the event leading edge or trailing edge, how persistence within tolerance is judged, and how time resolution affects the reported boundary. The 35 microsecond amplitude crossing alone cannot establish phase or variance recovery. Retain the pre-event baseline, reference waveform, event history, receiver state, detector averaging, and trigger behavior. Distinguish observed system recovery from the physical recovery of a particular limiter. The data may support several narrower recovery times as long as each is labeled by its observable and conditions. Review: Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-014 — Identify the complete path from the protection network through amplifiers, gain control, digital filtering, detector, and trigger logic. Shorter detector averaging changes the observation response and its noise variability; the difference supports a processing contribution but does not uniquely quantify every analog delay. Retain a weak reference and compare time-resolved amplitude or phase with appropriate raw observations under controlled event conditions. If a bypass or alternate detector is allowed, keep all remaining hardware within ratings and state exactly which subsystem was isolated. Define recovery using the intended measurement tolerance and account for changed estimator variability. A strong answer produces bounded attribution and preserves unresolved contributions rather than converting a trace-duration difference into a device-specific recovery specification. Review: Measure protection in the small-signal and recovery states; Table 3A.

Review: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-015 — In the nonlimiting state, insertion loss, return loss, and reactive loading affect desired transfer and the noise budget. During a large event, stored carriers alter RF resistance; the external current path and device geometry influence the mounted response. Removal or recombination of carriers contributes to the return toward the low-loss state. These mechanisms justify observing leakage and recovery over time as well as measuring a settled small-signal sweep. Do not derive a universal numerical recovery law from the qualitative explanation. State the circuit, bias where applicable, source and load conditions, event waveform, and required observable. Cite the identified MACOM explanation for the mechanism while distinguishing original acceptance reasoning from a manufacturer rating. Review: Measure protection in the small-signal and recovery states; source note 10.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-016 — Establish both generator outputs and their harmonics, spurs, and relevant noise at the intended receiver input plane through the actual cables and combiner. Assess combiner isolation and linearity at the applied levels because generator interaction or passive/nonlinear combining elements can create the line before the receiver. Use suitable independent observations, isolation changes, or controlled source-path substitutions that preserve known applied levels. Retain a desired reference and vary tone frequencies or attenuation to test the predicted product behavior. A product-frequency relationship is evidence for a mechanism but not a unique generation location. State the measurement floor of the source control and the residual bound on pre-existing products rather than treating a nondetection as zero contamination. Review: An acceptance sequence that separates competing failures; Model 11A connection.

Review: Chapter 11 — Model 11A for cubic intermodulation and intercept metrics; Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-017 — Characterize or bound source spectral purity at the desired channel and the levels delivered through the actual combining path. Keep desired reference, effective bandwidth, detector operation, and reference plane controlled. Record gain-state changes and desired transfer while varying blocker level, offset, or preselection in ways predicted to affect the candidate mechanisms. A source with significant in-band noise can create the observed rise directly; a receiver mixing interpretation requires that alternative to be bounded. An automatic gain response can change raw and corrected noise differently. Retain linear integrated channel power and raw output alongside the input-referred result. Explain that several mechanisms can coexist and that the result may remain an upper bound or unresolved attribution. Review: An acceptance sequence that separates competing failures; Table 3A; Model 11B connection.

Review: Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge; Chapter 11 — Model 11B for reciprocal mixing and admitted noise; Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-018 — Begin by establishing source and combining-path validity, actual applied levels, and the operating ratings. Measure the quiet desired transfer and noise in the selected state, including the intended waveform bandwidth and relevant phase or quality. Introduce a bounded blocker in controlled increments with the desired source fixed, recording transfer, channel noise, discrete products, and state telemetry. Remove the blocker and observe return, then repeat an alternative filter or attenuation state chosen to discriminate the suspected mechanism. Keep raw and common-plane corrected records and identify uncertainty and source controls. Release only the frequency, level, waveform, and state range supported by the observations. The sequence should be informative about failure mechanisms rather than merely produce a pass/fail label. Review: An acceptance sequence that separates competing failures; Verification and Maintenance Controls.

Review: Chapter 3 — An acceptance sequence that separates competing failures; Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-019 — The comparison lost the ability to observe both quantities, so disappearance is consistent with several origins. The attenuation change does not by itself establish the suspect line's scaling law. Preserve the measured floor, raw levels, and corrections and state the unresolved alternatives. A follow-up might retain a stronger bounded desired reference, adjust valid downstream gain without overloading earlier stages, use narrower appropriate measurement bandwidth while accounting for signal retention, or test source frequency relationships. Each change needs its own validity assessment. Source and combiner products must still be bounded for receiver-specific attribution. Do not infer a numerical slope from a censored observation reported only as below the floor. Review: An acceptance sequence that separates competing failures; Assessment 3A.8.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-020 — The combined observations support a nonlinear product hypothesis because rejection of lower-frequency inputs can remove a line while the preselector nominally passes the displayed frequency. Verify the actual desired-reference transfer at 1.2 GHz through both installed states so the disappearance is not explained by lost observation capability. Establish the relevant lower-frequency levels and rejection, and bound source and combiner products at the receiver input plane. Test the predicted product-frequency and level relationships without exceeding valid test conditions. Receiver-front-end attribution requires evidence locating the generation, not only reproduction of the output frequency. Distinguish the observed component, the supported product mechanism, and any claim about an external source's identity or intent. Review: Hypothetical Case Adjudication; Model 11A connection.

Review: Chapter 11 — Model 11A for cubic intermodulation and intercept metrics; Chapter 3 — Hypothetical Case Adjudication: RF Front Ends, Preselection, Gain Distribution, and Input Protection.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-021 — Identify the new serialized components, connection conditions, relevant torque, filter state, and firmware or configuration. Compare applicable reference sweeps and bounded multi-tone or recovery checks with accepted baselines over the frequencies and levels required for use. Retain corrections, uncertainty, and any evidence of drift in contacts, tuning, bias, leakage, or isolation. The old record documents the prior configuration; it does not automatically validate the replacement path. Investigate differences exceeding the relevant uncertainty and distinguish ordinary wear from changed configuration. A release statement should define the supported state and operating range, name limitations, and link to the actual measurements. A generic passed label omits the conditions needed for later interpretation. Review: Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-022 — Suppose a valid raw desired output is -50 dBm before the step and -60 dBm afterward, with all other applicable gains unchanged. The added 10 dB input loss explains the raw decrease; adding back the appropriate state-specific correction gives the same external estimate. The raw record shows the physical output change while the corrected record supports a common-plane comparison. If only the corrected value remains, one may not reconstruct actual range use, noise, or overload; if only raw values remain, the external comparison lacks its transfer model. Retain the step's measured frequency response and repeatability, other state changes, bandwidth, detector, and timing. Equal corrected signal estimates do not establish equal sensitivity because the input attenuation changes the physical noise budget. Review: Gain Distribution and Attenuation; An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures; Chapter 3 — Gain Distribution and Attenuation.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-023 — Read the actual device and revision, conditioned pulse width and duty factor, frequency and temperature range, and distinction between specifications and absolute maximum ratings. Identify the installed topology, mounting, current path, thermal environment, and downstream components. Establish how leading and later leakage reach the protected circuitry and whether the desired measurement recovers within the required interval. The component value can inform a design but does not certify the assembled receiver or its accessories. Use the real instrument and accessory limits to bound any challenge, and preserve the data-sheet applicability rather than invent a universal multiplier. A useful conclusion separates component survival evidence, system exposure analysis, and validated weak-signal performance. Review: Measure protection in the small-signal and recovery states; source note 11.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-ESSAY-024 — State the injection plane, frequency, level, waveform, receiver state, output observation, and time. The check supports the exercised transfer or function under those conditions at that time. It may bypass the antenna, an external preselector, or upstream cabling, and it does not by itself establish uninterrupted validity during prior acquisition. Complement it with appropriate field or upstream terminal references, multiple relevant frequencies and levels, state records, and checks of recording/export functions when those are part of the intended claim. Temporal monitoring or bracketing can add evidence but should retain its own scope. The final statement should identify what was observed and which earlier or unexercised functions remain unsupported. Review: Verification and Maintenance Controls; Chapter 1 closing-verification qualification.

Review: Chapter 3 — Verification and Maintenance Controls; Chapter 1 — Evidence Record and Closing Verification.

V011-C03-ESSAY-025 — Define the intended observation, reference plane, desired waveform, and bounded interferer environment. Use frequency-specific gains to track desired and blocker levels through the actual order, then combine the noise-derived minimum gain with the downstream loading maximum. Check signal retention, state reproducibility, and the relevant protection and recovery behavior. Support each assumption with applicable source or measured evidence and retain source-path controls for artifact attribution. Raw output and corrected input records must allow reconstruction. A favorable scalar budget can still fail if a stage is nonlinear, a waveform is filtered away, gain history is unknown, source products are unbounded, or recovery misses the required interval. Release the supported envelope and document unresolved limits rather than averaging conflicting criteria into a universal score. Review: Chapter 3 synthesis; Equations 5 and 6; Table 3A.

Review: Chapter 3 — Equation 5. Linear cascaded gain; Chapter 3 — Equation 6. Input power after front-end correction; Chapter 3 — Table 3A. Evidence to retain during a constructed front-end challenge.

Discussion Guidance

V011-C03-DISCUSSION-001 — Ask for the actual analog path and admitted spectrum before discussing the displayed trace. Identify the first vulnerable stage and the rejection preceding it. Consider the possibility of a wideband converter or amplifier followed by a narrow display filter. The discussion should produce an exposure survey and a bounded desired-reference challenge, not merely a wider screenshot. A clean display can be retained as an observation while the claim about internal validity remains unproved. Review: Front-End Purpose and Architecture; Find the first stage that can lose validity.

Review: Chapter 3 — Find the first stage that can lose validity; Chapter 3 — Front-End Purpose and Architecture.

V011-C03-DISCUSSION-002 — Compare the preceding-loss noise penalty with the spectrum admitted to the amplifier in each order. Require a desired-signal requirement and an internal blocker budget. The quiet case may favor early gain, while the strong-signal case can require rejection before that gain. Avoid a universal ranking based only on noise figure. Retain the exact physical state and model-specific option architecture when an instrument example is used. Review: Front-End Purpose and Architecture; Use preselection as a measured transfer function; source note 9.

Review: Chapter 3 — Use preselection as a measured transfer function; Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-003 — Require the desired waveform, occupied bandwidth, and success criterion. Compare retained amplitude, phase or modulation quality, noise, and strong-signal validity at a common plane. A lower trace can result from reduced gain or rejected desired energy. The useful endpoint is a demonstrated improvement or necessary validity restoration for the defined event, with the accompanying loss and uncertainty documented. Review: Use preselection as a measured transfer function.

Review: Chapter 3 — Use preselection as a measured transfer function.

V011-C03-DISCUSSION-004 — Have participants identify the permitted amplitude error, measured passband variation, temperature and state range, and the spectrum of the desired signal. A flat approximation can be justified within a bounded tolerance; it is not established by one center-frequency measurement. Filter skirts, switched boundaries, and notches require particular scrutiny. The team should state a validity interval and uncertainty for the simplification or retain a frequency-dependent correction. Review: Preselection and Filter State.

Review: Chapter 3 — Preselection and Filter State.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-005 — Distinguish the valid common-plane signal estimate from the physical noise and detection capability. Input loss can increase input-referred receiver noise even when the display compensates the desired amplitude exactly. Request corresponding raw and corrected noise, bandwidth, detector condition, and linearity evidence. The revision should preserve the useful agreement of the signal estimates without converting it into an unsupported equality of sensitivity. Review: Gain Distribution and Attenuation; Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval; Chapter 3 — Gain Distribution and Attenuation.

V011-C03-DISCUSSION-006 — The choice depends on the intended observation and the mechanisms behind the bounds. Discuss whether extra rejection occurs before the limiting stage and how its insertion loss changes the noise bound. Consider a lower-noise later stage or greater downstream range as alternatives. Require recomputation after each proposed change. A target may be revised only with an application-based rationale; no numerical compromise satisfies an empty interval. Review: Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-007 — Stable scaling is compatible with an external input under the tested conditions, but may also occur for internal behavior that scales similarly or is masked by correction. Ask which element was switched, where a possible artifact could originate, and whether the desired reference and gain state behaved as expected. Combine amplitude scaling with frequency, source-path, and configuration controls appropriate to the hypothesis. The conclusion should match the discriminatory power of the actual test. Review: Gain Distribution and Attenuation; An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures; Chapter 3 — Gain Distribution and Attenuation.

V011-C03-DISCUSSION-008 — Distinguish characterization of a fixed component transfer from evaluation of the operational closed-loop receiver. Disabling control can simplify the first question, while the second may require measuring its real response. In either case, retain the state and timing and label the quantity correctly. Discuss exposure limits and loss of dynamic range under a fixed setting. A control that remains enabled needs a characterized trajectory before quantitative amplitude correction is assumed. Review: Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-009 — Ask for native samples, analog gain states, converter range use, and corresponding input-referred converter contribution. Software scaling changes units and averaging changes estimator behavior; neither alone changes analog SNR or reverses clipping. A useful comparison holds the waveform and processing definition fixed while assessing the physical analog state and its valid range. Separate a visual improvement from a measurement-performance result. Review: Choose gain from a feasible interval.

Review: Chapter 3 — Choose gain from a feasible interval.

V011-C03-DISCUSSION-010 — Survival history concerns one aspect of protection, while ordinary insertion loss, return loss, and reactive loading remain in the signal path. Ask what measured small-signal response is available and whether it varies with frequency, temperature, or prior events. A negligible contribution can be justified within the measurement uncertainty, but it should not be inferred solely from lack of damage. Keep the assembly conditions explicit. Review: Input Protection and Recovery; Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Input Protection and Recovery.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-011 — They may be reporting different observables. Reconcile the event waveform, time origin, state, detector response, tolerance, and persistence rule before comparing numbers. A receiver can meet amplitude tolerance while still having excessive variance or phase error. A productive outcome reports observable-specific times and the joint time needed by the intended task. Avoid forcing one catalog-like number onto different measurement requirements. Review: Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-DISCUSSION-012 — A normal later state supports the observed functions at that time; it does not establish event leakage, temporary desensitization, or the duration of unusable intervals. Discuss what contemporaneous state, overload, timing, or reference evidence exists and which intervals can still support the intended result. Future characterization should retain the event and weak reference through recovery. Do not reconstruct an unobserved recovery history from the final trace alone. Review: Measure protection in the small-signal and recovery states; Verification and Maintenance Controls.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-013 — Require the actual peak, duration, repetition, waveform, frequency, coupling, and source/load conditions. Compare them with the conditional instrument and accessory limits and with the measurement's required recovery interval. Low average power does not remove peak stress or leading-edge leakage. Conversely, matching peak power alone does not reproduce thermal or charge history. The discussion should yield a bounded representativeness argument, not a universal safe-test rule. Review: Input Protection and Recovery; source note 11.

Review: Chapter 3 — Input Protection and Recovery; Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-DISCUSSION-014 — Establish that the permitted bypass changed only the claimed subsystem in a meaningful way and that the remaining path stayed within ratings. Compare applied event levels, downstream gain, matching, processing, and detector variability. The difference can include interactions with amplifier bias or gain control. Report the measured system comparison and its scope; isolate a device-specific time only when the measurement model and controls support that attribution. Review: Measure protection in the small-signal and recovery states.

Review: Chapter 3 — Measure protection in the small-signal and recovery states.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-015 — Begin with the applied source and combining path because contamination there can enter the receiver as an ordinary signal. Discuss isolation, linearity, source harmonics, phase noise, and the floor of the independent input-plane observation. Then use controlled receiver-state changes to locate any additional generation. The ordering avoids treating a plausible product-frequency relationship as proof of its location. Review: An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-DISCUSSION-016 — Identify which bandwidth is physical admission and which belongs to later processing. Use matched processing bandwidth where feasible or a justified model that accounts for noise integration and desired-signal retention. Preserve each state's gain and calibration. A raw noise difference cannot be assigned entirely to rejection when bandwidth changed too. The comparison should state the common measurand and retain any irreducible difference in capability. Review: An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-017 — It can be a useful bounded result if the reason for nondiscrimination is retained. Examples include both lines falling below the floor, unrecorded gain changes, or source contamination that cannot be bounded. Ask what follow-up would separate the remaining mechanisms and whether the existing record still supports a narrower claim. Avoid rewarding a confident attribution when the test removed its own observation capability. Review: An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

V011-C03-DISCUSSION-018 — Retain the manufacturer, model, option, manual edition, and applicable firmware context. Use the example to illustrate why component order matters, then state the general reasoning separately. The same indicator name can correspond to different physical paths. Participants should distinguish accurate source attribution from a universal design assertion and identify what evidence is needed for the instrument actually being used. Review: Front-End Purpose and Architecture; source note 9.

Review: Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Front-End Purpose and Architecture; Chapter 3 — Find the first stage that can lose validity.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-019 — It may appear if the quantities are clearly separated and their purposes and conditions are explicit. Stress ratings do not certify gain accuracy, noise, distortion, or recovery at the boundary. Discuss how assembly limits and accessory constraints can be more restrictive. An acceptance table should preserve the distinctions between operation, survival, and the desired measurement criterion rather than imply they are interchangeable thresholds. Review: Measure protection in the small-signal and recovery states; source note 11.

Review: Chapter 3 — Measure protection in the small-signal and recovery states; Chapter 3 — Measure protection in the small-signal and recovery states.

V011-C03-DISCUSSION-020 — The model label and nominal length provide context but do not establish identical installed loss and mismatch. Compare the serialized replacement's applicable response, connection conditions, frequency range, and uncertainty against the prior correction. A difference small relative to the required tolerance may justify retention with documented evidence. Otherwise update the correction and verify affected observations. The decision should follow the measurement need, not the purchase description alone. Review: Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-021 — Polarization changes coupling for desired and unwanted fields and can also alter multipath. Retain geometry, timing, desired-reference capability, and receiver state. The change may improve a practical observation while leaving the component's origin unresolved. Discuss complementary spatial, frequency, and input-path controls needed for a stronger interpretation. Do not treat a single polarization response as unique identification. Review: Front-End Characterization and Field Decisions.

Review: Chapter 3 — Front-End Characterization and Field Decisions.

V011-C03-DISCUSSION-022 — Require the actual configuration, applicable frequencies and levels, waveform and timing conditions, observables, tolerances, uncertainty, and identified limitations. A concise pass statement can summarize a referenced bounded record, but cannot replace it. Ask whether protection, recovery, and source-path controls were included when relevant. The discussion should end with a release statement that can be compared with a future intended use. Review: Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls.

V011-C03-DISCUSSION-023 — Raw output reveals actual range use, gain changes, and noise behavior before correction. Corrected values can conceal a changed attenuator state or a normalization error if the underlying data and state are absent. Retaining both allows an independent reviewer to reconstruct the transformation and assess validity. Discuss storage and metadata choices in terms of that evidential need, with native samples or physical output quantities appropriate to the task. Review: An acceptance sequence that separates competing failures.

Review: Chapter 3 — An acceptance sequence that separates competing failures.

Copyright 2026, James M. Atkinson

V011-C03-DISCUSSION-024 — It can contribute to a broader argument together with contemporaneous state records, bracketing, known failure behavior, and relevant monitoring. Its direct observation remains time- and function-bounded. Require the team to state which inference connects the later check to the earlier interval and what evidence supports that inference. A final response alone cannot establish uninterrupted validity or exercise an upstream path it bypasses. Review: Verification and Maintenance Controls; Chapter 1 closing-verification qualification.

Review: Chapter 3 — Verification and Maintenance Controls; Chapter 1 — Evidence Record and Closing Verification.

V011-C03-DISCUSSION-025 — Ask participants to define the intended event and then map each quoted metric to its own conditions. A reproducible operational result still needs technical validity; reproducible overload is not success. Combine noise, internal loading, desired transfer, recovery, and source controls to determine the supported operating envelope. Different states can be preferable for different environments. The final argument should identify the governing limitations rather than select one universal headline metric. Review: Chapter 3 synthesis; Choose gain from a feasible interval; Verification and Maintenance Controls.

Review: Chapter 3 — Verification and Maintenance Controls; Chapter 3 — Choose gain from a feasible interval.

Chapter Glossary

AGGREGATE INPUT POWER: The combined power presented by all relevant admitted components at a specified stage input. Mean powers can be summed when the applicable cross-power terms vanish under the defined averaging or ensemble convention. The aggregate mean does not by itself establish peak voltage, crest behavior, or the nonlinear products generated by several strong signals.

BLOCKER-SOURCE NOISE: Noise carried by the applied interfering source into the desired observation channel or another relevant admitted region. It can produce a measured noise rise without requiring the proposed receiver mechanism. A reciprocal-mixing interpretation therefore needs this contribution bounded or accounted for under the same source, frequency, and path conditions.

BLOCKER TRANSFER: Frequency-specific gain or loss connecting an external interfering signal to a vulnerable receiver stage.

CARRIER STORAGE: Retention of excess charge carriers in a semiconductor after they are introduced by a large event or bias condition. In the chapter's PIN-limiter explanation, stored charge changes RF resistance and its removal contributes to recovery. This qualitative mechanism does not supply a universal numerical recovery time for an arbitrary mounted network.

Copyright 2026, James M. Atkinson

COMBINER ISOLATION: The degree to which a combining network prevents energy from one input port from reaching another under specified conditions. In a two-source challenge, inadequate isolation can let generators interact and produce artifacts before the receiver. Isolation must be considered with the combiner's linearity and actual applied levels; it is not the same as insertion loss.

DOWNSTREAM LOADING: The signal, noise, and interference presented to a later stage after the gains and losses preceding it. It is evaluated at that stage's own plane and frequencies, not inferred from the final corrected display. Additional early gain can reduce a later noise contribution while simultaneously increasing this loading and reducing the later stage's valid margin.

FILTER-BANK BOUNDARY: A tuning region where a receiver changes between discrete preselector or filter paths. The transition can change gain, phase, noise, or correction applicability even if the displayed frequency changes smoothly. Reference observations on both sides, together with actual band identifiers, are needed to assess continuity and the validity of comparisons across the boundary.

FILTER TUNING REPEATABILITY: The consistency of a tunable or switched filter's realized response when commanded to return to a specified state. It includes the response relevant to the intended amplitude, phase, or rejection measurement, not merely agreement of the displayed tuning value. Boundary crossings, temperature, and switching history can require explicit comparison.

Copyright 2026, James M. Atkinson

FLAT LEAKAGE: The leakage level during the comparatively settled limiting portion of a specified large-signal event, as distinguished from an initial leading transient. The term does not imply identical behavior for every pulse width, frequency, source impedance, or load. It must be tied to the applicable test definition and does not alone establish survival or recovery.

GAIN ALLOCATION: Choice and placement of gain that satisfies a noise requirement while preserving the valid signal range of later stages.

GAIN-FEASIBILITY INTERVAL: The overlap between a lower gain bound required by a noise objective and an upper gain bound permitted by downstream loading, under declared models and conditions. An empty overlap means no gain choice satisfies both requirements. A nonempty interval identifies candidate settings but does not independently establish stability, mismatch behavior, or transient validity.

GAIN-STATE TELEMETRY: A retained record of actual receiver gain settings or gain-control behavior associated with acquisition time. Its temporal resolution must be sufficient for the amplitude interpretation being made. A final setting or average gain does not describe brief transitions, and telemetry cannot restore information lost by clipping or samples that were never acquired.

GROUP DELAY: A description of how a transfer function’s phase changes with frequency, representing delay for a sufficiently narrow group of spectral components under the applicable linear model. Variation across a modulated signal can distort its relative timing even when center-frequency insertion loss is acceptable. The actual filter state and frequency interval must accompany a useful group-delay claim.

Copyright 2026, James M. Atkinson

HEADROOM: Difference between operating level and a specified compression, overload, clipping, or damage limit.

INPUT INTERCEPT POINT: Extrapolated input level at which selected nonlinear products would equal the fundamental output under a defined test.

INPUT-REFERRED CONVERTER NOISE: The converter-added noise contribution expressed at an earlier selected input plane through the applicable analog signal power gain. Increasing valid analog gain can reduce this referred contribution while leaving the analog signal-to-noise ratio already present unchanged. The conversion requires the actual state and does not justify exceeding converter or upstream-stage range.

LEADING-EDGE LEAKAGE: The early portion of a strong event that reaches the protected downstream path before the later limiting response is established. Its peak and duration can differ from the subsequent leakage. A measurement of only the settled limited level may therefore underdescribe the actual exposure of the protected component.

LIMITER CURRENT-RETURN PATH: The external circuit path through which current associated with a limiter's large-signal operation can flow. Its implementation influences the mounted protection response alongside the device itself. Characterizing only the isolated component can omit this circuit dependence, particularly when interpreting leakage, stored charge, and return to small-signal transfer.

LIMITER LEAKAGE: Signal power or transient energy that reaches the downstream path while a protection limiter is responding to a strong input.

Copyright 2026, James M. Atkinson

NOTCH FILTER: A filter designed to reject a selected frequency region while retaining other regions. In a front end it can reduce a dominant interferer before a vulnerable component, but it also removes any desired signal content occupying the notch. Its installed response, placement, and power handling determine whether it improves the intended observation.

PASSBAND PHASE DISTORTION: A change in the relative phases of a signal's admitted spectral components that alters the intended waveform or modulation representation through the passband. Center-frequency magnitude alone does not reveal it. Its significance depends on the signal spectrum, measurement objective, and applicable phase or group-delay response of the installed filter state.

PASSBAND RIPPLE: Variation of transmission magnitude within a filter's declared useful passband, expressed under a specified normalization and frequency interval. A correction measured only at the center cannot establish the amplitude of a wide waveform across the ripple. The relevant tolerance follows the intended level or modulation measurement, rather than a passband label alone.

PEAK INPUT POWER: The largest input power under the stated waveform and time-resolution convention at a specified plane. It is distinct from average power and must be related to the applicable pulse or continuous-wave rating. For pulsed exposure, duration, repetition, source and load conditions, and leading transients can matter alongside the peak value.

PRESELECTION: Filtering placed before vulnerable gain or conversion stages to limit admitted spectrum.

Copyright 2026, James M. Atkinson

PROTECTION RECOVERY CRITERION: Declared observable and tolerance used to decide when a valid weak-signal measurement has returned after a strong event.

PROTECTION SURVIVABILITY: The ability of specified hardware to remain within the stated survival criterion after a defined exposure. The criterion and waveform conditions must be retained; survival is distinct from accurate transfer during the event and from prompt recovery afterward. Component survivability data do not automatically establish the survivability or measurement capability of a complete receiver assembly.

PULSE DUTY FACTOR: The fraction of a stated interval during which a defined pulse condition is present. For a periodic rectangular pulse it is pulse width divided by repetition period. Multiplying constant peak power by this fraction gives mean power only when the stipulated waveform and off-state assumptions apply; the peak exposure remains a separate quantity.

RECOVERY ATTRIBUTION: The assignment of an observed post-event delay or disturbance to a particular subsystem or mechanism using discriminating evidence. Protection, amplifier bias, gain control, digital filtering, detector averaging, and trigger behavior can all contribute. A delay observed in the final display is a system observation until the relevant path contributions have been separated.

RECOVERY BASELINE: The pre-event reference behavior against which post-event return is evaluated, including the desired response and any required noise or variability measure. It must belong to the same relevant state and processing definition. A later quiet trace cannot substitute for an unrecorded baseline when the recovery criterion depends on a quantitative change.

Copyright 2026, James M. Atkinson

RECOVERY TIME: Time required for a protection or gain stage to return to specified behavior after a strong event.

RELEASE ENVELOPE: The documented range of configuration, frequency, level, waveform, environmental, and timing conditions for which a receiver path's stated acceptance criteria are supported. It connects the tests to permitted interpretation and records limitations. A blanket pass without this envelope cannot establish applicability to a changed front-end state or exposure.

RETURN LOSS: A logarithmic measure of reflection at a stated port and reference impedance, conventionally expressed as a positive decibel value for a passive mismatch. It characterizes port matching rather than through-path insertion loss. Changes in input match can alter delivered power and source interaction, so a matched-port transmission correction may not describe every installed antenna condition.

SMALL-SIGNAL PROTECTION LOSS: The ordinary signal attenuation introduced by a protection network when it is not in its limiting state. It affects the desired transfer and, when dissipative and preceding gain, the input-equivalent noise budget. Survival of large events does not establish that this loss is negligible, stable, or unchanged after an event.

SMALL-SIGNAL VALIDITY: Operating condition in which the linear gain and added-noise law used by the measurement model remain applicable.

Copyright 2026, James M. Atkinson

SOURCE-PATH CONTROL: A measurement or controlled comparison that bounds signals and artifacts already present in the sources, cables, and combining network before the receiver input. It is needed when receiver-generated intermodulation or noise is being claimed. Its measurement floor and applicability must be retained because an undetected contribution is bounded, not necessarily absent.

SOURCE SPECTRAL PURITY: The extent and distribution of a test source's unwanted spectral components under the applied operating conditions, including harmonics, spurs, and relevant broadband noise. It must be assessed at the receiver plane through the actual path when artifact attribution depends on it. A source's nominal carrier level does not characterize these unwanted contributions.

STEP-ATTENUATOR REPEATABILITY: The consistency of the realized insertion loss when an attenuator returns to the same nominal setting under stated frequency and connection conditions. Contact behavior and switching history can produce variation distinct from nominal step accuracy. Repeated-state evidence matters when a small level difference is used to infer linearity or external-signal scaling.

STOPBAND REJECTION: Attenuation supplied by a filter over a declared unwanted-frequency region relative to the stated transfer reference. In a blocker budget it must apply at the blocker frequency and before the vulnerable stage. A desired-frequency insertion-loss value does not establish rejection, and a rejection specification does not establish desired-signal retention.

Copyright 2026, James M. Atkinson

TRACKING FILTER: Tunable filter whose passband follows the receiver tuning frequency.

TRANSITION WIDTH: Frequency interval connecting specified passband and stopband boundaries of a filter. The boundary criteria must be stated because different level definitions give different widths. Signals occupying this region can experience rapidly changing magnitude and phase; a tuning frequency by itself does not show whether a broadband desired waveform remains inside the usable response.

MACOM. Designing with Diodes: Protecting Sensitive Components. September 2, 2022. Receiver-protector operation and recovery discussion. https://www.macom.com/updates/articles/2022/designing-with-diodes-protecting

Annotation. Supports the qualitative explanation of PIN-limiter charge storage, RF resistance, external current path, and return toward the nonlimiting state. The chapter does not infer an instrument-independent numerical recovery law from that explanation. The component or engineering reference concerns protection against excessive RF drive and the nonlinear behaviour inherent in an input limiter. Front-end loss, limiting threshold, recovery time and spectral products should be checked against the actual arrangement before characterising a faint signal. A protection device that prevents damage does not guarantee accurate level measurement or freedom from in-band artefacts. The cited work is a methodological reference; the worked examples and the conclusions drawn from them remain separate authorial derivations requiring their own checks.

Analog Devices. ADL8201: DC to 30 GHz, RF Limiter. Data sheet, revision 0. January 2026. Tables 1–6, pages 3–5. https://www.analog.com/media/en/technical-documentation/data-sheets/adl8201.pdf

Annotation. Illustrates the separate conditions for small-signal performance, leakage, recovery, survivability, and absolute maximum ratings. Device-specific numerical limits are not transferred to the

Copyright 2026, James M. Atkinson

constructed assessment cases or to an unspecified assembled receiver. The component or engineering reference concerns protection against excessive RF drive and the nonlinear behaviour inherent in an input limiter. Front-end loss, limiting threshold, recovery time and spectral products should be checked against the actual arrangement before characterising a faint signal. A protection device that prevents damage does not guarantee accurate level measurement or freedom from in-band artefacts. Interpretation requires separating the publication's stated scope from the chapter's constructed experimental examples and their necessarily conditional conclusions. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported.

Chapter 4. Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses

Copyright 2026, James M. Atkinson

4.1 Frequency Conversion as Multiplication

A mixer combines an RF input with a local oscillator and produces components related to sums, differences, harmonics, and device nonlinearity. In an ideal multiplication model, the desired first-order products are easy to predict. Practical mixers also exhibit port leakage, conversion loss, impedance sensitivity, intermodulation, direct feedthrough, and products involving harmonic indices. The selected intermediate frequency is therefore one member of a larger product set.[1]

Frequency conversion can occur in active or passive devices, switching mixers, sampling mixers, image-reject structures, quadrature converters, and digital downconverters. Each architecture changes spur behavior, noise, dynamic range, and calibration. A receiver block diagram should identify the number of conversions, high-side or low-side injection, tunable ranges, fixed intermediate frequencies, and filter locations. Without that information, a displayed frequency may be assigned to the wrong external source.

4.2 Model 4A: a declared conversion map

A conversion calculation has two jobs: identify the frequency that a selected path will deliver, and preserve the amplitude and phase convention used to describe that delivery. The familiar absolute-difference expression performs only the first job for a real, first-order difference product. It does not state the loaded voltage gain, distinguish opposite complex-frequency signs, or identify the particular hardware mechanism that generated an observed peak. Model 4A supplies those missing conventions before using the retained Equations 7 and 8 in a challenge test.

Use positive RF and LO frequencies, a peak RF voltage A, and a nonnegative voltage scale g. The real multiplier is defined to multiply the RF voltage by twice g times a unit-amplitude LO cosine. The factor two makes the selected difference-product peak equal to $g\,A$. It is a normalization for this model. A physical mixer may have conversion loss or gain, and its source and load impedances, LO drive, and operating level determine the measured value. Analog Devices explicitly distinguishes an ideal multiplier from a switching mixer and explains why their scaling must be specified.[2]

In the equations, f_{RF} and f_{LO} are in hertz, t is in seconds, and the phases θ_{RF} and θ_{LO} are in radians. A and the selected voltage phasors are in volts; g is dimensionless. R_{RF} and R_{IF} are the positive loaded resistances in ohms, and P_{RF} and P_{IF} are powers in watts. The sign ε records conversion orientation

These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

and is either plus or minus one away from zero difference. A decibel gain or finite power ratio additionally requires positive input and selected-output powers.

Equation 7A. RF and normalized real LO

$$x_{RF}(t)=A\cos\left(2\pi f_{RF}t+\theta_{RF}\right)$$
$$l_R(t)=2g\cos\left(2\pi f_{LO}t+\theta_{LO}\right)$$

Equation 7B. The two real multiplier products

$$y(t)=gA\cos\left(2\pi(f_{RF}-f_{LO})t+\theta_{RF}-\theta_{LO}\right)$$
$$+gA\cos\left(2\pi(f_{RF}+f_{LO})t+\theta_{RF}+\theta_{LO}\right)$$

The product identity follows by adding the cosine of the sum angle to the cosine of the difference angle. The sum term is removed only if the selected path rejects it. The remaining signed difference can be negative. Rewriting a negative-frequency cosine at positive frequency changes the sign of its phase, so high-side injection reverses the orientation of a small RF frequency change and conjugates the associated positive-frequency phasor. Taking an absolute value too early erases this information. At exact equality of RF and LO, the output contains a DC term; its power and phase conventions need separate treatment, so the present tone examples keep the difference nonzero.

Equation 7C. Selected difference and orientation

$$\Delta f=f_{RF}-f_{LO},\varepsilon=sgn(\Delta f),\Delta f\neq 0$$
$$f_{IF}=|\Delta f|,\theta_{IF}=\varepsilon(\theta_{RF}-\theta_{LO})$$

Voltage gain and power gain coincide numerically only after the impedance convention has been settled. With a loaded RF resistance and loaded IF resistance, both real and positive, average sinusoidal power is peak voltage squared divided by twice resistance. The selected product therefore has the

Copyright 2026, James M. Atkinson

power-gain expression in Equation 7D. This is a comparison between declared loaded planes. It is not automatically the available-power conversion gain that a data sheet quotes, and it does not justify replacing either impedance with a nominal value when a mismatched path is under test.

Equation 7D. Loaded selected-product power gain

$$P_{RF}=\frac{A^2}{2R_{RF}},\ P_{IF}=\frac{g^2A^2}{2R_{IF}}$$
$$G_P=\frac{P_{IF}}{P_{RF}}=g^2\frac{R_{RF}}{R_{IF}},\ A,g>0$$

An analytic complex representation keeps the sign of frequency. Let the RF analytic signal be a finite-band complex envelope translated to a carrier sufficiently high that its admitted band remains at positive physical frequency. Multiplication by a complex LO translates that band without folding. If the calculation starts with the real waveform, the conjugate band must be rejected and the factor-of-two normalization retained. The resulting sign convention must agree with the I/Q channel order and complex-exponential convention used in Chapter 10. A reversal of Q changes apparent frequency orientation even when every displayed magnitude looks reasonable.

Equation 7E. Complex conversion without frequency folding

$$x_a(t)=u(t)\exp\left(j2\pi f_{RF}t\right)$$
$$y_a(t)=gu(t)\exp\left(j\left(2\pi(f_{RF}-f_{LO})t-\theta_{LO}\right)\right)$$

For first-order real difference conversion, reflecting the desired RF frequency about the LO gives the conventional image. That reflected frequency is relevant only if it is physically positive and can reach the mixer through the actual RF path. A predicted negative value does not identify a

Copyright 2026, James M. Atkinson

second positive RF tone in the same simple architecture. At finite bandwidth, the whole admitted IF interval maps to two RF intervals. Preselection or a verified image-reject path is what separates them; the label on an IF spectrum alone cannot do so.

Equation 7F. Conventional image and RF interval mapping

$$f_{image} = 2 f_{LO} - f_{RF} > 0$$
$$f_{IF} \in [a, b], 0 < a \leq b$$
$$RF\ set: [f_{LO} - b, f_{LO} - a] \cup [f_{LO} + a, f_{LO} + b]$$
$$Retain\ only\ positive\ admitted\ RF\ frequencies.$$

Two external inputs that arrive at the same IF can be coherent. Their selected IF voltages then add before power is formed, with the high-side phase convention already applied. Depending on phase, the result can exceed or fall below the desired-only response. Power addition is valid when the measurement establishes zero cross power over its averaging operation. Merely calling one tone the image does not make it statistically independent. This distinction becomes especially visible in a controlled test where both generators share a reference.

Equation 7G. Coherent collision and the zero-cross-power condition

$$|a_d + a_i|^2 = |a_d|^2 + |a_i|^2 + 2\Re\left(a_d a_i^*\right)$$
$$\langle P \rangle = \frac{\left\langle |a_d|^2 \right\rangle + \left\langle |a_i|^2 \right\rangle}{2 R_{IF}} \text{ if } \Re\langle a_d a_i^* \rangle = 0$$

Equation 8 is best used as a bounded hypothesis generator. Choose integer indices and a finite search order from the known architecture, then calculate signed candidate frequencies before applying the real-output absolute value. A matching number is cheap to obtain if enough parent signals and integer combinations are admitted. Stronger evidence comes from a predeclared perturbation: change one parent or the LO by a known

Copyright 2026, James M. Atkinson

increment and predict the movement of each candidate. Away from a zero crossing, the signed movement follows the corresponding integer coefficient. Near a crossing, the absolute-frequency trace has a cusp, so a single constant slope no longer describes both sides.

Equation 7H. Bounded integer product search

$$F_{mn}=mf_{RF}+nf_{LO},f_{mn}=|F_{mn}|$$
$$m,n\in\mathbb{Z},1\leq|m|+|n|\leq K,K\in\mathbb{Z}_{¿0}$$

Equation 7I. Retuning a signed and an absolute product

$$\Delta F_{mn}=n\Delta f_{LO}$$
$$\Delta f_{mn}=|F_{mn}+n\Delta f_{LO}|-|F_{mn}|$$
$$\frac{df_{mn}}{df_{LO}}=n\,sgn(F_{mn}),F_{mn}\neq 0$$

Several conversion stages can reverse orientation more than once. Track a local signed derivative through each selected path. For a real first-order difference stage away from zero IF, the derivative is plus one for low-side injection and minus one for high-side injection. Multiplying these signs gives the orientation of the final selected output relative to a small original RF change, provided no stage switches path or crosses zero. A dual-conversion receiver may therefore have the same final IF in two settings while presenting opposite spectral orientation.

Equation 7J. Orientation through selected real difference stages

$$f_i=|f_{i-1}-f_{LO,i}|,\varepsilon_i=sgn(f_{i-1}-f_{LO,i})$$
$$\frac{df_q}{df_0}=\prod_{i=1}^{q}\varepsilon_i\quad\text{on fixed nonzero branches}$$

All ten applications below are constructed examples. Their numbers test the stated conversion map; they do not specify a commercial receiver, predict an unmeasured mixer spur amplitude, or establish an external source

Copyright 2026, James M. Atkinson

identity. The same discipline applies when a frequency plan is supplied by a manufacturer: confirm the active band-switch and correction state for the actual observation rather than treating a generic block diagram as the live configuration.

4.3 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

4.4 Application 4A.1: Locate a low-side image

A desired tone is at 145.1 MHz and the LO is at 134.4 MHz. Subtracting gives a positive 10.7 MHz IF. Reflecting the desired tone about the LO gives 123.7 MHz, also 10.7 MHz from the LO. The desired and image inputs are separated by 21.4 MHz. This separation is a frequency-plan result; it says nothing about the rejection actually supplied by the front end.

The practical test uses separate calibrated injections at those two RF frequencies while holding the IF path and gain state fixed. A difference in output level can then be attributed to the two path responses under those conditions. If the generator level, preselector, or automatic attenuation changes between injections, the comparison no longer measures image rejection alone. The image frequency belongs in the challenge record even if no environmental signal is presently known there.

Copyright 2026, James M. Atkinson

4.5 Application 4A.2: Track high-side spectral inversion

Tune a 900 MHz input with a 970 MHz LO. The signed difference is −70 MHz and the real IF is 70 MHz. With RF phase 30 degrees and LO phase 10 degrees, the negative-frequency difference term has phase 20 degrees; expressed at positive 70 MHz, it has phase −20 degrees. The conventional image is 1,040 MHz. Increasing the desired RF tone by 1 MHz lowers the real IF to 69 MHz.

This example explains why a frequency axis cannot be calibrated from its center alone. A 70 MHz tone is compatible with either injection side, but a small known frequency step reveals orientation. In a complex recording, retain the signed frequency and I/Q convention as well. Conjugating a stored record to make its spectrum look familiar is a processing operation that must be recorded, especially if later phase or delay comparisons use that record.

Figure 14. Spectral inversion and local-oscillator injection.

Copyright 2026, James M. Atkinson

4.6 Application 4A.3: Separate loaded voltage gain from power gain

Let the loaded RF peak be 0.2 V across 50 Ω, the selected-product voltage scale be 3, and the IF load be 200 Ω. The IF peak is 0.6 V. The input power is 0.4000 mW and the output power is 0.9000 mW. Their ratio is 2.25, or 3.5218 dB, although the voltage ratio is 3.

The corresponding levels are -3.9794 dBm and -0.4576 dBm. Applying twenty times the logarithm of 3 as a power gain would overstate the result because the output resistance is four times larger. The calculation is useful for checking a simulation or a loaded-voltage calibration. An available-power measurement requires its own source and load conditions and should not inherit these numbers without that conversion.

Copyright 2026, James M. Atkinson

4.7 Application 4A.4: Expose the multiplier normalization

Multiply a 1 V peak RF cosine by a unit-amplitude LO cosine with no leading factor two. Either selected product has peak 0.5 V. At equal 50 Ω resistances, the power ratio is one quarter, or -6.0206 dB. Reintroducing the model's factor two returns a 1 V selected-product peak and unity power ratio.

The apparent 6.0206 dB disagreement between those results is entirely a normalization difference. It is resolved by writing the multiplier equation, not by changing an RF calibration file. A digital downconverter may likewise use a scale factor that differs from a real mixer convention. Track that factor through the sampling and arithmetic models before reporting physical watts. The normalized mathematical multiplier is not a passive circuit whose energy balance has been established.

Copyright 2026, James M. Atkinson

4.8 Application 4A.5: Allocate image rejection ahead of equal conversion

Suppose the desired input is −90 dBm and an image-frequency input is −30 dBm. The preselector loses 3 dB at the desired frequency and 70 dB at the image; both selected conversion paths then have −6 dB gain. The desired output is −99 dBm, while the image output is −106 dBm. The desired signal is only 7 dB above the image despite the apparently large 70 dB rejection figure.

To obtain a 10 dB desired-over-image margin with the other assumptions unchanged, the image path needs at least 73 dB loss. The calculation compares the external level difference with the differential path loss. It also assumes the strong image input has not compressed a preceding component or changed gain. If it does, the linear subtraction is no longer the relevant acceptance result; the blocker tests in Chapter 11 must be applied to that state.

Copyright 2026, James M. Atkinson

4.9 Application 4A.6: Combine coherent desired and image fields

Let the selected desired IF peak be 1 mV and the image contribution 0.25 mV at the same frequency. Relative phases of 0, 90, and 180 degrees give powers 1.5625, 1.0625, and 0.5625 times the desired-only power. Those ratios are 1.9382, 0.2633, and -2.4988 dB, respectively.

The zero-cross-power sum is 1.0625 times the desired-only power. It happens to equal the coherent 90-degree result, but the reason is different: the coherent cross term vanishes at that phase, whereas an incoherent average requires a justified averaging relationship. A single power reading therefore cannot distinguish those mechanisms. Varying relative phase in a controlled injection can expose the collision; assuming independent powers would conceal the possible cancellation.

Copyright 2026, James M. Atkinson

4.10 Application 4A.7: Keep opposite complex-frequency bins distinct

A complex converter with a 10 MHz LO receives a tone at 10.01 MHz or, in a separate trial, at 9.99 MHz. Their baseband frequencies are +10 kHz and −10 kHz. At 50,000 complex samples per second with a 100-point DFT, the ordinary array indices are 20 and 80. Under the signed-bin convention they are +20 and −20.

A real magnitude display at 10 kHz could show either input, while the correctly ordered complex record distinguishes them. This is a useful end-to-end acceptance stimulus because it simultaneously tests tuning sign, I/Q order, and frequency-axis labeling. The discrete frequencies still belong to sampling equivalence classes, so the analog admitted band in Chapter 10 remains part of the claim. Complex representation does not eliminate aliases outside that band.

Copyright 2026, James M. Atkinson

4.11 Application 4A.8: Test the movement of a candidate harmonic product

An RF parent at 103 MHz and an LO at 100 MHz give the candidate $2f_{\mathrm{RF}} - 2f_{\mathrm{LO}}$ at 6 MHz. Raising the LO by 0.1 MHz moves that candidate to 5.8 MHz, a slope of −2 Hz per hertz of LO change. The first-order difference instead moves from 3 to 2.9 MHz, with slope −1. The two hypotheses make different, testable movement predictions.

Before retuning, specify the IF band in which both observations remain measurable and the tolerance allowed for frequency estimation. A measured slope near −2 supports this candidate relationship, but it still does not identify the nonlinear device or rule out another clock-derived combination with the same slope. A second independent parent change, a level-dependence test, or a path bypass can discriminate further. Products that disappear into the filter during the first change remain unresolved by that observation.

Copyright 2026, James M. Atkinson

4.12 Application 4A.9: Track inversion through two real conversions

The first conversion again uses 900 MHz RF and 970 MHz LO, giving a real 70 MHz IF with reversed orientation. A second LO at 60 MHz produces a 10 MHz output without another reversal. A second LO at 80 MHz also produces 10 MHz, but adds a second reversal. Increasing the original RF by 1 MHz consequently gives 9 MHz in the first arrangement and 11 MHz in the second.

The final center frequency is identical in both arrangements, so a center-tone verification misses the difference. A two-tone or small frequency-step check establishes the final axis orientation. The recorded configuration should retain both LO choices, including any automatic change at a band boundary. If a later analysis compares phase or modulation sidebands across that boundary, it must use the appropriate orientation for each segment.

Copyright 2026, James M. Atkinson

4.13 Application 4A.10: Map an admitted IF interval back to both RF intervals

A real converter uses a 100 MHz LO and admits positive IF frequencies from 9.9 through 10.1 MHz. The corresponding upper RF interval is 109.9 through 110.1 MHz, and the lower interval is 89.9 through 90.1 MHz. Both intervals therefore belong in the external-source search and preselector verification. A single image center frequency would leave their edges unexamined.

Here the admitted interval is an ideal set used to make the mapping exact. A real filter has a transition response and a measurement threshold, so its useful admission boundary must be defined from the intended decision. For amplitude calibration, the acceptable flatness may determine the band; for a spurious-response challenge, a much weaker skirt response may still matter. Use the same frequency map with the measured weighting rather than pretending that the labeled bandwidth is a perfect rectangle.

Copyright 2026, James M. Atkinson

4.14 Local-Oscillator Purity and Leakage

The local oscillator determines tuning accuracy and contributes phase noise, harmonics, subharmonics, reference spurs, and modulation. Leakage from the LO to the RF input or antenna can radiate outside the receiver, couple into nearby systems, or be detected by another instrument. Reverse isolation depends on mixer type, switching, preselection, input termination, and gain state. A receiver used in a sensitive area may therefore be both a sensor and an unintended emitter.

LO leakage tests compare terminated and connected inputs, change tuning while observing with an independent receiver, and vary preselection or isolation. The test should separate radiation from the receiver enclosure, cable common-mode current, and re-radiation through the antenna. A detected LO component identifies receiver activity but does not by itself expose the complete tuning plan or prove that the instrument is malfunctioning.

4.15 Image Responses and Image Rejection

An image frequency is an unwanted RF input that produces the same intermediate frequency as the desired input. Image location depends on the injection scheme and IF. Preselection and image-reject mixing suppress the response, but rejection varies with frequency, alignment, amplitude, temperature, and quadrature balance. Direct-conversion receivers avoid a conventional first IF image but introduce other challenges, including DC offset, even-order distortion, LO leakage, and I/Q imbalance.

Figure 16. Image-response folding and oscillator retuning.

Image testing injects equal calibrated signals at the desired and predicted image frequencies and compares the indicated outputs under identical settings. The source path must not itself generate harmonics or leak through switches. Strong images can also arise from overloaded front ends

Copyright 2026, James M. Atkinson

or filter bypass paths. A signal seen at one displayed frequency is not attributed until image and alias possibilities have been challenged.

Copyright 2026, James M. Atkinson

4.16 Spur Tables and Product Search

Spurious responses can be organized with product indices m and n, where an output occurs near $|mf_{\mathrm{RF}} \pm nf_{\mathrm{LO}}|$ or from combinations of multiple input signals. Real receivers add harmonics of references, synthesizer dividers, clocks, ADC sample rates, digital numerically controlled oscillators, and power converters. Spur tables should therefore combine analog and digital architecture rather than listing only mixer products.

A practical search begins with measured strong signals and known internal clocks. Candidate products are calculated and compared with the observation. The test then changes one parent frequency, input level, attenuation, LO plan, sample rate, or reference clock. A true product moves or changes according to the generating relationship. This challenge is more persuasive than a numerical coincidence between one observed peak and one predicted formula.

Copyright 2026, James M. Atkinson

4.17 Conversion Gain, Loss, and Calibration

Conversion gain or loss is measured between declared RF and IF reference planes with specified LO drive, source and load impedance, frequency, temperature, and signal level. Mixers can compress on total input power or on LO disturbance. Filters and amplifiers around the mixer contribute to the measured result, so de-embedding is needed if the mixer alone is the measurand.

Calibration of a tunable receiver may contain frequency-dependent corrections for preselection, mixing, IF gain, detector, and digitizer response. Those corrections can become invalid after repair, firmware change, alignment, or option change. Independent verification at several points across each band is preferable to assuming a single correction. Spur-free performance also requires tests at several input levels because some products grow faster than the desired response.

Copyright 2026, James M. Atkinson

4.18 From a product map to a discriminating test

Start a conversion challenge by recording the complete active plan: antenna or injection port, preselector, attenuation, amplifier state, every known LO and IF, selected bandwidth, detector or sample path, and frequency-reference state. Mark the external reference plane and the point at which the output is measured. A direct-sampling mode, an alternate first IF, and an image-reject mode are different configurations even if the front-panel center frequency is unchanged. Confirm the path with a known tone before applying a strong parent or image stimulus.

For each candidate response, write a predicted change that could be observed without destroying the measurement. An image challenge changes the injected RF frequency while preserving its input level. A spur movement challenge changes one parent frequency. A level challenge changes a known parent while keeping the desired reference measurable. A leakage challenge compares a terminated input with controlled coupling paths and, where appropriate, an independent receiver. The useful result is the relationship between controlled change and response, not the largest collection of screenshots.

Stimulus purity is part of the experiment. A generator harmonic can enter through the desired path and imitate receiver image response. Two combined sources can intermodulate in a passive junction or in one source output before reaching the receiver. Attenuation and isolation between sources, a terminated-path check, and an independently measured source spectrum constrain these alternatives. If the stimulus cannot be verified at

Copyright 2026, James M. Atkinson

the required level, report a bound or an unresolved result rather than assigning all observed output to the receiver.

Keep movement and amplitude evidence separate until the observations justify joining them. A frequency relationship can be accurate even when compression makes the amplitude response invalid. Conversely, a stable calibrated amplitude can belong to an image whose external frequency was misidentified. A conversion-state boundary may change both path loss and orientation. Repeat a small known frequency step and a level reference on each side of the boundary, then compare each environmental observation only with the applicable state.

A response that survives these tests still requires an appropriate external claim. The tests may establish that energy entered through an RF path, that it is compatible with one source frequency, or that a particular internal product is favored. They do not by themselves locate an emitter or identify an operator. Chapter 16 turns these bounded conversion results into an artifact-discrimination record with explicit competing explanations and unresolved outcomes.

Copyright 2026, James M. Atkinson

4.19 Conversion-State Challenge Protocol

Receiver conversion states are challenged across adjacent bands, high-side and low-side injection, alternate IF paths, and direct-sampling modes where available. The test matrix includes known desired signals, predicted images, selected harmonic products, terminated-input residuals, and strong out-of-band parents. Results are captured at more than one input level so that response slope can distinguish linear transfer from nonlinear generation.

A conversion-state change is treated as a configuration event. Native setup files, correction tables, synthesizer lock state, and band-switch boundaries are preserved. When a signal appears only in one conversion plan, the report explains whether the evidence supports an external source, an image, an LO-related product, or an unresolved mechanism.

Copyright 2026, James M. Atkinson

4.20 Quantitative Model for Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses

Equation 1. First intermediate-frequency relation

$$f_{\mathrm{IF}} = \left| f_{\mathrm{RF}} - f_{\mathrm{LO}} \right|$$

For a first-order difference conversion, the intermediate frequency equals the absolute difference between RF and local-oscillator frequencies. Sum conversion and higher-order products must also be considered in a practical receiver.

Equation 2. General mixer-product family

$$f_{\mathrm{spur}} = \left| m f_{\mathrm{RF}} \pm n f_{\mathrm{LO}} \right|$$

A candidate spur can occur at integer harmonic indices m and n. The expression is a search aid, not proof that a product exists. Device nonlinearity, filtering, port isolation, and input amplitude determine observable products.

Model 4A and Applications 4A.1–4A.10 retain the sign of the selected conversion before forming the magnitude in Equation 7. Its integer product lattice supplies Equation 8’s candidate locations. Product order and receiver measurements are needed to decide which candidates have appreciable amplitude.

Copyright 2026, James M. Atkinson

Table 1. Chapter 4 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
LO plan	Frequency, injection side, tuning range, step, reference, and phase noise	Maps display frequency to physical conversion	Undocumented conversion stages create ambiguous attribution
Image response	Predicted image, injected level, desired response, and rejection	Tests an alternate external frequency producing the same IF	Overload or leakage can imitate a poor image response
Spurious product	Parent frequencies, indices, input levels, attenuation, and movement test	Explains internally generated peaks	A numerical frequency match alone is weak evidence
Conversion calibration	RF and IF planes, LO drive, gain or loss, impedance, and temperature	Supports corrected amplitude across bands	Repairs and firmware changes can invalidate stored correction

4.21 Hypothetical Applied Calculation: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses

A superheterodyne receiver uses a 70 MHz first IF and high-side injection. Tuning 900 MHz places the LO at 970 MHz. An input at 1.040 GHz also converts to 70 MHz and is the first image. A 1.040 GHz test signal should therefore be included before attributing a displayed 900 MHz component.

Copyright 2026, James M. Atkinson

4.22 Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses

A recurring peak is displayed at 312.5 MHz on several antennas. Changing the receiver reference clock from its internal 10 MHz source to a verified external reference shifts the peak by the exact fractional clock change, while a second receiver shows no external signal. The clock-dependent movement supports testing a clock-related mechanism. Equation 23I also shows how clock calibration can move the displayed frequency of a fixed external tone. Distinguishing an internal spur from that relabeling requires the actual LO and sample-clock mapping, an independent physical-frequency reference, and a comparison receiver with characterized sensitivity and coverage. The stated observations leave that classification open.

Copyright 2026, James M. Atkinson

4.23 Signed-frequency conversion maps and the forensic construction of a spur atlas

A mixer is a time-varying system whose outputs cannot be interpreted solely by naming a nominal intermediate frequency. For a real product mixer fed by sinusoids at f_{RF} and f_{LO}, the first-order output contains components at $|f_{RF} - f_{LO}|$ and $f_{RF} + f_{LO}$. In practical receiving chains harmonics of the oscillator, input and other local clocks can yield additional combinations $m f_{RF}$ plus or minus $n f_{LO}$, with integer orders m and n determined by the nonlinear mechanism and effective filtering. The frequency relation predicts where an artefact might occur; it does not determine its amplitude without the circuit's conversion response and drive conditions. Importantly, a receiver's software frequency label may use a chosen sign convention for complex sampling that differs from the spectrum of real intermediate-frequency voltage. Record the convention explicitly before interpreting a spectral mirror as an independent radiating source.

Copyright 2026, James M. Atkinson

Figure 17. Mixer harmonic products and spur lattice.

An instrument-specific spur atlas should be built with input-port terminations and calibrated reference sources, at several local oscillator settings and gain states. Index each candidate feature by physical output frequency, displayed frequency, local oscillator frequency, source settings

Copyright 2026, James M. Atkinson

and known aliases. Predict the differential slope of a candidate under a controlled oscillator shift: a first-order desired conversion may shift in a documented direction, whereas a locally generated fixed clock harmonic can remain at a fixed physical output or move according to a different order. A change in displayed position is not evidence of external motion unless the software frequency mapping and its state are established. Coupled oscillators, leakage into the antenna path and synthesiser fractional spurs can defeat a simplistic one-frequency challenge, so alternative controls are indispensable.

For a purely numerical illustration, a 120 MHz real input mixed with a 100 MHz oscillator generates first-order terms at 20 MHz and 220 MHz. If the IF chain passes 20 MHz, a different real input at 80 MHz can also yield 20 MHz before preselection, creating the familiar image ambiguity. A calibrated RF filter that passes 120 MHz while strongly rejecting 80 MHz can discriminate these two source possibilities, provided its actual transfer and the mixer's operating state are known. A software frequency-label convention cannot by itself eliminate the ambiguity. The laboratory should repeat the comparison with a known reference injected at each potential RF input and record the physical IF output, rather than assuming that an ideal sideband diagram describes the installed hardware.

Reciprocal mixing complicates the atlas because a strong blocker and oscillator phase-noise sidebands can produce a raised background in the desired IF channel without a stable discrete new line. The relevant calculation integrates the blocker's converted noise contribution through the channel response and the oscillator noise spectrum under a clearly stated normalization. A single phase-noise value at one offset is not

Copyright 2026, James M. Atkinson

sufficient for arbitrary channel shapes. Separately document synthesiser lock transitions, fractional-divider configuration and reference-source changes. The result is a falsifiable catalogue of observed and predicted instrument products, not a universal guarantee that an unlisted spectral component must have arrived from the environment.

Copyright 2026, James M. Atkinson

4.24 A multiconversion receiver must be audited as a frequency-sign system, not merely as a chain of nominal intermediate-frequency labels

Consider a receiver with two translation stages. For each stage the algebraic image of an input frequency depends upon whether the local oscillator is above or below the selected radio-frequency component, and upon the sideband that the subsequent filter retains. A positive absolute frequency on an instrument screen can conceal a reversal of spectral orientation, since a waveform described through complex analytic coordinates retains a sign convention that a magnitude display discards. Define the first local oscillator f_{L1}, the second oscillator f_{L2} and the signed offsets f_1 and f_2. Under an expressly chosen complex mixing convention, a desired first translation can be written $f_1 = f_{RF} - f_{L1}$ and the next $f_2 = f_1 - f_{L2}$. The recorded frequency must also include the choice of analytic sideband and the final sampling convention. Substituting magnitudes at every step destroys signs and can lead an analyst to assign two physically different RF frequencies to the same displayed line. Forensic frequency inference therefore calls for an ordered mapping table, not a single arithmetic subtraction.

A mixer does not operate as a perfect multiplication by one pure sinusoid. Practical switching waveforms contain harmonics, local-oscillator paths can leak to the input or output, and finite isolation admits coupling that depends upon termination and bias state. An observed product may be approximated by $f_p = |m f_{RF} + n f_{LO}|$ for specified signed integers m and n, but a catalogue of possible integer combinations does not prove that any particular product is generated with observable amplitude. The relevant

Copyright 2026, James M. Atkinson

nonlinear order, conversion gain, excitation level, port impedance, mixing direction and filtering determine whether the product is physically plausible. A spur atlas should therefore contain a predicted frequency, a predicted level or bounded level if known, an instrument state, a reference-plane statement, and a discriminating test. Merely finding integers that explain a frequency is vulnerable to post hoc pattern matching when many candidate carriers and oscillators are present.

The analyst should distinguish three responses to a controlled change in first-oscillator frequency. A genuine external input at a fixed RF frequency follows the selected frequency-translation law; a product involving the local oscillator may move at an integer multiple of the commanded change; and a digitally generated display marker may remain fixed in bin coordinates while its indicated physical frequency shifts with the software frequency origin. This experimental distinction fails when the receiver retunes the preselector or changes intermediate-frequency plans automatically at the same time. Retain actual synthesizer readback, not merely the requested tuning command. If a local oscillator is fractional-N synthesised, a change in its fractional division sequence may also alter the spur distribution without materially changing its nominal centre frequency. Harmonic arithmetic is a map of hypotheses rather than an independent validation of the synthesiser's spectral purity.

For an illustrative acceptance exercise, take an RF candidate at 2,410 MHz and a first oscillator at 2,300 MHz, with selected difference IF 110 MHz. A separate RF input at 2,190 MHz can produce the same 110 MHz magnitude as an image through the corresponding difference term. A first-stage preselector with only 3 dB rejection of the image frequency cannot by itself

Copyright 2026, James M. Atkinson

establish a single-valued inverse from IF to RF. If its measured rejection is 65 dB at 2,190 MHz and the actual interferer powers are bounded, the image hypothesis may be weakened quantitatively, but it is not eliminated by naming the filter alone. A second RF source placed at the predicted image frequency can challenge the architecture in a controlled setting. The test must also establish its own source harmonics, combiner isolation and output calibration to avoid attributing a generator product to the receiver.

Image-reject and quadrature mixers add a complex-balance problem. With ideal in-phase and quadrature paths a selected sideband cancels at one combination, but amplitude mismatch and phase error leave a residual. A small calibration error might be negligible at a weak input yet devastating when a strong image lies tens of decibels above the desired component. Define separate amplitude balance, phase balance, frequency dependence, temperature and LO drive as measurement inputs. A quoted image-rejection ratio measured at one frequency and one gain setting is not a certificate covering every input band or dynamic state. It should be measured using an independent reference that challenges both spectral sides over the proposed operating interval. In particular, correction algorithms should not fit and certify themselves on the same dataset.

Conversion loss is itself a calibrated measurement, not just a number that can be copied from a component catalogue. A two-port small-signal ratio may omit image-side noise, mismatch and pumped nonlinear source dependence. If an apparent receiver noise figure is computed from a mixer whose data sheet uses a double-sideband convention, the model and measured quantity must be reconciled before the value enters a selected-channel single-sideband cascade. Similarly, when a conversion product

Copyright 2026, James M. Atkinson

appears at a frequency predicted by multiple nonlinear pathways, an amplitude-versus-input-level sweep may discriminate second-order, third-order and other mechanisms only within a range where the slopes are observed consistently. Amplifier compression, interstage filtering and source impurity can invalidate a simple integer-slope expectation.

The engineering chapter should culminate in a reproducible frequency-plan examination: declare the oscillator frequencies and phase conventions; trace desired and image paths through every stage; compute candidate spur combinations within a justified order range; measure relevant rejection and transfer states; vary one source frequency or amplitude at a time; document actual LO state and lock quality; and preserve both accepted and rejected explanations. The resulting map permits the reviewer to ask a precise question about each suspicious line rather than accepting the most elegant arithmetic coincidence as proof of its origin.

4.25 Additional study: switching mixers as periodically time-varying multiport networks

A frequency mixer is frequently introduced as a multiplier, but this elementary representation neglects how a physical switching network couples three ports and the terminations attached to them. The multiplication model is useful because it correctly predicts translations of a deliberately small signal under a specified sinusoidal local oscillator. It is not, without further qualification, an adequate model of the energy distribution in a diode ring, an active Gilbert cell, or a converter exposed to several strong signals. An advanced treatment must distinguish a mathematical multiplication operator from a periodically time-varying network, whose operating point and internal junction impedances are functions of both local-oscillator phase and applied radio-frequency voltage. This distinction matters for forensic receivers because a spectral feature may be an image, a harmonic mixing product, leakage from another port, or a genuine input signal that has been translated into the same output passband.

Consider a symmetric idealised polarity-reversing switch, with switching function $s(t)$ that is $+1$ during the positive half of a local-oscillator cycle and -1 during the negative half. Its Fourier series contains odd harmonics: $s(t) = (4/\pi)[\cos(\omega_{LO} t) - \cos(3\omega_{LO} t)/3 + \cos(5\omega_{LO} t)/5 - \ldots]$, for a suitable choice of phase origin and Fourier convention. A small signal $v_{RF}(t)$ multiplied by $s(t)$ produces translated components near odd multiples of the switching frequency, not solely near the fundamental. With a single input $v_{RF}(t) = A \cos(\omega_{RF} t + \varphi)$, the fundamental term generates output tones proportional to $2A/\pi$ at angular frequencies $|\omega_{RF} \pm \omega_{LO}|$. The actual port

Copyright 2026, James M. Atkinson

loading, filter response and available power set the realised conversion loss. The coefficient 2/π describes a waveform-amplitude result under the stipulated ideal switch convention; it must not be applied as a universal measured conversion factor at a nominal fifty-ohm connector. A diode ring's commutation quality, balanced transformers, lead parasitics and output termination can all alter the ratio. This is one reason an input-to-output calibration must specify the local-oscillator drive and the third-port load in addition to its centre frequency.

There are at least three distinct levels at which the ideal switch model can fail. First, a local oscillator that does not completely commutate the switching elements creates intervals of intermediate conduction, modifying desired conversion loss, isolation and higher-order content. Secondly, finite transformer balance permits an LO-derived voltage at the RF or IF port even when the desired small-signal transfer is acceptable. Thirdly, large RF inputs influence the conduction state and generate terms beyond the linear periodically switched response. The third effect is not always visible as ordinary one-decibel compression. A converter may produce an unwanted mixing component that compromises an adjacent weak-signal channel while the desired tone remains close to its normal level. The relevant acceptance envelope therefore includes in-band distortion, spurious response and phase integrity at the levels and modulation conditions of interest; it cannot be replaced by a single compression-number comparison.

A useful engineering representation is to assign a measured complex transfer coefficient $H_k(f_{RF}, P_{RF}, P_{LO}, Z_{RF}, Z_{IF}, T)$ to each allowed mixing order k. The arguments identify RF frequency, RF level, LO drive, loaded RF and IF impedances, and physical temperature. The output near

Copyright 2026, James M. Atkinson

frequency $f_{RF} + k f_{LO}$ is then modelled by the input complex amplitude multiplied by H_k, provided small-signal superposition remains valid in the chosen operating domain. Unlike a simple product-frequency table, this representation records amplitude and phase as well as frequency location. It also makes clear why an observed line at the predicted frequency is insufficient proof of a particular mechanism: a source harmonic or signal-generator intermodulation product can enter through an entirely different route. The coefficient is an experimentally characterised property of a particular complete state, not a presumed number from an ideal circuit diagram.

The test fixture has an evidential role. A two-tone measurement that combines generators through an inadequately isolated passive combiner can generate third-order products in the generators themselves. A spectrum analyser attached to the IF output may additionally overload on LO feedthrough, rendering the observed distortion a property of the instrument used to characterise the mixer. The remedy is to verify source spectral purity at the actual mixer input, to characterise the combining path and terminating impedances, and to use enough independently measured attenuation or filtering to keep the observing receiver in its accepted state. The measurement plan should specify where each frequency component is measured, how levels are referred through the fixture, and which artefact mechanisms remain unexcluded. Independent signal-source and observation controls should be repeated after a component is declared anomalous, not merely performed once at the beginning of a test campaign.

A converter's apparent image selectivity requires the same discipline. In a real scalar downconverter, two RF frequencies symmetrically located about

Copyright 2026, James M. Atkinson

the LO can produce the same positive difference frequency. RF preselection may remove one of those possibilities, but only when its transfer and actual switching state are demonstrated at the image frequency. In a complex I/Q converter, the two spectral signs can be distinguished if quadrature phase and amplitude match the applied correction model. At high frequencies or over broad instantaneous spans, the ratio between the desired complex response and the conjugate leakage response becomes a function of frequency. A single image-rejection number measured at the centre of a band cannot certify every channel in a wide receiver. A defensible acceptance test therefore sweeps both desired and image input families across the full working frequency interval and independently measures the phase response of the complex channel.

The state of the source must be included in the validity claim. A local oscillator synthesiser can change phase-noise density, output level or fractional-N spur structure between tuning states, even if the displayed LO frequency is exact. The mixer may also experience LO pulling through coupling from a strong RF source. These behaviours are relevant to a technical-surveillance examination where an intermittent external event and a spur produced by the instrument may coincide for only one synthesiser configuration. A useful counterfactual test changes LO frequency by a known increment while maintaining the same RF input environment and repeats it with a separately synthesised reference. An external RF signal and a converter-order product generally predict different shifts in output frequency. The comparison becomes persuasive only after confirming that the LO change did not also alter hidden preselection, gain, acquisition bandwidth or receiver saturation.

Copyright 2026, James M. Atkinson

The relation between measurement and inference should be written as an explicit proposition. An observation may establish that an IF component moved by a measured frequency increment when LO frequency changed. It may support the bounded interpretation that a known mixing order explains the movement. It cannot, without additional evidence, establish that the RF input was absent, that the component originated entirely inside the receiver, or that every other product sharing the same frequency was excluded. Forensic strength comes from discriminating experiments that alter a relevant causal mechanism while retaining observation capability. This chapter's new treatment extends the existing signed-frequency maps by requiring measured amplitude, phase, load and state-dependent coefficients for any numerical claim about a physical converter.

Copyright 2026, James M. Atkinson

4.26 Experimental protocol: comparing passive and active conversion

The comparison begins with two separately qualified paths operated at common RF, LO and IF reference planes. In the passive path, measure loss and port isolation while varying LO drive over a specified range without exceeding any rating. In the active path, measure conversion gain, bias dependence and its corresponding noise and compression behaviour. Do not compare a passive mixer's conversion loss with an active mixer's voltage gain without first reconciling load impedance, delivered versus available power, and output noise. A fixed IF amplitude can conceal a large difference in input sensitivity when the active path contributes more noise. Conversely, an active converter with useful gain may place downstream filters or analogue-to-digital converters closer to overload, even when its nominal RF input limit has not been reached.

Take a matrix of RF test frequencies, LO frequencies, levels and temperatures. At each matrix point record the desired converted tone, the corresponding unwanted image response, LO-to-IF and LO-to-RF feedthrough, the noise floor in a declared equivalent bandwidth, and evidence of clipping or gain changes. A differential comparison between the two topologies is meaningful only on the intersection of their valid operating ranges. If one mixer requires a drive level or bias that cannot be maintained over the full band, that part of the matrix should be labelled inapplicable rather than filled by extrapolation. If output correction files are interpolated between measured reference points, the interpolation method and uncertainty become inputs to the comparison.

Copyright 2026, James M. Atkinson

For a constructed numerical illustration, let a passive mixer have an RF input of −65 dBm and calibrated conversion loss of 7.2 dB at a specified LO drive. Its expected desired IF output is −72.2 dBm before downstream gain. An active mixer with 9.5 dB conversion gain at the same input instead predicts −55.5 dBm. The difference of 16.7 dB in output level is not an equal improvement in sensitivity: the comparison needs each path's noise contribution, linearity, dynamic range and load conditions. If the active mixer's gain becomes 7.5 dB under a different blocker state, the uncorrected output changes to −57.5 dBm even when the input source remains constant. A display that applies the old 9.5 dB correction could then overstate or understate the input depending on its convention. This example is hypothetical; it is not evidence about a manufacturer component.

A second constructed test assigns desired and image transfer levels of −6 dB and −46 dB respectively at one frequency, resulting in 40 dB image rejection for equal injected inputs. At another frequency the corresponding levels are −8 dB and −33 dB, yielding 25 dB rejection. The apparent 15 dB deterioration could originate in the RF preselector, quadrature error, conversion response or the measurement fixture. The proper test retains a vector transfer measurement and repeats the image injection with independent source and receiver paths. A catalogue value of 40 dB at one reference frequency cannot be applied without qualification to a survey at the second frequency.

A third test probes an IF line suspected to be a harmonic translation. Suppose the nominal RF frequency is 915 MHz and the LO is 900 MHz. The first-order difference is 15 MHz. If the LO is increased to 901 MHz while the

Copyright 2026, James M. Atkinson

same RF source is held fixed, the difference falls to 14 MHz. A line that instead rises by 3 MHz is incompatible with this simple first-order difference model, although it might satisfy a different converter order or arise from an internal synthesis product. The examiner should log the measured movement, not assert a frequency-order attribution from the output alone. The final decision is a comparison of predicted trajectories across several independent LO changes, with each relevant source, image and receiver response calibrated.

The production outcome of this protocol is a converter acceptance surface, not a single recommended mixer type. It identifies the subset of frequency, signal level, blocker condition, temperature and LO state for which a chosen transfer coefficient and uncertainty are supported. Outside that subset, the study retains uncertainty about the conversion law. The model is falsifiable because a held-out test condition can be applied after the acceptance surface is frozen; disagreement is then recorded as evidence of model inadequacy or previously uncharacterised state dependence, rather than repaired silently by editing the coefficient table.

4.27 Advanced technical expansion. Harmonic-mixing lattices and an inverse interpretation of observed spurs

A frequency converter cannot be adequately understood by writing only fIF = |fRF - fLO|. The observed output may contain an entire lattice of frequencies generated by harmonics of the RF input and local oscillator, nonlinear interactions between multiple RF tones, leakage paths and later aliasing. An analytical search begins with signed frequencies f = m fRF + n fLO for bounded integers m and n, augmented by multitone terms when the RF input contains several sources. The index set must be physically restricted by a characterised nonlinear device model and by filtering; the mere mathematical existence of a combination frequency does not establish that the device generates it at an observable amplitude. This distinction matters when a spectrum analyser displays a weak line near an expected intermediate frequency. A plausible arithmetic relationship is a hypothesis for a conversion artefact, not evidence that the hypothetical nonlinear term was present.

Consider a receiver tuned with an illustrative local oscillator at 1,020 MHz and an intermediate frequency of 20 MHz. A desired 1,000 MHz signal produces a 20 MHz difference, but a 1,040 MHz signal produces the same magnitude when a real rather than quadrature conversion discards the frequency sign. A measured preselector attenuation at the image frequency is therefore part of the interpretation, not a menu preference. If the image undergoes 46 dB rejection and the desired path undergoes 2 dB insertion loss, the different front-end transfers must be applied to their respective source frequencies. These numbers are hypothetical. Their importance lies

Copyright 2026, James M. Atkinson

in the independent requirement to demonstrate that the image was sufficiently rejected during the actual observation, including mismatch and dynamic front-end state, before an IF line can be assigned to one of the two RF origins.

Complex mixing retains a sign convention that can distinguish upper and lower sidebands, but practical quadrature channels suffer relative gain and phase errors. For small mismatch, an image-suppression ratio can be predicted by an explicitly calibrated complex I/Q transformation rather than by assuming equal channels. Suppose one channel has a 1% relative amplitude mismatch and a quadrature phase error of two degrees. A small-error approximation gives an image amplitude fraction on the order of one half the magnitude of the complex mismatch, and an image power suppression near 34 dB; the numerical value depends on the convention and exact nonlinear ratio adopted. It must therefore be checked against a precisely defined complex measurement law before use as a numerical acceptance claim. More importantly, correction derived from one LO frequency or temperature may be invalid when the channel phase imbalance varies across IF bandwidth or gain state.

Mixer conversion loss and noise cannot be separated from the sideband architecture. A single-sideband noise figure and a double-sideband noise figure describe different treatment of image-frequency noise; inserting one into an otherwise matched cascade without defining the admitted image path can give a formally coherent but physically incorrect input noise result. Gain compression, LO-drive variation and intermodulation further restrict the simple scalar model. In a controlled bench experiment, vary the LO drive, individual RF input powers and input preselection independently,

Copyright 2026, James M. Atkinson

while observing both the wanted conversion and potential spur frequencies. A valid inference must distinguish a spur that scales with RF power from an LO leak, a source-generated harmonic and an alias created downstream in the digitiser.

An inverse-spur investigation should preserve several candidate source combinations rather than selecting the first that solves a frequency equation. Build a table of each observed output, permitted integer order, hypothetical input frequency, predicted behaviour when LO frequency changes, and the actual evidence obtained from controlled retuning. If a spur moves by twice the LO-frequency change, it suggests a different conversion order from a component that moves once, but the observation alone may still be compatible with another integer combination or a shared clock. Compare the observed slopes against the predicted signed lattice while maintaining a time-coherent record of the LO and converter settings. This turns an otherwise anecdotal observation into a falsifiable engineering claim.

The complete experiment must also control the sources. A two-generator test may create products in a combiner; a spectrum analyser used to inspect the receiver output may itself introduce overload; and an uncalibrated reference clock may make frequency relationships appear inconsistent. Preserve generator purity records, calibrated power at the DUT plane, output analyser attenuation, frequency-reference state and raw sweep files. The acceptance conclusion should be framed by what was actually challenged: a particular converter and LO configuration under stated source levels, not an assertion that every image and spur in a future environment has been excluded.

Chapter Summary

Frequency conversion produces a family of desired and undesired responses. LO plan, images, spur tables, movement tests, and level scaling are essential before a displayed frequency is assigned to an external emitter.

Model 4A retains signed RF-minus-LO frequency, selected-product amplitude and phase before real-frequency folding. Loaded power conversion also depends on the two resistances. Complex conversion preserves orientation only under consistent analytic-band, I/Q, normalization and sampling conventions.

An image is an admitted positive RF frequency reflected about the LO. Map complete IF intervals and their transfers, not only center frequencies. Colliding desired and image phasors combine before power is formed unless a zero-cross-power average is justified. Spur tables identify candidate locations, not guaranteed amplitudes.

Use predeclared LO or parent-frequency changes to test movement, treating zero-crossing cusps piecewise. Conversion-branch signs determine final orientation. Verify stimulus purity and preserve actual filters, gain, clock state, references and native records. Keep frequency movement separate from amplitude validity under compression. A supported product relationship or admitted RF interval does not alone establish an emitter’s identity, location or purpose.

Chapter 4 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C04-MCQ-001. A model predicts a 12 MHz mixer output but gives no loaded resistance or multiplier scale. Which claim remains unsupported by that prediction?

A. The need to identify which output product the path selects.

B. The distinction between the parent RF and LO frequencies.

C. The selected output power or conversion gain.

D. The candidate frequency under the declared frequency map.

Answer: C. A frequency relation alone does not specify voltage normalization, load power, or an actual device transfer. Those require additional declared quantities.

Review: Model 4A: a declared conversion map. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why the selected alternative fits: The selected output power or conversion gain.

Distinguishing consideration: compare this with option A, “The need to identify which output product the path selects”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

V011-C04-MCQ-002. Two positive external RF frequencies produce the same real IF in a declared first-order difference converter. What evidence is needed to decide which supplied an observation?

A. Admitted-path information and a discriminating RF or image challenge.

B. More decimal places in the same IF magnitude.

C. An assumption that the frequency nearest the receiver display is the desired source.

D. A conversion-loss correction applied equally to both candidates.

Answer: A. The real absolute-difference map can admit two RF inputs. A magnitude label cannot distinguish them without path rejection or additional observations.

Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: Admitted-path information and a discriminating RF or image challenge.

Distinguishing consideration: compare this with option B, “More decimal places in the same IF magnitude”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-003. A receiver changes its first IF automatically at a band boundary. Which configuration record is needed for reconstruction?

A. The active conversion stages, LO choices, IF path and filter state for each segment.

B. Only the first LO frequency, assuming later stages are unchanged whenever the final IF label is unchanged.

C. One nominal conversion-gain value for the complete instrument.

D. Only the final center-frequency label if the displayed bandwidth is unchanged.

Answer: A. A state change can alter both loss and orientation. The active plan, rather than a generic block diagram, controls the frequency mapping. Review: From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: The active conversion stages, LO choices, IF path and filter state for each segment.

Distinguishing consideration: compare this with option B, “Only the first LO frequency, assuming later stages are unchanged whenever the final IF label is unchanged”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-004. In Model 4A, why does rejecting the sum product require an explicit path condition?

A. The LO phase makes the sum product vanish for every RF phase.

B. A negative difference frequency necessarily cancels the sum product.

C. The multiplier creates both products; their mathematical generation does not select one physically.

D. The difference product is generated only after the sum product is removed.

Answer: C. The product identity contains sum and difference terms. An actual filter or selected processing path must establish which reaches the reported output.

Review: Equations 7A and 7B. Source: Equation 7A. RF and normalized real LO (p. 1925)

Why the selected alternative fits: The multiplier creates both products; their mathematical generation does not select one physically.

Distinguishing consideration: compare this with option A, “The LO phase makes the sum product vanish for every RF phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7A. RF and normalized real LO; Chapter 4 — Equation 7B. The two real multiplier products.

V011-C04-MCQ-011. A high-side conversion has RF phase 40 degrees and LO phase 15 degrees. What phase describes its selected real IF at positive frequency?

A. 55 degrees.

B. -25 degrees.

C. 25 degrees.

D. -55 degrees.

Answer: B. The signed difference term has phase 25 degrees. Rewriting its negative-frequency cosine at positive frequency negates that phase. Review: Equation 7C. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why the selected alternative fits: -25 degrees.

Distinguishing consideration: compare this with option A, “55 degrees”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7C. Selected difference and orientation.

Review: Chapter 4 — Equation 7C. Selected difference and orientation.

V011-C04-MCQ-012. A low-side conversion has RF phase -15 degrees and LO phase 25 degrees. What is the selected positive-IF phase under Model 4A?

A. 40 degrees.

B. -10 degrees.

C. 10 degrees.

D. -40 degrees.

Answer: D. Low-side conversion has positive orientation, so the RF-minus-LO phase remains -15 minus 25 degrees. Review: Equation 7C. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why the selected alternative fits: -40 degrees.

Distinguishing consideration: compare this with option A, “40 degrees”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7C. Selected difference and orientation.

Review: Chapter 4 — Equation 7C. Selected difference and orientation.

V011-C04-MCQ-013. The RF and LO frequencies become exactly equal in a proposed tone example. Why does the chapter exclude this point from its nonzero-IF examples?

A. Choosing either orientation sign at equality preserves the same nonzero-frequency phase convention.

B. Its selected DC power is still the peak squared divided by twice the load, independently of relative phase.

C. The selected term becomes DC and requires separate phase and average-power treatment.

D. The positive- and negative-frequency descriptions supply two independent DC tones whose powers must be added.

Answer: C. The cosine at zero frequency is a constant whose value depends on phase. The nonzero sinusoidal power convention cannot be transferred mechanically to it. Review: Model 4A: a declared conversion map. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why the selected alternative fits: The selected term becomes DC and requires separate phase and average-power treatment.

Distinguishing consideration: compare this with option A, “Choosing either orientation sign at equality preserves the same nonzero-frequency phase convention”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

V011-C04-MCQ-014. A calculation sets the selected voltage scale to zero and then requests a finite decibel power gain. What should the reviewer state?

A. The RF-to-IF resistance ratio alone determines a finite logarithmic result.

B. The output must equal the input because the LO scale was removed.

C. Zero output is outside the stated positive-power domain for a finite logarithmic gain.

D. The finite power gain is necessarily 0 dB.

Answer: C. A power ratio can be zero, but its logarithm is not finite. Equation 7D explicitly restricts the finite gain case to positive input and selected output powers.

Review: Equation 7D. Source: Equation 7D. Loaded selected-product power gain (p. 1926)

Why the selected alternative fits: Zero output is outside the stated positive-power domain for a finite logarithmic gain.

Distinguishing consideration: compare this with option A, “The RF-to-IF resistance ratio alone determines a finite logarithmic result”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7D. Loaded selected-product power gain.

Review: Chapter 4 — Equation 7D. Loaded selected-product power gain.

V011-C04-MCQ-015. Which unit specification can be inserted directly into the phase argument $2\pi f t+\theta$ exactly as written, without additional conversion factors?

A. Frequency in hertz, time in seconds and phase in radians.

B. Frequency in megahertz, time in seconds and phase in radians.

C. Frequency in hertz, time in seconds and phase in degrees.

D. The quantity f as angular frequency in radians per second, time in seconds and phase in radians.

Answer: A. Frequency times time is a cycle count, multiplied by two pi to form radians. An additive phase must use that angular convention. Review: Model 4A: a declared conversion map. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why the selected alternative fits: Frequency in hertz, time in seconds and phase in radians.

Distinguishing consideration: compare this with option B, “Frequency in megahertz, time in seconds and phase in radians”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

V011-C04-MCQ-016. A physical analog multiplier is written as output voltage equal to the product of two input voltages. What additional scale is needed for dimensional consistency?

A. Treat the two physical voltage inputs as dimensionless without specifying how their volt values were normalized.

B. Only a dimensionless load-resistance ratio, assumed sufficient to convert the voltage product back to volts.

C. Only a unit-amplitude cosine notation, with no statement of how the physical LO voltage enters the transfer.

D. A declared voltage normalization or equivalent gain constant with the necessary units.

Answer: D. The chapter distinguishes its normalized mathematical multiplier from a physical voltage multiplier. The physical transfer must retain its dimensional scale.

Review: Model 4A; MT-080 multiplier-scaling discussion. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why the selected alternative fits: A declared voltage normalization or equivalent gain constant with the necessary units.

Distinguishing consideration: compare this with option A, “Treat the two physical voltage inputs as dimensionless without specifying how their volt values were normalized”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-017. An ideal polarity-switching mixer and the chapter's cosine multiplier give different selected amplitudes. What is the first comparison to make?

A. Compare only their LO frequencies and assume that this fixes the selected amplitude.

B. Compare their LO waveforms and normalization before treating the difference as a calibration error.

C. Assume every ideal mixer has the same conversion loss.

D. Equate their peak LO amplitudes and assume that this alone makes the selected amplitudes equal.

Answer: B. A square-wave sign switch contains a harmonic series, while the normalized cosine multiplier is a different operation. The declared model controls the scale. Review: Model 4A: a declared conversion map. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why the selected alternative fits: Compare their LO waveforms and normalization before treating the difference as a calibration error.

Distinguishing consideration: compare this with option A, "Compare only their LO frequencies and assume that this fixes the selected amplitude"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

V011-C04-MCQ-018. A real mixer's LO drive changes while its nominal LO frequency stays fixed. Which conclusion is justified?

A. Only the displayed frequency can change; amplitude cannot.

B. Conversion gain and other operating properties may change and need an applicable state measurement.

C. The ideal multiplier normalization determines the actual gain without further evidence.

D. All conversion properties remain fixed because frequency is unchanged.

Answer: B. The actual conversion transfer depends on LO drive, loading and operating level. A frequency map does not freeze those physical conditions. Review: Conversion Gain, Loss, and Calibration. Source: §4.17 Conversion Gain, Loss, and Calibration (p. 1948)

Why the selected alternative fits: Conversion gain and other operating properties may change and need an applicable state measurement.

Distinguishing consideration: compare this with option A, "Only the displayed frequency can change; amplitude cannot"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — Conversion Gain, Loss, and Calibration.

Review: Chapter 4 — Conversion Gain, Loss, and Calibration.

V011-C04-MCQ-019. A predicted harmonic product falls exactly on an observed line. Which additional claim does that coincidence fail to establish?

A. That the enumerated arithmetic combination has that candidate frequency.

B. That the candidate belongs to the selected finite search list.

C. That a movement challenge can be designed for the chosen coefficient pair.

D. That the receiver generates the line with a particular amplitude or at a particular internal component.

Answer: D. A product lattice supplies locations. Physical generation, strength and location require evidence beyond the arithmetic match. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: That the receiver generates the line with a particular amplitude or at a particular internal component.

Distinguishing consideration: compare this with option A, “That the enumerated arithmetic combination has that candidate frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-020. Model 4A declares a nonnegative voltage scale. An equivalent hardware description uses a negative real scale. What extra convention must be handled before comparison?

A. Negate the selected power ratio along with the voltage coefficient.

B. The sign can be represented as an additional phase reversal, which must be retained explicitly.

C. Conjugate the entire output frequency coordinate instead of retaining an additional phase shift.

D. Use only the scale magnitude and discard its sign because the power gain is unchanged.

Answer: B. A sign on a sinusoidal voltage corresponds to a phase change. Power is not negative merely because a voltage coefficient is negative; the chapter keeps this choice outside g. Review: Model 4A: a declared conversion map. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why the selected alternative fits: The sign can be represented as an additional phase reversal, which must be retained explicitly.

Distinguishing consideration: compare this with option A, “Negate the selected power ratio along with the voltage coefficient”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

V011-C04-MCQ-021. A loaded RF sine wave has peak 0.10 V across 50 ohms. What is its average input power?

A. 0.20 mW.

B. 1.00 mW.

C. 0.05 mW.

D. 0.10 mW.

Answer: D. Square the peak voltage and divide by twice the resistance: 0.01 divided by 100 watts gives 0.0001 W. Review: Equations 7A-7D; Applications 4A.3 and 4A.4.

Source: Equation 7A. RF and normalized real LO (p. 1925)

Why the selected alternative fits: 0.10 mW.

Distinguishing consideration: compare this with option A, “0.20 mW”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-022. For RF peak 0.10 V across 50 ohms, scale 2 and IF load 200 ohms, what is the selected loaded power gain?

A. Unity, or 0 dB.

B. Two, or about 3.01 dB.

C. Four, or about 6.02 dB.

D. One quarter, or about -6.02 dB.

Answer: A. The voltage doubles, but the load resistance is four times larger. The ratio is 2 squared times 50 divided by 200, equal to one. Review: Equations 7A-7D; Applications 4A.3 and 4A.4. Source: Equation 7A. RF and normalized real LO (p. 1925)

Why the selected alternative fits: Unity, or 0 dB.

Distinguishing consideration: compare this with option B, “Two, or about 3.01 dB”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-023. The voltage scale is 0.5, the RF load is 50 ohms and the IF load is 200 ohms. What is the selected power-gain ratio?

A. 0.25.

B. 1.0.

C. 0.5.

D. 0.0625.

Answer: D. The loaded ratio is 0.5 squared times 50 divided by 200. Both the squared voltage reduction and the resistance ratio contribute. Review: Equations 7A-7D; Applications 4A.3 and 4A.4. Source: Equation 7A. RF and normalized real LO (p. 1925)

Why the selected alternative fits: 0.0625.

Distinguishing consideration: compare this with option A, “0.25”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-025. At equal positive real RF and IF loads, a selected voltage scale of 3 corresponds to which power gain?

A. One third, or approximately -4.77 dB.

B. 9, or approximately 9.54 dB.

C. 3, or approximately 4.77 dB.

D. 6, or approximately 7.78 dB.

Answer: B. With equal loads, power gain is the squared voltage ratio. Twenty times $\log_{10}$ of 3 and ten times $\log_{10}$ of 9 are equivalent here. Review: Equations 7A-7D; Applications 4A.3 and 4A.4. Source: Equation 7A. RF and normalized real LO (p. 1925)

Why the selected alternative fits: 9, or approximately 9.54 dB.

Distinguishing consideration: compare this with option A, “One third, or approximately -4.77 dB”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-028. With equal loads, removing the leading factor two from a normalized cosine multiplier changes selected power by what factor?

A. It is unchanged.

B. It becomes one quarter of its former value.

C. It becomes one half of its former value.

D. It doubles.

Answer: B. Selected voltage is halved; power at the same resistance is therefore reduced by the square of one half. Review: Equations 7A-7D; Applications 4A.3 and 4A.4. Source: Equation 7A. RF and normalized real LO (p. 1925)

Why the selected alternative fits: It becomes one quarter of its former value.
Distinguishing consideration: compare this with option A, “It is unchanged”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-030. A loaded-voltage calculation is compared with an available-power conversion-gain data-sheet value. What must be reconciled?

A. Only equality of nominal impedance labels, assumed to establish matching at both physical planes.

B. Reference planes, source and load conditions, and the distinction between loaded and available power.

C. Only replacement of ten-times-log power scaling by twenty-times-log voltage scaling.

D. Only conversion frequency and injection side, since nominal impedance labels are assumed to establish matched available power.

Answer: B. The two power conventions are not automatically the same. A nominal impedance label cannot replace the actual matching and measurement definition.
Review: Equations 7A-7D; Applications 4A.3 and 4A.4. Source: Equation 7A. RF and normalized real LO (p. 1925)
Why the selected alternative fits: Reference planes, source and load conditions, and the distinction between loaded and available power.
Distinguishing consideration: compare this with option A, “Only equality of nominal impedance labels, assumed to establish matching at both physical planes”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-031. An LO at 200 MHz converts a desired 215 MHz input to a real 15 MHz IF. What is the conventional first-order image candidate?

A. 185 MHz.

B. 15 MHz.

C. 400 MHz.

D. 230 MHz.

Answer: A. Reflect the desired frequency about the LO: twice 200 minus 215 gives 185 MHz. It is observable only if the actual RF path admits it. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: 185 MHz.

Distinguishing consideration: compare this with option B, “15 MHz”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-033. A real difference converter uses 100 MHz LO for a desired 250 MHz input. The reflection formula gives -50 MHz. What follows in the chapter's positive physical-RF domain?

A. Every other mixer or sampling response has been excluded.

B. A 50 MHz input must be the conventional reflected image.

C. The desired 250 MHz input cannot produce a real difference output.

D. There is no second positive RF image from that particular first-order reflection.

Answer: D. A negative reflected frequency is outside the stipulated positive-RF domain. This does not eliminate other product families or sampling mechanisms. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: There is no second positive RF image from that particular first-order reflection.

Distinguishing consideration: compare this with option A, "Every other mixer or sampling response has been excluded"; that competing statement does not meet the question's stated requirement.

V011-C04-MCQ-034. A desired frequency coincides exactly with the LO. How should a proposed ordinary image-rejection calculation be treated?

A. The usual separated-image injection pair can be retained unchanged even though both frequencies now coincide.

B. The two real-frequency branches remain independent inputs whose DC powers can always be added.

C. The nonzero sinusoidal power rule applies directly to the DC term without regard to relative phase.

D. The zero-IF coincidence requires its own DC and quadrature analysis; the separated nonzero-image example does not apply directly.

Answer: D. The conventional two-branch tone picture degenerates at zero difference. The chapter keeps that boundary separate from its nonzero-IF examples. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: The zero-IF coincidence requires its own DC and quadrature analysis; the separated nonzero-image example does not apply directly.

Distinguishing consideration: compare this with option A, “The usual separated-image injection pair can be retained unchanged even though both frequencies now coincide”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion;....

Review: Chapter 4 — Equation 7F. V011-C04-MCQ-035. A 10 MHz LO feeds a real difference path admitting IF from 2 through 3 MHz. Which RF intervals are mapped to that path?

A. 7 through 8 MHz and 12 through 13 MHz.

B. 8 through 12 MHz only.

C. 7 through 13 MHz as one unbroken interval.

D. 2 through 3 MHz and 10 through 13 MHz.

Answer: A. Subtract the IF interval from the LO with reversed endpoint order for the lower branch, then add it for the upper branch. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: 7 through 8 MHz and 12 through 13 MHz.
Distinguishing consideration: compare this with option B, “8 through 12 MHz only”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion;....

V011-C04-MCQ-036. A 2 MHz LO feeds a real path admitting positive IF from 1 through 4 MHz. After restricting physical RF to positive values, which RF set remains?

A. Only 1 through 4 MHz because the IF filter defines the RF band directly.

B. The whole interval from -2 through 6 MHz.

C. Only 3 through 6 MHz because the lower interval has one negative endpoint.

D. Frequencies greater than zero through 1 MHz, together with 3 through 6 MHz.

Answer: D. The algebraic lower interval is -2 through 1 MHz. Intersect it with positive RF rather than discarding its positive portion or retaining negative physical frequencies. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: Frequencies greater than zero through 1 MHz, together with 3 through 6 MHz.

Distinguishing consideration: compare this with option A, “Only 1 through 4 MHz because the IF filter defines the RF band directly”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion;....

Review: Chapter 4 — Equation 7F. V011-C04-MCQ-037. With LO fixed and a low-side desired RF increased by 1 MHz, how does its conventional reflected image candidate move?

A. It remains fixed.

B. It increases by 2 MHz.

C. It increases by 1 MHz.

D. It decreases by 1 MHz.

Answer: D. The image is twice the fixed LO minus desired RF, so its derivative with respect to the desired frequency is minus one. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: It decreases by 1 MHz.

Distinguishing consideration: compare this with option A, “It remains fixed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion;....

V011-C04-MCQ-038. For a conventional positive first-order image, what is the desired-to-image frequency separation?

A. The sum of desired RF and IF.

B. Twice the LO frequency.

C. Twice the nonzero real IF.

D. Exactly the real IF.

Answer: C. The desired and image lie on opposite sides of the LO at the same IF distance. The separation follows geometry, not a rejection specification. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: Twice the nonzero real IF.

Distinguishing consideration: compare this with option A, “The sum of desired RF and IF”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion;....

Review: Chapter 4 — Equation 7F. V011-C04-MCQ-039. Desired input is -100 dBm and image input is -50 dBm. Desired-path loss is 2 dB; both conversion paths have 6 dB loss. What image-path loss is needed for at least 10 dB desired-over-image output margin in the valid linear model?

A. At least 50 dB.

B. At least 12 dB.

C. At least 58 dB.

D. At least 62 dB.

Answer: D. The desired output is -108 dBm. The image output is -56 dBm minus its preselection loss; requiring it to be at most -118 dBm gives 62 dB. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: At least 62 dB.

Distinguishing consideration: compare this with option A, “At least 50 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion;....

Review: Chapter 4 — Equation 7F. V011-C04-MCQ-040. An image input is 55 dB stronger than the desired input. Desired-path loss is 3 dB, image-path loss is 68 dB, and conversion gains are equal. What desired-over-image output margin results?

A. 10 dB.

B. 65 dB.

C. -10 dB.

D. 13 dB.

Answer: A. Differential path loss is 68 minus 3, or 65 dB. Subtract the 55 dB external level disadvantage to obtain a 10 dB output margin. Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why the selected alternative fits: 10 dB.

Distinguishing consideration: compare this with option B, “65 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion;....

Review: Chapter 4 — Equation 7F. Copyright 2026, James M. Atkinson

V011-C04-MCQ-041. Equal calibrated desired and image injections produce outputs differing by 43 dB in the same valid state. What does this comparison support?

A. Proof that any environmental line at the displayed frequency is the desired input.

B. A 43 dB relative response at those two frequencies and specified conditions.

C. Proof that no image energy can reach an earlier vulnerable component.

D. A universal 43 dB rejection at every frequency and input level.

Answer: B. The measured ratio is conditional on the injected frequencies, levels and receiver state. It does not establish a universal rejection envelope. Review: Image Responses and Image Rejection. Source: §4.15 Image Responses and Image Rejection (p. 1944)

Why the selected alternative fits: A 43 dB relative response at those two frequencies and specified conditions.

Distinguishing consideration: compare this with option A, “Proof that any environmental line at the displayed frequency is the desired input”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Image Responses and Image Rejection.

Review: Chapter 4 — Image Responses and Image Rejection.

V011-C04-MCQ-042. An image-rejection comparison changes automatic attenuation between desired and image injections. What is the main problem?

A. The comparison includes a state-dependent transfer change and no longer isolates image response without reconstruction.

B. Normalizing both outputs to the same noise bandwidth automatically removes the attenuation-state difference.

C. Only the injected-level difference matters because an attenuator does not change the image-frequency map.

D. Averaging the two output levels isolates image rejection regardless of which attenuation state was used.

Answer: A. The intended comparison holds the IF path and relevant state fixed. A changed transfer must be measured and accounted for, or the test redesigned.

Review: Application 4A.1; Image Responses and Image Rejection. Source: §4.4 Application 4A.1: Locate a low-side image (p. 1931)

Why the selected alternative fits: The comparison includes a state-dependent transfer change and no longer isolates image response without reconstruction.

Distinguishing consideration: compare this with option B, “Normalizing both outputs to the same noise bandwidth automatically removes the attenuation-state difference”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Image Responses and Image Rejection.

Review: Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Image Responses and Image Rejection.

V011-C04-MCQ-043. A positive image candidate is rejected by the measured RF path. Which statement is appropriate?

A. The measured rejection applies to every alternate conversion state with the same center-frequency label.

B. The candidate must be removed from the frequency map because the current filter suppresses its response.

C. The measured attenuation establishes absence of image contribution independently of the possible image input level.

D. The frequency map still identifies a candidate, while the measured path limits its observable contribution.

Answer: D. Candidate location and admission are distinct. A valid map need not produce an observable response when the physical path suppresses that input.
Review: Equation 7F; Applications 4A.1, 4A.5 and 4A.10. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)
Why the selected alternative fits: The frequency map still identifies a candidate, while the measured path limits its observable contribution.
Distinguishing consideration: compare this with option A, “The measured rejection applies to every alternate conversion state with the same center-frequency label”; that competing statement does not meet the question’s stated requirement.

V011-C04-MCQ-044. Why should an image challenge include RF interval edges when the intended IF passband has finite width?

A. An image exists only at the mathematical center of each interval.

B. Checking the LO center automatically measures all filter skirts.

C. Both admitted RF intervals have width and their edge responses can differ from their center responses.

D. The RF interval endpoints are independent of the IF endpoints.

Answer: C. The entire IF interval maps through both branches. A center-frequency check does not establish rejection or amplitude response across its edges. Review: Application 4A.10. Source: §4.13 Application 4A.10: Map an admitted IF interval back to both RF intervals (p. 1941)

Why the selected alternative fits: Both admitted RF intervals have width and their edge responses can differ from their center responses.

Distinguishing consideration: compare this with option A, “An image exists only at the mathematical center of each interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Application 4A.10: Map an admitted IF interval back to both RF intervals.

Review: Chapter 4 — Application 4A.10: Map an admitted IF interval back to both RF intervals.

V011-C04-MCQ-045. A quadrature image-reject path has finite amplitude and phase imbalance. What should be expected?

A. Residual image response can remain and needs measurement under the relevant conditions.

B. The mathematical label image-reject guarantees zero image response.

C. Only conversion gain can change; rejection cannot.

D. The ordinary RF-to-LO difference ceases to describe any candidate frequency.

Answer: A. Cancellation depends on the implemented balance. Architecture alone is not a measured rejection specification. Review: Image Responses and Image Rejection. Source: §4.15 Image Responses and Image Rejection (p. 1944)

Why the selected alternative fits: Residual image response can remain and needs measurement under the relevant conditions.

Distinguishing consideration: compare this with option B, “The mathematical label image-reject guarantees zero image response”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Image Responses and Image Rejection.

Review: Chapter 4 — Image Responses and Image Rejection.

V011-C04-MCQ-046. A direct-conversion mode avoids a conventional nonzero first IF. Which further checks remain relevant?

A. Only the positive-frequency baseband response, because the quadrature side is automatically redundant.

B. Only a center-tone amplitude check, because removal of a nonzero IF establishes complete conversion validity.

C. DC offset, even-order response, LO leakage and I/Q imbalance.

D. Only the analog low-pass cutoff, without testing the quadrature transfer or DC behavior.

Answer: C. Moving the desired band to zero IF changes the artifact set. It does not eliminate the need to characterize the actual conversion and quadrature path.

Review: Image Responses and Image Rejection. Source: §4.15 Image Responses and Image Rejection (p. 1944)

Why the selected alternative fits: DC offset, even-order response, LO leakage and I/Q imbalance.

Distinguishing consideration: compare this with option A, “Only the positive-frequency baseband response, because the quadrature side is automatically redundant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Image Responses and Image Rejection.

Review: Chapter 4 — Image Responses and Image Rejection.

V011-C04-MCQ-047. No image line is visible during a quiet environmental observation. What does this say about receiver image rejection?

A. The quiet output floor can be used as an image-response denominator with an assumed input level.

B. It supplies the same differential transfer information as equal calibrated desired and image injections.

C. A previously quoted image-rejection figure can be transferred to the current state without a stimulus check.

D. It does not quantify rejection unless a suitable image-frequency stimulus or bound is present.

Answer: D. Image response is conditional on energy entering at the relevant RF frequency. Absence of a line can reflect absence of stimulus. Review: Image Responses and Image Rejection. Source: §4.15 Image Responses and Image Rejection (p. 1944)

Why the selected alternative fits: It does not quantify rejection unless a suitable image-frequency stimulus or bound is present.

Distinguishing consideration: compare this with option A, “The quiet output floor can be used as an image-response denominator with an assumed input level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Image Responses and Image Rejection.

Review: Chapter 4 — Image Responses and Image Rejection.

V011-C04-MCQ-048. An injected image-frequency generator also produces a harmonic in the desired RF passband. What is required before attributing the IF response to an image path?

A. Correct only the generator fundamental level and assign every remaining IF component to image transfer.

B. Assume the receiver preselector removes the harmonic even though it lies in the desired RF passband.

C. Average the IF power longer and assume this removes the source harmonic's contribution.

D. Bound the harmonic and other stimulus-path contributions at the receiver input plane.

Answer: D. Source contamination can enter through the ordinary desired path. The actual stimulus spectrum must support the intended image-response interpretation. Review: From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: Bound the harmonic and other stimulus-path contributions at the receiver input plane.

Distinguishing consideration: compare this with option A, "Correct only the generator fundamental level and assign every remaining IF component to image transfer"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test.

V011-C04-MCQ-049. A correctly calibrated IF amplitude is associated with an unchallenged image alternative. Which claim remains uncertain?

A. Whether the declared correction was numerically applied.

B. Whether a power unit can be stated at the IF plane.

C. The external RF frequency assigned to the observation.

D. Whether the measured IF amplitude was recorded.

Answer: C. Amplitude calibration and source-frequency attribution are separate obligations. Correct amplitude does not select one of two admitted RF origins.

Review: From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: The external RF frequency assigned to the observation.

Distinguishing consideration: compare this with option A, “Whether the declared correction was numerically applied”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test.

V011-C04-MCQ-050. Which condition is sufficient for adding desired and image mean powers at one IF under the stated averaging operation?

A. The image input is weaker than the desired input.

B. The relative source phase is unknown at the beginning of the observation.

C. The generators share a frequency reference but no phase-resolved record was retained.

D. The real part of their averaged cross product is zero.

Answer: D. The cross term controls whether the mean of squared summed voltage equals the sum of the individual mean squares. Naming or relative size does not remove it. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: The real part of their averaged cross product is zero.

Distinguishing consideration: compare this with option A, “The image input is weaker than the desired input”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-051. The selected image phasor is 0.4 times the desired phasor magnitude and is in phase with it. What is the total power relative to desired-only power?

A. 1.40.

B. 1.16.

C. 0.36.

D. 1.96.

Answer: D. The voltage magnitudes add to 1.4 times the desired magnitude, whose square is 1.96. Incoherent power addition would give a different result. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: 1.96.

Distinguishing consideration: compare this with option A, “1.40”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-052. The same 0.4-amplitude image is exactly opposite in phase to the desired contribution. What power ratio results?

A. 0.60.

B. 0.36.

C. 1.16.

D. 1.96.

Answer: B. The net amplitude is 1 minus 0.4, or 0.6. Squaring gives 0.36, so a coherent contaminant can reduce the observed power. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: 0.36.

Distinguishing consideration: compare this with option A, “0.60”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-053. A 0.4-amplitude image is in quadrature with the desired IF phasor. What is the total-to-desired power ratio?

A. 1.16.

B. 1.40.

C. 1.96.

D. 0.36.

Answer: A. The coherent cross term is zero at a 90-degree relative phase, leaving one plus 0.4 squared. This does not establish statistical independence. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: 1.16.

Distinguishing consideration: compare this with option B, “1.40”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-054. Equal-magnitude desired and image IF phasors are exactly opposite in phase in the ideal model. What is the resulting selected output?

A. Four times the desired-only power.

B. Twice the desired-only power.

C. Zero net phasor, so no finite logarithmic level follows from the ideal zero power.

D. The desired-only power because an image cannot cancel a desired term.

Answer: C. Coherent voltages cancel exactly under these ideal conditions. Finite noise or imbalance in an experiment requires its own treatment. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: Zero net phasor, so no finite logarithmic level follows from the ideal zero power.

Distinguishing consideration: compare this with option A, “Four times the desired-only power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-056. Relative phase was not recorded during a short desired-plus-image observation. Is adding their separately measured powers automatically justified?

A. Yes; weak images are always statistically independent.

B. No; the relevant cross-power condition must be established for the actual averaging operation.

C. No; powers can never add for signals at one IF.

D. Yes; unrecorded phase is equivalent to uniformly random phase.

Answer: B. Lack of a phase record is a lack of information, not a probability model. Power addition can be valid, but needs an applicable cross-power condition. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: No; the relevant cross-power condition must be established for the actual averaging operation.

Distinguishing consideration: compare this with option A, “Yes; weak images are always statistically independent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-057. A coherent 90-degree collision and a zero-cross-power average give the same total power. What additional observation can distinguish their mechanisms?

A. Applying the same gain correction to both powers.

B. Controlled phase variation or an appropriate phase-resolved record.

C. Another decimal place in the same scalar power reading alone.

D. Use a longer scalar average without establishing how relative phase changes during it.

Answer: B. One scalar mean can be consistent with different cross-term mechanisms. Controlled phase response provides information absent from that scalar. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: Controlled phase variation or an appropriate phase-resolved record.

Distinguishing consideration: compare this with option A, “Applying the same gain correction to both powers”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-058. Two test generators share a reference and feed desired and image inputs. Which assumption deserves explicit checking?

A. That their selected IF contributions have zero cross power over the measurement.

B. That accurate common referencing alone makes the two selected phases statistically independent.

C. That equal frequency accuracy forces a fixed quadrature relationship at the IF.

D. That equal nominal source powers determine the relative selected IF phase.

Answer: A. A shared reference can support stable coherence. Its presence does not establish a particular phase or justify automatically adding powers. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: That their selected IF contributions have zero cross power over the measurement.

Distinguishing consideration: compare this with option B, “That accurate common referencing alone makes the two selected phases statistically independent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-059. Desired and image RF phases are known, with one input on the high-side branch. What must precede their IF phasor addition?

A. Discard both phases because the output frequencies are equal.

B. Add the two powers first and then assign their common phase.

C. Map each RF phase into the declared positive-IF phase convention, including high-side conjugation.

D. Add the RF phases directly without considering conversion orientation.

Answer: C. The phasors must be expressed in the same IF convention before addition. A branch sign changes the positive-frequency phase. Review: Equations 7C and 7G. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why the selected alternative fits: Map each RF phase into the declared positive-IF phase convention, including high-side conjugation.

Distinguishing consideration: compare this with option A, “Discard both phases because the output frequencies are equal”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-060. A reviewer adds selected desired and image voltage magnitudes, squares the result, and calls it the average for arbitrary phase. What was silently assumed?

A. Constructive phase alignment of the two contributions.

B. Zero cross power under the averaging operation.

C. A uniformly distributed relative phase over the observation.

D. A fixed quadrature phase relationship between the two contributions.

Answer: A. Adding magnitudes selects the constructive extreme. It does not represent an arbitrary relative phase or a general incoherent average. Review: Equation 7G; Application 4A.6. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why the selected alternative fits: Constructive phase alignment of the two contributions.

Distinguishing consideration: compare this with option B, “Zero cross power under the averaging operation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-MCQ-061. An analytic complex signal at 20 MHz is mixed with a complex 21 MHz LO under the chapter's convention. Where is the translated carrier?

A. -1 MHz.

B. +1 MHz only.

C. 41 MHz only.

D. Both +1 MHz and -1 MHz necessarily remain because every complex multiplier duplicates the real cosine products.

Answer: A. Complex translation retains the signed RF-minus-LO frequency rather than folding negative values to a real magnitude. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: -1 MHz.

Distinguishing consideration: compare this with option B, "+1 MHz only"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-062. At 100000 complex samples per second and DFT length 200, a +20 kHz baseband tone occupies which ordinary array index?

A. 40.

B. 160.

C. 20.

D. 100.

Answer: A. Bin spacing is 500 Hz, so 20000 Hz corresponds to index 40 within the stated ordinary DFT convention. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: 40.

Distinguishing consideration: compare this with option B, “160”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-063. With the same sample rate and DFT length, which ordinary array index represents -20 kHz?

A. 200.

B. 40.

C. 160.

D. -160.

Answer: C. The signed index is -40. Adding the length 200 gives ordinary array index 160; this preserves the sign information before display labeling. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: 160.

Distinguishing consideration: compare this with option A, “200”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-064. Only the sign of the Q samples is reversed in a stored complex record. What operation has been performed?

A. Removal of all sampling aliases.

B. Complex conjugation, reversing signed spectral orientation and phase.

C. A change only to the absolute RF reference frequency.

D. A pure positive real gain with no phase effect.

Answer: B. Changing I plus jQ to I minus jQ conjugates the record. Magnitude plots can hide the resulting orientation change. Review: Equation 7E; Application 4A.7.

Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: Complex conjugation, reversing signed spectral orientation and phase.

Distinguishing consideration: compare this with option A, “Removal of all sampling aliases”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-065. A real RF waveform is used to obtain a single analytic complex translated band. What must the derivation retain?

A. The conjugate-band rejection and the appropriate factor-of-two normalization.

B. Both conjugate bands with no distinction in normalization.

C. An assumption that the real input already contains only one complex-frequency band.

D. An unconditional absolute value of every translated frequency.

Answer: A. A real waveform has conjugate spectral structure. Obtaining the selected analytic band requires an explicit selection and scale. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: The conjugate-band rejection and the appropriate factor-of-two normalization.

Distinguishing consideration: compare this with option B, “Both conjugate bands with no distinction in normalization”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-066. Why does the analytic RF-envelope example require the admitted band to remain at positive physical frequency?

A. It guarantees that the envelope bandwidth is less than half any later sample rate.

B. It removes the need for conjugate-band selection when the starting waveform is real.

C. It keeps the declared analytic carrier-and-envelope representation consistent with the selected physical band.

D. It establishes physical image rejection independently of the implemented quadrature balance.

Answer: C. The condition belongs to the continuous-time analytic representation. Sampling, gain and oscillator phase still need their own conventions. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: It keeps the declared analytic carrier-and-envelope representation consistent with the selected physical band.

Distinguishing consideration: compare this with option A, “It guarantees that the envelope bandwidth is less than half any later sample rate”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-067. A complex baseband display distinguishes positive and negative offsets. What ambiguity can still remain in a sampled receiver?

A. Different admitted analog frequencies can alias into the same discrete frequency class.

B. A mandatory folding of every negative baseband bin onto a positive one within the retained complex record.

C. An unavoidable ambiguity between opposite signed bins even when I/Q order and the full complex record are known.

D. A frequency-origin ambiguity from FFT shift that cannot be resolved by retained indexing metadata.

Answer: A. Complex representation avoids real-frequency folding inside its selected convention; it does not remove sampling equivalence or the need to know the admitted analog band. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: Different admitted analog frequencies can alias into the same discrete frequency class.

Distinguishing consideration: compare this with option B, “A mandatory folding of every negative baseband bin onto a positive one within the retained complex record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-068. Which end-to-end test best checks whether an I/Q frequency axis has the intended orientation?

A. Compare only total integrated power before and after conjugation.

B. Inject separately known tones above and below the LO and verify their signed output locations.

C. Check only one tone exactly at the center frequency.

D. Compare integrated noise powers at one positive baseband offset without a known RF ordering.

Answer: B. Opposite known offsets exercise the sign convention and channel ordering. A center tone or magnitude total cannot establish orientation. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: Inject separately known tones above and below the LO and verify their signed output locations.

Distinguishing consideration: compare this with option A, “Compare only total integrated power before and after conjugation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-069. An analyst conjugates a capture to match a familiar display convention. What should the analysis record retain?

A. Only an amplitude correction, assuming the changed phase convention is recoverable from a magnitude spectrum alone.

B. Only the revised magnitude plot because conjugation cannot affect interpretation.

C. The conjugation as an explicit processing step and the resulting frequency/phase convention.

D. A changed physical LO value used to represent the software conjugation as if it were an acquisition retune.

Answer: C. The operation is reversible but changes orientation and phase. Reproducible processing needs its identity and convention. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: The conjugation as an explicit processing step and the resulting frequency/phase convention.

Distinguishing consideration: compare this with option A, “Only an amplitude correction, assuming the changed phase convention is recoverable from a magnitude spectrum…”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-070. A finite analytic RF band lies entirely above its carrier's chosen LO in one state and below it in another. What should a complex converter do under the same convention?

A. Translate it to the corresponding positive or negative baseband interval without absolute-value folding.

B. Discard the below-LO interval even when it is admitted and within the complex passband.

C. Treat the change of offset sign as a change in sample rate and rescale the frequency axis accordingly.

D. Reflect both intervals onto positive frequency automatically.

Answer: A. Complex translation preserves signed frequency. Whether the translated band is retained depends on the selected path and passband. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why the selected alternative fits: Translate it to the corresponding positive or negative baseband interval without absolute-value folding.

Distinguishing consideration: compare this with option B, "Discard the below-LO interval even when it is admitted and within the complex passband"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-MCQ-071. For RF 101 MHz and LO 100 MHz, consider the signed candidate twice RF minus twice LO. Raising LO by 0.2 MHz produces which positive output?

A. 2.2 MHz.

B. 1.8 MHz.

C. 2.4 MHz.

D. 1.6 MHz.

Answer: D. The original candidate is 2 MHz and the LO coefficient is -2. The signed change is -0.4 MHz, leaving 1.6 MHz on the same positive branch. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: 1.6 MHz.

Distinguishing consideration: compare this with option A, “2.2 MHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-072. For RF 97 MHz and LO 100 MHz, the first-order signed difference is negative. Raising LO by 1 MHz changes the real difference IF how?

A. It stays at 3 MHz.

B. It falls from 3 to 2 MHz.

C. It rises from 3 to 4 MHz.

D. It becomes a negative real-display frequency.

Answer: C. The signed difference moves from -3 to -4 MHz. Taking magnitudes increases the real IF by 1 MHz. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: It rises from 3 to 4 MHz.

Distinguishing consideration: compare this with option A, “It stays at 3 MHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-073. A signed candidate starts at +0.1 MHz with LO coefficient -1. An LO increase of 0.2 MHz leaves the same 0.1 MHz absolute output. What happened?

A. The source frequency necessarily stayed at the displayed IF.

B. The signed candidate crossed zero; equal endpoint magnitudes do not imply zero LO dependence.

C. The candidate must have LO coefficient zero.

D. The receiver necessarily rejected both observations.

Answer: B. The signed value moves to -0.1 MHz. The absolute map has a cusp, so a single constant derivative cannot describe the crossing. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: The signed candidate crossed zero; equal endpoint magnitudes do not imply zero LO dependence.

Distinguishing consideration: compare this with option A, “The source frequency necessarily stayed at the displayed IF”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-074. A candidate uses RF coefficient 3 and LO coefficient -2. What is its total integer order under the chapter's bounded search?

A. 1.

B. 5.

C. -5.

D. 6.

Answer: B. The search order is the sum of the absolute coefficient values, three plus two, rather than their algebraic sum or product. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: 5.

Distinguishing consideration: compare this with option A, "1"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-075. A search is explicitly limited to total order 4. May a coefficient pair 3 and -2 appear in its reported enumerated results?

A. No; that pair has order 5 and lies outside the declared bound.

B. Yes; opposite signs reduce its order to 1.

C. No; negative coefficients are excluded from all mixer-product searches.

D. Yes; only the larger coefficient determines order.

Answer: A. Both signs are allowed, but the finite bound applies to the sum of absolute indices. Expanding the search must be declared. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: No; that pair has order 5 and lies outside the declared bound.

Distinguishing consideration: compare this with option B, “Yes; opposite signs reduce its order to 1”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-076. Pairs of coefficients related by changing both signs predict the same absolute output frequency. What does this imply for a real-spectrum candidate list?

A. One pair must be discarded because negative signed frequencies are physically forbidden in the calculation.

B. Every duplicate magnitude proves two independent generated tones.

C. The output amplitude is twice the value predicted by either pair alone.

D. Duplicate magnitudes need not identify distinct observable mechanisms.

Answer: D. Absolute-value mapping loses the global sign. Candidate bookkeeping must not count equivalent arithmetic descriptions as independent evidence. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: Duplicate magnitudes need not identify distinct observable mechanisms.

Distinguishing consideration: compare this with option A, “One pair must be discarded because negative signed frequencies are physically forbidden in the calculation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-077. A bounded search includes RF coefficient zero and LO coefficient one. What does that arithmetic candidate establish?

A. A possible LO-frequency location, without proving a leakage path or amplitude.

B. That LO-to-RF isolation has been measured.

C. That pure LO leakage is the only physical mechanism capable of placing energy at that frequency.

D. That an external RF emitter exists exactly at the LO.

Answer: A. A zero RF coefficient can represent a clock or LO-related location. Observing and locating its physical coupling remains an experimental task. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: A possible LO-frequency location, without proving a leakage path or amplitude.

Distinguishing consideration: compare this with option B, “That LO-to-RF isolation has been measured”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-078. A very large set of integer combinations is searched after seeing an unexplained line. What strengthens a selected candidate beyond a numerical coincidence?

A. Select the lowest-order arithmetic match and treat that alone as physical identification.

B. Reporting the best frequency match without its search scope.

C. Increasing the search order until many candidates match.

D. A predeclared independent perturbation with a testable movement prediction.

Answer: D. A predicted response to a controlled change can discriminate hypotheses. Broad retrospective arithmetic matching alone supplies weak attribution. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: A predeclared independent perturbation with a testable movement prediction.

Distinguishing consideration: compare this with option A, “Select the lowest-order arithmetic match and treat that alone as physical identification”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-079. An LO movement test pushes a candidate outside the retained IF filter before its new frequency can be measured. What is the warranted conclusion?

A. The movement remains unresolved by that observation unless the changed admission is accounted for.

B. The line must have been external rather than receiver-generated.

C. The candidate has been confirmed at the predicted frequency despite no measurement.

D. The candidate relationship is disproved because the line disappeared.

Answer: A. The planned observable must remain within a measurable path. Disappearance through filtering can fit several mechanisms. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: The movement remains unresolved by that observation unless the changed admission is accounted for.

Distinguishing consideration: compare this with option B, “The line must have been external rather than receiver-generated”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-080. Away from zero and with LO fixed, what sets the local real-output slope with respect to a small RF-parent change for a chosen integer candidate?

A. The sum of the absolute coefficient values, regardless of sign.

B. Its LO coefficient alone.

C. Its RF coefficient multiplied by the sign of the signed candidate frequency.

D. Its RF coefficient divided by its LO coefficient, independently of the signed-frequency branch.

Answer: C. Differentiate the signed candidate with respect to RF, then apply the local derivative of absolute value. The branch condition is essential. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: Its RF coefficient multiplied by the sign of the signed candidate frequency.

Distinguishing consideration: compare this with option A, “The sum of the absolute coefficient values, regardless of sign”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-081. A spectral label moves when the receiver clock calibration is changed, but the actual external tone may be fixed. What additional evidence is needed?

A. A conversion-loss correction at the original IF.

B. Only a demonstration that the indicated shift is proportional to the nominal clock correction.

C. An independent physical-frequency reference and the actual LO/sample-clock mapping.

D. An assumption that every clock-dependent movement proves an internally generated spur.

Answer: C. Clock calibration can relabel a fixed physical input. The chapter's hypothetical case keeps internal generation and relabeling as competing explanations. Review: Hypothetical Case Adjudication; From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: An independent physical-frequency reference and the actual LO/sample-clock mapping.

Distinguishing consideration: compare this with option A, "A conversion-loss correction at the original IF"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test; Chapter 4 — Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 4 — Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses.

V011-C04-MCQ-082. Why is the derivative of absolute candidate frequency not assigned one fixed value through a zero-frequency crossing?

A. The RF and LO coefficients must be interchanged whenever the signed product changes sign.

B. A monotonic LO change requires the displayed product frequency to remain monotonic through zero.

C. The absolute-value function changes branch at zero.

D. The signed product relation necessarily stops being linear even when its parent frequencies change linearly.

Answer: C. The signed relation remains linear in the stipulated frequency increment, but its absolute representation has a cusp. Review: Equations 7H and 7I; Application 4A.8. Source: Equation 7H. Bounded integer product search (p. 1928)

Why the selected alternative fits: The absolute-value function changes branch at zero.

Distinguishing consideration: compare this with option A, “The RF and LO coefficients must be interchanged whenever the signed product changes sign”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

V011-C04-MCQ-083. A 750 MHz RF passes first through an 800 MHz LO and then a 40 MHz LO, retaining real difference outputs. What is the final local RF orientation?

A. Zero.

B. Positive.

C. Negative.

D. Undefined despite both selected differences remaining nonzero.

Answer: C. The first IF is 50 MHz with a negative sign; the second IF is 10 MHz with a positive sign. Their product is negative. Review: Equation 7J; Application 4A.9. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why the selected alternative fits: Negative.

Distinguishing consideration: compare this with option A, “Zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

V011-C04-MCQ-084. The same 750 MHz RF and 800 MHz first LO instead use a 60 MHz second LO. What is the final local RF orientation?

A. Negative.

B. Zero.

C. Positive.

D. Determined only by the 10 MHz center frequency.

Answer: C. The first 50 MHz IF is inverted, and the 60 MHz second LO adds a second inversion. The two signs multiply to plus one. Review: Equation 7J; Application 4A.9.

Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why the selected alternative fits: Positive.

Distinguishing consideration: compare this with option A, “Negative”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

V011-C04-MCQ-085. In those two arrangements, an original RF increase of 0.5 MHz gives which final IF pair, ordered as second LO 40 MHz then 60 MHz?

A. 10 MHz and 10 MHz.

B. 10.5 MHz and 9.5 MHz.

C. 9.5 MHz and 10.5 MHz.

D. 9.5 MHz and 9.5 MHz.

Answer: C. The first IF falls to 49.5 MHz. Its distances from 40 and 60 MHz are respectively 9.5 and 10.5 MHz. Review: Equation 7J; Application 4A.9. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why the selected alternative fits: 9.5 MHz and 10.5 MHz.

Distinguishing consideration: compare this with option A, “10 MHz and 10 MHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

V011-C04-MCQ-086. Three fixed nonzero difference stages have orientation signs negative, positive and negative. What is their composite local RF orientation?

A. Negative.

B. The sum of the signs, equal to negative one.

C. Positive.

D. Zero.

Answer: C. Cascade orientation multiplies the three local derivatives. Two reversals restore positive orientation. Review: Equation 7J; Application 4A.9. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why the selected alternative fits: Positive.

Distinguishing consideration: compare this with option A, “Negative”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-087. A proposed RF perturbation crosses zero IF in one stage of a cascade. How should the constant orientation-product calculation be used?

A. Restrict it to separate fixed branches and evaluate the crossing explicitly.

B. Apply the original product unchanged across the whole perturbation.

C. Use the final IF magnitude alone to assign one orientation to every earlier stage.

D. Average the local signs over the whole excursion and use that average as one exact transfer slope.

Answer: A. The stated derivative product is local to fixed nonzero branches. A crossing changes the applicable sign and can change path admission. Review: Equation 7J; Application 4A.9. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why the selected alternative fits: Restrict it to separate fixed branches and evaluate the crossing explicitly.

Distinguishing consideration: compare this with option B, “Apply the original product unchanged across the whole perturbation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-088. Two dual-conversion plans share the same final center IF but have opposite orientation products. A center-tone check reports equal frequencies and equal corrected amplitudes. What does it still miss?

A. Whether the two measured center-frequency values coincide under the tested settings.

B. Whether the measured center-tone amplitudes agree in those tested states.

C. Whether an output response is present at the tested center in each state.

D. The direction in which nearby original RF frequencies map around that center.

Answer: D. Center agreement is compatible with opposite sideband ordering. A frequency step or ordered two-tone stimulus tests the missing local mapping.

Review: Equation 7J; Application 4A.9. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why the selected alternative fits: The direction in which nearby original RF frequencies map around that center.

Distinguishing consideration: compare this with option A, “Whether the two measured center-frequency values coincide under the tested settings”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-089. Which stimulus most directly verifies spectral orientation across a conversion-state boundary?

A. One center tone measured only before the boundary.

B. A conversion-gain comparison using equal RF powers only at the two state centers.

C. A known small RF frequency step or ordered pair of nearby tones in each state.

D. A constant power reading with no known RF frequency.

Answer: C. The known RF ordering must be compared with the output ordering on each side. A single center point cannot establish the sign. Review: Equation 7J; Application 4A.9. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why the selected alternative fits: A known small RF frequency step or ordered pair of nearby tones in each state.

Distinguishing consideration: compare this with option A, “One center tone measured only before the boundary”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

V011-C04-MCQ-090. What should be rechecked when an automatic band change can alter both conversion loss and orientation?

A. Only a DC continuity check at the unchanged RF port.

B. A level reference and a known frequency-step response in each applicable state.

C. Only a matched noise-bandwidth check without a calibrated RF stimulus.

D. Only the final center-frequency label.

Answer: B. Gain and orientation are different aspects of the transfer. The state-specific checks establish both rather than assuming continuity. Review: From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: A level reference and a known frequency-step response in each applicable state.

Distinguishing consideration: compare this with option A, “Only a DC continuity check at the unchanged RF port”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test.

V011-C04-MCQ-091. An independent receiver detects a component that follows the examined receiver's tuning with its input terminated. What is supported initially?

A. An LO- or clock-related emission hypothesis that still needs coupling-path and frequency-plan checks.

B. A complete reconstruction of every internal conversion stage.

C. Proof that the examined receiver is defective.

D. A radiated frequency necessarily equal to the RF frequency shown on the examined receiver's display.

Answer: A. Tuning-dependent radiation can reveal receiver activity, but does not by itself identify the exact path, full plan or malfunction. Review: Local-Oscillator Purity and Leakage. Source: §4.14 Local-Oscillator Purity and Leakage (p. 1942)

Why the selected alternative fits: An LO- or clock-related emission hypothesis that still needs coupling-path and frequency-plan checks.

Distinguishing consideration: compare this with option B, "A complete reconstruction of every internal conversion stage"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-092. A leakage signal changes when the antenna cable is replaced by a termination. Which alternatives should the test distinguish?

A. Antenna reradiation, cable common-mode coupling and enclosure radiation.

B. Only the IF output level after applying the existing gain correction.

C. Only the leakage level at one tuning frequency with the same antenna connection.

D. Only the first-order image frequency computed from the final IF.

Answer: A. Several physical paths can radiate LO energy. A controlled path comparison is needed before attributing the observed field to one route. Review: Local-Oscillator Purity and Leakage. Source: §4.14 Local-Oscillator Purity and Leakage (p. 1942)

Why the selected alternative fits: Antenna reradiation, cable common-mode coupling and enclosure radiation.

Distinguishing consideration: compare this with option B, “Only the IF output level after applying the existing gain correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

V011-C04-MCQ-093. Two comparison receivers share the same external clock and show the same weak line. Why is independence still unresolved?

A. A shared line necessarily proves a physical external transmitter.

B. The shared clock can supply a common coupling or spur mechanism.

C. That use of two front ends eliminates any clock-related mechanism common to their measurements.

D. That agreement establishes independence as soon as the two receivers use different antennas.

Answer: B. A nominally separate instrument may share a relevant error source. The comparison must change or bound that dependency. Review: From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: The shared clock can supply a common coupling or spur mechanism.

Distinguishing consideration: compare this with option A, “A shared line necessarily proves a physical external transmitter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-094. A mixer calibration is repeated with different LO drive, temperature and termination. Which interpretation is appropriate?

A. It must equal the previous calibration because RF and IF frequencies match.

B. It characterizes a different operating condition whose applicability must be established.

C. It measures only a frequency offset and cannot affect amplitude.

D. It can be substituted without documenting the changed conditions.

Answer: B. The chapter defines conversion gain through specified planes and operating conditions. Those changes can alter the measured transfer. Review: Conversion Gain, Loss, and Calibration. Source: §4.17 Conversion Gain, Loss, and Calibration (p. 1948)

Why the selected alternative fits: It characterizes a different operating condition whose applicability must be established.

Distinguishing consideration: compare this with option A, “It must equal the previous calibration because RF and IF frequencies match”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Conversion Gain, Loss, and Calibration.

Review: Chapter 4 — Conversion Gain, Loss, and Calibration.

Copyright 2026, James M. Atkinson

V011-C04-MCQ-095. A measured RF-to-IF path includes a preselector and IF amplifier, but the intended measurand is the mixer alone. What is needed?

A. Substitute a published mixer loss as if it were directly measured in the assembled path.

B. Applicable de-embedding or separate characterization of the surrounding path.

C. Subtract only nominal cable loss, assuming the preselector and IF amplifier contributions cancel.

D. Assign all measured gain to the mixer by definition.

Answer: B. The included filters and amplifiers contribute to the measured result. Their effects must be separated if the claim is specific to the mixer. Review: Conversion Gain, Loss, and Calibration. Source: §4.17 Conversion Gain, Loss, and Calibration (p. 1948)

Why the selected alternative fits: Applicable de-embedding or separate characterization of the surrounding path.

Distinguishing consideration: compare this with option A, “Substitute a published mixer loss as if it were directly measured in the assembled path”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Conversion Gain, Loss, and Calibration.

Review: Chapter 4 — Conversion Gain, Loss, and Calibration.

V011-C04-MCQ-096. A firmware update changes automatic conversion-state selection. What is the appropriate treatment of old frequency-dependent correction tables?

A. Transfer the correction from whichever old state is nearest in tuning frequency without checking its mapping.

B. Apply the old correction whenever the center-frequency label matches, without checking the active conversion state.

C. Treat correction-table identity as proof of current physical response.

D. Verify their applicability to the new active states before using them for the intended result.

Answer: D. State selection and processing changes can alter the relationship between the stored correction and actual path. Preserve both provenance and new verification evidence. Review: Conversion Gain, Loss, and Calibration; Conversion-State Challenge Protocol. Source: §4.17 Conversion Gain, Loss, and Calibration (p. 1948)

Why the selected alternative fits: Verify their applicability to the new active states before using them for the intended result.

Distinguishing consideration: compare this with option A, “Transfer the correction from whichever old state is nearest in tuning frequency without checking its mapping”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — Conversion Gain, Loss, and Calibration; Chapter 4 — Conversion-State Challenge Protocol.

Review: Chapter 4 — Conversion Gain, Loss, and Calibration; Chapter 4 — Conversion-State Challenge Protocol.

V011-C04-MCQ-097. An observed product grows faster with input level than the desired response. What further evidence helps identify its mechanism?

A. The line must be ignored because linear calibration is unavailable.

B. Its frequency relationship, controlled parent perturbations and source-path controls.

C. The growth alone proves one particular physical component.

D. A higher-order label can be assigned solely from one pair of amplitudes.

Answer: B. Level dependence can support a nonlinear hypothesis but is not a complete mechanism identifier. Frequency and path evidence constrain alternatives. Review: From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: Its frequency relationship, controlled parent perturbations and source-path controls.

Distinguishing consideration: compare this with option A, “The line must be ignored because linear calibration is unavailable”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test.

V011-C04-MCQ-098. A candidate line follows the predicted retuning law while the receiver is compressed. Which separation is necessary?

A. Compression makes every measured frequency necessarily meaningless.

B. The line's power must equal the ideal multiplier prediction.

C. Frequency-movement evidence may remain useful while the amplitude-transfer interpretation is invalid.

D. Correct movement proves all amplitude calculations are linear.

Answer: C. Movement and amplitude are different observations with different validity requirements. The chapter advises keeping them separate until evidence supports combining them. Review: From a product map to a discriminating test.

Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: Frequency-movement evidence may remain useful while the amplitude-transfer interpretation is invalid.

Distinguishing consideration: compare this with option A, "Compression makes every measured frequency necessarily meaningless"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test.

V011-C04-MCQ-099. A clock-dependent peak is absent on a comparison receiver whose sensitivity at that frequency is unknown. What conclusion remains unsupported?

A. That the peak cannot be an external signal.

B. That the two instruments produced different reported observations.

C. That a better-characterized comparison could discriminate hypotheses.

D. That the first receiver's label changed under the clock intervention.

Answer: A. A nondetection requires adequate coverage and sensitivity to exclude an external alternative. The clock intervention can also change frequency labeling.

Review: Hypothetical Case Adjudication. Source: §4.22 Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses (p. 1955)

Why the selected alternative fits: That the peak cannot be an external signal.

Distinguishing consideration: compare this with option B, "That the two instruments produced different reported observations"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 4 — Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses.

V011-C04-MCQ-100. After valid conversion challenges, a line is consistent with one admitted RF input but no location or device linkage is available. What is the strongest supported report?

A. A unique physical emitter location inferred from one IF magnitude.

B. A bounded RF-path and frequency interpretation, with unresolved emitter identity and location stated.

C. A claim that all receiver artifacts have been excluded universally.

D. A confirmed operator identity inferred from the mixer equation.

Answer: B. Conversion tests support the quantities and alternatives they actually exercise. They do not supply spatial or identity evidence absent from the observations. Review: From a product map to a discriminating test. Source: §4.18 From a product map to a discriminating test (p. 1949)

Why the selected alternative fits: A bounded RF-path and frequency interpretation, with unresolved emitter identity and location stated.

Distinguishing consideration: compare this with option A, “A unique physical emitter location inferred from one IF magnitude”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 4 — From a product map to a discriminating test.

Fill-in-the-Blank Questions

V011-C04-FIB-001. A mixer frequency relation identifies a candidate location but does not by itself specify the selected output _____.

Answer: amplitude or power. The amplitude result needs a multiplier scale, declared reference planes and loading, plus evidence that the physical path remains in the applicable state. Review: Model 4A: a declared conversion map. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why this term is required: “amplitude or power” completes the stated technical proposition.

Question context: A mixer frequency relation identifies a candidate location but does not by itself specify the selected output _____

Basis and qualification: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

Copyright 2026, James M. Atkinson

V011-C04-FIB-002. The numerical scale assigned to an ideal multiplication operation is its multiplier _____.

Answer: normalization. This fixes how the input voltage maps to each product. A change of normalization can explain a gain difference without implying that a physical calibration changed. Review: Model 4A: a declared conversion map. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

Why this term is required: “normalization” completes the stated technical proposition.

Question context: The numerical scale assigned to an ideal multiplication operation is its multiplier _____

Basis and qualification: Chapter 4 — Model 4A: a declared conversion map.

Review: Chapter 4 — Model 4A: a declared conversion map.

V011-C04-FIB-011. An RF at 260 MHz and LO at 240 MHz produce a nonzero real first-order difference IF of _____ MHz.

Answer: 20. Subtracting RF minus LO gives positive 20 MHz. The same fixed branch has positive local RF orientation. Review: Equation 7C. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why this term is required: “20” completes the stated technical proposition.

Question context: An RF at 260 MHz and LO at 240 MHz produce a nonzero real first-order difference IF of _____ MHz

Basis and qualification: Chapter 4 — Equation 7C. Selected difference and orientation.

Review: Chapter 4 — Equation 7C. Selected difference and orientation.

Copyright 2026, James M. Atkinson

V011-C04-FIB-012. An RF at 260 MHz and LO at 280 MHz have a signed difference of _____ MHz.

Answer: -20. The real IF is the magnitude 20 MHz, but the signed value must be retained for orientation and phase interpretation. Review: Equation 7C. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why this term is required: "-20" completes the stated technical proposition.

Question context: An RF at 260 MHz and LO at 280 MHz have a signed difference of _____ MHz

Basis and qualification: Chapter 4 — Equation 7C. Selected difference and orientation.

Review: Chapter 4 — Equation 7C. Selected difference and orientation.

Copyright 2026, James M. Atkinson

V011-C04-FIB-013. For 260 MHz RF and a 280 MHz LO, raising RF by 0.5 MHz with LO fixed changes the real difference IF to _____ MHz.

Answer: 19.5. The signed difference moves from -20 to -19.5 MHz. Its magnitude decreases because the path remains on the high-side branch. Review: Equation 7C.

Source: Equation 7C. Selected difference and orientation (p. 1925)

Why this term is required: “19.5” completes the stated technical proposition.

Question context: For 260 MHz RF and a 280 MHz LO, raising RF by 0.5 MHz with LO fixed changes the real difference IF to _____ MHz

Basis and qualification: Chapter 4 — Equation 7C. Selected difference and orientation.

Review: Chapter 4 — Equation 7C. Selected difference and orientation.

Copyright 2026, James M. Atkinson

V011-C04-FIB-014. For 260 MHz RF, lowering a 240 MHz LO to 239 MHz changes the selected real difference IF to _____ MHz.

Answer: 21. The RF-minus-LO difference becomes 21 MHz. This is a change of LO with RF fixed, distinct from the RF-perturbation orientation convention. Review: Equation 7I. Source: Equation 7I. Retuning a signed and an absolute product (p. 1928)

Why this term is required: “21” completes the stated technical proposition.

Question context: For 260 MHz RF, lowering a 240 MHz LO to 239 MHz changes the selected real difference IF to _____ MHz

Basis and qualification: Chapter 4 — Equation 7I. Retuning a signed and an absolute product.

Review: Chapter 4 — Equation 7I. Retuning a signed and an absolute product.

V011-C04-FIB-015. A high-side difference has RF phase 12 degrees and LO phase -8 degrees. Its positive-IF phase is _____ degrees.

Answer: -20. The signed difference phase is 20 degrees. Conjugating the negative-frequency real cosine representation gives the negative of that phase. Review: Equation 7C. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why this term is required: "-20" completes the stated technical proposition.

Question context: A high-side difference has RF phase 12 degrees and LO phase -8 degrees. Its positive-IF phase is _____ degrees

Basis and qualification: Chapter 4 — Equation 7C. Selected difference and orientation.

Review: Chapter 4 — Equation 7C. Selected difference and orientation.

Copyright 2026, James M. Atkinson

V011-C04-FIB-016. A low-side difference has RF phase 23 degrees and LO phase 7 degrees. Its selected positive-IF phase is _____ degrees.

Answer: 16. The difference phase is 23 minus 7 degrees. Positive conversion orientation leaves that phase sign unchanged. Review: Equation 7C. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why this term is required: “16” completes the stated technical proposition.

Question context: A low-side difference has RF phase 23 degrees and LO phase 7 degrees. Its selected positive-IF phase is _____ degrees

Basis and qualification: Chapter 4 — Equation 7C. Selected difference and orientation.

Review: Chapter 4 — Equation 7C. Selected difference and orientation.

V011-C04-FIB-031. For 140 MHz desired RF and 130 MHz LO, the conventional image candidate is _____ MHz.

Answer: 120. The reflection about the LO is twice 130 minus 140. Both desired and candidate lie 10 MHz from the LO, on opposite sides. Review: Equation 7F. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why this term is required: “120” completes the stated technical proposition.

Question context: For 140 MHz desired RF and 130 MHz LO, the conventional image candidate is _____ MHz

Basis and qualification: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Copyright 2026, James M. Atkinson

V011-C04-FIB-032. For 140 MHz desired RF and 155 MHz LO, the conventional positive image candidate is _____ MHz.

Answer: 170. The desired is 15 MHz below the LO, so the reflected candidate is 15 MHz above it. Actual admission remains a measured path condition. Review: Equation 7F. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)
Why this term is required: “170” completes the stated technical proposition.
Question context: For 140 MHz desired RF and 155 MHz LO, the conventional positive image candidate is _____ MHz
Basis and qualification: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.
Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Copyright 2026, James M. Atkinson

V011-C04-FIB-033. For 360 MHz desired RF and 150 MHz LO, the reflection formula gives -60 MHz. The number of additional positive first-order reflected RF candidates is _____.

Answer: zero. Negative physical RF is outside the stated domain. Do not replace -60 MHz with +60 MHz and call it the same conventional reflected candidate. Review: Equation 7F. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why this term is required: “zero” completes the stated technical proposition.

Question context: For 360 MHz desired RF and 150 MHz LO, the reflection formula gives -60 MHz. The number of additional positive first-order reflected RF candidates is _____

Basis and qualification: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Copyright 2026, James M. Atkinson

V011-C04-FIB-034. When both first-order reflected RF frequencies are positive, their separation is _____ times the real IF.

Answer: two. Each lies one IF distance from the LO on opposite sides. This geometric separation does not state how strongly either path is admitted. Review: Equation 7F. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)
Why this term is required: “two” completes the stated technical proposition.
Question context: When both first-order reflected RF frequencies are positive, their separation is _____ times the real IF
Basis and qualification: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.
Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

V011-C04-FIB-044. Equal calibrated desired and image injections produce selected outputs differing by 28 dB. Their measured relative rejection at those conditions is _____ dB.

Answer: 28. Equal input powers make the output ratio the relative path response. Preserve frequencies, state, level, uncertainty and stimulus purity; the result is not a universal rejection claim. Review: Image Responses and Image Rejection. Source: §4.15 Image Responses and Image Rejection (p. 1944)

Why this term is required: “28” completes the stated technical proposition.

Question context: Equal calibrated desired and image injections produce selected outputs differing by 28 dB. Their measured relative rejection at those conditions is _____ dB

Basis and qualification: Chapter 4 — Image Responses and Image Rejection.

Review: Chapter 4 — Image Responses and Image Rejection.

V011-C04-FIB-045. With desired RF fixed, raising LO by 1 MHz moves the reflection-formula image candidate by _____ MHz.

Answer: 2. The image expression contains twice the LO frequency minus the fixed RF frequency. This is movement of the candidate input location, not a claim about environmental emitter motion. Review: Equation 7F. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why this term is required: “2” completes the stated technical proposition.

Question context: With desired RF fixed, raising LO by 1 MHz moves the reflection-formula image candidate by _____ MHz

Basis and qualification: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Copyright 2026, James M. Atkinson

V011-C04-FIB-046. A frequency-plan image separation supplies no numerical _____ specification by itself.

Answer: rejection. Rejection depends on the admitted RF transfer and any image-canceling structure. Location arithmetic and measured response are separate parts of the analysis. Review: Equation 7F. Source: Equation 7F. Conventional image and RF interval mapping (p. 1927)

Why this term is required: “rejection” completes the stated technical proposition.

Question context: A frequency-plan image separation supplies no numerical _____ specification by itself

Basis and qualification: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

V011-C04-FIB-047. When desired and image contributions are coherent at one IF, add their complex _____ before forming power.

Answer: voltages or phasors. The magnitude square of their sum includes a phase-dependent cross term. Adding only powers would discard possible constructive or destructive interference. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “voltages or phasors” completes the stated technical proposition.

Question context: When desired and image contributions are coherent at one IF, add their complex _____ before forming power

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-048. The sum-of-powers formula is valid when the real part of the averaged cross product is _____.

Answer: zero. This is a condition on the actual averaging or ensemble operation. Different labels, separate cables or unequal amplitudes do not establish it. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “zero” completes the stated technical proposition.

Question context: The sum-of-powers formula is valid when the real part of the averaged cross product is _____

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-049. An in-phase image with 0.2 times the desired IF amplitude yields total-to-desired power ratio _____.

Answer: 1.44. The net amplitude is 1.2 times the desired amplitude, and its square is 1.44. The incoherent sum would instead be 1.04. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: "1.44" completes the stated technical proposition.

Question context: An in-phase image with 0.2 times the desired IF amplitude yields total-to-desired power ratio _____

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-050. An image with 0.2 times the desired IF amplitude in opposite phase yields total-to-desired power ratio _____.

Answer: 0.64. The net amplitude becomes 0.8 times the desired amplitude. The result demonstrates that coherent contamination can lower an observed level.

Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “0.64” completes the stated technical proposition.

Question context: An image with 0.2 times the desired IF amplitude in opposite phase yields total-to-desired power ratio _____

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-051. An image with 0.2 times the desired IF amplitude in quadrature yields total-to-desired power ratio _____.

Answer: 1.04. The cross term vanishes at 90 degrees, leaving one plus 0.2 squared. This particular coherent result does not prove a random-phase average. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “1.04” completes the stated technical proposition.

Question context: An image with 0.2 times the desired IF amplitude in quadrature yields total-to-desired power ratio _____

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-052. Two equal IF phasors in phase yield _____ times the power of either alone.

Answer: four. The amplitude doubles and the common-load power is proportional to squared amplitude. It is not merely the sum of the two individual powers. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “four” completes the stated technical proposition.

Question context: Two equal IF phasors in phase yield _____ times the power of either alone

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-053. Two equal IF phasors in exact phase opposition produce a net phasor of _____.

Answer: zero. That is an ideal coherent cancellation. A real observation will have its own residual, noise and uncertainty, so the exact ideal result must not be treated as a guaranteed measurement floor. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “zero” completes the stated technical proposition.

Question context: Two equal IF phasors in exact phase opposition produce a net phasor of _____

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-054. For an image-to-desired amplitude ratio 0.5, arbitrary relative phase gives power-ratio bounds _____ through _____.

Answer: 0.25; 2.25. The minimum and maximum amplitudes are 0.5 and 1.5 times desired. Squaring yields the bounds; 1.25 is the zero-cross-power sum, not the whole possible range. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “0” completes the stated technical proposition.

Question context: For an image-to-desired amplitude ratio 0.5, arbitrary relative phase gives power-ratio bounds _____ through _____

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-055. A vanishing averaged cross term is sufficient for power addition, but it does not necessarily establish full statistical _____.

Answer: independence. The cross-power condition concerns the relevant second-order quantity. Stronger distributional statements need their own evidence. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “independence” completes the stated technical proposition.

Question context: A vanishing averaged cross term is sufficient for power addition, but it does not necessarily establish full statistical _____

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-056. Before coherent addition, a high-side input's phase must be mapped into the same positive-IF _____ as the desired contribution.

Answer: convention. The high-side mapping reverses the phase sign of the negative-frequency real term. Combining unconverted RF phases can predict the wrong interference. Review: Equations 7C and 7G. Source: Equation 7C. Selected difference and orientation (p. 1925)

Why this term is required: "convention" completes the stated technical proposition.

Question context: Before coherent addition, a high-side input's phase must be mapped into the same positive-IF _____ as the desired contribution

Basis and qualification: Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-057. An unrecorded relative phase is missing information, not proof of a _____ phase distribution.

Answer: uniform random. Averaging away the cross term requires a justified mechanism and observation interval. Uncertainty about phase is not itself such a physical condition. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “uniform random” completes the stated technical proposition.

Question context: An unrecorded relative phase is missing information, not proof of a _____ phase distribution

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-058. A cross-power claim must identify the measurement's averaging _____ or ensemble.

Answer: operation. The relevant cross term can depend on integration time, coherence and changes of state. A condition established for one operation need not hold for another. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: "operation" completes the stated technical proposition.

Question context: A cross-power claim must identify the measurement's averaging _____ or ensemble

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-059. A common frequency reference can make two generator contributions _____ enough that their phase relationship matters at the IF.

Answer: coherent. Sharing a reference does not prescribe a particular phase, but it removes any justification for automatically treating the powers as independent solely because there are two sources. Review: Equation 7G. Source: Equation 7G. Coherent collision and the zero-cross-power condition (p. 1927)

Why this term is required: “coherent” completes the stated technical proposition.

Question context: A common frequency reference can make two generator contributions _____ enough that their phase relationship matters at the IF

Basis and qualification: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-FIB-060. If the strong image drives a preceding stage beyond its valid state, the simple linear image-margin calculation needs its _____ reestablished.

Answer: applicability. Frequency reflection can still identify a candidate while the assumed gain and interference amplitudes fail. Validate the strong-signal state separately. Review: Application 4A.5. Source: §4.8 Application 4A.5: Allocate image rejection ahead of equal conversion (p. 1936)

Why this term is required: “applicability” completes the stated technical proposition.

Question context: If the strong image drives a preceding stage beyond its valid state, the simple linear image-margin calculation needs its _____ reestablished

Basis and qualification: Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion.

Review: Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion.

Copyright 2026, James M. Atkinson

V011-C04-FIB-061. An analytic input carrier at 12.003 MHz and complex LO at 12 MHz translate to _____ kHz.

Answer: +3. Complex translation retains RF minus LO with sign. The positive offset is distinct from a corresponding below-LO input. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why this term is required: "+3" completes the stated technical proposition.

Question context: An analytic input carrier at 12.003 MHz and complex LO at 12 MHz translate to _____ kHz

Basis and qualification: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Copyright 2026, James M. Atkinson

V011-C04-FIB-062. An analytic input carrier at 11.997 MHz with the same 12 MHz complex LO translates to _____ kHz.

Answer: -3. The negative complex frequency is retained rather than folded to +3 kHz. I/Q ordering and the exponential convention must agree. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why this term is required: "-3" completes the stated technical proposition.

Question context: An analytic input carrier at 11.997 MHz with the same 12 MHz complex LO translates to _____ kHz

Basis and qualification: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Copyright 2026, James M. Atkinson

V011-C04-FIB-063. At 24000 complex samples per second and a 96-point DFT, the bin spacing is _____ Hz.

Answer: 250. Divide sample rate by transform length. This arithmetic uses the complex sample rate and ordinary DFT indexing convention. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why this term is required: “250” completes the stated technical proposition.

Question context: At 24000 complex samples per second and a 96-point DFT, the bin spacing is _____ Hz

Basis and qualification: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Copyright 2026, James M. Atkinson

V011-C04-FIB-064. At 24000 complex samples per second with a 96-point DFT, a +3 kHz tone has ordinary array index _____.

Answer: 12. Three thousand divided by 250 gives 12. This is below the positive Nyquist boundary and requires no index wrap. Review: Equation 7E; Application 4A.7. Source: Equation 7E. Complex conversion without frequency folding (p. 1926)

Why this term is required: “12” completes the stated technical proposition.

Question context: At 24000 complex samples per second with a 96-point DFT, a +3 kHz tone has ordinary array index _____

Basis and qualification: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-FIB-079. A signed candidate starts at +0.2 MHz with LO coefficient -2. Raising LO by 0.2 MHz leaves absolute output _____ MHz.

Answer: 0.2. The signed shift is -0.4 MHz, so the candidate ends at -0.2 MHz. Equal endpoint magnitudes conceal a zero crossing rather than proving zero dependence.

Review: Equations 7H and 7I. Source: Equation 7H. Bounded integer product search (p. 1928)

Why this term is required: “0.2” completes the stated technical proposition.

Question context: A signed candidate starts at +0.2 MHz with LO coefficient -2. Raising LO by 0.2 MHz leaves absolute output _____ MHz

Basis and qualification: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product.

Copyright 2026, James M. Atkinson

V011-C04-FIB-080. At a zero crossing, the absolute-frequency trajectory has a _____ rather than one constant derivative through the crossing.

Answer: cusp. Evaluate the signed relation and then its magnitude, or handle each branch separately. Extrapolating a single slope across zero gives the wrong movement. Review: Equations 7H and 7I. Source: Equation 7H. Bounded integer product search (p. 1928)

Why this term is required: “cusp” completes the stated technical proposition.

Question context: At a zero crossing, the absolute-frequency trajectory has a _____ rather than one constant derivative through the crossing

Basis and qualification: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product.

Copyright 2026, James M. Atkinson

V011-C04-FIB-081. For 600 MHz RF, a 660 MHz first LO and a 50 MHz second LO, the final real difference IF is 10 MHz and composite orientation is _____.

Answer: negative. The first stage reverses orientation at 60 MHz; the second has positive orientation because 60 exceeds 50. Their sign product is negative. Review: Equation 7J. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why this term is required: “negative” completes the stated technical proposition.

Question context: For 600 MHz RF, a 660 MHz first LO and a 50 MHz second LO, the final real difference IF is 10 MHz and composite orientation is _____

Basis and qualification: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Copyright 2026, James M. Atkinson

V011-C04-FIB-082. For 600 MHz RF, a 660 MHz first LO and a 70 MHz second LO, the final real difference IF is 10 MHz and composite orientation is _____.

Answer: positive. The second stage now reverses as well. Two reversals preserve the local ordering of original RF offsets at the final IF. Review: Equation 7J. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why this term is required: “positive” completes the stated technical proposition.

Question context: For 600 MHz RF, a 660 MHz first LO and a 70 MHz second LO, the final real difference IF is 10 MHz and composite orientation is _____

Basis and qualification: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Copyright 2026, James M. Atkinson

V011-C04-FIB-083. For 600 MHz RF, a 660 MHz first LO and a 50 MHz second LO, raising the original RF by 2 MHz changes the final real difference IF to _____ MHz.

Answer: 8. The first IF falls from 60 to 58 MHz. The distance from the 50 MHz second LO is 8 MHz, consistent with negative composite orientation. Review: Equation 7J. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why this term is required: “8” completes the stated technical proposition.

Question context: For 600 MHz RF, a 660 MHz first LO and a 50 MHz second LO, raising the original RF by 2 MHz changes the final real difference IF to _____ MHz

Basis and qualification: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Copyright 2026, James M. Atkinson

V011-C04-FIB-084. For 600 MHz RF, a 660 MHz first LO and a 70 MHz second LO, raising the original RF by 2 MHz changes the final real difference IF to _____ MHz.

Answer: 12. The first IF again becomes 58 MHz, but its distance below 70 MHz becomes 12 MHz. The extra reversal changes the direction of the final offset.
Review: Equation 7J. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)
Why this term is required: “12” completes the stated technical proposition.
Question context: For 600 MHz RF, a 660 MHz first LO and a 70 MHz second LO, raising the original RF by 2 MHz changes the final real difference IF to _____ MHz
Basis and qualification: Chapter 4 — Equation 7J. Orientation through selected real difference stages.
Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Copyright 2026, James M. Atkinson

V011-C04-FIB-085. Three orientation reversals on fixed nonzero branches produce an overall _____ orientation.

Answer: negative. Multiplying three minus-one derivatives gives minus one. Counting center-frequency values alone would not reveal that sideband ordering.

Review: Equation 7J. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why this term is required: “negative” completes the stated technical proposition.

Question context: Three orientation reversals on fixed nonzero branches produce an overall _____ orientation

Basis and qualification: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Copyright 2026, James M. Atkinson

V011-C04-FIB-086. Two orientation reversals on fixed nonzero branches produce an overall _____ orientation.

Answer: positive. The local derivatives multiply. This restores frequency ordering, but does not by itself establish unwanted-product rejection or gain calibration.

Review: Equation 7J. Source: Equation 7J. Orientation through selected real difference stages (p. 1928)

Why this term is required: “positive” completes the stated technical proposition.

Question context: Two orientation reversals on fixed nonzero branches produce an overall _____ orientation

Basis and qualification: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

V011-C04-FIB-091. The suppression of unwanted coupling from one mixer port to another is port _____.

Answer: isolation. It depends on the physical mixer and operating state. A frequency-product formula does not provide a measured leakage level. Review: Local-Oscillator Purity and Leakage. Source: §4.14 Local-Oscillator Purity and Leakage (p. 1942)

Why this term is required: “isolation” completes the stated technical proposition.

Question context: The suppression of unwanted coupling from one mixer port to another is port _____

Basis and qualification: Chapter 4 — Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

Copyright 2026, James M. Atkinson

V011-C04-FIB-092. A leakage test should distinguish antenna reradiation, enclosure radiation and cable _____ coupling.

Answer: common-mode. The observed field can change when the external cable or termination changes. The experiment should identify which physical route was actually altered. Review: Local-Oscillator Purity and Leakage. Source: §4.14 Local-Oscillator Purity and Leakage (p. 1942)

Why this term is required: “common-mode” completes the stated technical proposition.

Question context: A leakage test should distinguish antenna reradiation, enclosure radiation and cable _____ coupling

Basis and qualification: Chapter 4 — Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

Copyright 2026, James M. Atkinson

V011-C04-FIB-093. A terminated RF input does not automatically exclude radiation from the receiver _____.

Answer: enclosure. Termination challenges the antenna-input path. Internal circuitry can still couple to an enclosure or cable, so broader leakage claims need corresponding observations. Review: Local-Oscillator Purity and Leakage. Source: §4.14 Local-Oscillator Purity and Leakage (p. 1942)

Why this term is required: “enclosure” completes the stated technical proposition.

Question context: A terminated RF input does not automatically exclude radiation from the receiver _____

Basis and qualification: Chapter 4 — Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

V011-C04-ESSAY-017. A desired RF frequency of 150 MHz is converted with a 100 MHz LO. During an image test at 50 MHz, the generator delivers -30 dBm at 50 MHz and a third harmonic of -80 dBm at 150 MHz. The desired-path conversion gain is -6 dB and the measured output is -86 dBm at 50 MHz IF. Assess the attribution and propose a stronger test.

- Opening: Present a thesis that answers this precise question: A desired RF frequency of 150 MHz is converted with a 100 MHz LO. Identify which evidence would falsify the proposed conclusion Source: §4.18 From a product map to a discriminating test (p. 1949)
- Core terminology and scope: Define converted, generator, delivers in the question's particular technical setting; explain how harmonic, attribution, stronger differ if that distinction would change the analysis of "A desired RF frequency of 150 MHz is converted with a 100 MHz LO" Source: §4.18 From a product map to a discriminating test (p. 1949)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Both 150 MHz and the conventional image at 50 MHz reach the same 50 MHz real IF Source: §4.18 From a product map to a discriminating test (p. 1949)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting A desired RF frequency of 150 MHz is converted with a 100 MHz LO to the claimed result, following "Application 4A.2: Track high-side spectral inversion"; name the intermediate states and measurable outputs Source: §4.5 Application 4A.2: Track high-side spectral inversion (p. 1932)
- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for A

Discussion Questions

[Discussion instructions: For each discussion question, prepare approximately 500 spoken words for delivery over 2.5–3 minutes (approximately 167–200 words per minute). Address the ten subject prompts below in their stated order. Use the opening to frame the issue and the closing to synthesise the principal findings, conclusions and unresolved questions.]

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-001. Two conversion plans give the same final center IF. May a team reuse one frequency-axis interpretation for both plans?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Two conversion plans give the same final center IF. May a team reuse one frequency-axis interpretation for both plans?” Put this particular dispute to the panel: Two conversion plans give the same final center IF. May a team reuse one frequency-axis interpretation for both plans. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §4.12 Application 4A.9: Track inversion through two real conversions (p. 1940)

- 02. Student A, terminology and scope: Agree the operational meanings of conversion, plans, final and center, reuse, interpretation in “Two conversion plans give the same final center IF. May a team reuse one frequency-axis interpretation for both plans”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §4.12 Application 4A.9: Track inversion through two real conversions (p. 1940)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of Two conversion plans give the same final center IF; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §4.5 Application 4A.2: Track high-side spectral inversion (p. 1932)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Application 4A.2: Track high-side spectral inversion”. Use a known frequency step or ordered tone pair to distinguish equal center values with opposite final orientation Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §4.5 Application 4A.2: Track high-side spectral inversion (p. 1932)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Two conversion plans give the

Copyright 2026, James M. Atkinson

same final center IF; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Application 4A.2: Track high-side spectral inversion”. Use a known frequency step or ordered tone pair to distinguish equal center values with opposite final orientation Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §4.5 Application 4A.2: Track high-side spectral inversion (p. 1932)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Ask the team to trace each selected stage and multiply its local orientation signs on the applicable nonzero branches Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §4.12 Application 4A.9: Track inversion through two real conversions (p. 1940)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving Two conversion plans give the same final center IF: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §4.12 Application 4A.9: Track inversion through two real conversions (p. 1940)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Two conversion plans give the same final center IF; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving Two conversion plans give the same final center IF: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion.

Copyright 2026, James M. Atkinson

Ask Student H to identify an alternative that could survive the proposed test. Source: §4.12 Application 4A.9: Track inversion through two real conversions (p. 1940)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving Two conversion plans give the same final center IF, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §4.5 Application 4A.2: Track high-side spectral inversion (p. 1932)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving Two conversion plans give the same final center IF: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §4.12 Application 4A.9: Track inversion through two real conversions (p. 1940)

Copyright 2026, James M. Atkinson

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for Two conversion plans give the same final center IF. The discussion should produce state-specific axis and phase conventions, including any I/Q conjugation, rather than an assumption based on the matching center Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §4.2 Model 4A: a declared conversion map (p. 1924)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving Two conversion plans give the same final center IF, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §4.5 Application 4A.2: Track high-side spectral inversion (p. 1932)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for Two conversion plans give the same final center IF. The discussion should produce state-specific axis and phase conventions, including any I/Q conjugation, rather than an

Chapter 4 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C04-ESSAY-001 — Write the RF as a peak-amplitude cosine and the real LO multiplier as twice the nonnegative voltage scale times a unit cosine. Apply the cosine product identity to obtain a difference-frequency term and a sum-frequency term, each with peak voltage $g\,A$. Their phase arguments respectively contain the RF phase minus and plus the LO phase. The derivation predicts both terms; it does not remove the sum term. The actual selected path must reject the unwanted product adequately for the intended observation. Retain the signed difference until the real positive-frequency representation is formed. If the RF is below the LO, negate the difference phase when rewriting the cosine at positive frequency. State the nonzero-difference restriction, frequencies in hertz, phases in radians, peak voltage convention, and dimensionless multiplier scale. A physical mixer additionally needs measured conversion behavior, loading, LO drive, and operating-state evidence; the normalization does not establish its loss or spur amplitudes. Review: Model 4A Equations 7A–7C; source notes 12 and 13.

Review: Chapter 4 — Model 4A: a declared conversion map; Chapter 4 — Equation 7A. RF and normalized real LO; Chapter 4 — Equation 7B. The two real multiplier products; Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Frequency Conversion as Multiplication; Chapter 4 — Model 4A: a declared conversion map.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-002 — The signed difference is -23 MHz, so the selected real IF is 23 MHz. The signed difference phase is -55 degrees; rewriting the negative-frequency cosine at positive frequency gives +55 degrees. Reflection about the LO gives an image candidate at 478 MHz, provided that positive RF frequency reaches the mixer. Raising the RF to 432.4 MHz changes the signed difference to -22.6 MHz and the real IF to 22.6 MHz. Thus the local RF-to-IF orientation is negative. All phases use the same time origin and the declared real cosine convention. The calculation assumes fixed LO, unchanged selected path, and no zero crossing. It predicts frequency and phase orientation, not the actual rejection of the image or a calibrated output level. A useful verification therefore includes the known RF step and separate desired/image injections with recorded physical levels. Review: Equations 7C and 7F; Applications 4A.1 and 4A.2.

Review: Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.2: Track high-side spectral inversion.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-003 — The selected IF peak is 0.36 V. The RF power is $\frac{0.18^2}{2 \times 75}$, or 0.216 mW. The IF power is $\frac{0.36^2}{2 \times 300}$, also 0.216 mW. The loaded power gain is therefore unity, or 0 dB. Equivalently, Equation 7D gives g^2 multiplied by the resistance ratio: $4 \times \frac{75}{300} = 1$. Using the squared voltage ratio alone would report a factor of 4, or approximately 6.02 dB, because it silently assumes equal resistances. The quantities are loaded sinusoidal powers at two declared planes; they do not automatically equal an available-power conversion specification. A physical measurement must establish those actual loads and the applicable small-signal state. Uncertain or complex impedances require an appropriate circuit or power-wave treatment rather than substitution into this positive-real-resistance example. Review: Equation 7D; Application 4A.3.

Review: Chapter 4 — Equation 7D. Loaded selected-product power gain; Chapter 4 — Application 4A.3: Separate loaded voltage gain from power gain.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-004 — An unscaled unit cosine LO gives a selected real product with 0.2 V peak. The RF power is 1.6 mW and the selected IF power is 0.4 mW, so the ratio is one quarter, approximately -6.02 dB. With the leading factor two and $g=1$, the selected peak is 0.4 V and the loaded selected-product ratio is unity. In the analytic representation, a unit-magnitude complex LO translates the analytic amplitude without the real product identity splitting it into two terms. If starting from the real signal, one must retain the intended positive-frequency band and the corresponding factor-of-two convention. Do not equate the squared magnitude of an analytic signal directly with the real average power without its power convention. The three statements can be consistent because they describe different declared operations. They do not establish a passive physical circuit or justify changing an RF calibration table. Review: Equations 7A, 7D and 7E; Application 4A.4.

Review: Chapter 4 — Equation 7A. RF and normalized real LO; Chapter 4 — Equation 7D. Loaded selected-product power gain; Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.4: Expose the multiplier normalization.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-005 — The desired output is $-96-2.5-7=-105.5$ dBm. A 12 dB margin requires the image output to be no greater than -117.5 dBm. If the image preselection loss is L dB, its output is $-34-L-8=-42-L$ dBm. The required inequality therefore gives L at least 75.5 dB. Use the two actual conversion gains separately; the equal-conversion simplification in Application 4A.5 is not assumed here. The large external level difference consumes most of the rejection. State that the scalar budget requires linear transfer, applicable frequency-dependent losses, and no gain-state change or preceding overload caused by the image. The result is a design requirement under those assumptions, not evidence that a real filter supplies it. A calibrated injection must test both desired retention and image suppression at the actual state and level. Review: Equation 7F; Application 4A.5; Conversion Gain, Loss, and Calibration.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion; Chapter 4 — Conversion Gain, Loss, and Calibration.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-006 — The upper RF interval is 65 through 68 MHz, and the lower interval is 52 through 55 MHz. Increasing RF within the upper interval increases IF; increasing RF within the lower interval decreases IF. The reversal of interval endpoints follows directly from subtracting the IF endpoints from the LO. The admitted RF set is the union of both intervals intersected with the physically positive RF domain and the actual front-end admission. For example, with a 4 MHz LO and IF interval 3 through 6 MHz, the algebraic lower interval is -2 through 1 MHz. Its positive part is greater than zero through 1 MHz, while the upper interval is 7 through 10 MHz. Negative algebraic frequencies must not be reported as additional positive RF inputs. Real filter skirts require an explicit response or threshold convention rather than a perfect rectangular admission assumption. Review: Equation 7F; Application 4A.10.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.10: Map an admitted IF interval back to both RF intervals.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-007 — The desired-only power is 40 nW. The image-to-desired peak ratio is 0.3, so the normalized powers are 1.69 at zero phase, 1.09 at 90 degrees, and 0.49 at 180 degrees. The corresponding powers are 67.6, 43.6, and 19.6 nW. Add the complex selected IF voltages before forming power; both phasors must already use the positive-frequency orientation convention. The zero-cross-power sum also gives 43.6 nW, but agreement with the coherent quadrature result does not identify the mechanism. One scalar power cannot reveal the relative phase history, separate the two RF contributions, or demonstrate statistical independence. A controlled relative-phase change can expose constructive and destructive interference. The load, time origin, observation interval, and coherent-source conditions belong in the result, and real compression would invalidate this linear phasor calculation. Review: Equation 7G; Application 4A.6.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-008 — Expand the squared magnitude of the sum of the two selected IF phasors. The result contains the two squared magnitudes and twice the real part of their cross product. After applying the declared averaging operation, power addition requires that the averaged real cross term vanish. Statistical independence with suitable zero-mean phase behavior can justify that condition in a particular model, but the label image does not do so. A fixed 90-degree phase relation makes the real cross term zero deterministically, without making the sources independent. Unknown phase is also not equivalent to a uniform phase distribution. State the integration or ensemble convention and any shared frequency-reference relationship. A sound answer explains why equal observed sums can hide different phase sensitivities and why an injection test that varies phase provides information absent from one average-power reading. Review: Equation 7G; Application 4A.6.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-009 — The signed baseband frequencies are +12.5 kHz and -12.5 kHz. The bin spacing is 500 Hz, so the signed bin numbers are +25 and -25. Under ordinary zero-based array indexing, those correspond to indices 25 and 135. The test should retain the known RF ordering, LO frequency, complex-exponential convention, I/Q order, sampling rate, and any FFT-shift operation. Reversing the sign of Q conjugates the complex record and exchanges the two signed-frequency interpretations. A real magnitude plot at 12.5 kHz would not distinguish the trials. Retain the analog admitted band because sampled frequencies remain equivalent modulo the sample rate; a correct signed bin does not exclude an out-of-band alias. The acceptance observation is that both known tones appear with the predicted opposite signs in the actual saved and processed data. Review: Equation 7E; Application 4A.7; Chapter 10 sampling connection.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct; Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation; Chapter 10 — Sampling application 7 Complex coordinates retain a sign.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-010 — Translating those envelope offsets to a 3 MHz carrier produces nominal support from -1 through +7 MHz, so the stated band is not wholly at positive physical RF frequency. It therefore violates the particular analytic-band assumption used to connect this envelope directly to the real RF waveform. One cannot simply label the entire translated band the positive-frequency analytic RF signal. A valid setup may choose a carrier above 4 MHz with a suitable physical band, restrict the admitted envelope support, or explicitly reformulate the analytic representation for the actual signal. The complex translation operation itself still has an algebraic meaning, but its identification with the physical real-input band requires the stated representation conditions. If starting from a real signal, account for its conjugate spectral band and the factor-of-two construction before assigning loaded power. The issue is representation and admission, not a newly discovered mixer spur. Review: Equation 7E and its analytic-signal assumptions.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-011 — The candidate starts at 6 MHz and has total harmonic order 5, so a search bounded below order 5 must exclude it. Raising the LO by 0.25 MHz changes the signed product by -0.5 MHz, giving a real output at 5.5 MHz. Restoring the LO and raising the RF by 0.1 MHz changes the product by +0.3 MHz, giving 6.3 MHz. Neither perturbation crosses zero. These independent predictions test the coefficient pair more strongly than one frequency coincidence. Before changing either parent, define the IF region, measurable level, frequency-estimation tolerance, and fixed receiver state. Agreement supports that frequency relationship under the tested conditions; it does not identify the physical nonlinear element, prove that the candidate is the only possible parent combination, or determine conversion amplitude. Source-generated products and other clock combinations remain relevant alternatives. Review: Equations 7H and 7I; Application 4A.8.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-012 — The signed change is -0.20 MHz, so the final signed frequency is -0.05 MHz and the real frequency is 0.05 MHz. The endpoint change in the real frequency is therefore -0.10 MHz. Before the crossing, the local real-frequency slope with respect to LO is -2; after it, the slope is +2. The zero occurs after a +0.075 MHz LO change. Extrapolating the initial slope across the full step would ignore the absolute-value cusp. Preserve the signed candidate trajectory and evaluate the absolute values at each state. A test near DC must also establish that both portions remain observable through the selected path and processing. Disappearance around the crossing may reflect filtering or a DC exclusion, so it cannot automatically reject the product hypothesis. Phase and sinusoidal-power conventions at the exact DC point need separate treatment. Review: Equation 7I; Equation 7C nonzero-difference restriction.

Review: Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Equation 7C. Selected difference and orientation.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-013 — At order no greater than 3, the difference pair with coefficients +1 and -1 gives 1 MHz; reversing both signs gives the same real frequency. No other nonzero integer combination inside that order bound falls in the stated interval. At order 4, the pair +2 and -2 adds a 2 MHz candidate, again with a redundant globally negated representation. The zero pair is excluded by the model. A useful answer distinguishes coefficient pairs from distinct absolute-frequency locations and records the order bound before examining the result. Increasing the search order expands arithmetic possibilities without demonstrating a generating mechanism or amplitude. For a suspected 2 MHz product, an LO perturbation predicts a local slope of -2 on the positive signed branch, whereas the 1 MHz difference predicts -1. These movements, source controls, and maintained observability provide a discriminating test. Review: Equations 7H and 7I; Spur Tables and Product Search.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Spur Tables and Product Search.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-014 — The first two real outputs are 50 and 10 MHz, with local orientations negative and positive. A 12 MHz third LO gives 2 MHz with a negative third orientation, so the product of signs is positive. Raising the original RF to 1,200.5 MHz gives successive outputs 49.5, 9.5, and 2.5 MHz. With an 8 MHz third LO, the center output is also 2 MHz but the third orientation is positive, giving a negative overall orientation. The same RF increase then produces 49.5, 9.5, and 1.5 MHz. A center-only check cannot distinguish the final axes. State that each selected stage remains on a fixed nonzero branch and that filtering continues to select the intended product. This calculation validates a local map; it does not establish spur rejection or amplitude calibration through the three physical stages. Review: Equation 7J; Application 4A.9.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-015 — Treat the boundary as a change in physical conversion state. Record the selected RF path, every available LO and IF, preselection, attenuation, gain, sample path, correction identity, and lock state on both sides. Apply a known tone or ordered tone pair with a small frequency separation that remains within each selected path, and establish the sign and scale of the frequency map. Separately measure a calibrated level reference at the declared input plane to test the applicable amplitude correction. A correct center amplitude can coexist with reversed spectral orientation, and a correct frequency step can coexist with an erroneous gain table. Repeat transitions in both directions if state history may matter, retain native data and setup files, and identify the interval belonging to each state. The acceptance record should state what frequency and level behavior was actually tested and preserve unresolved transient or boundary regions. Review: Application 4A.9; From a product map to a discriminating test; Conversion-State Challenge Protocol.

Review: Chapter 4 — Application 4A.9: Track inversion through two real conversions; Chapter 4 — From a product map to a discriminating test; Chapter 4 — Conversion-State Challenge Protocol.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-016 — The desired transfer is -6 dB and the image transfer is -52 dB. Their difference is 46 dB, so the measured path rejection under these conditions is 46 dB. The raw output separation is only 43 dB because the image input was 3 dB stronger. Refer both outputs to their actual calibrated RF-plane levels before comparing transfer. This is equivalent to equalizing the stimulus levels analytically only while the paths remain linear and in the same state. Automatic gain, preselector, or attenuation changes between trials would add configuration differences that must be controlled or separately modeled. Retain source purity, frequency-specific cable corrections, measurement floor, and applicable uncertainty. The result concerns the tested pair of frequencies and levels; it is not a universal image-rejection rating over all tuning states or strong-signal exposures. Review: Image Responses and Image Rejection; Application 4A.1.

Review: Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Image Responses and Image Rejection.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-017 — Both 150 MHz and the conventional image at 50 MHz reach the same 50 MHz real IF. The generator harmonic already present at the desired RF frequency would alone predict -86 dBm through the stated desired path. Thus the observation does not establish a measurable image response from the 50 MHz fundamental. It is compatible with source contamination even if the receiver rejects the true image strongly. Characterize or suppress the generator harmonic at the actual receiver plane, for example with an applicable source filter and an independent spectral check whose floor is adequate. Preserve the 50 MHz delivered level and receiver state while improving purity. If contributions remain coherent at one IF, naive subtraction of powers may be invalid; use a bounded result or a controlled phase-sensitive comparison. The source nameplate or fundamental setting cannot replace this input-plane control. Review: Image Responses and Image Rejection; Stimulus purity in From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 4 — Image Responses and Image Rejection.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-018 — The arithmetic relation twice 40 minus 30 equals 50 MHz supplies a plausible multi-parent product, but the final 10 MHz IF does not identify where it arose. First establish the actual spectrum at the receiver input plane with sufficient measurement capability, considering generator reverse coupling, combining-network nonlinearity, and source output interaction. Compare individual-source, combined-source, and appropriately isolated or filtered-source conditions while retaining known delivered parent levels. Then use bounded receiver-state or attenuation changes with a desired reference still measurable to test additional internal generation. Frequency movement with a parent can support the product relation regardless of its location, so location needs the path controls. A nondetection in the source-path observation supplies a bound set by that measurement, not proof of zero contamination. Keep any unresolved combination of upstream and receiver-generated contributions explicit. Review: Spur Tables and Product Search; From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 4 — Spur Tables and Product Search.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-019 — Use an independent observation path with documented frequency coverage, sensitivity, geometry, and its own artifact controls. Compare a properly terminated RF input with controlled antenna and cable configurations, changing one coupling path at a time where feasible. Track known tuning changes and the resulting candidate LO-related frequencies, while retaining receiver gain, preselection, termination, and lock state. Spatial or coupling changes can help separate enclosure radiation from cable and antenna paths, but they also alter the observation transfer and therefore require calibrated or bounded comparison. Tuning-dependent detection supports a relationship with receiver activity; it does not reveal every hidden conversion stage, establish the dominant radiation path, or prove malfunction without an applicable performance criterion. Report the measured emission or coupling under the actual state and geometry, with alternative paths and observation limits retained. Review: Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-020 — Multiplying 312.5 MHz by 100 parts per million gives 31.25 kHz, so a purely numerical scale change can produce the stated indication even if the physical input frequency is unchanged. The change is compatible with relabeling; a hardware clock or LO change may also alter physical conversion, and its direction and magnitude must come from the actual mapping. Retain the native sample rate, LO plan, reference state, and the software scale used in each record. Compare against an independent physical-frequency reference or a calibrated injected tone to separate axis changes from movement of the entering signal. A second receiver must have characterized sensitivity and coverage before its nondetection becomes informative. Matching a clock-related fractional change supports a testable hypothesis but does not by itself locate generation inside the first receiver or establish an external source identity. Review: Hypothetical Case Adjudication; Chapter 10 Equation 23I connection.

Review: Chapter 12 — Equation 23I. Actual sample-clock time and frequency scaling; Chapter 4 — Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-021 — The known surrounding gains sum to +3 dB: $-2+8-3$. The mixer gain must therefore be -15 dB, corresponding to 15 dB conversion loss under the same power and reference-plane conventions. The subtraction is meaningful only if all quantities apply to the same frequencies, loading, LO drive, temperature, level, and selected conversion state. If interface mismatch changes when components are connected, isolated scalar gain values may not describe the installed cascade. Likewise, compression or LO disturbance defeats the assumed linear transfer. State whether the intended measurand is the complete receiver path or the mixer alone; removing surrounding elements is unnecessary and potentially misleading when the full path is the quantity of interest. Retain correction provenance and associated uncertainty without claiming that mathematical subtraction alone supplies an independently measured mixer characteristic. Review: Conversion Gain, Loss, and Calibration; Equation 7D.

Review: Chapter 4 — Equation 7D. Loaded selected-product power gain; Chapter 4 — Conversion Gain, Loss, and Calibration.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-022 — The desired tone lies above the LO, so its selected positive-frequency phase is $30-10=20$ degrees. The image lies below the LO; its signed difference phase is $50-10=40$ degrees, which becomes -40 degrees at positive 10 MHz IF. The relative selected phase is therefore -60 degrees. The normalized combined power is $1+0.25+2\times 0.5\times \cos(60°)$, or 1.75. Using the original RF phase difference of 20 degrees would be wrong because it ignores high-side phase conjugation. Both RF phases and the LO phase must refer to a common time origin, and the tones must retain the stated coherent relationship over the observation. The result is a loaded linear phasor comparison at the common IF plane, not an independent-power sum or a prediction of real image-path attenuation. Review: Equations 7C and 7G; Applications 4A.2 and 4A.6.

Review: Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.2: Track high-side spectral inversion; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-023 — The measured frequency trajectory may remain evidence for the proposed coefficient relationship if frequency estimation and path selection are still valid. It does not make the amplitude response a valid linear conversion measurement. Reference compression shows that the state used for at least part of the observation has lost the intended weak-signal transfer, so rejection or gain inferred by linear subtraction is unsupported there. Retain the original frequency and amplitude data with that limitation rather than discarding useful frequency evidence or declaring full acceptance. Repeat at bounded parent levels, improved rejection, or a suitable gain state while keeping the predicted product and desired reference observable. Source controls remain necessary because an upstream product can share the same movement. The eventual report should distinguish a supported frequency hypothesis, a failed amplitude-validity condition, and any unresolved generation location. Review: Application 4A.8; From a product map to a discriminating test.

Review: Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product; Chapter 4 — From a product map to a discriminating test.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-024 — The two nominal RF intervals are 68 through 70 MHz and 100 through 102 MHz. Their centers alone do not cover the image-band edges. Measure or obtain applicable transfer across both intervals and relevant filter transitions, while retaining the selected receiver state. For amplitude work, the useful interval may be limited by a specified flatness or correction uncertainty. For a spur challenge, a much weaker response in a filter skirt may still pass enough of a strong input to matter. These are different decision thresholds applied to the same physical frequency-dependent transfer. The ideal interval map locates candidate inputs, whereas the measured weighting determines their influence. A sound review states its response threshold, desired waveform bandwidth, input-level bounds, and correction applicability rather than treating the nominal IF label as a perfectly rectangular exclusion of every other RF frequency. Review: Equation 7F; Application 4A.10; Image Responses and Image Rejection.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping; Chapter 4 — Application 4A.10: Map an admitted IF interval back to both RF intervals; Chapter 4 — Image Responses and Image Rejection.

Copyright 2026, James M. Atkinson

V011-C04-ESSAY-025 — Retain the complete active conversion plan, input and output planes, source and clock states, filters, gain, detector or sampling path, correction identity, and native observations. For each tested explanation, record the predicted response, controlled perturbation, observed movement or level change, remaining observation capability, and applicable uncertainty or bound. Desired and image injections establish the tested frequency map only under their actual transfer conditions; spur movements constrain relationships but do not automatically locate generation. Clock comparisons must distinguish physical movement from axis relabeling. State which alternatives were excluded within the tested domain, which remain compatible, and any intervals invalidated by compression or state transitions. The strongest justified result may be a bounded external-frequency interpretation or an unresolved conversion artifact. Neither establishes emitter position, operator identity, or intent without separate evidence appropriate to those claims. Review: From a product map to a discriminating test; Conversion-State Challenge Protocol; Chapter 16 connection.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 4 — Conversion-State Challenge Protocol; Chapter 16 — Localize an artifact by changing the stage that could create it; Chapter 16 — Write findings that preserve the strength and limit of each test.

Discussion Guidance

V011-C04-DISCUSSION-001 — Ask the team to trace each selected stage and multiply its local orientation signs on the applicable nonzero branches. Use a known frequency step or ordered tone pair to distinguish equal center values with opposite final orientation. The discussion should produce state-specific axis and phase conventions, including any I/Q conjugation, rather than an assumption based on the matching center. Amplitude calibration is a separate check. Review: Equation 7J; Application 4A.9.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages; Chapter 4 — Application 4A.9: Track inversion through two real conversions.

V011-C04-DISCUSSION-002 — Separate frequency-reference agreement from loaded gain, LO drive, impedance, filter response, detector scaling, and correction applicability. A locked oscillator can coexist with wrong amplitude normalization or an altered physical path. Require a declared amplitude measurand and an applicable calibrated level reference. The useful outcome is a list of distinct observations supporting frequency and level claims, not an expanded meaning of lock. Review: Equation 7D; Conversion Gain, Loss, and Calibration.

Review: Chapter 4 — Equation 7D. Loaded selected-product power gain; Chapter 4 — Conversion Gain, Loss, and Calibration.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-003 — First compare the real LO multiplier, analytic-signal convention, selected product, peak-versus-RMS definition, and impedance ratio. The factor-two normalization alone can create this power difference. Determine whether the disagreement is mathematical scaling or a measured physical transfer error before changing corrections. A consistent normalization does not certify a real mixer, and a real measurement discrepancy should not be hidden by renaming the convention. Review: Application 4A.4; Equation 7E.

Review: Chapter 4 — Application 4A.4: Expose the multiplier normalization; Chapter 4 — Equation 7E. Complex conversion without frequency folding.

V011-C04-DISCUSSION-004 — Return to the stated first-order real-difference architecture and its domain of positive physical RF inputs. A negative reflected value is not a second positive input in that simple map. Taking another absolute value would create an unsupported candidate. Other harmonic or multistage responses may still exist, but they require their own architecture and coefficient analysis. Preserve the domain limitation rather than claiming universal image immunity. Review: Equation 7F.

Review: Chapter 4 — Equation 7F. Conventional image and RF interval mapping.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-005 — The conventional desired/image separation is twice the IF for a valid positive image, so changing IF changes the frequency-separation challenge. Actual rejection also depends on preselection, image-reject balance, alternate paths, levels, and conversion architecture. Discuss which measured transfer evidence is needed for the proposed plan rather than ranking receivers by separation alone. Retain any changes in usable bandwidth, gain, or downstream conditions as separate design considerations. Review: Applications 4A.1 and 4A.5; Image Responses and Image Rejection.

Review: Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Application 4A.5: Allocate image rejection ahead of equal conversion; Chapter 4 — Image Responses and Image Rejection.

V011-C04-DISCUSSION-006 — The comparison now includes a state change. Determine whether the intended measurand is the complete operational receiver behavior or differential rejection at a fixed conversion state. For the latter, hold or explicitly characterize the settings and their corrections. For the former, report the automatic states as part of the result. Equal generator settings alone do not establish equal physical input levels or isolate image-path rejection. Review: Image Responses and Image Rejection; Application 4A.1.

Review: Chapter 4 — Application 4A.1: Locate a low-side image; Chapter 4 — Image Responses and Image Rejection.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-007 — Unknown phase does not establish a zero averaged cross term. Use the observation interval, source relationship, and measured coherence to justify any averaging law. Where phase remains unspecified, report phase-dependent possibilities or bounds appropriate to the question. Participants should distinguish lack of knowledge from a chosen random-phase model and explain how a controlled phase change could add evidence. Review: Equation 7G; Application 4A.6.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition; Chapter 4 — Application 4A.6: Combine coherent desired and image fields.

V011-C04-DISCUSSION-008 — Consider destructive combination of the selected IF phasors before concluding that the desired path vanished. Change the relative phase or use separate calibrated injections while holding the receiver state fixed. Also test compression and source interaction. The result may show cancellation at the observation plane even while both inputs are admitted. A nondetection at one phase cannot establish absence of either physical input. Review: Equation 7G.

Review: Chapter 4 — Equation 7G. Coherent collision and the zero-cross-power condition.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-009 — The sign is a coordinate relative to the declared LO and complex convention. Reconstruct the physical RF interval using the actual translation map and admitted band. Negative baseband can represent a positive RF input below the LO. Retain sampling equivalence and I/Q order, because the signed bin alone does not identify a unique physical source outside the verified analog band. Review: Equation 7E; Application 4A.7.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

V011-C04-DISCUSSION-010 — Conjugation reverses complex-frequency sign and changes phase relationships. It may be a valid documented transformation, but it must remain in the processing lineage, especially for sideband, phase, delay, or modulation comparisons. Require a known-tone orientation check and retain the original record. A magnitude plot can conceal the operation while downstream interpretation changes. Review: Equation 7E; Applications 4A.2 and 4A.7.

Review: Chapter 4 — Equation 7E. Complex conversion without frequency folding; Chapter 4 — Application 4A.2: Track high-side spectral inversion; Chapter 4 — Application 4A.7: Keep opposite complex-frequency bins distinct.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-011 — No candidate earns acceptance solely from arithmetic agreement. Record the parent set, search order, tolerances, and any search expansion after observing the peak. Compare predeclared movement predictions, level behavior, path controls, and continued observability. The discussion should rank testable hypotheses and preserve ambiguity when different mechanisms share predictions, rather than choosing the most familiar formula. Review: Equations 7H and 7I; Spur Tables and Product Search.

Review: Chapter 4 — Equation 7H. Bounded integer product search; Chapter 4 — Equation 7I. Retuning a signed and an absolute product; Chapter 4 — Spur Tables and Product Search.

V011-C04-DISCUSSION-012 — A slope can support a frequency relationship without locating the nonlinear element. Different paths or clock combinations can have the same coefficient, and a source-generated signal may be converted by the receiver. Ask which independent parent perturbation or physical-path control would distinguish the remaining hypotheses. The report should name the relationship actually tested and avoid converting it into a component diagnosis. Review: Application 4A.8.

Review: Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-013 — Check whether the predicted trajectory remained within the selected IF path, detector range, and measurement floor. If the test removed observation capability, disappearance is inconclusive about generation. Replan a smaller perturbation or an observation band that covers both predicted positions, with a retained reference. An informative negative result requires a stated capability to see the response if the hypothesis were true. Review: Application 4A.8; From a product map to a discriminating test.

Review: Chapter 4 — Application 4A.8: Test the movement of a candidate harmonic product; Chapter 4 — From a product map to a discriminating test.

V011-C04-DISCUSSION-014 — Avoiding a crossing can simplify a local-slope test, but a deliberately observed cusp can itself discriminate a signed product map. Either design must state the piecewise prediction and verify observability near DC. A single straight-line slope should not be fitted across both branches without justification. Discuss the separate phase and power conventions at exact zero and any instrument DC exclusions. Review: Equations 7C and 7I.

Review: Chapter 4 — Equation 7C. Selected difference and orientation; Chapter 4 — Equation 7I. Retuning a signed and an absolute product.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-015 — The product gives a local derivative only while each selected branch and state remains fixed and nonzero. It does not establish that the intended path was actually selected, that unwanted products are rejected, or that the mapping remains valid across a band switch. Combine the sign calculation with known-tone checks and actual state records. The result should be scoped to the verified interval. Review: Equation 7J.

Review: Chapter 4 — Equation 7J. Orientation through selected real difference stages.

V011-C04-DISCUSSION-016 — Separate observation of leakage from an applicable acceptance criterion. Retain the emitting receiver state, coupling geometry, reference relationship, and independent observer limitations. LO-related energy can indicate activity without revealing the full tuning plan or establishing a fault. A malfunction conclusion requires evidence that the observed behavior violates a relevant condition or impairs the intended measurement. Review: Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

V011-C04-DISCUSSION-017 — The cable can also change common-mode coupling, termination, enclosure currents, and the observing antenna transfer. Plan controlled substitutions and geometry changes that distinguish those paths while retaining the receiver state. Stronger detection is useful evidence of a configuration effect, but it does not uniquely identify one radiation mechanism. Report any remaining coupled contributions explicitly. Review: Local-Oscillator Purity and Leakage.

Review: Chapter 4 — Local-Oscillator Purity and Leakage.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-018 — Reconstruct how the reference change affects actual LOs, sample timing, and software frequency scale. Use an independent physical-frequency observation or calibrated injected tone to constrain the mapping. A proportional shift is compatible with more than one explanation. The discussion should produce a discriminating measurement with stated sensitivity and state control, not a classification based on the word clock. Review: Hypothetical Case Adjudication; Chapter 10 Equation 23I connection.

Review: Chapter 12 — Equation 23I. Actual sample-clock time and frequency scaling; Chapter 4 — Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses.

V011-C04-DISCUSSION-019 — Require comparable frequency coverage, time coverage, antenna or injection transfer, bandwidth, detection criterion, and sensitivity. A less capable or differently timed observation cannot exclude an external component seen by the first receiver. A characterized nondetection can provide a useful bound. Preserve that bound separately from the first receiver’s clock or conversion evidence. Review: Hypothetical Case Adjudication.

Review: Chapter 4 — Hypothetical Case Adjudication: Mixers, Local Oscillators, Frequency Conversion, Images, and Spurious Responses.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-020 — The display label does not show whether an LO plan, filter selection, detector path, or correction algorithm changed. Review the actual configuration and applicable release information, then verify relevant level and orientation behavior across the used bands. Retain a correction only with evidence of continued applicability. The discussion should connect verification scope to the intended measurement rather than requiring unrelated blanket testing. Review: Conversion Gain, Loss, and Calibration; Conversion-State Challenge Protocol.

Review: Chapter 4 — Conversion Gain, Loss, and Calibration; Chapter 4 — Conversion-State Challenge Protocol.

V011-C04-DISCUSSION-021 — Relate the specified residual to the required rejection measurement, actual frequency and level, connected filters and combining path, and the receiver's desired-path sensitivity. A small harmonic may dominate a very weak image response. The relevant question is whether source contamination is bounded adequately at the receiver plane under the test conditions. A specification can contribute evidence but should not be assumed to cover an altered assembly or a deeper measurement floor. Review: Image Responses and Image Rejection; Stimulus purity in From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 4 — Image Responses and Image Rejection.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-022 — Require compatible power conventions, reference planes, actual loading, frequency, LO drive, level, and state. Discuss whether mismatch or interaction makes the isolated component values inapplicable to the installed path. If the complete path is the actual measurand, de-embedding may answer a different question. A defensible calculation retains uncertainty and clearly distinguishes inferred mixer behavior from an independent mixer measurement. Review: Conversion Gain, Loss, and Calibration; Equation 7D.

Review: Chapter 4 — Equation 7D. Loaded selected-product power gain; Chapter 4 — Conversion Gain, Loss, and Calibration.

V011-C04-DISCUSSION-023 — The behavior supports investigation of nonlinear generation, but source outputs, combiners, connectors, and earlier equipment may generate the same product before the receiver. Retain desired-reference validity and actual delivered parent levels while characterizing the source path. Frequency relationships and path controls help locate generation. Do not extrapolate a small-range slope through compression or assume one mechanism from an unqualified rate of growth. Review: Spur Tables and Product Search; From a product map to a discriminating test.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 4 — Spur Tables and Product Search.

Copyright 2026, James M. Atkinson

V011-C04-DISCUSSION-024 — A return check assesses the functions exercised at that later time. It can reveal persistent change or support a broader stability argument, but it cannot alone prove uninterrupted earlier validity. Review contemporaneous lock, gain, state, and reference records to identify any compressed or transitional intervals. Preserve useful earlier data with bounded interpretation instead of transferring the final successful check backward without evidence. Review: From a product map to a discriminating test; Chapter 1 closing-verification qualification.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 1 — Evidence Record and Closing Verification.

V011-C04-DISCUSSION-025 — State the observed component, the tested conversion states, the surviving explanations, and the limits that prevented discrimination. Identify a specific next perturbation or independent reference that would separate their predictions while preserving observation capability. A bounded unresolved result is more reproducible than an unsupported external attribution. The discussion should end with an evidence record and a decisive next test, without claiming emitter identity or location. Review: From a product map to a discriminating test; Chapter 16 connection.

Review: Chapter 4 — From a product map to a discriminating test; Chapter 16 — Localize an artifact by changing the stage that could create it; Chapter 16 — Write findings that preserve the strength and limit of each test.

Copyright 2026, James M. Atkinson

Chapter Glossary

ABSOLUTE-FREQUENCY CUSP: The change of slope produced when a signed conversion product passes through zero and its displayed frequency is represented by an absolute value. The signed trajectory can remain linear while the nonnegative trajectory has two branches. Endpoint changes must be calculated from the absolute values or the appropriate piecewise map; one local slope cannot be extended across the crossing.

ADMITTED RF BAND: The physical RF-frequency region that can influence a selected receiver path under its actual filter and switching state. It may extend beyond the displayed span, and weak skirt transmission can matter for a strong input. A nominal bandwidth label does not define a perfect exclusion boundary. Conversion claims therefore combine the frequency map with an applicable measured transfer or stated admission threshold.

ANALYTIC SIGNAL: A complex representation of a real signal that retains its positive-frequency content with the corresponding amplitude convention and removes the redundant negative-frequency conjugate content. In Model 4A the admitted translated envelope must remain at positive physical RF frequency. Its complex magnitude and the real waveform’s average loaded power require their declared normalization; they must not be interchanged without that convention.

Copyright 2026, James M. Atkinson

AVAILABLE SOURCE POWER: The power a source could supply under its specified matching condition, distinguished from the power actually delivered to a particular connected load. A mixer specification stated using available input power cannot automatically be substituted for the chapter's ratio of loaded sinusoidal powers at positive real resistances. The source, load, matching, and selected output conventions must be reconciled before comparing the quantities.

CANDIDATE SPUR LATTICE: A bounded set of integer parent-frequency combinations used to test possible product locations without predicting their amplitudes.

CASCADED CONVERSION BRANCH: A particular sequence of selected sum or difference choices and sign regions through a receiver's conversion stages. The chapter's first-order real-difference orientation rule applies to a fixed sequence of nonzero branches, multiplying their local signs. A different LO choice can give the same final center IF with a different orientation. State changes therefore require an updated branch record and verification.

COHERENT IMAGE COLLISION: Combination of desired and image contributions at the same selected IF with a retained phase relationship. Their IF phasors add before power is formed, so the observed power can increase or decrease relative to the desired-only result. The high-side phase transformation must already be applied. One power reading cannot separate the contributions or establish that their powers add independently.

Copyright 2026, James M. Atkinson

COMPLEX ENVELOPE: The complex amplitude-and-phase function that describes a signal relative to a chosen carrier in an analytic representation. Multiplying that envelope by the carrier exponential locates its spectrum around the carrier. Carrier choice, envelope bandwidth, and admitted physical RF band must be consistent. The envelope is a representation of the waveform, not proof that an image or an alias has been rejected by the receiver.

COMPLEX LOCAL OSCILLATOR: A rotating complex multiplier used to translate an analytic band without the absolute-frequency folding of a real difference display. The chapter uses a negative complex-exponential frequency convention for downconversion and retains the LO phase. The sign of that convention must agree with I/Q ordering and subsequent frequency-axis labeling. A mathematical unit-magnitude rotation does not state a physical mixer's conversion loss.

CONJUGATE-BAND REJECTION: Selection that removes the unwanted conjugate spectral band when constructing or processing the intended analytic complex signal from a real input. It is part of the representation and filtering required by the stated conversion convention. The associated factor-of-two amplitude normalization must be tracked. Merely naming an output I/Q does not demonstrate adequate rejection, correct channel ordering, or freedom from sampling aliases.

Copyright 2026, James M. Atkinson

CONJUGATE SYMMETRY: The paired relationship between positive- and negative-frequency components of a real waveform: the coefficients at opposite frequencies are complex conjugates. This redundancy explains why a real magnitude observation cannot by itself distinguish the two sides of a conversion LO. An analytic representation removes the redundant band under an explicit normalization; a correctly retained complex record can then preserve signed-frequency information.

CONVERSION LOSS: Ratio of available input power at one mixer port to desired output power at the selected product port.

CONVERSION ORIENTATION: The sign with which a local RF-frequency change maps into the selected real or complex output-frequency coordinate.

CONVERSION-STATE BOUNDARY: A transition between receiver configurations that may change an LO plan, selected IF, injection side, preselector, or correction path. Both amplitude transfer and frequency orientation can change across it. Retaining state identity and timing allows observations to be interpreted with the applicable map. Verification should exercise relevant frequencies on each side and distinguish settled states from uncharacterized transition intervals.

CROSS-POWER TERM: The interference contribution that appears when power is formed from the sum of two selected IF fields. Its value depends on their relative phase and on the averaging operation. Adding the individual mean powers is justified only when the relevant averaged real cross term vanishes. An unknown phase is not sufficient evidence for that condition, and a fixed quadrature relationship is distinct from statistical independence.

Copyright 2026, James M. Atkinson

DIFFERENCE PRODUCT: A mixer output component whose signed frequency is formed by subtracting one parent frequency from another under the selected conversion relation. For Model 4A the signed first-order value is RF minus LO; its real positive-frequency representation also depends on the sign of that difference. The component is distinct from the sum product, and selecting it requires a suitable actual signal path.

FREQUENCY-AXIS CALIBRATION: Establishing the relationship between known frequency values and a receiver or processing system's frequency indications under specified conditions. The relationship includes scale, offset, and orientation where relevant, together with applicable uncertainty. A center-tone agreement does not establish the direction of a frequency increment, and a reference or software-scale change can move labels without proving that a physical external tone moved.

HARMONIC PRODUCT ORDER: The declared integer-search measure equal to the sum of the absolute parent coefficients in the chapter's bounded product lattice. It limits which candidate combinations are enumerated. This bookkeeping order does not itself identify the physical nonlinearity, establish that every candidate is generated, or predict amplitude. A search report should retain the bound and any later expansion that increases the number of possible matches.

IMAGE FREQUENCY: Unwanted input frequency that produces the same selected intermediate frequency as the desired input.

Copyright 2026, James M. Atkinson

IMAGE REJECTION: Suppression of the response to an unwanted RF input that reaches the same selected IF as the desired input, evaluated under declared frequency, level, and receiver-state conditions. A differential path measurement refers outputs to the actual calibrated input levels and controls source contamination. Rejection can vary with tuning, alignment, temperature, quadrature balance, and overload; a single tested pair does not establish a universal receiver value.

INJECTION SIDE: Whether the local oscillator lies above or below the desired RF frequency for a selected conversion.

INTERMEDIATE FREQUENCY: A frequency coordinate at an internal selected conversion output used for subsequent filtering, amplification, detection, or sampling. A receiver can contain several IFs, and the same final IF can arise through different conversion plans. Its magnitude alone does not identify the external RF input, the injection side, the phase orientation, or which unwanted response may have reached the selected path.

I/Q ORDERING: The assignment and sign convention by which the in-phase and quadrature channels form a complex sample sequence. Reversing the sign of the quadrature channel conjugates that sequence and reverses its signed-frequency interpretation. A magnitude display may conceal the change. Known tones on both sides of the LO provide an end-to-end check of the saved data and frequency-axis convention.

Copyright 2026, James M. Atkinson

LOADED CONVERSION POWER GAIN: The ratio of selected IF power to RF power at the two declared loaded planes in Model 4A. For positive real loaded resistances, it equals the squared voltage scale multiplied by RF resistance divided by IF resistance. It therefore differs from the squared voltage ratio when the loads differ. This defined ratio is not automatically an available-power data-sheet gain.

LOCAL CONVERSION SLOPE: The derivative describing a small change in selected output-frequency coordinate with respect to a specified parent frequency on a fixed conversion branch. In the integer lattice its magnitude and sign depend on the relevant coefficient and, for a real absolute-frequency output, the sign of the current product. It is conditional on unchanged path selection and does not apply across an unmodeled switch or cusp.

LOCAL-OSCILLATOR LEAKAGE: Unintended appearance of oscillator energy at mixer ports, cables, enclosure, or antenna.

LO DRIVE: The actual local-oscillator excitation applied to a mixer under a stated waveform, level, frequency, and port condition. It influences physical conversion behavior and cannot be replaced by the dimensionless normalization of an ideal multiplier. A conversion measurement must retain the applicable drive and any disturbance caused by strong input signals. The correct LO frequency alone does not establish the intended conversion gain.

Copyright 2026, James M. Atkinson

MIXER DE-EMBEDDING: Removal or accounting of surrounding filter, amplifier, cable, and interface effects so that an inferred result refers to the mixer itself at declared planes. Scalar gain subtraction requires compatible power conventions and applicable linear installed-path values; mismatch and interaction can require a more complete treatment. De-embedding changes the measurand and must not be confused with directly measuring the complete receiver transfer.

MULTIPLIER NORMALIZATION: The declared numerical scale of an ideal mixing operation that determines selected-product voltage and power.

PARENT-FREQUENCY PERTURBATION: A controlled change in one frequency used to test a candidate conversion relationship while other relevant parents and receiver states are held fixed or accounted for. The signed movement follows that parent’s integer coefficient in the stated lattice. The absolute movement may change branch at zero. A useful test predeclares the expected response and keeps the candidate within a measurable region.

PEAK-TO-RMS CONVERSION: The relation between the peak amplitude of a nonzero-frequency sinusoid and its root-mean-square amplitude: RMS equals peak divided by the square root of two. It gives average power equal to peak voltage squared divided by twice the positive real load resistance. The rule does not apply unchanged to DC, arbitrary pulsed waveforms, or an analytic-signal magnitude without its own power convention.

Copyright 2026, James M. Atkinson

PHASE CONJUGATION: Reversal of a complex phasor's phase sign. In the chapter's real conversion map, rewriting a negative-frequency difference cosine at positive frequency conjugates its associated phasor. Conjugating a saved I/Q record also reverses signed-frequency orientation. The operation must be retained in the interpretation and processing history whenever phase, sideband, timing, or modulation comparisons depend on the original convention.

PORT ISOLATION: Suppression of unwanted transfer between identified mixer or receiver ports under specified frequencies, terminations, and operating states. Finite LO-to-RF isolation can contribute leakage into an input cable or antenna, while other coupling paths may involve the enclosure. Isolation belongs to the installed configuration and relevant direction; it should not be inferred solely from mixer type or the absence of one displayed line.

RF INTERVAL MAPPING: The relationship between an admitted IF interval and the RF intervals that can reach it through the stated conversion. A real first-order difference path generally has a lower and an upper interval around the LO, restricted to positive physically admitted RF frequencies. Mapping the complete interval exposes edge and skirt responses that a single image-center calculation omits.

SELECTED CONVERSION PRODUCT: The particular output component admitted by the chosen mixer, filter, and processing path for the intended measurement. A multiplier can generate several mathematical or physical candidates, so a frequency formula must be tied to this selection. Changing an IF path or filter state can change which product is observed even when the front-panel tuning label remains the same.

Copyright 2026, James M. Atkinson

SIGNED DIFFERENCE FREQUENCY: The algebraic RF-minus-LO frequency retained before any conversion to a nonnegative real-frequency display.

SOURCE HARMONIC CONTAMINATION: An unwanted harmonic already present in a test source or its delivery path that enters the receiver as an ordinary RF input. During an image test, such a harmonic can fall in the desired path and imitate response to the intended image-frequency fundamental. Bounding the contamination at the actual receiver plane is necessary before assigning the measured IF output to receiver image rejection.

SPURIOUS RESPONSE: Receiver output caused by an unwanted internal or external frequency-conversion mechanism.

SUM PRODUCT: The first-order real-multiplier component at the sum of the positive RF and LO frequencies. In the normalized ideal cosine model it has the same peak scale as the difference product before output selection, with the sum of their phases. It is not absent merely because a receiver intends to use the difference IF. Actual filtering and path response determine whether it influences the observation.

ZERO-DIFFERENCE BOUNDARY: The conversion condition at which RF and LO frequencies coincide in the selected first-order difference model. The real difference output then includes a DC term, so the nonzero sinusoidal phase and power conventions used for the chapter’s tone examples cannot be transferred unchanged. Crossing the boundary also changes the sign of the real-frequency orientation and requires piecewise interpretation.

Kester, Walt. MT-080: Mixers and Modulators. Revision 0. Analog Devices, October 2008. Pages 1–2 and 5, including the multiplier discussion and Image Response. https://www.analog.com/media/en/training-seminars/tutorials/mt-080.pdf

Annotation. Supports mixer terminology, dimensional scaling, and conventional image locations. The printed sine-product identities on page 5, Equations 1 and 1a, have incorrect sum-term signs; those signs are not adopted. Model 4A develops its own cosine-product derivation, loading conventions, and constructed cases. Neither its normalization nor its candidate product lattice supplies a commercial mixer loss or spur-amplitude specification. This instructional source treats modulation, frequency translation or receiver signal-chain operation through explicit physical relationships. Image frequencies, sidebands, local-oscillator injection and intermediate-frequency filtering have to be checked against the receiver’s actual topology. Ideal mixer identities do not establish that a real component is free of compression, leakage, spurs or path-dependent calibration errors. In this chapter the citation should be read against the local receiver model and the expressly defined quantities, not as a general endorsement of every design choice.

Chapter 5. Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors

Copyright 2026, James M. Atkinson

5.1 Intermediate Frequency as a Controlled Band

An intermediate-frequency chain places the selected information into a band where stable gain, filtering, detection, and digitization can be implemented. A receiver may use several IFs, with each conversion trading image rejection, filter realizability, tuning range, dynamic range, and spur behavior. Fixed crystal, ceramic, surface-acoustic-wave, cavity, lumped, digital, or hybrid filters may be used. The IF is therefore a designed measurement environment, not merely a numerical difference between the RF and local oscillator.[1]

The practitioner identifies the center frequency, filter family, selectable bandwidths, shape factor, group delay, gain distribution, limiter state, detector takeoff, and calibration injection points. In a wideband survey receiver, one IF path may feed the displayed spectrum while another feeds audio or a demodulator. Results from those paths can differ because of bandwidth, AGC, detector, and scaling. The record states which path produced each observation.

5.2 Filter Shape, Selectivity, and Time Response

Selectivity depends on more than nominal bandwidth. Passband ripple changes amplitude accuracy, skirt response determines adjacent-signal rejection, group-delay variation distorts modulation and pulses, and finite impulse response creates settling and ringing. A narrow filter can reveal a weak continuous component near a strong carrier while suppressing a short burst whose energy is spread in time. Conversely, a wide filter can preserve pulse shape while admitting more noise and interference.

Copyright 2026, James M. Atkinson

Figure 18. IF-filter response and pulse distortion.

Filter bandwidth should be selected from the signal's occupied spectrum and the question being answered. Measuring total channel power, modulation deviation, close-in spurs, pulse rise time, or frequency stability requires different filters. A receiver's labeled bandwidth may refer to -3 dB

Copyright 2026, James M. Atkinson

width, -6 dB width, noise bandwidth, or a digital design parameter. Verification uses a swept or stepped source and, when timing matters, an impulse or modulated test.

5.3 Choose an IF path for the quantity being measured

An IF path has both a frequency response and a time response. A narrow channel can improve the separation of continuous tones while delaying or reducing the peak of a short event. The same filter can preserve total energy over a long record yet produce a misleading instantaneous peak. Decide whether the measurand is a tone amplitude, integrated channel power, modulation waveform, onset time, or burst peak before selecting the path. That choice determines which part of its response requires calibration.

The loaded-Q expression in Equation 9 describes one bandwidth ratio. Two paths with the same center and -3 dB width can have different skirts, passband ripple, delay, and ringing. Reuse the weighted noise and spectrum conventions in Chapters 2, 9, and 11 when noise power or spectral density is the quantity of interest. For a transient, preserve the impulse or step response and the sample history needed by the filter. A scalar Q does not supply either of those missing records.

Group delay is a local frequency-domain descriptor obtained from the slope of unwrapped transfer phase. It is meaningful over frequencies where the transfer is measurable and the phase reference is coherent. It does not imply that every waveform traverses the filter as an unchanged delayed copy. That stronger claim requires sufficiently flat amplitude and linear phase across the waveform band. Near a deep notch, phase estimates can be unstable, so a dramatic apparent delay may mostly reflect an ill-conditioned measurement.

5.4 Model 5A: an identified one-pole gain-control response

Equation 10 is developed here as a local control-state model. It describes a real voltage approaching a constant target with a positive time constant from a known initial value. The model does not infer the entire detector, feedback topology, or overload recovery from that one response. The AD8367 data sheet provides a concrete example of this distinction: it identifies a single-pole response for small level changes and separately discusses integrating action, slew limits, and overdrive behavior. The numerical applications below are independent synthetic cases, not specifications for that device.[2]

2 Joint Committee for Guides in Metrology, International vocabulary of metrology: Basic and general concepts and associated terms, VIM3 online edition, entries 2.48, 2.49 and 2.53, https://jcgm.bipm.org/vim/en/2.48.html, https://jcgm.bipm.org/vim/en/2.49.html and https://jcgm.bipm.org/vim/en/2.53.html, read November 2, 2026. These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

Why it matters: a short burst and the gain-control transient may not support the same amplitude calibration.

Figure 20. AGC attack, release and burst recovery.

Equation 10A. Identified control-state equation

$$\frac{dv}{dt}=\frac{v_\infty - v}{\tau}, \tau>0, v(0)=v_0$$

Copyright 2026, James M. Atkinson

The state v, its initial value v_0, target v_∞ and reference v_{ref} are control voltages in volts. Time t and time constant τ use the same time unit. Gain d and its reference d_{ref} are in decibels, and the signed local slope s is in decibels per volt. The voltage residual e is v minus v_∞; the gain-error magnitude E_d is the absolute slope times its magnitude. These distinct units determine which positive tolerance is inserted into the settling calculation.

Equation 10B. Control voltage and residual

$$v(t) = v_\infty + (v_0 - v_\infty)\exp\left(\frac{-t}{\tau}\right)$$

$$e(t) = v(t) - v_\infty = (v_0 - v_\infty)\exp\left(\frac{-t}{\tau}\right)$$

Subtracting the constant target converts the equation into exponential decay of the residual. The solution preserves its sign and moves monotonically between the initial state and target. This property gives a useful validity check: a measured overshoot, sign reversal, delayed start, or sustained oscillation cannot be explained by the same uninterrupted one-pole segment. Such behavior may be real and important, but it requires an additional state, a changed target, or a different identified model.

Control voltage becomes RF gain only through an explicit calibration. In this chapter the local relation is linear in decibels, with a signed slope and a reference voltage. All points between the initial and final states must remain within the range where that relation applies. A negative slope means rising control voltage reduces gain. A positive slope requires the opposite control direction for the same leveling objective. A mislabeled polarity can turn a plausible exponential voltage trace into a completely wrong amplitude correction.

Copyright 2026, James M. Atkinson

Equation 10C. Local control-to-gain law

$$d(v)=d_{ref}+s(v-v_{ref}),v\in[v_{min},v_{max}]$$

Equation 10D. Output level and gain-error magnitude

$$P_{out,dBm}=P_{\text{in,dBm}}+d(v)$$
$$E_d(t)=|s||v_0-v_\infty|\exp\left(\frac{-t}{\tau}\right)=E_0\exp\left(\frac{-t}{\tau}\right)$$

For a fixed RF input in the calibrated small-signal path, adding the gain in decibels to input power in dBm gives output power in dBm. This does not turn an envelope detector voltage into power without its own law. It also does not mean that averaging gain in decibels is equivalent to averaging output power. If the gain changes during a record, the correct operation depends on whether the desired result is a time-resolved input waveform, an average physical power, or a control-state summary.

A settling requirement must specify its error units and a positive tolerance. For an initial error larger than that tolerance, solving the exponential inequality gives the logarithmic settling time. If the initial error is already acceptable, the earliest time is zero. Exact zero error is not reached at finite time from a nonzero residual in this model. For gain tolerance, use the absolute gain slope to convert the initial voltage residual into a gain-error magnitude. A zero slope makes this inversion uninformative rather than infinitely fast.

Equation 10E. Settling time for a positive error tolerance

$$t_\varepsilon=0\,if\;0\le E_0\le\varepsilon$$
$$t_\varepsilon=\tau\ln\left(\frac{E_0}{\varepsilon}\right)if\;E_0>\varepsilon>0$$

Copyright 2026, James M. Atkinson

Two same-sign residual observations can identify a candidate time constant when their magnitude decreases. Taking their ratio eliminates the unknown initial amplitude, and taking its logarithm isolates the elapsed-time difference divided by the time constant. The fit should then be challenged at additional times and levels. Two points always support an exponential interpolation under favorable signs; they do not establish that the actual loop has only one relevant state.

Equation 10F. Two-point identification of the local time constant

$$\tau = \frac{t_2 - t_1}{\ln\left(\left|\frac{e_1}{e_2}\right|\right)}$$
$$t_2 > t_1, e_1 e_2 > 0, \mid e_1 \mid > \mid e_2 \mid$$

A burst or a sequence of levels rarely leaves the control at equilibrium before the next change. Carry the actual terminal state into the next interval. Separate attack and release constants can be used if both have been identified and the switch condition is declared. A hang interval is a separate state that holds or modifies the target; it cannot be represented simply by calling the previous time constant slow. Retuning, a detector bandwidth change, or a new gain range can likewise invalidate the previous segment parameters.

Equation 10G. Carry state across a target change

$$v(t) = v_{\infty,j} + \left(v(t_j) - v_{\infty,j}\right)\exp\left(\frac{-(t - t_j)}{\tau_j}\right)$$
$$t_j \le t \le t_{j+1}, \tau_j > 0; carry\ v(t_{j+1})\ forward$$

For recorded control samples, the exact discrete recurrence follows directly by evaluating the continuous solution one sample interval later. Its coefficient lies strictly between zero and one for positive interval and time

Copyright 2026, James M. Atkinson

constant. Forward Euler gives another coefficient that can become negative or exceed unity in magnitude. A large simulated oscillation can therefore be a numerical error even when the physical one-pole model is stable. Prefer the exact recurrence for this model and record any different numerical implementation that is actually being assessed.

Equation 10H. Exact sampled-state recurrence

$$v_{k+1}=a\,v_k+(1-a)\,v_\infty$$
$$a=\exp\left(\frac{-\Delta t}{\tau}\right),\Delta t>0,0<a<1$$

Equation 10I. Forward-Euler residual and its validity range

$$e_{k+1}=(1-\frac{\Delta t}{\tau})e_k$$
$$stable:0<\frac{\Delta t}{\tau}<2$$
$$nonalternating\,residual:0<\frac{\Delta t}{\tau}\leq 1$$

Uncertainty in the initial state contracts by the same positive exponential factor when the target and time constant are fixed. An initial interval therefore maps to another interval without needing a statistical distribution. A negative gain slope reverses the order of the corresponding gain endpoints, although their width remains the absolute slope times the control-state width. Uncertainty in the target or time constant is an additional contribution and must not be hidden inside this initial-state calculation.

Equation 10J. Propagation of an initial-state interval

$$v_0\in[l,u],a(t)=\exp\left(\frac{-t}{\tau}\right)$$
$$v(t)\in[v_\infty+a(t)(l-v_\infty),v_\infty+a(t)(u-v_\infty)]$$

5.5 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

5.6 Application 5A.1: Read a voltage step and its 95 percent settling time

A control voltage starts at 0.2 V and approaches 0.8 V with a 0.4 ms time constant. At 0.8 ms, two time constants have elapsed, so the residual is $\exp(-2)$ of its initial value. The control has reached 0.718799 V, completing 86.466 percent of the step. The 95 percent settling time is 1.198293 ms.

The voltage result alone does not give an RF amplitude correction. It becomes useful for gain only after the control-to-gain relation and the applicable operating interval have been verified. A measured control value beyond 0.8 V during this segment would contradict the stated monotone model. The response record should retain that discrepancy rather than silently replacing the observed trace with the fitted exponential.

Copyright 2026, James M. Atkinson

5.7 Application 5A.2: Set a gain-error settling requirement

An initial voltage residual has magnitude 0.3 V. With a gain slope of −50 dB/V, its initial gain error is 15 dB. The requirement is an error no larger than 0.1 dB, and the time constant is 2 ms. Equation 10E gives $2\ \mathrm{ms}\ \ln\backslash(150\backslash)$, or 10.021271 ms. A generic instruction to wait three time constants would leave about 0.747 dB error and would not meet this requirement.

The result is tied to the declared slope and gain tolerance. A different gain range can have another slope, and a detector-based indication may add settling of its own. The acceptance test should compare the gain error directly, or use a control-voltage correction whose calibration uncertainty is small enough for the 0.1 dB decision. Crossing a nominal voltage threshold is insufficient if the RF path remains in recovery.

Copyright 2026, James M. Atkinson

5.8 Application 5A.3: Convert a control state into an output level

The local gain is 30 dB at 0.1 V and decreases by 40 dB per volt. Starting at 0.1 V, the control approaches 0.5 V with a 0.5 ms time constant. At 0.3 ms it is 0.280475 V, giving 22.780986 dB gain. A fixed −60 dBm input therefore produces -37.219014 dBm at that instant. The final output is −46 dBm.

Using the final gain throughout the record would understate the early output and overcorrect an input-referred trace. A time-resolved correction requires synchronized control and RF observations, including their relative delay. If control telemetry is sampled much more slowly than the burst, the exponential may provide an interpolation only after its model has been validated for that burst regime. It does not recreate unobserved saturation behavior.

Copyright 2026, James M. Atkinson

5.9 Application 5A.4: Check the required control polarity after a level step

A 12 dB input increase must be balanced by a 12 dB gain decrease. At −50 dB/V, the target voltage therefore rises by 0.24 V, from 0.30 to 0.54 V. One 1 ms time constant later the control is 0.451709 V. Gain has changed by -7.585447 dB, leaving an output increase of 4.414553 dB.

The residual is a transient consequence of the stated response, not evidence that the steady-state target is wrong. Its sign also checks the control polarity: a falling control voltage with this negative slope would increase gain and worsen the initial output rise. If the input changes again before settling, use the carried state from Application 5A.6. Do not restart the calculation from the old equilibrium simply because a new trigger occurred.

Copyright 2026, James M. Atkinson

5.10 Application 5A.5: Identify a time constant from two signed residuals

Residuals relative to the same target are +0.12 V at 0.5 ms and +0.04 V at 1.6 ms. Their ratio is three over an elapsed 1.1 ms, giving a time constant 1.001263 ms. Extrapolating the first residual backward gives an initial error of 0.197722 V. Both residuals have the same sign and decrease in magnitude, as the one-pole hypothesis requires.

Now measure additional points before using that fitted constant in an acceptance decision. A residual floor can indicate a wrong target or a detector offset; an early straight ramp can indicate slew limiting; different slopes in a semilogarithmic residual plot can indicate more than one time constant. These observations change the model choice. They should not be discarded as inconvenient outliers merely because two selected points fit well.

Copyright 2026, James M. Atkinson

5.11 Application 5A.6: Carry state across two target intervals

Begin at 0.2 V, approach 0.8 V for 0.4 ms with a 0.5 ms time constant, then approach 0.3 V for another 0.6 ms with the same constant. The first interval ends at 0.530403 V. Using that actual value as the second initial condition gives 0.369396 V at the end of the sequence.

The second response is a decay from the carried value toward 0.3 V. Starting it at 0.8 V would incorrectly assume that the first interval had fully settled. This distinction matters in repeated bursts, where a reproducible periodic control trajectory can differ substantially from either steady-state target. A valid burst-level correction must therefore retain enough preceding history to determine the state at the beginning of the burst.

Copyright 2026, James M. Atkinson

5.12 Application 5A.7: Use separately identified attack and release constants

Use a 0.2 ms attack constant for a change from 0.1 toward 0.7 V lasting 0.5 ms. Then use a separately identified 2 ms release constant while returning toward 0.1 V for 1 ms. The end-of-attack state is 0.650749 V, and the end-of-release state is 0.434046 V. The slower release preserves appreciable control displacement after the strong interval has ended.

This piecewise calculation does not include a hang timer. If the measured receiver holds its control for a fixed duration before releasing, add that observed interval explicitly and define which event starts the timer. A later weak signal can otherwise be mistaken for a sensitivity failure when it is being measured during intentional gain hold. Fixed-gain and automatic-gain observations should remain separately labeled in the evidence record.

Copyright 2026, James M. Atkinson

5.13 Application 5A.8: Compare burst duration with control settling

A 0.3 ms burst changes the control target from 0.2 to 1 V, but the time constant is 3 ms. Only 9.516 percent of the step occurs during the burst; its final control voltage is 0.276130 V. Reaching 95 percent would require 8.987197 ms, far longer than the burst.

A steady-state gain reading cannot characterize this short event. The model predicts only the identified control trajectory, while the initial RF peak may encounter a separate overload limit before the gain changes appreciably. Record both the control response and the signal-path behavior. If the burst is shorter than the detector or telemetry response as well, the displayed control history may not reveal the actual peak condition at all.

Copyright 2026, James M. Atkinson

5.14 Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation

For a 1 ms time constant sampled every 2.5 ms, the exact residual multiplier is 0.08208500. Forward Euler instead uses −1.5. From an initial 0.4 V residual, five exact steps leave 0.000001491 V. Five Euler steps give -3.0375 V, with alternating sign and growing magnitude.

The second sequence is an unstable approximation to a stable differential equation. It is not a prediction that the physical control voltage reaches those values, and it may lie well outside the calibrated control range. This example is a software verification case: compare the implemented recurrence with the exact sampled solution before interpreting a simulated oscillation as a receiver defect. If the actual controller is discrete rather than a sampled continuous loop, identify its own governing recurrence instead.

Copyright 2026, James M. Atkinson

5.15 Application 5A.10: Propagate an initial-state interval

The initial voltage is known only to lie between 0.2 and 0.3 V. With a fixed 0.6 V target, 0.4 ms time constant, and 0.8 ms elapsed time, the possible state lies between 0.545866 and 0.559399 V. Its width is 0.013534 V. A −20 dB/V gain slope maps this to a 0.270671 dB gain interval.

The larger voltage corresponds to the smaller gain, so the endpoint order reverses when the gain interval is written. The width calculation remains positive. These are deterministic initial-state bounds; they do not include uncertainty in the target, time constant, slope, or timing alignment. A complete gain-correction uncertainty budget adds those contributions under the measurement model in Chapter 14, rather than treating this one interval as the entire error budget.

Copyright 2026, James M. Atkinson

5.16 Automatic Gain Control and Hidden State

Automatic gain control maintains a useful output range by changing gain in response to detected signal level. Attack, decay, hang time, detector law, threshold, gain range, and control location determine how the receiver responds to bursts and multiple signals. AGC can mask fading, compression, and true amplitude differences. A strong signal outside the displayed channel can reduce gain for a weak signal through a shared control path.

For quantitative work, AGC should be disabled or its state recorded and calibrated. If it cannot be disabled, the practitioner captures gain-control voltage or reported gain, uses reference signals around the event, and tests with alternate input levels. Audio volume and digital display normalization are not substitutes for an RF gain record. A component that changes when AGC is held may have been a control artifact rather than a change in the environment.

An integrating automatic-gain-control loop has a memory that the displayed amplitude alone cannot reveal. In a representative controller, the unsaturated command may be written as $u_c(t) = K_p e(t) + z(t)$, with $e(t)$ the setpoint error, K_p the proportional coefficient and $z(t)$ the integral state; the physical gain actuator can deliver only $u(t) = \mathrm{clamp}[u_c(t), u_{min}, u_{max}]$. When u_c attempts to exceed a limit while the integral state continues to accumulate, the controller can display a prolonged recovery after the original overload or input-step condition has ended. This mechanism is termed integrator windup. Its manifestation depends upon the detector bandwidth, loop polarity, integration constant, actuator bounds, anti-windup design and internal signal routing. A published square-law-detector

Copyright 2026, James M. Atkinson

AGC example demonstrates integration onto a control capacitor; it does not establish that an unidentified receiver implements clamping, back-calculation or any particular recovery topology.

The appropriate forensic challenge is a state-conditioned step-and-recovery experiment, not an assumption drawn from a smooth trace. With the permitted signal source and loading fixed, vary the incoming amplitude across the suspected control limit, retain input and output envelope records, record the control voltage or digital gain word where available, and measure recovery against elapsed time and preceding overload duration. Repeat at more than one starting state. If the hardware design permits examination of the controller, conditional integration or clamping may suspend integration while an output limit is active; back-calculation instead uses the difference between requested and saturated commands to unwind the integral state. These are alternative general control methods, not proof of their presence in any specific commercial or field receiver. A reported change in observed signal strength must remain qualified until control-loop dynamics have been separated from an actual change at the antenna reference plane.

Copyright 2026, James M. Atkinson

5.17 Logarithmic Amplifiers, Detectors, and Scaling

Logarithmic amplifiers compress a wide input range into a manageable output, making them useful for spectrum displays, pulse measurements, and direction-finding amplitude comparison. Their slope, intercept, ripple, temperature coefficient, video bandwidth, recovery, and pulse response determine accuracy. At low levels, noise and offsets dominate; near the upper range, compression and detector saturation can create apparent plateaus or altered pulse width.

Detectors may respond to peak, sample, average, root-mean-square, quasi-peak, envelope, phase, or digital power estimates. The appropriate detector depends on waveform and measurement objective. A peak detector reports rare excursions differently from an averaging detector. Root-mean-square detection is meaningful only within its crest-factor and bandwidth limits. The trace label, detector, dwell, averaging count, and video filtering should accompany the result.

5.18 IF Alignment, Calibration, and Failure Localization

Analog IF chains can drift through component aging, mechanical adjustment, temperature, supply state, or repair. Alignment affects center frequency, symmetry, gain, image rejection, detector linearity, and demodulation. Digital filters reduce some drift but depend on sample clocks, coefficients, scaling, and firmware. A calibration file can conceal a degraded analog path until a direct response measurement is made.

Failure localization compares responses before and after each IF stage where access is authorized. Injected signals, noise, swept frequency, pulses, and modulation exercise different properties. An apparently deaf receiver can result from a mistuned filter, failed switch, AGC fault, detector offset, reference-clock error, or software scaling. The closing test covers several bandwidths and levels so that one successful center-frequency tone does not mask residual defects.

Copyright 2026, James M. Atkinson

5.19 Verify the detector and control path as part of the IF result

A detector defines an operation on a waveform, not merely a preferred display style. A peak trace can retain a rare excursion; a sample trace can miss it; a power average estimates mean squared amplitude under its stated selection; an average of logarithmic levels estimates something else. Reuse the finite-record averaging treatment in Chapter 8 to keep these operations separate. The accepted detector must also remain within its bandwidth, level, crest-factor, and recovery limits for the actual waveform.

A useful IF verification sequence first fixes gain and disables avoidable automatic changes. Measure several continuous tones through the passband and skirts, then a calibrated noise input under the declared effective bandwidth. Next apply a pulse or burst whose duration and timing can be changed independently. Observe the path before and after detection where accessible. Finally enable the intended gain-control mode and repeat the stimuli that exercise attack, release, shared-channel loading, and recovery. Each step tests a different part of the measurement chain.

Separate amplitude normalization from physical recovery. A flat displayed output after a strong input may mean successful leveling, a limiter plateau, clipping, a saturated log detector, or software normalization. A weak reference carried through the same interval helps distinguish these alternatives if it remains measurable. Verify that its amplitude and phase return to the accepted range after the disturbance. A control voltage that has settled does not prove that every preceding stage has recovered.

Copyright 2026, James M. Atkinson

Where two IF paths serve different outputs, compare them only after accounting for their filters and detectors. Audio, a spectrum trace, and stored I/Q data may be drawn from different points. A narrow audio path can hide an interferer that still drives a wider AGC detector. A wide digitizer path can preserve an event whose displayed trace is averaged away. Label each derived product with its source path and state so that these differences become interpretable observations rather than apparent contradictions.

Acceptance ends with a retained set of responses tied to the exact configuration. Include filter and gain boundaries, a short-event case, and a recovery case in addition to the center-frequency tone. After repair or software change, repeat the cases whose assumptions could have changed. Where a proprietary control algorithm cannot be reconstructed, preserve its observed input/output behavior and configuration limits instead of claiming that the simple one-pole fit describes its internal implementation.

5.20 IF Acceptance and Regression Tests

Acceptance uses a matrix of center frequencies, bandwidths, gain states, detectors, levels, and transient waveforms. Each result is compared with declared specifications or an approved baseline using the same reference planes and correction method. Automatic filter selection and shared AGC paths are exercised at their boundaries, because many intermittent failures occur only when the receiver changes mode.

Regression testing preserves characteristic traces for representative continuous, pulsed, and modulated references. After alignment or repair, those traces are repeated before the receiver is released. A passing narrowband amplitude point is not allowed to conceal degraded skirt response, group delay, transient recovery, or detector scaling.

5.21 Quantitative Model for Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors

Equation 1. Loaded quality factor

$$Q_{\mathrm{L}} = \frac{f_0}{B_{3\mathrm{dB}}}$$

Loaded quality factor Q_{L} is center frequency f_0 divided by the -3 dB bandwidth $B_{3\mathrm{dB}}$ for a resonance whose response supports that approximation. Filter shape, coupling, multiple poles, and digital definitions may require a different descriptor.

Equation 2. First-order AGC response

$$v_c(t) = v_{\mathrm{final}} + \left(v_{\mathrm{initial}} - v_{\mathrm{final}}\right)\exp\left(\frac{-t}{\tau_{\mathrm{AGC}}}\right)$$

A simple first-order model describes gain-control voltage v_c moving toward a new value with time constant τ_{AGC}. Practical AGC can have separate attack and decay constants, thresholds, hang states, and nonlinear gain mapping.

Equation 9 is a response descriptor for a specified resonance, not a complete filter design or settling law. Equation 10 is the identified control-voltage response developed in Model 5A and its ten applications. Its voltage-to-gain map and attack, decay, clamp, and local-validity limits must accompany any prediction of usable signal recovery.

Table 1. Chapter 5 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
IF filter	Center, bandwidth definition, shape factor, ripple, group delay, and settling	Determines selectivity and time response	Nominal bandwidth alone does not describe pulse or modulation fidelity
AGC state	Control point, gain value, attack, decay, hang, threshold, and shared paths	Explains hidden amplitude normalization	A strong off-channel signal can suppress a weak channel
Detector	Peak, sample, average, RMS, quasi-peak, envelope, or digital estimator	Defines the statistic shown or recorded	Different detectors cannot be compared without waveform context
Alignment and calibration	Stage response, switching, center frequency, gain, scaling, and temperature	Separates hardware drift from software correction	A center-frequency tone can miss skirt or dynamic defects

5.22 Hypothetical Applied Calculation: Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors

An IF filter is centered at 10.7 MHz and has a measured -3 dB bandwidth of 180 kHz. Its simple loaded quality factor is about 59.4. A second filter labeled 180 kHz but with steeper skirts and greater group-delay variation may produce the same Q value while giving different adjacent-channel rejection and modulation fidelity.

Copyright 2026, James M. Atkinson

5.23 Hypothetical Case Adjudication: Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors

A burst appears 6 dB lower when the receiver is set to a narrow bandwidth, even though the signal spectrum fits inside the nominal filter. Time-domain capture shows that the burst is shorter than the filter settling time and the peak detector samples before the response reaches steady state. The discrepancy is attributed to IF transient response, not propagation loss.

Copyright 2026, James M. Atkinson

5.24 Intermediate-frequency detector memory, settling and comparable measurement statistics

An intermediate-frequency chain is not defined completely by its nominal centre frequency and 3 dB passband width. Filter amplitude and phase response, group-delay variation, limiting, logarithmic-amplifier dynamics and the selected detector each impose a distinct transformation upon short events. A narrow IF filter can extend a brief incident pulse into a longer ringing envelope; a quasi-peak detector weights pulse recurrence differently from a peak or root-mean-square detector; and video filtering can smooth the display while losing temporal detail. The observer should therefore distinguish event duration at the RF input from the duration of the particular IF or displayed response. An apparently long pulse need not indicate a long RF transmission, especially where detector memory is substantial compared with the source event.

One controlled test uses a precisely timed reference pulse with duration T_p and independently monitored amplitude. Record the analogue IF output if accessible, the detector output, the digitised trace and the exported display under fixed source and gain conditions. Repeat across pulse width and repetition interval, including a spacing long enough for the detector to return to baseline. For a first-order envelope response with time constant tau, a rectangular pulse of amplitude A produces at its end $A[1 - \exp(-T_p/\tau)]$ when initial state is zero. With $\tau = 2$ ms and $T_p = 0.2$ ms, the end value is about 0.09516A, not A. That example shows why calibrating a detector with a long continuous source and using the same amplitude interpretation for a short transient can give a severe systematic

Copyright 2026, James M. Atkinson

underestimate. It is not a prediction of any named commercial IF instrument, whose response must be measured.

Detection statistics require a stated averaging law. A peak over an interval, a mean of linear power, a root-mean-square envelope and a mean of logarithmic labels are not the same physical quantity; changing the number of displayed points can change the effective observation. A 10 dB difference in mean power means a factor of ten in the corresponding linear powers, but that rule does not turn a mean of dBm values into a mean power. When comparing receiver modes, preserve a native trace at sufficient rate to recompute the declared statistic and distinguish detector latency from sample timestamp. A calibration adjusted to align two display modes at one constant-wave level does not establish agreement for another modulation or pulse recurrence distribution.

The forensic question should direct the detector choice. A rare transient investigation benefits from capture modes that retain its temporal envelope and actual observation intervals; an interference compliance measurement may require a precisely specified weighting detector whose result intentionally embodies recurrence. Those instruments can disagree without either being defective because they estimate different quantities. The report must identify detector mode, weighting and dwell, cite the relevant apparatus specification only within its applicable scope, and avoid treating a weighted quasi-peak indication as a reconstructed waveform amplitude. The boundary between acquisition and representation remains visible when raw IF evidence is retained wherever lawful and technically feasible.

Copyright 2026, James M. Atkinson

5.25 Detector dynamics and intermediate-frequency filters as temporally extended measurement operators

An intermediate-frequency chain is commonly specified by centre frequency, nominal bandwidth, gain and perhaps selectivity. These quantities are insufficient when the intended observation is a short burst or a waveform with appreciable occupied bandwidth. The complete linear filter contributes a complex transfer H(f), whose amplitude affects energy passage and whose phase changes temporal structure. Under a stable linear time-invariant approximation, the output waveform is the convolution of the input with the impulse response. When gain control, logarithmic compression or threshold decisions follow the filter, the receiver no longer reduces to one linear convolution. The ordering of filtering, detection and smoothing must therefore be specified explicitly. A detected pulse width can increase because the filter rings after the excitation ceases, even though the external RF emission was brief.

A useful example is a first-order IF low-pass response to a positive envelope step. Define y(t) as the normalised detected envelope, tau as the known filter time constant, and assume a settled zero initial state. The response is y(t) = 1 - exp(-t/tau) for nonnegative t. The time to cross threshold fraction alpha, with zero less than alpha less than one, is t_alpha = -tau ln(1-alpha). With tau = 2 ms, a 90 per cent threshold occurs after about 4.605 ms. A 3 ms physical pulse cannot bring the idealised step response to 90 per cent, regardless of how clean its steady-state spectral measurement might appear. At the pulse end the filter stores state, which then decays; a later threshold crossing or persistence on a waterfall can be a processing

Copyright 2026, James M. Atkinson

consequence. The model is deliberately elementary, but it demonstrates why steady-state filter bandwidth does not establish the response to every temporal event.

Logarithmic detectors introduce a further conceptual trap. An ideal logarithmic output is proportional to a logarithm of an admissible positive input quantity. It does not follow that the mean of displayed decibels equals the decibel of mean input power. For a signal with two equal-duration states at 1 and 100 arbitrary linear power units, the mean power is 50.5 units whereas the mean of the individual power levels in decibels corresponds to a geometric mean of 10 units. The discrepancy is 10 log10(50.5/10), approximately 7.03 dB. This is not a numerical defect of a logarithmic display; it is a difference between estimands. A detector operated in average-of-log mode and one operated in log-of-average mode may therefore produce different trace values from the same fluctuating input even before considering overload, video filtering or peak-hold logic.

A receiver with automatic gain control should be represented by a control state g(t) that is driven by one or more filtered statistics of the admitted signal. The displayed output depends on both current input and past input through that state. Attack and release constants are not always equal, and a nominal single time constant may apply only to a specific stimulus range. A short strong interferer can depress the gain seen by a weak target long after the interferer has gone. The resulting blank interval must not be interpreted as evidence that the weak transmitter was inactive. To determine which interval is truly observed, measure the weak reference waveform through the entire disturbance and define a recovery criterion tied to the actual required measurement, such as amplitude accuracy within

Copyright 2026, James M. Atkinson

0.5 dB and stable detector variance. The detector's own smoothing must be characterised separately, otherwise one recovery mechanism masks another.

IF group delay merits independent measurement when coherent phase or timing is important. Define group delay tau_g(f) as the negative frequency derivative of transfer phase divided by 2 pi when phase is expressed in radians against frequency in hertz. If group delay varies materially across the signal band, different spectral components of a pulse can arrive at different times, changing its shape without introducing a corresponding change at the source. A narrow continuous tone may still have a well-defined gain and phase at its centre. This is why a one-tone calibration cannot certify a wideband time-of-arrival measurement. Controlled multitone or swept vector measurements, with phase unwrapping and reference-plane corrections, are needed to establish timing distortion within a stated frequency region.

Quasi-peak and other weighted detectors deserve treatment as specified decision operations rather than cosmetic display modes. Their prescribed time constants and weighting laws are designed for particular measurement purposes and are not interchangeable with simple instantaneous peak or RMS detection. A spectrum analyser's video bandwidth changes a smoothing process after a selected RF resolution filter, while the resolution filter governs admitted spectral energy and temporal response before detection. Lowering VBW may make a trace visually calmer without improving the receiver's ability to preserve a rare short event. If the detector's output does not capture a transient because the integration is too slow, no later display magnification can reconstruct the missing peak. A

Copyright 2026, James M. Atkinson

controlled acceptance procedure should therefore inject pulses spanning a range of durations and repetition intervals, measure each detector mode's transfer to a declared statistic, and report which event classes were actually represented.

The analytical conclusion is that an IF chain produces a measurement only after its time-domain and statistical transfer is declared. Acceptance must include frequency response, group delay, gain compression, overload recovery, detector law, noise distribution and timing of setting changes. Where some of these cannot be determined, the released claim should narrow to the properties actually tested rather than treating one calibrated amplitude marker as assurance for every time-dependent measurement.

5.26 Additional study: IF filters as dynamical systems and the meaning of transient measurement validity

Intermediate-frequency filtering is often treated as a bandwidth setting, yet any practical linear filter has an impulse response that determines what it remembers of the past. Two filters with an identical nominal three-decibel bandwidth can differ substantially in phase response, group delay, overshoot, settling time and response to a brief pulse. The quantity displayed by a detector downstream is therefore not simply the instantaneous power entering the filter. It is the consequence of convolution with a physical or digital impulse response, sometimes followed by a nonlinear detector and an adaptive control system. For transient evidence the observation time must be associated with the entire relevant processing chain. An event ending before an IF detector settles can remain visible after it has physically disappeared; conversely, a short weak event can be suppressed by earlier states that persist into its interval.

Represent the small-signal filter by a causal impulse response $h(t)$. For an input $x(t)$, output $y(t)$ equals the convolution integral of $h(\tau)x(t-\tau)$ over nonnegative delay τ when the fixed-state linear approximation is valid. Frequency response $H(f)$ is the Fourier transform of $h(t)$. The magnitude $|H(f)|$ characterises amplitude selection, while its phase determines the delay experienced by different spectral components. Group delay is $\tau_g(f) = -(1/2\pi)\, d \arg H(f)/df$, with the phase unwrapped under a declared transform convention. This derivative must not be taken blindly across discontinuous phase wrappers or near a transmission zero where phase is poorly determined. The group-delay curve is a property of the signal path at a

Copyright 2026, James M. Atkinson

particular gain, loading, temperature and calibration state, not an inherent attribute of a displayed bandwidth label.

For a first-order low-pass prototype $H(s) = 1/(1+s\tau)$, the impulse response is $h(t) = \exp(-t/\tau)/\tau$ for t at least zero, with τ positive in seconds. The step response is $1-\exp(-t/\tau)$. The −3 dB frequency is $f_c = 1/(2\pi\tau)$, while the time to reach 95 percent of a unit step is $t_{95} = -\tau \ln(0.05)$, approximately 2.996τ. Thus bandwidth and settling are connected for this prototype. A real IF response with multiple poles, zeros, equalisation or switched bandwidth states can violate any simple one-pole extrapolation. In particular, deliberately shaped filters may trade frequency selectivity for a longer impulse tail. A nominally narrow detector sometimes appears more sensitive on a stationary tone while having lower probability of registering an isolated burst of equal total energy.

Group delay affects coherent reconstruction as well as absolute timing. If two frequency components separated by Δf pass through a filter whose group delay differs by Δτ, their relative phase changes by approximately $2\pi\Delta f\,\Delta\tau$ beyond the intended ideal-delay relationship, provided the local approximation is valid. For broadband pulses, the time-domain consequence depends on the entire phase function, not one scalar delay measured at the centre. Pulse broadening, post-cursor ringing and pre-cursor effects in noncausal offline processing should be distinguished. A causal physical IF chain cannot produce a response before an input reaches it, but a zero-phase offline filter that operates on samples before and after an event can display apparent pre-ringing. This is not retrocausal RF energy; it is a property of the reconstruction algorithm and must be labelled as such in the provenance record.

Copyright 2026, James M. Atkinson

Intermediate-frequency gain control adds a hidden dynamical state. Suppose a detector estimates an envelope a(t) and a controller adjusts log gain g(t). A simplified first-order law is $dg/dt = (g_{target}(a) - g)/\tau_s$, where τ_s is an attack or release constant selected by the current transition. The target can be nonlinear and can saturate at gain limits. An output sample then depends on both the present input and the gain state inherited from earlier strong inputs. Merely recording the displayed gain setting may be inadequate when the controller is still settling. A forensic interpretation of an intermittent weak transmission therefore needs a model of the gain-state trajectory, preferably measured or logged at sufficient time resolution. Where state telemetry does not exist, controlled weak-reference tests can bound the recovery interval, but they do not reconstruct an unobserved signal that was suppressed during that interval.

Separate IF filter persistence from detector persistence experimentally. Drive the input with a source whose amplitude step is substantially faster than both candidate dynamics, and observe an independent broadband reference before the filtering or detection path. Measure the complex IF output where possible, then compare it with rectified or logarithmic outputs under the same actual configuration. If the complex IF decays while the displayed envelope remains high, the detector or post-detection filter contributes additional memory. If gain telemetry changes while both outputs respond, the control loop must be treated as another state variable. These tests should be conducted at more than one input level because detector and gain-control time constants may be signal dependent; one result at the reference calibration level does not necessarily cover near-threshold events.

Copyright 2026, James M. Atkinson

The comparison of detector statistics requires a defined measurement population. A positive-peak detector selects the maximum over an interval; its expected value increases with the number of noise opportunities even if mean noise power is unchanged. An RMS detector instead estimates the square root of a mean of squared values over a declared band and time. A sample detector can preserve the instantaneous trace at selected points but can miss a narrow excursion between them. An average detector's behaviour depends on whether the averaging is performed in linear voltage, linear power, logarithmic amplitude or a derived trace quantity. Those operations are not interchangeable, and a report should never describe a smooth trace as evidence that a signal was absent unless its event criterion and the detector's capture properties are established.

A hypothetical filter example uses $\tau = 0.40$ ms. Its one-pole cutoff frequency is 397.887 Hz, and 95 percent step settling occurs at 1.1983 ms. A 0.10 ms pulse ends well before the filter settles; treating its peak filtered output as the original peak amplitude would produce a biased result. Specifically, during a unit rectangular pulse the first-order response rises to $1-\exp(-0.10/0.40)$, approximately 0.2212 of the steady-state amplitude. The output then decays with the same time constant after the pulse ends. These numbers are consequences of the stipulated idealised filter. They are not a general pulse correction for a spectrum analyser with an unspecified IF topology or a nonlinear detector.

A second synthetic example uses a narrow pulse seen immediately after a strong interfering burst. Suppose the AGC gain is 12 dB below its quiet target at the end of the blocker and returns exponentially in the logarithmic gain coordinate with release constant 4 ms. At 2 ms after the blocker, the

Copyright 2026, James M. Atkinson

remaining gain deficit is 12 exp(−0.5) = 7.278 dB, assuming the simplified law applies. At 8 ms the residual deficit is 12 exp(−2) = 1.624 dB. A weak source whose unattenuated level is fixed may therefore appear to rise by more than 5.6 dB across those observation times. An analyst who interprets the later amplitude increase as evidence of transmitter activation has omitted a testable receiver-state explanation. The physically correct inference requires an actual gain-state record or a controlled measurement that supports the assumed response law.

A third example concerns an IF path with group delay changing from 3 μs to 8 μs across a 2 MHz occupied waveform. The variation is 5 μs, comparable to ten cycles of the 2 MHz spectral separation used for illustration. The product $\Delta f\,\Delta\tau$ equals ten and corresponds to a relative phase change of 20π radians, which reduces to zero modulo 2π for these endpoints but does not make the intervening phase function flat. This illustrates why endpoints alone are insufficient: an integer multiple of 2π can conceal substantial differential phase and time spreading between frequencies. A useful acceptance test samples the continuous unwrapped phase response across the occupied band and evaluates the recovered waveform's distortion, rather than inferring fidelity from two equal endpoint phases.

5.27 Calibration and negative-survey validity for dynamic IF paths

For amplitude measurements, the calibration matrix should include input level, filter setting, gain state, detector mode, modulation or burst class, and observation duration. Each row should specify a measurand and reference plane. A steady continuous-wave amplitude result cannot automatically validate a microsecond burst because the detector may not reach the same state. A short impulsive reference that fails to cross the display threshold may indicate insufficient dwell, filtering loss or control-state suppression. It is not equivalent to the absence of an input pulse. The acceptance report must make this distinction visible by listing successful and unsuccessful trials with their actual timing and decision criteria.

For timing measurements, mark at least three event times: stimulus onset at the source reference plane, waveform change at the selected IF observation plane, and decision or display update. Let t_{src}, t_{IF} and t_{dec} denote those times, all in seconds. The differences $t_{IF}-t_{src}$ and $t_{dec}-t_{IF}$ may have separate calibration and uncertainty distributions. Summing their central values is legitimate only when the intended event definitions align and the latency is sufficiently stationary over the tested state. When the IF and decision paths share a clock, correlated clock errors must be retained in the variance of the combined latency. A timestamp assigned by a computer after file buffering may be precise to nanoseconds in its software representation while being milliseconds from the physical sampling event.

A defensible negative finding must specify the event class that the measurement could have registered. A continuous unmodulated signal

Copyright 2026, James M. Atkinson

above the qualified threshold may be excluded over a set of frequency-time intervals without establishing the same coverage for short chirps or short low-duty-cycle bursts. To test that difference, construct a blind reference schedule with randomised pulse start times relative to the sweep or monitoring cycle, varying pulse duration and amplitude. Preserve both the source truth and the receiver observation. The accepted event class should then be limited to the conditions where the detection rule has been independently shown to work. A model fit to a deliberately convenient subset does not justify statements about untested classes.

The acceptance record should also distinguish filter stability from calibration stability. A filter may maintain amplitude response yet exhibit temperature-dependent group delay, which matters for coherent phase or event timing. A detector may maintain its quiet baseline while drifting in its peak response after a strong pulse. A digital correction might reduce one of those errors while increasing noise or changing the temporal shape of an event. It is therefore necessary to retain the original complex or appropriately unaveraged IF record, the correction algorithm's version, the actual hardware state and any failure indicators. A derived scalar result does not carry every property of the original physical waveform.

A fourth hypothetical calculation illustrates a timing bound. Let a pulse's true onset be within ±10 μs of a source reference mark, with independently bounded IF-path latency between 25 and 40 μs and detection decision latency between 60 and 100 μs. The earliest possible decision after the source mark is 10 μs early plus 25 plus 60 = 75 μs; the latest is 10 μs late plus 40 plus 100 = 150 μs. The decision timestamp therefore falls in a constructed 75–150 μs interval relative to the marked time under those bounds. Treating

Copyright 2026, James M. Atkinson

112.5 μs as an exact correction would introduce a precision that the stated physical information does not establish. If the intervals are dependent, the endpoints must be constrained jointly; assuming independent uniform distributions solely to produce a standard deviation is not justified.

A fifth synthetic example concerns two detector modes with identical mean noise power but different peak-selection opportunities. If N independent noise-bin powers are exponentially distributed with common mean μ, the maximum has cumulative distribution $P(M \leq m) = [1-\exp(-m/\mu)]^N$ for $m \geq 0$. At $m=5\mu$ and $N=1$, exceedance probability is $\exp(-5)$, approximately 0.006738; at $N=100$, it is $1-[1-\exp(-5)]^{100}$, approximately 0.4916. This is not a change in physical thermal noise. It is the consequence of taking a maximum over more independent trials. Real detector samples may be correlated, so the independence hypothesis must be tested or replaced by a calibrated effective model. The example illustrates the difference between a displayed peak and the physical noise process producing the observation.

The output of the IF module should be a declared validity map. Its dimensions are amplitude, event duration, frequency, temperature, gain-control history, filter state and detector mode. Each validated cell includes the procedure, measured response, uncertainty, failure flags and tested hypothesis. Cells outside the tested map remain unqualified. This is more scientifically useful than a single nominal IF bandwidth because it identifies precisely when a receiver can support a conclusion about signal amplitude, timing or non-detection.

Copyright 2026, James M. Atkinson

5.28 Advanced technical expansion. Filter memory, log detection and hidden IF-state changes

An intermediate-frequency chain should be modelled as a dynamic system rather than a sequence of gain labels. A linear IF filter has an impulse response h(t), and its output is the convolution of h(t) with the admitted input under fixed-state conditions. A narrow spectral passband necessarily entails an impulse response extending over a nonzero interval; the detailed duration and ringing depend on the filter poles, zeros and phase characteristic, not merely the nominal resolution bandwidth. For a sudden burst whose duration is short compared with the filter settling time, the output peak may substantially underestimate the level a continuous-wave test would predict. The recorded response can persist after the physical RF burst ends. Neither effect implies that the transmitter's original pulse was necessarily weak or prolonged. The physical origin and observable consequence of filter memory must be separated.

A first-order illustrative envelope detector obeys tau dy/dt + y = u(t), where u(t) represents a nonnegative envelope estimate, y(t) is the detector state and tau is a positive time constant in seconds. If a unit step begins from zero, the response is y(t) = 1 - exp(-t/tau). At t = tau, the reading reaches approximately 0.632 of its final value; at three tau it reaches approximately 0.950. A two-millisecond event measured by a detector with tau = 5 ms reaches only 1 - exp(-0.4), or approximately 0.330 of its settled amplitude before the event ends. These results are for the stated mathematical detector, not a calibrated claim about every logarithmic or quasi-peak

Copyright 2026, James M. Atkinson

circuit. Changing the detector mode or the video filter alters the estimator and therefore the meaning of the displayed burst level.

Logarithmic amplification introduces another layer. A cascaded limiting or logarithmic detector may provide a useful approximate output proportional to the logarithm of input amplitude within a specified range, while individual stages saturate or change response near their transitions. The relevant error is not simply the departure of a calibration curve from a straight line. Temperature, pulse duration, modulation and detection bandwidth can cause the effective response to depend on the recent signal history. In an acceptance trial, calibrate several levels with a settled continuous wave, then repeat with finite bursts and varying duty factor while retaining the actual waveform at a suitable reference plane. If the same peak input produces a different reported output solely because its preceding quiet interval differs, a memory-dependent transfer must replace a static amplitude correction.

Automatic gain control should be identified as a closed-loop dynamical subsystem. Let g(t) denote effective small-signal gain and q(t) an internal envelope estimate that drives the control. Their coupled dynamics may be nonlinear, with a fast attack, slower release, discrete attenuation steps and clipping at gain limits. A weak reference present throughout a strong blocker illustrates gain pumping: during the blocker, the loop reduces gain; after the blocker disappears, the weak reference remains suppressed until control recovers. A trace with no observed weak event may therefore reflect temporary instrument desensitisation rather than absence of the emitter. Effective measurement coverage should exclude those intervals unless a validated state-dependent sensitivity model is available. A scalar average

Copyright 2026, James M. Atkinson

gain applied after the fact cannot reconstruct the omitted weak-signal samples.

Group-delay distortion is particularly consequential for wideband modulation. If phase transfer phi(f) varies with frequency, group delay tau_g(f) is minus its angular-frequency derivative. Constant group delay over the occupied signal band preserves relative timing up to an overall delay, whereas varying group delay distorts complex envelopes and pulse shape. A detector showing the correct integrated power may still conceal a demodulation failure due to differential phase distortion. Perform a swept vector or appropriate multitone measurement across the occupied band, compare against a stable phase reference and evaluate the response after any automatic IF state changes. Report both amplitude and phase deviations, because a single scalar passband-loss figure cannot quantify coherent waveform fidelity.

The validation procedure should separate five states: settled quiet response, signal attack, high-level control action, release, and regained measurement validity. Introduce a weak, independently observed reference and a bounded interferer with precisely recorded onset and duration; acquire an unsmoothed IF or complex-baseband record concurrently with the displayed detector output. Vary the filter, video bandwidth and gain control separately. A response change following one intervention is evidence of a candidate mechanism, not proof if the intervention also changes the admitted reference. In the released report retain measured recovery tolerances, state-transition times, the corresponding accepted sample ranges and the limitations of the mathematical model. A static noise-floor screenshot is no substitute for this time-resolved characterisation.

Chapter Summary

The IF chain shapes both spectrum and time. Filter response, AGC state, detector law, scaling, and alignment must be visible in the evidence record whenever amplitude, bandwidth, timing, or modulation is interpreted.

Choose the IF path for the intended amplitude, power, modulation or timing quantity. Nominal bandwidth and loaded Q omit ripple, skirts, phase and ringing. Verify the applicable transfer and retain the detector takeoff and acquisition configuration.

Model 5A describes a local voltage approaching a fixed target with a positive time constant. Its residual keeps its sign; RF gain follows only through a calibrated signed map. Declare error units and tolerance, carry the actual state through target changes, and distinguish attack, release and hang. Challenge fitted parameters and separate numerical artifacts from physical dynamics.

Peak, sampled, RMS-power and logarithmic detectors perform different operations within stated bandwidth, level and recovery limits. Shared control can respond outside the displayed channel. Align calibrated telemetry with the native record; it cannot recreate clipped data. Verify fixed gain before automatic operation with representative stimuli. A settled voltage or later passing check does not establish recovery of every function or uninterrupted earlier validity.

Chapter 5 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C05-MCQ-001. Two receivers report the same intermediate frequency but have different filters, detector takeoffs and gain control. What does the common IF establish by itself?

A. A shared frequency coordinate, without establishing equivalent measurement transfer.

B. Equivalent detector statistics because the carrier frequency is identical.

C. The same admitted noise power independently of filter shape.

D. The same transient response whenever their center-frequency gains agree.

Answer: A. An IF is a designed signal path as well as a frequency. Filtering, control and detection determine which quantity its output represents. Review: Intermediate Frequency as a Controlled Band. Source: §5.1 Intermediate Frequency as a Controlled Band (p. 2513)

Why the selected alternative fits: A shared frequency coordinate, without establishing equivalent measurement transfer.

Distinguishing consideration: compare this with option B, “Equivalent detector statistics because the carrier frequency is identical”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Intermediate Frequency as a Controlled Band.

Review: Chapter 5 — Intermediate Frequency as a Controlled Band.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-002. A receiver records a burst in stored I/Q data but shows little change on its audio output. Which explanation must be examined before calling either record erroneous?

A. The two outputs may use different IF bandwidths, detectors and control paths.

B. A missing audio response proves the digitizer created the RF event.

C. The narrower path must always have the larger instantaneous burst peak.

D. Any common RF input forces identical time-domain envelopes at all outputs.

Answer: A. The outputs are different observations unless their transfer and state have been reconciled. A narrow or averaged path can suppress a feature retained elsewhere. Review: Intermediate Frequency as a Controlled Band; Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: The two outputs may use different IF bandwidths, detectors and control paths.

Distinguishing consideration: compare this with option B, “A missing audio response proves the digitizer created the RF event”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Intermediate Frequency as a Controlled Band.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Intermediate Frequency as a Controlled Band.

V011-C05-MCQ-003. Two filters have equal center frequency and equal minus-3 dB width. Which additional property is still unconstrained by their equal loaded-Q ratios?

A. Their skirt attenuation, phase response and transient ringing.

B. The particular minus-3 dB width stipulated in the comparison.

C. The numerical ratio of center frequency to the stated width.

D. The center frequency used to form that ratio.

Answer: A. Loaded Q retains only one bandwidth ratio. Many response shapes can share it while differing in adjacent-signal rejection and waveform fidelity. Review: Equation 9; Choose an IF path for the quantity being measured. Source: Equation 9. Loaded quality factor (p. 2544)

Why the selected alternative fits: Their skirt attenuation, phase response and transient ringing.

Distinguishing consideration: compare this with option B, “The particular minus-3 dB width stipulated in the comparison”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 9. Loaded quality factor; Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Equation 9. Loaded quality factor; Chapter 5 — Choose an IF path for the quantity being measured.

V011-C05-MCQ-004. A resonance is centered at 10.7 MHz with a measured minus-3 dB width of 200 kHz. Under Equation 9, what is its loaded quality factor?

A. 53.5.

B. 53500.

C. 0.0535.

D. 18.7.

Answer: A. Express both frequencies in the same unit: 10.7 divided by 0.200 equals 53.5. The dimensionless result is a response descriptor, not a complete filter model.

Review: Equation 9. Source: Equation 9. Loaded quality factor (p. 2544)

Why the selected alternative fits: 53.5.

Distinguishing consideration: compare this with option B, “53500”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 9. Loaded quality factor.

Review: Chapter 5 — Equation 9. Loaded quality factor.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-005. For the same resonance convention, a center frequency of 21.4 MHz and loaded Q of 100 imply which minus-3 dB bandwidth?

A. 2.14 MHz.

B. 4.673 kHz.

C. 214 kHz.

D. 21.4 kHz.

Answer: C. Rearrange the ratio as bandwidth equal to center frequency divided by Q. The result is 0.214 MHz, or 214 kHz. Review: Equation 9. Source: Equation 9. Loaded quality factor (p. 2544)

Why the selected alternative fits: 214 kHz.

Distinguishing consideration: compare this with option A, “2.14 MHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 9. Loaded quality factor.

Review: Chapter 5 — Equation 9. Loaded quality factor.

V011-C05-MCQ-006. A filter shape factor is explicitly defined as its minus-60 dB width divided by its minus-6 dB width. Those widths are 360 kHz and 120 kHz. What value follows?

A. 240 kHz.

B. 3.

C. 480 kHz.

D. 0.333.

Answer: B. The stated definition is a dimensionless ratio of widths at two specified attenuation levels. It cannot be exchanged with a difference or an inverse ratio.

Review: Chapter Glossary: Shape factor; Filter Shape, Selectivity, and Time Response.

Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

Why the selected alternative fits: 3.

Distinguishing consideration: compare this with option A, “240 kHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Filter Shape, Selectivity, and Time Response; Chapter 5 — SHAPE FACTOR (glossary).

Review: Chapter 5 — Filter Shape, Selectivity, and Time Response; Chapter 5 — SHAPE FACTOR (glossary).

V011-C05-MCQ-007. Two front-panel settings are both labeled 100 kHz, but one denotes minus-3 dB width and the other equivalent noise bandwidth. What is required before comparing measured noise power?

A. Establish the actual weighting or effective noise bandwidth of each path.

B. Compare only passband center gain and ignore frequency weighting.

C. Replace both definitions with loaded Q without measuring their shapes.

D. Use the identical displayed number as proof of equal integrated noise.

Answer: A. Equal labels with different definitions need not admit equal noise. The relevant integration uses the actual power response or a compatible effective bandwidth. Review: Filter Shape, Selectivity, and Time Response; Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why the selected alternative fits: Establish the actual weighting or effective noise bandwidth of each path.

Distinguishing consideration: compare this with option B, “Compare only passband center gain and ignore frequency weighting”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Choose an IF path for the quantity being measured; Chapter 5 — Filter Shape, Selectivity, and Time Response.

Review: Chapter 5 — Choose an IF path for the quantity being measured; Chapter 5 — Filter Shape, Selectivity, and Time Response.

V011-C05-MCQ-008. The intended measurand changes from separation of two continuous tones to the peak of a short burst. Which decision must be revisited?

A. Only the final display offset, since a tone calibration characterizes any burst.

B. Only the carrier-frequency label, because filter response affects no peak.

C. The selected IF response and its calibration for the new temporal quantity.

D. Only the observation length, with no need to test the impulse response.

Answer: C. A narrow path useful for tone separation can smear or attenuate a short peak. The measurement objective determines which response properties must be known. Review: Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why the selected alternative fits: The selected IF response and its calibration for the new temporal quantity.

Distinguishing consideration: compare this with option A, “Only the final display offset, since a tone calibration characterizes any burst”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

V011-C05-MCQ-009. A filter preserves the measured energy of a burst over a sufficiently long, appropriately calibrated record but reduces its instantaneous peak. Which interpretation is sound?

A. Energy agreement does not establish instantaneous peak fidelity.

B. Equal integrated energy forces the waveform to be an unchanged delayed copy.

C. The original peak can always be recovered from total energy alone.

D. Any reduced peak proves that all burst energy was lost.

Answer: A. Temporal spreading can change a maximum while preserving an integrated quantity. Energy and peak are different measurands, and one scalar cannot reconstruct the waveform. Review: Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why the selected alternative fits: Energy agreement does not establish instantaneous peak fidelity.

Distinguishing consideration: compare this with option B, “Equal integrated energy forces the waveform to be an unchanged delayed copy”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

V011-C05-MCQ-010. Group delay is evaluated from transfer phase expressed in radians. Which derivative has the stated units and convention?

A. The negative phase derivative with respect to frequency in hertz with no factor conversion.

B. The positive derivative of transfer magnitude with respect to frequency.

C. Phase divided by center frequency for every possible phase intercept.

D. The negative phase derivative with respect to angular frequency.

Answer: D. Angular frequency in radians per second gives a delay in seconds. A derivative against hertz requires the corresponding two-pi conversion and is not numerically interchangeable. Review: Chapter Glossary: Group delay; Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why the selected alternative fits: The negative phase derivative with respect to angular frequency.

Distinguishing consideration: compare this with option A, “The negative phase derivative with respect to frequency in hertz with no factor conversion”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Choose an IF path for the quantity being measured; Chapter 5 — GROUP DELAY (glossary).

Review: Chapter 5 — Choose an IF path for the quantity being measured; Chapter 5 — GROUP DELAY (glossary).

V011-C05-MCQ-011. Over a measurable coherent passband, unwrapped phase has slope minus 4 microseconds when differentiated with respect to angular frequency. What is the group delay?

A. Zero because the phase slope is negative.

B. Positive 4 microseconds.

C. Negative 4 microseconds.

D. Positive 4 times two pi microseconds.

Answer: B. The definition contains a minus sign. A negative phase slope with angular frequency therefore gives positive group delay of the same magnitude.
Review: Chapter Glossary: Group delay. Source: §5.25 Detector dynamics and intermediate-frequency filters as temporally extended measurement operators (p. 2550)
Why the selected alternative fits: Positive 4 microseconds.
Distinguishing consideration: compare this with option A, “Zero because the phase slope is negative”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 5 — GROUP DELAY (glossary).
Review: Chapter 5 — GROUP DELAY (glossary).

V011-C05-MCQ-012. A group-delay calculation differentiates principal phase values across a jump from positive pi to negative pi. What must be checked first?

A. Whether the magnitude response can replace the missing phase convention.

B. Phase unwrapping and a coherent reference before estimating the local slope.

C. Whether the jump can simply be interpreted as an impulse delay in the filter.

D. Whether averaging the two wrapped angles automatically reconstructs the branch.

Answer: B. A representation wrap is not a physical discontinuity of an otherwise smooth transfer phase. Differentiation must use a consistent branch supported by the measurement. Review: Choose an IF path for the quantity being measured.

Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why the selected alternative fits: Phase unwrapping and a coherent reference before estimating the local slope.

Distinguishing consideration: compare this with option A, “Whether the magnitude response can replace the missing phase convention”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

V011-C05-MCQ-013. An enormous apparent group delay occurs at a deep notch where the transfer is near the measurement floor. What is the strongest immediate interpretation?

A. The notch phase is always more precise because its transmitted amplitude is smaller.

B. The phase-derived estimate may be ill-conditioned and needs a capability check.

C. The notch proves that every waveform experiences that same large delay.

D. A large numerical derivative establishes correspondingly large stored energy without other evidence.

Answer: B. Phase becomes poorly determined when the measured transfer approaches noise or residuals. A dramatic derivative alone is not a reliable physical-delay claim. Review: Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why the selected alternative fits: The phase-derived estimate may be ill-conditioned and needs a capability check.

Distinguishing consideration: compare this with option A, “The notch phase is always more precise because its transmitted amplitude is smaller”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-014. Which combination supports treating a band-limited waveform as an approximately unchanged delayed copy through the selected IF path?

A. Sufficiently flat amplitude and approximately linear phase over its occupied band.

B. Only a single measured group-delay value at the center frequency.

C. Only equality of the input and output carrier frequencies.

D. Only a high loaded Q independent of the waveform bandwidth.

Answer: A. Constant amplitude scaling and linear phase across the waveform band support undistorted delay. A local derivative at one frequency cannot establish the full-band condition. Review: Choose an IF path for the quantity being measured.

Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why the selected alternative fits: Sufficiently flat amplitude and approximately linear phase over its occupied band.

Distinguishing consideration: compare this with option B, “Only a single measured group-delay value at the center frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

V011-C05-MCQ-015. A burst falls 6 dB when a narrower IF setting is selected; a time capture shows that the peak is sampled before the filter settles. What should be corrected before inferring a propagation change?

A. The RF source location, because a bandwidth change cannot alter a peak.

B. Only the steady-state center-frequency gain, assumed sufficient for every burst.

C. The path-dependent transient and detection interpretation.

D. The gain-control polarity, regardless of whether AGC was enabled.

Answer: C. The observation is compatible with the receiver path changing the measured peak. A timing-sensitive calibration or a suitable path is needed before assigning the difference to propagation. Review: Hypothetical Case Adjudication; Filter Shape, Selectivity, and Time Response. Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

Why the selected alternative fits: The path-dependent transient and detection interpretation.

Distinguishing consideration: compare this with option A, “The RF source location, because a bandwidth change cannot alter a peak”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Filter Shape, Selectivity, and Time Response; Chapter 5 — Hypothetical Case Adjudication: Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors.

V011-C05-MCQ-016. In Model 5A, the control state is in volts and the time constant is in milliseconds. Which form of the exponent is dimensionally valid?

A. Negative control volts divided by the time constant.

B. Negative elapsed seconds divided directly by a numerical millisecond value without conversion.

C. Negative elapsed time in milliseconds divided by the time constant in milliseconds.

D. Negative elapsed time multiplied by the time constant.

Answer: C. The exponential argument must be dimensionless. Matching time units is essential even when all displayed numbers look plausible. Review: Equations 10A and 10B. Source: Equation 10A. Identified control-state equation (p. 2520)

Why the selected alternative fits: Negative elapsed time in milliseconds divided by the time constant in milliseconds.

Distinguishing consideration: compare this with option A, “Negative control volts divided by the time constant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10B. Control voltage and residual.

V011-C05-MCQ-017. The initial control voltage equals the constant target in the stipulated one-pole model. What follows?

A. The time constant becomes negative.

B. The voltage must first overshoot before reaching equilibrium.

C. The state must decay toward zero volts regardless of the target.

D. The residual is zero for the entire segment.

Answer: D. The homogeneous residual starts at zero and remains zero. The equilibrium is the specified target, not necessarily zero voltage. Review: Equations 10A and 10B. Source: Equation 10A. Identified control-state equation (p. 2520)

Why the selected alternative fits: The residual is zero for the entire segment.

Distinguishing consideration: compare this with option A, “The time constant becomes negative”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10B. Control voltage and residual.

V011-C05-MCQ-018. A control voltage starts at 0.9 V and approaches 0.3 V with a 2 ms time constant. What is its value after 2 ms?

A. Exactly 0.3 V.

B. Approximately 0.22073 V.

C. Approximately 0.67927 V.

D. Approximately 0.52073 V.

Answer: D. One time constant leaves the initial 0.6 V residual multiplied by exp of minus one. Add the remaining 0.22073 V to the 0.3 V target. Review: Equation 10B; Application 5A.1. Source: Equation 10B. Control voltage and residual (p. 2521)

Why the selected alternative fits: Approximately 0.52073 V.

Distinguishing consideration: compare this with option A, “Exactly 0.3 V”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.

V011-C05-MCQ-019. For a nonzero initial step in Model 5A, what fraction of the total voltage change has occurred after one time constant?

A. Approximately 63.21 percent.

B. Approximately 95 percent.

C. Approximately 36.79 percent.

D. Exactly 100 percent.

Answer: A. The residual fraction is exp of minus one, approximately 0.3679. The completed fraction is one minus that value. Review: Equation 10B; Application 5A.1.

Source: Equation 10B. Control voltage and residual (p. 2521)

Why the selected alternative fits: Approximately 63.21 percent.

Distinguishing consideration: compare this with option B, “Approximately 95 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.

V011-C05-MCQ-020. An observed control voltage crosses its fixed target and then returns while the fitted model assumes one uninterrupted positive-time-constant segment. What does this indicate?

A. The observation proves that the RF input was clipped.

B. Changing only the sign of the gain slope makes the voltage crossing consistent.

C. Ordinary first-order settling necessarily overshoots once.

D. The stipulated one-pole segment is insufficient for that observation.

Answer: D. The exponential residual preserves its sign. Overshoot requires a changed target, additional dynamics, measurement error or another explanation; it does not uniquely identify clipping. Review: Equation 10B and its monotonicity discussion. Source: Equation 10B. Control voltage and residual (p. 2521)

Why the selected alternative fits: The stipulated one-pole segment is insufficient for that observation.

Distinguishing consideration: compare this with option A, “The observation proves that the RF input was clipped”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

V011-C05-MCQ-021. A fitted time constant is negative for a supposedly relaxing segment. Can it be inserted unchanged into Model 5A as an ordinary settling time?

A. No; it violates the stated positive-time-constant model and requires investigation.

B. Yes; a negative gain slope requires a negative time constant.

C. Yes; only the absolute value of elapsed time matters.

D. Yes; changing the voltage reference automatically changes its sign.

Answer: A. The gain-map polarity and the time constant are different quantities. A negative fitted constant describes residual growth under this equation, not the stipulated stable relaxation. Review: Equations 10A, 10C and 10F. Source: Equation 10A. Identified control-state equation (p. 2520)

Why the selected alternative fits: No; it violates the stated positive-time-constant model and requires investigation.

Distinguishing consideration: compare this with option B, “Yes; a negative gain slope requires a negative time constant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10F. Two-point identification of the local time constant.

V011-C05-MCQ-022. A small-change voltage trace fits Model 5A closely. Which additional claim remains unestablished?

A. The fitted local response over the actual tested interval.

B. The units assigned to the recorded control voltage.

C. The full internal detector topology and recovery from large overdrive.

D. The residual predicted by that fitted equation at a tested sample time.

Answer: C. An input/output fit is local evidence. Integrating control, slew, clamps and additional stages can behave differently outside the tested range. Review: Model 5A introduction; source note 15. Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)

Why the selected alternative fits: The full internal detector topology and recovery from large overdrive.

Distinguishing consideration: compare this with option A, “The fitted local response over the actual tested interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — Model 5A: an identified one-pole gain-control response.

V011-C05-MCQ-023. A voltage trajectory stays between its endpoints, but both endpoints lie outside the calibrated gain-map range. What can the analyst infer about RF gain from the trajectory alone?

A. The endpoint gains can be assumed equal because the state is bounded.

B. No calibrated gain prediction follows merely from the monotone voltage fit.

C. The local gain slope must become zero outside the calibrated interval.

D. Monotonicity automatically extends the gain calibration to all voltages.

Answer: B. The state model and the voltage-to-gain calibration have separate applicability limits. A well-behaved state trajectory does not validate an extrapolated gain law. Review: Equation 10C and its operating interval. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: No calibrated gain prediction follows merely from the monotone voltage fit.

Distinguishing consideration: compare this with option A, “The endpoint gains can be assumed equal because the state is bounded”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-024. During a fitted segment the receiver changes its control target in response to a new input level. What is required for subsequent prediction?

A. Reset the state to the previous target whether or not it was reached.

B. Start a new applicable segment using the actual state at the target change.

C. Set the residual to zero at every trigger.

D. Keep the original constant target for the whole record because the time constant is unchanged.

Answer: B. The constant-target solution applies within a segment. A target change preserves the actual state while changing the equilibrium and possibly the identified parameters. Review: Equation 10G; Application 5A.6. Source: Equation 10G. Carry state across a target change (p. 2523)

Why the selected alternative fits: Start a new applicable segment using the actual state at the target change.

Distinguishing consideration: compare this with option A, “Reset the state to the previous target whether or not it was reached”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

V011-C05-MCQ-025. A calibrated gain slope is minus 25 dB/V. A control-voltage increase of 0.16 V produces which gain change within that local range?

A. Plus 4 dB.

B. Plus 25.16 dB.

C. Minus 0.0064 dB.

D. Minus 4 dB.

Answer: D. Multiply the signed slope by the voltage change. The negative sign means a rising control voltage reduces gain. Review: Equation 10C. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: Minus 4 dB.

Distinguishing consideration: compare this with option A, “Plus 4 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-029. A detector reports 0.6 V while a separate AGC telemetry channel also reports 0.6 V. May those voltages be assigned the same RF-power meaning?

A. Only if the separate detector and control-to-gain laws justify that interpretation.

B. Yes; equal voltages always denote equal powers in the same receiver.

C. No detector voltage can ever support a calibrated power result.

D. Yes; the gain slope in dB/V is automatically the detector power slope.

Answer: A. Control voltage and detected output are different physical quantities. Each requires its own calibrated relationship and operating conditions. Review: Equations 10C and 10D; Logarithmic Amplifiers, Detectors, and Scaling. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: Only if the separate detector and control-to-gain laws justify that interpretation.

Distinguishing consideration: compare this with option B, “Yes; equal voltages always denote equal powers in the same receiver”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

V011-C05-MCQ-030. At fixed input power, equal-duration valid gain states are 0 dB and 20 dB. What is the mean linear output power relative to the input?

A. 20 times, because the numerical dB values can be averaged as powers.

B. 100 times, because the larger gain controls every average.

C. 50.5 times, equivalent to approximately 17.03 dB.

D. 10 times, because the arithmetic mean gain is 10 dB.

Answer: C. The two power gains are 1 and 100. Average those linear quantities to get 50.5, then convert to decibels if desired. Review: Equation 10D discussion; Verify the detector and control path as part of the IF result. Source: Equation 10D. Output level and gain-error magnitude (p. 2522)

Why the selected alternative fits: 50.5 times, equivalent to approximately 17.03 dB. Distinguishing consideration: compare this with option A, “20 times, because the numerical dB values can be averaged as powers”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Verify the detector and control path as part of the IF result. Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-031. Initial gain-error magnitude is 10 dB, tolerance is 0.1 dB, and the time constant is 0.5 ms. What is the earliest settling time under Model 5A?

A. Exactly 1.5 ms.

B. Approximately 0.05 ms.

C. Approximately 2.3026 ms.

D. Approximately 0.2303 ms.

Answer: C. The error ratio is 100. Multiplying its natural logarithm by 0.5 ms gives 2.302585 ms; a generic three-time-constant wait would not meet this tolerance.

Review: Equation 10E; Application 5A.2. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why the selected alternative fits: Approximately 2.3026 ms.

Distinguishing consideration: compare this with option A, “Exactly 1.5 ms”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement.

V011-C05-MCQ-032. An initial gain-error magnitude of 0.05 dB is already within a 0.1 dB tolerance. What earliest acceptance time does Equation 10E assign within its stipulated model?

A. Zero.

B. Exactly one time constant.

C. A negative time from the logarithmic branch.

D. An infinite time because the residual is nonzero.

Answer: A. The piecewise rule assigns zero whenever the initial error is no greater than the positive tolerance. The logarithmic branch is only for a larger initial error.

Review: Equation 10E. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why the selected alternative fits: Zero.

Distinguishing consideration: compare this with option B, “Exactly one time constant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

V011-C05-MCQ-033. Starting from a nonzero residual, a requirement demands exactly zero error under the uninterrupted exponential model. What finite settling time follows?

A. Zero because exactness removes the tolerance calculation.

B. Three time constants for every initial residual.

C. None; exact zero is approached asymptotically.

D. One time constant because that is the defined decay interval.

Answer: C. The exponential remains positive at every finite time. A positive practical tolerance or a separately justified deadband is needed for finite acceptance. Review: Equation 10E and its zero-error qualification. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why the selected alternative fits: None; exact zero is approached asymptotically.

Distinguishing consideration: compare this with option A, “Zero because exactness removes the tolerance calculation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

V011-C05-MCQ-034. The local gain-map slope is zero. What does a gain-based settling test reveal about control-voltage settling in that interval?

A. It cannot identify the voltage residual from gain changes under that map.

B. It proves that every earlier RF stage has recovered.

C. It forces the physical time constant to zero.

D. It proves that the voltage reaches its target instantaneously.

Answer: A. Zero slope makes gain insensitive to control voltage locally. That lack of sensitivity is an uninformative inversion, not evidence of instantaneous state or chain recovery. Review: Equations 10C through 10E. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: It cannot identify the voltage residual from gain changes under that map.

Distinguishing consideration: compare this with option B, “It proves that every earlier RF stage has recovered”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-035. An initial voltage error is 0.4 V and the slope magnitude is 25 dB/V. After three time constants, which gain-error magnitude remains?

A. Approximately 0.498 dB.

B. Approximately 0.020 dB.

C. Approximately 9.502 dB.

D. Exactly 0.1 dB.

Answer: A. The initial gain error is 10 dB. Multiply by exp of minus three to obtain approximately 0.49787 dB; the completed portion is not the remaining error.

Review: Equations 10D and 10E; Application 5A.2. Source: Equation 10D. Output level and gain-error magnitude (p. 2522)

Why the selected alternative fits: Approximately 0.498 dB.

Distinguishing consideration: compare this with option B, “Approximately 0.020 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement.

Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement.

V011-C05-MCQ-036. For the same initial error above both tolerances, the permitted residual is tightened by a factor of ten. How much additional settling time is required?

A. Exactly ten additional time constants.

B. Ten times the original settling time in every case.

C. No extra time because the decay rate is unchanged.

D. The time constant multiplied by the natural logarithm of ten.

Answer: D. Subtract the two logarithmic settling expressions. The initial error cancels, leaving the time constant times the logarithm of the tolerance ratio.

Review: Equation 10E. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why the selected alternative fits: The time constant multiplied by the natural logarithm of ten.

Distinguishing consideration: compare this with option A, “Exactly ten additional time constants”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

V011-C05-MCQ-037. What multiple of the time constant completes 95 percent of a nonzero voltage step in the one-pole model?

A. Exactly 5.

B. Approximately 0.0513.

C. Exactly 0.95.

D. Approximately 2.996.

Answer: D. Five percent residual means exp of minus time over time constant equals 0.05. The required ratio is the natural logarithm of 20. Review: Equation 10B; Application 5A.1. Source: Equation 10B. Control voltage and residual (p. 2521)

Why the selected alternative fits: Approximately 2.996.

Distinguishing consideration: compare this with option A, “Exactly 5”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.

V011-C05-MCQ-038. A settling calculation divides an initial error of 0.3 V by a tolerance of 0.1 dB inside a logarithm. What is wrong?

A. Voltage errors can never be converted into gain errors.

B. The numerator and denominator are different quantities and must first be expressed in compatible error units.

C. The logarithm must always be base ten because gain is in decibels.

D. A signed slope must be replaced by a signed time constant.

Answer: B. The logarithm requires a dimensionless ratio of like errors. Use the absolute calibrated gain slope to convert voltage-error magnitude to decibels when appropriate. Review: Equations 10D and 10E. Source: Equation 10D. Output level and gain-error magnitude (p. 2522)

Why the selected alternative fits: The numerator and denominator are different quantities and must first be expressed in compatible error units.

Distinguishing consideration: compare this with option A, “Voltage errors can never be converted into gain errors”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

V011-C05-MCQ-039. A permitted gain error is 2 dB and the valid slope is minus 40 dB/V. What voltage-error magnitude corresponds to that tolerance?

A. 0.05 V.

B. 20 V.

C. 80 V.

D. Minus 0.05 V.

Answer: A. Divide the nonnegative gain-error tolerance by the slope magnitude. Error magnitude remains positive despite the negative gain-map polarity. Review: Equations 10C through 10E. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: 0.05 V.

Distinguishing consideration: compare this with option B, “20 V”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-040. The positive time constant is known only to lie between 1 ms and 2 ms; the initial error and target are fixed. Which endpoint sets the conservative wait for a smaller positive tolerance?

A. 2 ms, because the larger time constant gives slower residual decay.

B. Their arithmetic mean without any additional assumption.

C. 1 ms, because smaller time constants always produce larger residuals.

D. Neither endpoint because the gain slope changes sign with the time constant.

Answer: A. The settling expression is proportional to the time constant when the error ratio exceeds one. A bound must retain the slower admissible case. Review: Equation 10E; uncertainty qualification following Equation 10J. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why the selected alternative fits: 2 ms, because the larger time constant gives slower residual decay.

Distinguishing consideration: compare this with option B, “Their arithmetic mean without any additional assumption”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Equation 10J. Propagation of an initial-state interval.

V011-C05-MCQ-041. Two voltage steps have the same time constant but different magnitudes. Under the same one-pole model, which settling comparison is correct?

A. Both percentage and absolute-tolerance settling times are necessarily identical.

B. The larger step always has a proportionally larger percentage-settling time.

C. A percentage requirement has units of volts and cannot be used.

D. The time to complete the same percentage is equal, but a common absolute-error tolerance can give different times.

Answer: D. Fractional residual depends only on normalized time. An absolute tolerance introduces the initial magnitude through the logarithmic error ratio.

Review: Equations 10B and 10E. Source: Equation 10B. Control voltage and residual (p. 2521)

Why the selected alternative fits: The time to complete the same percentage is equal, but a common absolute-error tolerance can give different times.

Distinguishing consideration: compare this with option A, “Both percentage and absolute-tolerance settling times are necessarily identical”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

V011-C05-MCQ-042. A 12 dB input increase requires an eventual 12 dB gain reduction. With a valid one-pole response, what output increase remains after one time constant?

A. Exactly 12 dB.

B. Approximately 7.585 dB.

C. Exactly 0 dB.

D. Approximately 4.415 dB.

Answer: D. The residual correction is 12 times exp of minus one dB. The gain has completed about 7.585 dB of the required reduction, leaving about 4.415 dB.

Review: Application 5A.4. Source: §5.9 Application 5A.4: Check the required control polarity after a level step (p. 2529)

Why the selected alternative fits: Approximately 4.415 dB.

Distinguishing consideration: compare this with option A, “Exactly 12 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Review: Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-043. An input increases by 8 dB and the local control slope is minus 20 dB/V. What target-voltage change would restore the previous output level if the path stays valid?

A. A rise of 2.5 V.

B. No voltage change because only input power changed.

C. A rise of 0.4 V.

D. A fall of 0.4 V.

Answer: C. Restoring the output requires minus 8 dB of gain change. Dividing by minus 20 dB/V gives plus 0.4 V, provided the new target is within the valid range. Review: Equation 10C; Application 5A.4. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: A rise of 0.4 V.

Distinguishing consideration: compare this with option A, “A rise of 2.5 V”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

V011-C05-MCQ-044. The gain calibration is valid only from 0.1 V through 0.7 V, while a proposed settling segment runs from 0.2 V toward 0.9 V. What must be limited or re-established?

A. The gain prediction once the control leaves the calibrated interval.

B. Only the initial gain, because a valid starting point validates every later point.

C. Only the time unit, because calibration range cannot affect gain.

D. Nothing, provided the exponential is mathematically monotone.

Answer: A. The state equation may still produce numbers, but the stipulated voltage-to-gain law does not justify gain beyond its interval. Extend calibration or restrict the claim. Review: Equation 10C. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: The gain prediction once the control leaves the calibrated interval.

Distinguishing consideration: compare this with option B, “Only the initial gain, because a valid starting point validates every later point”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

V011-C05-MCQ-045. Control telemetry reaches its accepted gain-error tolerance after an overload. What still needs separate verification before accepting the entire signal path?

A. Only whether the time constant was positive in the fitted control equation.

B. The relevant RF and detector response, including any stages with independent recovery.

C. Only whether the final target voltage equals its stored setting.

D. Nothing else, because a settled control voltage proves all stages linear.

Answer: B. Control-state settling is one observable. Earlier amplifiers, limiters or detectors can remain disturbed even when telemetry appears settled. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: The relevant RF and detector response, including any stages with independent recovery.

Distinguishing consideration: compare this with option A, “Only whether the time constant was positive in the fitted control equation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-046. Residuals relative to one fixed target are minus 0.20 V and minus 0.05 V, separated by 2 ms. What positive time constant does Equation 10F infer?

A. Exactly 0.5 ms.

B. Minus 1.443 ms.

C. Approximately 1.443 ms.

D. Approximately 2.773 ms.

Answer: C. The ratio of the signed residuals is four, so the natural logarithm is positive. Divide 2 ms by that logarithm; the common negative sign is allowed.

Review: Equation 10F; Application 5A.5. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why the selected alternative fits: Approximately 1.443 ms.

Distinguishing consideration: compare this with option A, “Exactly 0.5 ms”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-047. Two nonzero residuals about the same fixed target have opposite signs. Can they identify an uninterrupted positive-time-constant segment through Equation 10F?

A. Yes; taking absolute values always makes the physical model valid.

B. No; the stipulated exponential cannot reverse residual sign.

C. Yes; a negative gain slope requires a residual sign reversal.

D. Yes; the time constant is simply the elapsed time divided by two.

Answer: B. Absolute values would conceal a model contradiction. Investigate target changes, overshoot, measurement error or additional dynamics before fitting.

Review: Equations 10B and 10F. Source: Equation 10B. Control voltage and residual (p. 2521)

Why the selected alternative fits: No; the stipulated exponential cannot reverse residual sign.

Distinguishing consideration: compare this with option A, “Yes; taking absolute values always makes the physical model valid”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10F. Two-point identification of the local time constant.

V011-C05-MCQ-048. Two equal nonzero residual magnitudes of the same sign are observed at different times about a fixed target. What follows for an exact finite positive one-pole fit?

A. The time constant equals the time separation.

B. The time constant is zero.

C. No such decaying fit follows; the logarithmic denominator is zero.

D. The residual has necessarily reached equilibrium.

Answer: C. A finite positive time constant causes strict magnitude decrease from a nonzero residual. Equal values may reflect a floor, hold state or insufficient resolution, but not the exact stipulated decay. Review: Equation 10F. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why the selected alternative fits: No such decaying fit follows; the logarithmic denominator is zero.

Distinguishing consideration: compare this with option A, “The time constant equals the time separation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

V011-C05-MCQ-049. Same-sign residual magnitudes grow between two observations about the claimed fixed target. Which conclusion is justified?

A. They fail the decreasing-magnitude condition for the stated relaxation model.

B. They validate an ordinary positive settling time after taking an absolute logarithm.

C. They prove that the target voltage is physically zero.

D. They show that the gain slope must be negative.

Answer: A. Taking an absolute logarithm would hide the direction of change. Growth requires a different state description, target or error explanation. Review: Equation 10F and its identification conditions. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why the selected alternative fits: They fail the decreasing-magnitude condition for the stated relaxation model.

Distinguishing consideration: compare this with option B, “They validate an ordinary positive settling time after taking an absolute logarithm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-050. Two residual measurements produce a plausible positive time constant. What is the next substantive validation step?

A. Declare the complete internal AGC topology uniquely identified.

B. Challenge the fitted response at additional times and relevant levels or states.

C. Use the same constant through all clamps, hang intervals and overloads.

D. Discard any later point that departs from the two-point fit.

Answer: B. Two favorable points can interpolate an exponential without proving model adequacy. Additional observations can expose target errors, slew, multiple time constants or state changes. Review: Equation 10F; Application 5A.5. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why the selected alternative fits: Challenge the fitted response at additional times and relevant levels or states.

Distinguishing consideration: compare this with option A, “Declare the complete internal AGC topology uniquely identified”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

V011-C05-MCQ-052. A semilogarithmic plot of measured residual magnitude shows two distinct slopes over the retained interval. What should be reconsidered?

A. Whether changing the final gain offset can always make both slopes identical.

B. Whether one time constant adequately describes the whole interval.

C. Whether the time axis should be ignored because only residual sign matters.

D. Whether any two-slope response must be attributed to RF fading alone.

Answer: B. A single exponential gives one slope when its target is correct. Multiple slopes can reveal additional dynamics, changing state or measurement effects that need evaluation. Review: Equation 10F; Application 5A.5. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why the selected alternative fits: Whether one time constant adequately describes the whole interval.

Distinguishing consideration: compare this with option A, “Whether changing the final gain offset can always make both slopes identical”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

V011-C05-MCQ-053. An overdriven control response begins with an approximately constant voltage slope and later approaches its target exponentially. What is the best model treatment?

A. Infer that the later positive time constant also proves the early ramp exponential.

B. Replace the signed gain slope with the voltage slew rate because they have the same units.

C. Force one exponential through both regions and discard the early deviation.

D. Distinguish the possible slew-limited segment from the later local exponential segment.

Answer: D. A voltage rate has units of volts per time, whereas the gain map has units of decibels per volt. Large-change slew and local small-change response are separate mechanisms. Review: Model 5A introduction; Application 5A.5; source note 15. Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)

Why the selected alternative fits: Distinguish the possible slew-limited segment from the later local exponential segment.

Distinguishing consideration: compare this with option A, “Infer that the later positive time constant also proves the early ramp exponential”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals; Chapter 5 — Model 5A: an identified one-pole gain-control….

Review: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals; Chapter 5 — Model 5A: an identified one-pole gain-control response.

V011-C05-MCQ-054. Residual observations have a fixed dimensionless ratio, and their time separation is entered in milliseconds. In what unit does Equation 10F return the time constant?

A. Seconds automatically, regardless of the entered unit.

B. Milliseconds.

C. Volts per millisecond.

D. A dimensionless value.

Answer: B. The logarithm of the residual ratio is dimensionless, so the numerator supplies the time unit. No implicit factor of one thousand is introduced. Review: Equation 10F. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why the selected alternative fits: Milliseconds.

Distinguishing consideration: compare this with option A, “Seconds automatically, regardless of the entered unit”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

V011-C05-MCQ-055. Control starts at 0 V and approaches 1 V for a duration equal to the time constant times $\ln(2)$. It then approaches 0 V for the same duration and time constant. What is the final state?

A. 0.50 V.

B. 0.25 V.

C. 0.75 V.

D. 0 V.

Answer: B. Each interval leaves half of its starting residual. The first ends at 0.5 V; the second halves that carried value to 0.25 V. Review: Equation 10G; Application 5A.6. Source: Equation 10G. Carry state across a target change (p. 2523)

Why the selected alternative fits: 0.25 V.

Distinguishing consideration: compare this with option A, “0.50 V”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

V011-C05-MCQ-056. A second burst begins before the control has reached the first burst's target. Which starting condition should its model use?

A. The actual control state at the second burst's start.

B. The first target, because a target change resets the physical state.

C. Zero residual at each trigger, independent of history.

D. The arithmetic mean of the two targets without a dynamic calculation.

Answer: A. The state is continuous under the stipulated finite-rate model. Discarding its unresolved residual misrepresents the second interval. Review: Equation 10G; Application 5A.6. Source: Equation 10G. Carry state across a target change (p. 2523)

Why the selected alternative fits: The actual control state at the second burst's start.

Distinguishing consideration: compare this with option B, "The first target, because a target change resets the physical state"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

V011-C05-MCQ-057. Control rises from 0.2 V toward 0.6 V for 0.5 ms with a 0.25 ms attack constant, then releases toward 0.2 V for 1 ms with a 2 ms release constant. What final value follows?

A. Approximately 0.44261 V.

B. Approximately 0.40978 V.

C. Approximately 0.24681 V.

D. Exactly 0.2 V.

Answer: B. The attack ends at 0.545866 V. Carry that state into release and multiply its 0.345866 V displacement by exp of minus 0.5, then add 0.2 V. Review: Equation 10G; Application 5A.7. Source: Equation 10G. Carry state across a target change (p. 2523)

Why the selected alternative fits: Approximately 0.40978 V.

Distinguishing consideration: compare this with option A, “Approximately 0.44261 V”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.7: Use separately identified attack and release constants.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.7: Use separately identified attack and release constants.

V011-C05-MCQ-058. A receiver holds its gain-control state for a fixed time after a strong burst before beginning exponential release. How should this be represented?

A. As the same release exponential merely renamed with a larger time constant.

B. As an explicit hang state with its trigger and duration, followed by the applicable release segment.

C. As proof that the physical time constant is negative during the hold.

D. As an instantaneous reset to the pre-burst target.

Answer: B. A hold interval and a slow exponential have different trajectories. The timing rule and carried state must be declared. Review: Equation 10G discussion; Application 5A.7. Source: Equation 10G. Carry state across a target change (p. 2523)

Why the selected alternative fits: As an explicit hang state with its trigger and duration, followed by the applicable release segment.

Distinguishing consideration: compare this with option A, “As the same release exponential merely renamed with a larger time constant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.7: Use separately identified attack and release constants.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.7: Use separately identified attack and release constants.

V011-C05-MCQ-059. A burst lasts 0.5 ms while the identified time constant is 5 ms. What fraction of the target control step occurs during the burst?

A. Exactly 50 percent.

B. Approximately 9.516 percent.

C. Approximately 90.484 percent.

D. Approximately 99.995 percent.

Answer: B. The elapsed time is one tenth of a time constant. The completed fraction is one minus exp of minus 0.1, not the remaining fraction. Review: Equation 10B; Application 5A.8. Source: Equation 10B. Control voltage and residual (p. 2521)

Why the selected alternative fits: Approximately 9.516 percent.

Distinguishing consideration: compare this with option A, “Exactly 50 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.8: Compare burst duration with control settling.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.8: Compare burst duration with control settling.

V011-C05-MCQ-060. Identical repeated bursts settle into a reproducible periodic control trajectory that never reaches either target. What record is needed to correct the next burst's gain?

A. Only the final control sample after the complete acquisition.

B. Enough preceding state history or a validated periodic-state estimate to determine its actual initial condition.

C. Only the burst repetition frequency, with no amplitude or duration information.

D. Only the target associated with the new burst, treating it as already attained.

Answer: B. Reproducibility does not mean equilibrium. The unresolved residual from earlier intervals determines the next trajectory. Review: Equation 10G; Application 5A.6. Source: Equation 10G. Carry state across a target change (p. 2523)

Why the selected alternative fits: Enough preceding state history or a validated periodic-state estimate to determine its actual initial condition.

Distinguishing consideration: compare this with option A, "Only the final control sample after the complete acquisition"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

V011-C05-MCQ-061. For a 2 ms time constant and 1 ms sample interval, what is the exact sampled residual multiplier?

A. Exactly 0.5.

B. Exactly minus 0.5.

C. Approximately 1.64872.

D. Approximately 0.60653.

Answer: D. The exact coefficient is exp of minus interval divided by time constant, here exp of minus 0.5. The value 0.5 belongs to the Euler approximation. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why the selected alternative fits: Approximately 0.60653.

Distinguishing consideration: compare this with option A, “Exactly 0.5”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-062. An exact sampled coefficient is 0.8 for a 1 ms interval. What positive time constant is consistent with that coefficient?

A. Minus 4.4814 ms.

B. Approximately 0.2231 ms.

C. Approximately 4.4814 ms.

D. Exactly 5 ms.

Answer: C. Take the natural logarithm of 0.8 and solve time constant equal to minus 1 ms divided by that logarithm. The five-millisecond value would come from an Euler relation. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why the selected alternative fits: Approximately 4.4814 ms.

Distinguishing consideration: compare this with option A, “Minus 4.4814 ms”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-063. In the exact recurrence, current state is 0.2 V, target is 0.8 V and the coefficient is 0.25. What is the next state?

A. 0.65 V.

B. 0.95 V.

C. 0.20 V.

D. 0.35 V.

Answer: A. Weight the current state by 0.25 and the target by 0.75: 0.05 plus 0.60 equals 0.65 V. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why the selected alternative fits: 0.65 V.

Distinguishing consideration: compare this with option B, “0.95 V”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-064. Why does the exact sampled recurrence preserve the monotone segment for positive sample interval and time constant?

A. Its coefficient is independent of the sample interval.

B. Its coefficient is always zero, so every update reaches the target exactly.

C. Its coefficient lies strictly between zero and one, making the update a convex combination of current state and target.

D. Its coefficient is always negative, producing physical alternating convergence.

Answer: C. The positive exponential coefficient contracts the residual without changing its sign. This is the sampled form of the continuous solution. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why the selected alternative fits: Its coefficient lies strictly between zero and one, making the update a convex combination of current state and target.

Distinguishing consideration: compare this with option A, “Its coefficient is independent of the sample interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

V011-C05-MCQ-065. Forward Euler uses a sample interval equal to one quarter of the time constant. What is its residual multiplier?

A. 1.25.

B. 0.75.

C. Approximately 0.7788.

D. Minus 0.75.

Answer: B. Euler subtracts the interval-to-time-constant ratio from one. The exponential value approximately 0.7788 is the exact coefficient, which is close but different. Review: Equations 10H and 10I. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why the selected alternative fits: 0.75.

Distinguishing consideration: compare this with option A, “1.25”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-066. Forward Euler uses a sample interval 1.5 times the time constant. What behavior does its residual recurrence predict?

A. Alternating growth with multiplier minus 1.5.

B. An exact physical one-pole trajectory at the sample times.

C. Monotone decay with multiplier positive 0.5.

D. Alternating decay with multiplier minus 0.5.

Answer: D. The Euler coefficient is one minus 1.5. Its magnitude is less than one, but its negative sign creates alternation absent from the stipulated continuous relaxation. Review: Equation 10I. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why the selected alternative fits: Alternating decay with multiplier minus 0.5.

Distinguishing consideration: compare this with option A, “Alternating growth with multiplier minus 1.5”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

V011-C05-MCQ-067. At an Euler interval exactly twice the time constant, what happens to a nonzero residual?

A. It reaches zero after one step.

B. It necessarily grows in magnitude on every step.

C. It alternates with unchanged magnitude, so it does not asymptotically decay.

D. It follows the exact exponential coefficient exp of minus two.

Answer: C. The Euler coefficient is minus one at this boundary. The strict stability interval excludes equality at two. Review: Equation 10I. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why the selected alternative fits: It alternates with unchanged magnitude, so it does not asymptotically decay.

Distinguishing consideration: compare this with option A, “It reaches zero after one step”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-068. A simulation with an Euler interval 2.5 times the time constant produces alternating, increasing residuals. What should be checked before diagnosing physical instability?

A. The numerical update, whose multiplier is minus 1.5 and is unstable for this step.

B. Whether the continuous time constant should be made negative to match the simulation.

C. Only the logarithmic detector intercept, regardless of the simulated variable.

D. Only the RF generator phase, since the numerical scheme cannot cause growth.

Answer: A. The stated continuous one-pole system is stable for positive time constant. Euler is outside its stability interval and can manufacture the observed divergence. Review: Equation 10I; Application 5A.9. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why the selected alternative fits: The numerical update, whose multiplier is minus 1.5 and is unstable for this step.

Distinguishing consideration: compare this with option B, “Whether the continuous time constant should be made negative to match the simulation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range; Chapter 5 — Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range; Chapter 5 — Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation.

V011-C05-MCQ-069. Euler is used with interval equal to the time constant and predicts zero residual after one step. What is the corresponding exact residual fraction?

A. One, because a full time constant prevents decay.

B. Zero, because Euler is exact at that step size.

C. Minus one, because the exact solution changes sign.

D. Exp of minus one, approximately 0.3679.

Answer: D. Euler's coefficient is zero at this step, but the exact coefficient remains positive. Numerical finite-step extinction must not be mistaken for physical exact settling. Review: Equations 10H and 10I. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why the selected alternative fits: Exp of minus one, approximately 0.3679.

Distinguishing consideration: compare this with option A, "One, because a full time constant prevents decay"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

V011-C05-MCQ-070. The actual receiver implements a discrete controller rather than a sampled version of the continuous one-pole loop. What must govern its prediction?

A. Only the analog control-voltage units, which uniquely determine its dynamics.

B. Forward Euler with any chosen interval, irrespective of implemented logic.

C. The exponential recurrence automatically, because all digital controllers are exact samples of one pole.

D. Its own identified recurrence and state rules.

Answer: D. The exact recurrence is exact for the stipulated continuous model. A physically discrete controller can contain different updates, delays, quantization and mode transitions. Review: Application 5A.9. Source: §5.14 Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation (p. 2534)

Why the selected alternative fits: Its own identified recurrence and state rules.

Distinguishing consideration: compare this with option A, “Only the analog control-voltage units, which uniquely determine its dynamics”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation.

Review: Chapter 5 — Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation.

V011-C05-MCQ-072. The initial-state interval width is 0.2 V and the exact exponential factor is 0.25. What width remains when target and time constant are fixed?

A. 0.15 V.

B. 0.05 V.

C. 0.8 V.

D. 0.25 V.

Answer: B. The affine map multiplies the initial width by its positive coefficient. This is contraction of the initial-state contribution only. Review: Equation 10J. Source: Equation 10J. Propagation of an initial-state interval (p. 2524)

Why the selected alternative fits: 0.05 V.

Distinguishing consideration: compare this with option A, “0.15 V”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Review: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-073. A propagated voltage interval has width 0.05 V and the local gain slope is minus 40 dB/V. What is the corresponding gain-interval width?

A. Minus 2 dB.

B. 0.00125 dB.

C. 2 dB.

D. 40.05 dB.

Answer: C. Multiply voltage width by the absolute slope. A width is nonnegative even though the gain mapping reverses order. Review: Equations 10C and 10J.

Source: Equation 10C. Local control-to-gain law (p. 2522)

Why the selected alternative fits: 2 dB.

Distinguishing consideration: compare this with option A, “Minus 2 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10J. Propagation of an initial-state interval.

V011-C05-MCQ-074. A calibrated local gain slope is negative. When mapping an ordered voltage interval into an ordered gain interval, which endpoint supplies the minimum gain?

A. The smaller voltage endpoint.

B. The arithmetic midpoint regardless of the slope.

C. Both endpoints because interval propagation removes polarity.

D. The larger voltage endpoint.

Answer: D. A negative affine slope reverses order. Applying endpoint values without sorting would label the gain bounds incorrectly. Review: Equation 10J; Application 5A.10. Source: Equation 10J. Propagation of an initial-state interval (p. 2524)

Why the selected alternative fits: The larger voltage endpoint.

Distinguishing consideration: compare this with option A, “The smaller voltage endpoint”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10J. Propagation of an initial-state interval; Chapter 5 — Application 5A.10: Propagate an initial-state interval.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-075. Equation 10J propagates uncertainty only in the initial state while holding target and time constant fixed. What additional claim is unsupported?

A. That the resulting interval is the entire uncertainty budget for a gain correction.

B. That positive exponential weighting preserves voltage endpoint order.

C. That the initial-state contribution contracts by the stated exponential factor.

D. That the declared fixed-target model maps each included initial state.

Answer: A. Target, time constant, slope, timing and measurement effects can contribute separately. A partial deterministic bound must not be reported as a complete uncertainty result. Review: Equation 10J; Application 5A.10. Source: Equation 10J. Propagation of an initial-state interval (p. 2524)

Why the selected alternative fits: That the resulting interval is the entire uncertainty budget for a gain correction.

Distinguishing consideration: compare this with option B, “That positive exponential weighting preserves voltage endpoint order”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10J. Propagation of an initial-state interval; Chapter 5 — Application 5A.10: Propagate an initial-state interval.

Review: Chapter 5 — Equation 10J. Propagation of an initial-state interval; Chapter 5 — Application 5A.10: Propagate an initial-state interval.

V011-C05-MCQ-076. The initial voltage lies between 0.1 and 0.3 V, target is 0.6 V, slope magnitude is 20 dB/V, and time constant is 2 ms. What wait ensures the whole initial-state interval has gain error at most 0.1 dB?

A. Approximately 8.7641 ms using the midpoint.

B. Exactly 6 ms.

C. Approximately 9.2103 ms.

D. Approximately 4.6052 ms.

Answer: C. The largest initial voltage error is 0.5 V, giving 10 dB. Use 2 ms times ln of 100; choosing the midpoint would not cover the entire interval. Review: Equations 10E and 10J. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why the selected alternative fits: Approximately 9.2103 ms.

Distinguishing consideration: compare this with option A, “Approximately 8.7641 ms using the midpoint”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Equation 10J. Propagation of an initial-state interval.

V011-C05-MCQ-077. Initial-state uncertainty has nearly decayed away, but the target voltage remains uncertain. What can still limit a late-time gain correction?

A. Nothing, because contraction of initial uncertainty removes every parameter uncertainty.

B. Uncertainty in the limiting target and its calibrated gain mapping.

C. Only the discarded initial-state sign.

D. A mandatory return to the initial voltage after enough time constants.

Answer: B. As the state approaches its target, uncertainty in that target does not disappear. The initial-state contraction result must not be extended to fixed but uncertain parameters. Review: Equation 10J and its stated exclusions. Source: Equation 10J. Propagation of an initial-state interval (p. 2524)

Why the selected alternative fits: Uncertainty in the limiting target and its calibrated gain mapping.

Distinguishing consideration: compare this with option A, “Nothing, because contraction of initial uncertainty removes every parameter uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Review: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

V011-C05-MCQ-078. A gain correction uses calibrated control telemetry that is delayed relative to the RF samples during a fast transient. What is the main remaining problem?

A. Only the final settled gain matters for every sample in the record.

B. A fixed telemetry delay can never affect input-referred amplitude.

C. Calibration of the static gain map automatically removes all timing error.

D. The correction may apply a valid gain value to the wrong signal time.

Answer: D. A time-varying correction needs synchronized observations or an applicable delay correction. Static calibration alone does not establish temporal alignment. Review: Application 5A.3. Source: §5.8 Application 5A.3: Convert a control state into an output level (p. 2528)

Why the selected alternative fits: The correction may apply a valid gain value to the wrong signal time.

Distinguishing consideration: compare this with option A, “Only the final settled gain matters for every sample in the record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Application 5A.3: Convert a control state into an output level.

Review: Chapter 5 — Application 5A.3: Convert a control state into an output level.

V011-C05-MCQ-079. A strong signal outside a narrow displayed channel reduces a weak in-channel response. Which receiver mechanism is explicitly plausible in the chapter?

A. A narrower display necessarily disables all automatic gain changes.

B. Every out-of-display signal is physically excluded before all control detectors.

C. The weak source must have changed power because the displayed frequency is unchanged.

D. A wider shared detector controls gain used by the weak channel.

Answer: D. Display bandwidth and control-detector admission may differ. A shared path can let off-channel energy change the gain applied to the desired channel.

Review: Automatic Gain Control and Hidden State. Source: §5.16 Automatic Gain Control and Hidden State (p. 2536)

Why the selected alternative fits: A wider shared detector controls gain used by the weak channel.

Distinguishing consideration: compare this with option A, “A narrower display necessarily disables all automatic gain changes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Automatic Gain Control and Hidden State.

Review: Chapter 5 — Automatic Gain Control and Hidden State.

V011-C05-MCQ-080. AGC cannot be disabled during a quantitative observation. Which retained record best supports later amplitude interpretation?

A. Only the audio-volume setting.

B. Only the final settled gain, assumed constant throughout the event.

C. Only a normalized trace with its original gain history removed.

D. Calibrated, time-aligned gain state together with applicable signal-path and reference observations.

Answer: D. The control's changing effect must be reconstructible within its tested range. Display normalization and audio volume do not supply an RF gain history.

Review: Automatic Gain Control and Hidden State; Application 5A.3. Source: §5.8 Application 5A.3: Convert a control state into an output level (p. 2528)

Why the selected alternative fits: Calibrated, time-aligned gain state together with applicable signal-path and reference observations.

Distinguishing consideration: compare this with option A, "Only the audio-volume setting"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 5 — Application 5A.3: Convert a control state into an output level; Chapter 5 — Automatic Gain Control and Hidden State.

Review: Chapter 5 — Application 5A.3: Convert a control state into an output level; Chapter 5 — Automatic Gain Control and Hidden State.

V011-C05-MCQ-081. A detector is labeled RMS, but the waveform exceeds its stated crest-factor or bandwidth conditions. Which claim is unjustified?

A. That the operating conditions need to be retained in the record.

B. That the waveform may need a separately validated measurement path.

C. That the RMS label alone guarantees correct mean-square response for that waveform.

D. That detector recovery can affect a transient result.

Answer: C. An estimator name does not remove its physical limits. Waveform-dependent capability must be established for the actual peak and spectral content.

Review: Logarithmic Amplifiers, Detectors, and Scaling; source note 15. Source: §5.17 Logarithmic Amplifiers, Detectors, and Scaling (p. 2538)

Why the selected alternative fits: That the RMS label alone guarantees correct mean-square response for that waveform.

Distinguishing consideration: compare this with option A, “That the operating conditions need to be retained in the record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling; Chapter 5 — Model 5A: an identified one-pole gain-control response.

Review: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling; Chapter 5 — Model 5A: an identified one-pole gain-control response.

V011-C05-MCQ-082. A rare short excursion appears in a peak trace but not in a sparsely sampled display trace. What does this difference establish initially?

A. The peak trace must contain a false RF signal.

B. Different detector or selection operations can produce different observations of the same waveform.

C. Both traces necessarily estimate the same mean-square quantity.

D. The sample trace proves that the excursion never occurred.

Answer: B. A peak operation can retain an excursion missed by sample selection. Detector law, dwell and timing must be reconciled before comparing the reported quantities. Review: Verify the detector and control path as part of the IF result.

Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: Different detector or selection operations can produce different observations of the same waveform.

Distinguishing consideration: compare this with option A, “The peak trace must contain a false RF signal”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-083. Two equal-duration power levels are 0 dBm and 20 dBm. Their logarithmic average is 10 dBm. Which physical mean-power statement is correct?

A. The mean is 20 mW because the dBm values add.

B. The mean is 10 mW because averaging dBm is averaging power.

C. The mean is 50.5 mW, approximately 17.03 dBm.

D. The mean is 100 mW because the larger level determines every average.

Answer: C. Convert the two powers to 1 mW and 100 mW before equal-duration averaging. The mean of logarithms is a different operation. Review: Verify the detector and control path as part of the IF result; Chapter 8 averaging connection.

Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: The mean is 50.5 mW, approximately 17.03 dBm.

Distinguishing consideration: compare this with option A, “The mean is 20 mW because the dBm values add”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

V011-C05-MCQ-084. A displayed output remains flat as the input increases. What can the trace alone distinguish?

A. It does not uniquely distinguish successful leveling, limiting, clipping, detector saturation or software normalization.

B. It proves that only AGC is active.

C. It proves that a log amplifier has a perfectly calibrated intercept.

D. It proves that the receiver remains linear.

Answer: A. Several different mechanisms can create a plateau. Additional state records and a suitable reference are needed to establish valid transfer. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: It does not uniquely distinguish successful leveling, limiting, clipping, detector saturation or software normalization.

Distinguishing consideration: compare this with option B, “It proves that only AGC is active”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-085. A logarithmic detector is used close to its low-level floor. Which effects deserve particular attention?

A. Only high-power thermal damage, regardless of the weak input.

B. An assumption that logarithmic compression removes additive offsets.

C. A guarantee that its calibrated high-level slope extends indefinitely downward.

D. Noise and offsets that can dominate the indicated response.

Answer: D. The useful logarithmic law has a finite operating range. At low levels, residual noise and offsets can determine the indication and invalidate simple extrapolation. Review: Logarithmic Amplifiers, Detectors, and Scaling. Source: §5.17 Logarithmic Amplifiers, Detectors, and Scaling (p. 2538)

Why the selected alternative fits: Noise and offsets that can dominate the indicated response.

Distinguishing consideration: compare this with option A, “Only high-power thermal damage, regardless of the weak input”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Review: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

V011-C05-MCQ-086. Video bandwidth is reduced after detection while the IF filter is unchanged. Which interpretation is appropriate?

A. The displayed smoothing and temporal response can change without an identical change to RF/IF admission.

B. The operation changes only visual styling and cannot alter a measured peak.

C. All upstream overload exposure is reduced by the video-bandwidth ratio.

D. The IF selectivity necessarily narrows by exactly the same factor.

Answer: A. Post-detection filtering acts on a different quantity and stage. Its smoothing can change displayed peaks and timing without protecting earlier components. Review: Chapter Glossary: Video bandwidth; Logarithmic Amplifiers, Detectors, and Scaling. Source: §5.17 Logarithmic Amplifiers, Detectors, and Scaling (p. 2538)

Why the selected alternative fits: The displayed smoothing and temporal response can change without an identical change to RF/IF admission.

Distinguishing consideration: compare this with option B, “The operation changes only visual styling and cannot alter a measured peak”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling; Chapter 5 — VIDEO BANDWIDTH (glossary).

Review: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling; Chapter 5 — VIDEO BANDWIDTH (glossary).

Copyright 2026, James M. Atkinson

V011-C05-MCQ-087. A noise measurement uses an averaging detector and a selectable IF filter. Which information is needed to interpret the reported mean power?

A. Only a loaded-Q ratio without the noise weighting convention.

B. Only the nominal filter label and a claim that all averaging is equivalent.

C. The detector operation, actual effective bandwidth, gain state and acquisition conditions.

D. Only the peak value seen at any instant during the record.

Answer: C. Noise power depends on frequency weighting and the statistic applied. Detector selection and averaging history are part of the measurement definition. Review: Filter Shape, Selectivity, and Time Response; Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: The detector operation, actual effective bandwidth, gain state and acquisition conditions.

Distinguishing consideration: compare this with option A, “Only a loaded-Q ratio without the noise weighting convention”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Filter Shape, Selectivity, and Time Response.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Filter Shape, Selectivity, and Time Response.

V011-C05-MCQ-088. RF samples clip during a burst, but complete calibrated AGC telemetry is retained. Can gain correction reconstruct the lost waveform peaks uniquely?

A. Yes; the one-pole model supplies the original RF waveform as well as control state.

B. Yes; the final target voltage determines every clipped sample.

C. No; a gain record does not restore information lost through clipping.

D. Yes; dividing by the instantaneous gain reverses any saturation.

Answer: C. The state model predicts control, not missing signal values.

Noninvertible clipping can map many input peaks to the same recorded value.

Review: Application 5A.3; Verify the detector and control path as part of the IF result.

Source: §5.8 Application 5A.3: Convert a control state into an output level (p. 2528)

Why the selected alternative fits: No; a gain record does not restore information lost through clipping.

Distinguishing consideration: compare this with option A, “Yes; the one-pole model supplies the original RF waveform as well as control state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Application 5A.3: Convert a control state into an output level; Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-089. Two paths produce the same flat final output after a strong pulse, but one uses a limiter and the other a valid leveling loop. What distinguishes them for amplitude work?

A. Their measured transfer and retention of recoverable signal information, not the plateau alone.

B. Equal output level establishes identical input-referred amplitudes.

C. A limiter label always guarantees more faithful amplitude than calibrated gain control.

D. A stable plateau proves that neither path experienced recovery.

Answer: A. Similar scalar outputs can arise from different operations. A reference and state-dependent transfer test determine which amplitude claims remain supported. Review: Verify the detector and control path as part of the IF result.

Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: Their measured transfer and retention of recoverable signal information, not the plateau alone.

Distinguishing consideration: compare this with option B, “Equal output level establishes identical input-referred amplitudes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-090. A weak reference is carried through the same disturbed interval as the signal of interest. What condition is essential for that reference to assess continuing path validity?

A. Its absence is treated as successful verification regardless of the floor.

B. It is assumed unaffected simply because its input level is small.

C. It remains measurable with sufficient sensitivity and a known applicable transfer criterion.

D. Its last post-event sample is substituted for the entire event history.

Answer: C. An obscured or clipped reference cannot establish an uninterrupted valid transfer. Its own observability and acceptance condition must be retained.

Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: It remains measurable with sufficient sensitivity and a known applicable transfer criterion.

Distinguishing consideration: compare this with option A, “Its absence is treated as successful verification regardless of the floor”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-091. Why does the chapter's IF verification sequence first fix gain and disable avoidable automatic changes?

A. To prove that automatic gain control can never be used for measurements.

B. To remove the need to test detectors and bandwidths afterward.

C. To make every receiver stage physically linear at any input level.

D. To characterize the selected path without conflating its transfer with changing control state.

Answer: D. Holding state supports attribution of the measured response. The intended automatic mode is then tested separately with stimuli that exercise its dynamics. Review: Verify the detector and control path as part of the IF result.

Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: To characterize the selected path without conflating its transfer with changing control state.

Distinguishing consideration: compare this with option A, "To prove that automatic gain control can never be used for measurements"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-092. A repaired IF path passes a center-frequency tone amplitude test. Which further property remains unverified by that result alone?

A. The particular tested tone level at the stated center and configuration.

B. Whether an output indication was present in that test.

C. The identity of the applied test frequency in the retained setup record.

D. Skirt response, group-delay variation and transient recovery.

Answer: D. One scalar point cannot characterize a frequency- and time-dependent path. The chapter calls for representative passband, boundary and transient checks.

Review: IF Acceptance and Regression Tests. Source: §5.20 IF Acceptance and Regression Tests (p. 2543)

Why the selected alternative fits: Skirt response, group-delay variation and transient recovery.

Distinguishing consideration: compare this with option A, “The particular tested tone level at the stated center and configuration”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-093. A calibrated noise input is added after passband tone tests. What distinct property does it help exercise?

A. The receiver's entire control topology uniquely from one mean value.

B. Integrated path weighting and detector response under the declared effective bandwidth.

C. Every possible pulse rise time without any transient stimulus.

D. Only the center-frequency phase, independent of the noise spectrum.

Answer: B. Noise excites a frequency-weighted power observation different from a tone point. Its usefulness depends on the known spectrum and detector convention. Review: Verify the detector and control path as part of the IF result.

Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: Integrated path weighting and detector response under the declared effective bandwidth.

Distinguishing consideration: compare this with option A, "The receiver's entire control topology uniquely from one mean value"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-094. An audio path and a spectrum path give different amplitude histories for one event. What should a reproducible record identify?

A. A single average of both traces without retaining their separate origins.

B. Only one common receiver model number, assumed to define both paths.

C. Only the final displayed units, since matching units imply matching transfer.

D. Which IF takeoff, filter, detector and gain state produced each history.

Answer: D. Derived products can represent different filtered and controlled observations. Path identity makes the difference interpretable and supports valid comparison. Review: Verify the detector and control path as part of the IF result.

Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: Which IF takeoff, filter, detector and gain state produced each history.

Distinguishing consideration: compare this with option A, “A single average of both traces without retaining their separate origins”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-095. An IF filter is implemented digitally. Which change can still alter its physical or indicated response?

A. Only an analog mechanical adjustment inside the filter.

B. A change to sample clock, coefficients, scaling or firmware.

C. None; digital implementation establishes permanent calibration.

D. Only the RF antenna polarization, independent of the processing state.

Answer: B. Digital implementation reduces some analog drift but remains dependent on numerical and timing configuration. Its current transfer still needs applicable verification. Review: IF Alignment, Calibration, and Failure Localization.

Source: §5.18 IF Alignment, Calibration, and Failure Localization (p. 2540)

Why the selected alternative fits: A change to sample clock, coefficients, scaling or firmware.

Distinguishing consideration: compare this with option A, “Only an analog mechanical adjustment inside the filter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Review: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Copyright 2026, James M. Atkinson

V011-C05-MCQ-096. A stored amplitude-correction file produces an apparently correct center-tone level while the uncorrected analog response has degraded. What is the appropriate inference?

A. A numerical correction necessarily restores lost bandwidth and transient information.

B. The correction file proves that all analog stages remain unchanged.

C. The corrected point does not by itself establish unchanged physical path response.

D. An unchanged filename establishes the calibration's present applicability.

Answer: C. A correction can conceal one manifestation of drift while skirts, delay or dynamic range worsen. Direct response and applicability checks remain necessary. Review: IF Alignment, Calibration, and Failure Localization. Source: §5.18 IF Alignment, Calibration, and Failure Localization (p. 2540)

Why the selected alternative fits: The corrected point does not by itself establish unchanged physical path response.

Distinguishing consideration: compare this with option A, "A numerical correction necessarily restores lost bandwidth and transient information"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Review: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

V011-C05-MCQ-097. Firmware changes automatic IF selection at a bandwidth boundary. Which regression is most directly relevant?

A. Repeat only one unchanged center-tone setting far from the boundary.

B. Assume all old correction tables remain applicable because the RF connector is unchanged.

C. Repeat applicable level, response and transient cases on both sides of the changed boundary.

D. Test only the final display normalization without the active filter states.

Answer: C. Boundary behavior can alter path, gain and dynamics. The repeated cases should exercise the assumptions affected by the actual change. Review: IF Acceptance and Regression Tests. Source: §5.20 IF Acceptance and Regression Tests (p. 2543)

Why the selected alternative fits: Repeat applicable level, response and transient cases on both sides of the changed boundary.

Distinguishing consideration: compare this with option A, “Repeat only one unchanged center-tone setting far from the boundary”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Acceptance and Regression Tests.

V011-C05-MCQ-098. A proprietary control algorithm cannot be reconstructed from available documentation. What is an honest characterization outcome?

A. A claim that a fitted one-pole curve proves the hidden internal implementation.

B. An assumption that unknown control states can be removed by changing display units.

C. A universal recovery guarantee based on one small level step.

D. A retained input/output response and configuration-limited model with its tested scope stated.

Answer: D. An empirical model can be useful without an internal-circuit claim. Its limits and the observed configuration must remain explicit. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why the selected alternative fits: A retained input/output response and configuration-limited model with its tested scope stated.

Distinguishing consideration: compare this with option A, “A claim that a fitted one-pole curve proves the hidden internal implementation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-MCQ-099. A closing reference test passes after the event and after the chain has returned to its normal state. What does that check establish by itself?

A. All unexercised filter and gain combinations were also valid.

B. Every earlier transient sample was necessarily acquired in the same valid state.

C. Any preceding clipping can now be corrected from the passing final value.

D. The exercised functions met that check at its time, without proving uninterrupted validity during the earlier event.

Answer: D. A later check supplies temporally scoped evidence. Contemporaneous state and reference records are needed for claims about an earlier interval. Review: IF Acceptance and Regression Tests; Chapter 1 closing-verification qualification.

Source: §5.20 IF Acceptance and Regression Tests (p. 2543)

Why the selected alternative fits: The exercised functions met that check at its time, without proving uninterrupted validity during the earlier event.

Distinguishing consideration: compare this with option A, “All unexercised filter and gain combinations were also valid”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — IF Acceptance and Regression Tests; Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 5 — IF Acceptance and Regression Tests; Chapter 1 — Evidence Record and Closing Verification.

V011-C05-MCQ-100. An IF path passes the declared tone, noise, burst and recovery cases in specified configurations. What is the strongest warranted release statement?

A. The path met those stated criteria in the tested domain, with remaining configuration and waveform limits retained.

B. No future calibration or regression can be needed because all detector types are equivalent.

C. The simple fitted control equation is proven to describe every internal stage.

D. Every possible input waveform and hidden receiver state has been validated.

Answer: A. Acceptance is tied to measurands, criteria, configurations and stimulus coverage. It supports a bounded capability statement rather than an unlimited physical model. Review: IF Acceptance and Regression Tests; Table 5. Source: Table 5. Chapter 5 receiver controls and interpretation limits (p. 2545)

Why the selected alternative fits: The path met those stated criteria in the tested domain, with remaining configuration and waveform limits retained.

Distinguishing consideration: compare this with option B, “No future calibration or regression can be needed because all detector types are equivalent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 5 — Table 5. Chapter 5 receiver controls and interpretation limits; Chapter 5 — IF Acceptance and Regression Tests.

Review: Chapter 5 — Table 5. Chapter 5 receiver controls and interpretation limits; Chapter 5 — IF Acceptance and Regression Tests.

Fill-in-the-Blank Questions

V011-C05-FIB-001. An IF chain is a designed measurement _____, not merely the difference between two oscillator frequencies.

Answer: environment. Its filtering, gain, detection and sampling determine what quantity the output can represent. The numerical IF alone omits those operations.
Review: Intermediate Frequency as a Controlled Band. Source: §5.1 Intermediate Frequency as a Controlled Band (p. 2513)
Why this term is required: “environment” completes the stated technical proposition.
Question context: An IF chain is a designed measurement _____, not merely the difference between two oscillator frequencies
Basis and qualification: Chapter 5 — Intermediate Frequency as a Controlled Band.
Review: Chapter 5 — Intermediate Frequency as a Controlled Band.

Copyright 2026, James M. Atkinson

V011-C05-FIB-002. When audio and I/Q outputs come from different takeoffs, each observation should identify its source _____ and state.

Answer: path. Bandwidth and control may differ between outputs. Retaining the actual path makes their different responses interpretable. Review: Intermediate Frequency as a Controlled Band; Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why this term is required: “path” completes the stated technical proposition.

Question context: When audio and I/Q outputs come from different takeoffs, each observation should identify its source _____ and state

Basis and qualification: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Intermediate Frequency as a Controlled Band.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Intermediate Frequency as a Controlled Band.

V011-C05-FIB-009. A timing-sensitive IF calibration can use an impulse or step response to expose settling and _____.

Answer: ringing. A center-frequency tone cannot reveal the complete transient response. Retain the relevant input waveform and observation timing. Review: Filter Shape, Selectivity, and Time Response. Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

Why this term is required: “ringing” completes the stated technical proposition.

Question context: A timing-sensitive IF calibration can use an impulse or step response to expose settling and _____

Basis and qualification: Chapter 5 — Filter Shape, Selectivity, and Time Response.

Review: Chapter 5 — Filter Shape, Selectivity, and Time Response.

V011-C05-FIB-011. Group delay is the _____ derivative of transfer phase with respect to angular frequency.

Answer: negative. The minus sign makes a conventional linear phase lag correspond to positive delay. Use radians and compatible angular-frequency units.
Review: Chapter Glossary: Group delay. Source: §5.25 Detector dynamics and intermediate-frequency filters as temporally extended measurement operators (p. 2550)
Why this term is required: “negative” completes the stated technical proposition.
Question context: Group delay is the _____ derivative of transfer phase with respect to angular frequency
Basis and qualification: Chapter 5 — GROUP DELAY (glossary).
Review: Chapter 5 — GROUP DELAY (glossary).

Copyright 2026, James M. Atkinson

V011-C05-FIB-012. If transfer phase is differentiated with respect to frequency in hertz, the group-delay conversion includes division by _____.

Answer: two pi. The standard definition uses angular frequency. Its derivative differs from the hertz-frequency derivative by the factor relating those coordinates. Review: Choose an IF path for the quantity being measured; Chapter Glossary: Group delay. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518) Why this term is required: “two pi” completes the stated technical proposition. Question context: If transfer phase is differentiated with respect to frequency in hertz, the group-delay conversion includes division by _____
Basis and qualification: Chapter 5 — Choose an IF path for the quantity being measured; Chapter 5 — GROUP DELAY (glossary).
Review: Chapter 5 — Choose an IF path for the quantity being measured; Chapter 5 — GROUP DELAY (glossary).

V011-C05-FIB-013. Before differentiating phase through representation wraps, construct an appropriately _____ phase record.

Answer: unwrapped. A principal-value jump need not be a physical transfer discontinuity. The branch and coherent reference must support the derivative.

Review: Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why this term is required: “unwrapped” completes the stated technical proposition.

Question context: Before differentiating phase through representation wraps, construct an appropriately _____ phase record

Basis and qualification: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

Copyright 2026, James M. Atkinson

V011-C05-FIB-014. A phase-derived group-delay estimate needs transfer amplitude sufficiently _____ for the phase measurement to be meaningful.

Answer: measurable. Near the measurement floor, phase can become unstable and its derivative can amplify that instability. Review: Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why this term is required: “measurable” completes the stated technical proposition.

Question context: A phase-derived group-delay estimate needs transfer amplitude sufficiently _____ for the phase measurement to be meaningful

Basis and qualification: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

Copyright 2026, James M. Atkinson

V011-C05-FIB-015. An approximately unchanged delayed waveform requires flat amplitude and approximately _____ phase over its occupied band.

Answer: linear. A local group-delay value at one frequency is insufficient. The response must meet the relevant amplitude and phase conditions throughout the waveform band. Review: Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why this term is required: “linear” completes the stated technical proposition.

Question context: An approximately unchanged delayed waveform requires flat amplitude and approximately _____ phase over its occupied band

Basis and qualification: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

Copyright 2026, James M. Atkinson

V011-C05-FIB-016. A dramatic apparent delay at a deep notch may reflect an _____-conditioned phase measurement.

Answer: ill. The low transmitted amplitude can make phase sensitive to noise and residuals. A large number alone does not establish a reliable physical delay. Review: Choose an IF path for the quantity being measured. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Why this term is required: “ill” completes the stated technical proposition.

Question context: A dramatic apparent delay at a deep notch may reflect an _____-conditioned phase measurement

Basis and qualification: Chapter 5 — Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

V011-C05-FIB-017. The state, initial value and target in Model 5A are control voltages expressed in _____.

Answer: volts. They are not automatically RF amplitudes or power levels. The separate gain calibration gives their relevance to the signal path. Review: Equation 10A and its variable definitions. Source: Equation 10A. Identified control-state equation (p. 2520)

Why this term is required: “volts” completes the stated technical proposition.

Question context: The state, initial value and target in Model 5A are control voltages expressed in _____

Basis and qualification: Chapter 5 — Equation 10A. Identified control-state equation.

Review: Chapter 5 — Equation 10A. Identified control-state equation.

Copyright 2026, James M. Atkinson

V011-C05-FIB-018. The local signed gain-map slope has units of _____ per volt.

Answer: decibels. Multiplying that slope by a control-voltage displacement yields a gain change in decibels. Its sign determines control polarity. Review: Equation 10C.

Source: Equation 10C. Local control-to-gain law (p. 2522)

Why this term is required: “decibels” completes the stated technical proposition.

Question context: The local signed gain-map slope has units of _____ per volt

Basis and qualification: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

Copyright 2026, James M. Atkinson

V011-C05-FIB-019. Elapsed time and time constant must use the _____ time unit inside the exponential ratio.

Answer: same. The exponent is dimensionless. Convert seconds, milliseconds or microseconds consistently before substitution. Review: Equation 10B. Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “same” completes the stated technical proposition.

Question context: Elapsed time and time constant must use the _____ time unit inside the exponential ratio

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-FIB-020. The stipulated relaxation model requires its time constant to be strictly _____.

Answer: positive. This gives decaying rather than growing residual magnitude for positive elapsed time. The time-constant sign is separate from gain-map polarity.

Review: Equation 10A. Source: Equation 10A. Identified control-state equation (p. 2520)

Why this term is required: “positive” completes the stated technical proposition.

Question context: The stipulated relaxation model requires its time constant to be strictly _____

Basis and qualification: Chapter 5 — Equation 10A. Identified control-state equation.

Review: Chapter 5 — Equation 10A. Identified control-state equation.

Copyright 2026, James M. Atkinson

V011-C05-FIB-021. The signed residual is control voltage minus the constant _____.

Answer: target. Subtracting the target converts the state equation into exponential residual decay. A wrong target can distort the inferred decay. Review: Equation 10B.

Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “target” completes the stated technical proposition.

Question context: The signed residual is control voltage minus the constant _____

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-FIB-022. If the initial residual is zero, it stays _____ throughout the unchanged model segment.

Answer: zero. The system is already at the specified equilibrium. This does not imply that unrelated receiver stages are in a valid state. Review: Equations 10A and 10B. Source: Equation 10A. Identified control-state equation (p. 2520)

Why this term is required: “zero” completes the stated technical proposition.

Question context: If the initial residual is zero, it stays _____ throughout the unchanged model segment

Basis and qualification: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-FIB-023. A nonzero residual under one uninterrupted positive-time-constant segment preserves its _____.

Answer: sign. The exponential multiplier is positive. A target crossing therefore requires another explanation beyond the stipulated segment. Review: Equation 10B.

Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “sign” completes the stated technical proposition.

Question context: A nonzero residual under one uninterrupted positive-time-constant segment preserves its _____

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-FIB-024. Equation 10B assumes that the target is _____ during the modeled segment.

Answer: constant. A changed target requires a new applicable segment and state carryover, rather than continued use of the original equilibrium. Review: Equations 10B and 10G. Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “constant” completes the stated technical proposition.

Question context: Equation 10B assumes that the target is _____ during the modeled segment

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10G. Carry state across a target change.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10G. Carry state across a target change.

Copyright 2026, James M. Atkinson

V011-C05-FIB-025. Measured overshoot contradicts the _____ voltage approach predicted by the stated one-pole segment.

Answer: monotone. The state remains between its initial value and fixed target. Overshoot can indicate additional dynamics, target changes or measurement effects. Review: Equation 10B discussion. Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “monotone” completes the stated technical proposition.

Question context: Measured overshoot contradicts the _____ voltage approach predicted by the stated one-pole segment

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-FIB-026. After two time constants, the remaining residual is approximately _____ percent of its initial value.

Answer: 13.53. The residual multiplier is exp of minus two, approximately 0.135335. The completed fraction is instead approximately 86.47 percent. Review: Equation 10B; Application 5A.1. Source: Equation 10B. Control voltage and residual (p. 2521)
Why this term is required: “13.53” completes the stated technical proposition.
Question context: After two time constants, the remaining residual is approximately _____ percent of its initial value
Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.
Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.

Copyright 2026, James M. Atkinson

V011-C05-FIB-027. Control starts at 0.1 V and approaches 0.9 V. After a duration equal to the time constant times $\ln(4)$, the state is _____ V.

Answer: 0.7. The remaining residual fraction is one quarter. Add one quarter of minus 0.8 V to the 0.9 V target. Review: Equation 10B. Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “0.7” completes the stated technical proposition.

Question context: Control starts at 0.1 V and approaches 0.9 V. After a duration equal to the time constant times the state is _____ V

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-FIB-028. Control starts at 0.8 V and approaches 0.2 V. After a duration equal to the time constant times $\ln(2)$, the state is _____ V.

Answer: 0.5. The initial positive residual of 0.6 V is halved to 0.3 V, which is then added to the target. Review: Equation 10B. Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “0.5” completes the stated technical proposition.

Question context: Control starts at 0.8 V and approaches 0.2 V. After a duration equal to the time constant times the state is _____ V

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-FIB-029. For initial state and target both equal to 0.4 V, the state after any finite positive duration is _____ V.

Answer: 0.4. The residual is identically zero. The time constant controls perturbation decay but does not move an exact equilibrium. Review: Equation 10B.

Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “0.4” completes the stated technical proposition.

Question context: For initial state and target both equal to 0.4 V, the state after any finite positive duration is _____ V

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

V011-C05-FIB-030. A slope of minus 30 dB/V and a control rise of 0.2 V give a gain change of _____ dB.

Answer: minus 6. Multiply the signed quantities. Taking only the slope magnitude would reverse the physical interpretation. Review: Equation 10C. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why this term is required: “minus 6” completes the stated technical proposition.

Question context: A slope of minus 30 dB/V and a control rise of 0.2 V give a gain change of _____ dB

Basis and qualification: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

Copyright 2026, James M. Atkinson

V011-C05-FIB-031. Gain is 20 dB at 0.2 V with slope positive 25 dB/V. At 0.4 V, gain is _____ dB.

Answer: 25. The voltage displacement is 0.2 V and the gain increase is 5 dB. Add that change to the reference gain. Review: Equation 10C. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why this term is required: “25” completes the stated technical proposition.

Question context: Gain is 20 dB at 0.2 V with slope positive 25 dB/V. At 0.4 V, gain is _____ dB

Basis and qualification: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

Copyright 2026, James M. Atkinson

V011-C05-FIB-032. A fixed input of minus 80 dBm through valid gain of 25 dB gives output _____ dBm.

Answer: minus 55. Power level in dBm plus power gain in dB gives output level in dBm within the applicable transfer model. Review: Equation 10D. Source: Equation 10D. Output level and gain-error magnitude (p. 2522)

Why this term is required: “minus 55” completes the stated technical proposition.

Question context: A fixed input of minus 80 dBm through valid gain of 25 dB gives output _____ dBm

Basis and qualification: Chapter 5 — Equation 10D. Output level and gain-error magnitude.

Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude.

Copyright 2026, James M. Atkinson

V011-C05-FIB-033. To restore an unchanged output after a 10 dB input increase, the required gain change is _____ dB.

Answer: minus 10. The input-level and gain changes add in decibels. Their sum must be zero for the same output, subject to available gain range. Review: Equation 10D; Application 5A.4. Source: Equation 10D. Output level and gain-error magnitude (p. 2522)

Why this term is required: “minus 10” completes the stated technical proposition.

Question context: To restore an unchanged output after a 10 dB input increase, the required gain change is _____ dB

Basis and qualification: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Copyright 2026, James M. Atkinson

V011-C05-FIB-034. With a minus-50 dB/V slope, a 10 dB gain reduction requires a target-voltage change of _____ V.

Answer: plus 0.2. Divide minus 10 dB by minus 50 dB/V. The positive displacement must still lie in the calibrated control range. Review: Equation 10C; Application 5A.4.

Source: Equation 10C. Local control-to-gain law (p. 2522)

Why this term is required: “plus 0” completes the stated technical proposition.

Question context: With a minus-50 dB/V slope, a 10 dB gain reduction requires a target-voltage change of _____ V

Basis and qualification: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Copyright 2026, James M. Atkinson

V011-C05-FIB-035. With a positive 40 dB/V slope, an 8 dB gain reduction requires a target-voltage change of _____ V.

Answer: minus 0.2. A positive slope requires a falling control voltage for gain reduction. The polarity differs from the negative-slope example. Review: Equation 10C. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why this term is required: “minus 0” completes the stated technical proposition.

Question context: With a positive 40 dB/V slope, an 8 dB gain reduction requires a target-voltage change of _____ V

Basis and qualification: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

Copyright 2026, James M. Atkinson

V011-C05-FIB-036. Initial voltage-error magnitude is 0.25 V and the slope magnitude is 32 dB/V. Initial gain-error magnitude is _____ dB.

Answer: 8. Multiply the two magnitudes. This puts the initial error in the same units as a gain-error tolerance. Review: Equation 10D. Source: Equation 10D. Output level and gain-error magnitude (p. 2522)

Why this term is required: “8” completes the stated technical proposition.

Question context: Initial voltage-error magnitude is 0.25 V and the slope magnitude is 32 dB/V. Initial gain-error magnitude is _____ dB

Basis and qualification: Chapter 5 — Equation 10D. Output level and gain-error magnitude.

Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude.

Copyright 2026, James M. Atkinson

V011-C05-FIB-037. For initial gain error 8 dB, tolerance 0.2 dB and time constant 0.75 ms, the settling time is approximately _____ ms.

Answer: 2.7667. The ratio is 40, and 0.75 times ln 40 equals approximately 2.76666 ms. The logarithm is natural because the decay law is exponential. Review: Equation 10E. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why this term is required: “2.7667” completes the stated technical proposition.

Question context: For initial gain error 8 dB, tolerance 0.2 dB and time constant 0.75 ms, the settling time is approximately _____ ms

Basis and qualification: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Copyright 2026, James M. Atkinson

V011-C05-FIB-038. When initial error is already no greater than the positive tolerance, the earliest model acceptance time is _____.

Answer: zero. The piecewise definition avoids using a negative logarithmic time. Actual measurement acceptance still needs applicable model and calibration evidence. Review: Equation 10E. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why this term is required: “zero” completes the stated technical proposition.

Question context: When initial error is already no greater than the positive tolerance, the earliest model acceptance time is _____

Basis and qualification: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

V011-C05-FIB-039. Starting from nonzero error, exact zero residual is reached only as time tends to _____ in the ideal exponential model.

Answer: infinity. No finite positive time makes the exponential zero. A finite practical settling requirement therefore uses a positive tolerance. Review: Equation 10E qualification. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why this term is required: “infinity” completes the stated technical proposition.

Question context: Starting from nonzero error, exact zero residual is reached only as time tends to _____ in the ideal exponential model

Basis and qualification: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Copyright 2026, James M. Atkinson

V011-C05-FIB-040. The error ratio inside the settling logarithm must be _____.

Answer: dimensionless. Use numerator and denominator of the same quantity and unit, such as two gain-error magnitudes in decibels or two voltage-error magnitudes in volts. Review: Equation 10E. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why this term is required: “dimensionless” completes the stated technical proposition.

Question context: The error ratio inside the settling logarithm must be _____

Basis and qualification: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance.

Copyright 2026, James M. Atkinson

V011-C05-FIB-041. A time constant of 0.6 ms gives a 95-percent voltage-step completion time of approximately _____ ms.

Answer: 1.7974. Multiply 0.6 ms by $\ln(20)$. The remaining fraction is five percent, so this is distinct from one time constant. Review: Equation 10B; Application 5A.1.

Source: Equation 10B. Control voltage and residual (p. 2521)

Why this term is required: “1.7974” completes the stated technical proposition.

Question context: A time constant of 0.6 ms gives a 95-percent voltage-step completion time of approximately _____ ms

Basis and qualification: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Application 5A.1: Read a voltage step and its 95 percent settling time.

Copyright 2026, James M. Atkinson

V011-C05-FIB-042. Waiting three time constants leaves approximately _____ percent of a nonzero initial residual.

Answer: 4.979. Exp of minus three is approximately 0.049787. Whether this is adequate depends on the initial error and required absolute tolerance. Review: Equation 10E; Application 5A.2. Source: Equation 10E. Settling time for a positive error tolerance (p. 2522)

Why this term is required: “4.979” completes the stated technical proposition.

Question context: Waiting three time constants leaves approximately _____ percent of a nonzero initial residual

Basis and qualification: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement.

V011-C05-FIB-045. A zero local gain slope makes inversion from observed gain to control voltage _____.

Answer: uninformative. Gain has no local sensitivity to that voltage under the stated map. It does not prove that the physical state settles instantly. Review: Equation 10C and zero-slope qualification. Source: Equation 10C. Local control-to-gain law (p. 2522)

Why this term is required: “uninformative” completes the stated technical proposition.

Question context: A zero local gain slope makes inversion from observed gain to control voltage _____

Basis and qualification: Chapter 5 — Equation 10C. Local control-to-gain law.

Review: Chapter 5 — Equation 10C. Local control-to-gain law.

Copyright 2026, James M. Atkinson

V011-C05-FIB-046. Residuals of plus 0.16 V and plus 0.04 V separated by 1.4 ms give a time constant of approximately _____ ms.

Answer: 1.0099. The ratio is four, so divide 1.4 ms by $\ln(4)$. Additional data are needed to assess whether the fitted one-pole model is adequate. Review: Equation 10F. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)
Why this term is required: "1.0099" completes the stated technical proposition.
Question context: Residuals of plus 0.16 V and plus 0.04 V separated by 1.4 ms give a time constant of approximately _____ ms
Basis and qualification: Chapter 5 — Equation 10F. Two-point identification of the local time constant.
Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Copyright 2026, James M. Atkinson

V011-C05-FIB-047. Residuals of minus 0.18 V and minus 0.06 V separated by 0.8 ms give a time constant of approximately _____ ms.

Answer: 0.7282. The signed ratio is positive three. Divide 0.8 ms by $\ln(3)$; same-sign negative residuals satisfy the sign condition. Review: Equation 10F. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why this term is required: “0.7282” completes the stated technical proposition.

Question context: Residuals of minus 0.18 V and minus 0.06 V separated by 0.8 ms give a time constant of approximately _____ ms

Basis and qualification: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

V011-C05-FIB-048. Two nonzero residuals used in Equation 10F must have the _____ sign.

Answer: same. The uninterrupted exponential preserves residual sign. Taking absolute values of a genuine sign reversal would hide a model violation. Review: Equation 10F. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why this term is required: “same” completes the stated technical proposition.

Question context: Two nonzero residuals used in Equation 10F must have the _____ sign

Basis and qualification: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Copyright 2026, James M. Atkinson

V011-C05-FIB-049. For a positive fitted time constant, the later residual magnitude must be _____ than the earlier one.

Answer: smaller. The ratio of earlier to later same-sign residuals must exceed one, giving a positive logarithm for positive elapsed time. Review: Equation 10F. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why this term is required: “smaller” completes the stated technical proposition.

Question context: For a positive fitted time constant, the later residual magnitude must be _____ than the earlier one

Basis and qualification: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Copyright 2026, James M. Atkinson

V011-C05-FIB-050. The two residuals in a time-constant identification must refer to the _____ target.

Answer: same. Subtracting different targets would not produce two samples of the same homogeneous decay. Target changes require a segmented analysis. Review: Equation 10F. Source: Equation 10F. Two-point identification of the local time constant (p. 2523)

Why this term is required: “same” completes the stated technical proposition.

Question context: The two residuals in a time-constant identification must refer to the _____ target

Basis and qualification: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant.

V011-C05-FIB-051. A two-point exponential interpolation should be challenged using _____ observations before it is accepted as an adequate model.

Answer: additional. More times and relevant levels can expose wrong targets, floors, slew or multiple dynamics that two points cannot distinguish. Review: Application 5A.5. Source: §5.10 Application 5A.5: Identify a time constant from two signed residuals (p. 2530)

Why this term is required: “additional” completes the stated technical proposition.

Question context: A two-point exponential interpolation should be challenged using _____ observations before it is accepted as an adequate model

Basis and qualification: Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Review: Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Copyright 2026, James M. Atkinson

V011-C05-FIB-052. A small residual floor may arise from an incorrect target or a detector _____.

Answer: offset. A constant offset changes the apparent late residual. It should not automatically be interpreted as an extremely slow physical time constant. Review: Application 5A.5. Source: §5.10 Application 5A.5: Identify a time constant from two signed residuals (p. 2530)

Why this term is required: “offset” completes the stated technical proposition.

Question context: A small residual floor may arise from an incorrect target or a detector _____

Basis and qualification: Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Review: Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Copyright 2026, James M. Atkinson

V011-C05-FIB-053. An early approximately linear voltage ramp can indicate a _____ limit instead of ordinary small-change exponential response.

Answer: slew. A rate limit can dominate a large excursion even when a later local segment is well described by a pole. The regimes should be separated. Review: Application 5A.5; source note 15. Source: §5.10 Application 5A.5: Identify a time constant from two signed residuals (p. 2530)

Why this term is required: “slew” completes the stated technical proposition.

Question context: An early approximately linear voltage ramp can indicate a _____ limit instead of ordinary small-change exponential response

Basis and qualification: Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals; Chapter 5 — Model 5A: an identified one-pole gain-control response.

Review: Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals; Chapter 5 — Model 5A: an identified one-pole gain-control response.

V011-C05-FIB-055. At a target change, the next segment starts from the actual _____ state of the preceding segment.

Answer: terminal. Resetting to the old target would discard an unresolved residual. The physical state is carried forward under the stipulated finite-rate model. Review: Equation 10G. Source: Equation 10G. Carry state across a target change (p. 2523)

Why this term is required: “terminal” completes the stated technical proposition.

Question context: At a target change, the next segment starts from the actual _____ state of the preceding segment

Basis and qualification: Chapter 5 — Equation 10G. Carry state across a target change.

Review: Chapter 5 — Equation 10G. Carry state across a target change.

Copyright 2026, James M. Atkinson

V011-C05-FIB-056. Starting at 0.2 V toward target 1.0 V with exponential factor 0.5, the first segment ends at _____ V.

Answer: 0.6. The remaining displacement is half of minus 0.8 V. Add that minus 0.4 V residual to the 1.0 V target. Review: Equation 10G. Source: Equation 10G. Carry state across a target change (p. 2523)

Why this term is required: “0.6” completes the stated technical proposition.

Question context: Starting at 0.2 V toward target 1.0 V with exponential factor 0.5, the first segment ends at _____ V

Basis and qualification: Chapter 5 — Equation 10G. Carry state across a target change.

Review: Chapter 5 — Equation 10G. Carry state across a target change.

Copyright 2026, James M. Atkinson

V011-C05-FIB-057. Carry that 0.6 V state into a segment with target 0.4 V and exponential factor 0.25. The new terminal state is _____ V.

Answer: 0.45. One quarter of the initial 0.2 V displacement is 0.05 V, which remains above the new target. Review: Equation 10G. Source: Equation 10G. Carry state across a target change (p. 2523)

Why this term is required: “0.45” completes the stated technical proposition.

Question context: Carry that 0.6 V state into a segment with target 0.4 V and exponential factor 0.25. The new terminal state is _____ V

Basis and qualification: Chapter 5 — Equation 10G. Carry state across a target change.

Review: Chapter 5 — Equation 10G. Carry state across a target change.

V011-C05-FIB-063. The exact sampled coefficient is the exponential of the _____ sample-interval-to-time-constant ratio.

Answer: negative. Both interval and time constant are positive, so the coefficient is between zero and one. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why this term is required: “negative” completes the stated technical proposition.

Question context: The exact sampled coefficient is the exponential of the _____ sample-interval-to-time-constant ratio

Basis and qualification: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Copyright 2026, James M. Atkinson

V011-C05-FIB-064. For a sample interval equal to the time constant times $\ln(3)$, the exact residual multiplier is _____.

Answer: one third. Substitution gives exp of minus $\ln(3)$. The result is exact for the stipulated continuous one-pole model. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why this term is required: “one third” completes the stated technical proposition.

Question context: For a sample interval equal to the time constant times the exact residual multiplier is _____

Basis and qualification: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Copyright 2026, James M. Atkinson

V011-C05-FIB-065. With current state 0.3 V, target 0.9 V and exact coefficient one third, the next state is _____ V.

Answer: 0.7. The weights give 0.1 V from the current state plus 0.6 V from the target. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why this term is required: “0.7” completes the stated technical proposition.

Question context: With current state 0.3 V, target 0.9 V and exact coefficient one third, the next state is _____ V

Basis and qualification: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Copyright 2026, James M. Atkinson

V011-C05-FIB-066. For a positive interval and time constant, the exact coefficient lies strictly between _____ and _____.

Answer: zero; one. These bounds make the update a convex combination and preserve the residual sign. The endpoints are limiting cases, not finite positive-interval values. Review: Equation 10H. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why this term is required: “zero; one” completes the stated technical proposition.

Question context: For a positive interval and time constant, the exact coefficient lies strictly between _____ and _____

Basis and qualification: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence.

Copyright 2026, James M. Atkinson

V011-C05-FIB-067. An Euler interval equal to 0.4 time constants gives residual multiplier _____.

Answer: 0.6. Forward Euler uses one minus the normalized interval. It is an approximation to the exact exponential coefficient. Review: Equation 10I. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why this term is required: “0.6” completes the stated technical proposition.

Question context: An Euler interval equal to 0.4 time constants gives residual multiplier _____

Basis and qualification: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Copyright 2026, James M. Atkinson

V011-C05-FIB-068. An Euler interval equal to 1.2 time constants gives residual multiplier _____.

Answer: minus 0.2. The magnitude is less than one, so the sequence decays, but the negative sign makes it alternate across the target. Review: Equation 10I. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why this term is required: “minus 0” completes the stated technical proposition.

Question context: An Euler interval equal to 1.2 time constants gives residual multiplier _____

Basis and qualification: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Copyright 2026, James M. Atkinson

V011-C05-FIB-069. At an Euler interval of exactly two time constants, residual magnitude remains _____ while its sign alternates.

Answer: constant. The multiplier is minus one. This boundary does not provide asymptotic decay and is excluded from the strict stability interval. Review: Equation 10I. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why this term is required: “constant” completes the stated technical proposition.

Question context: At an Euler interval of exactly two time constants, residual magnitude remains _____ while its sign alternates

Basis and qualification: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Copyright 2026, James M. Atkinson

V011-C05-FIB-070. Forward-Euler asymptotic stability requires a positive normalized interval strictly less than _____.

Answer: two. The residual multiplier must have magnitude below one. Equality at two leaves undamped alternation. Review: Equation 10I. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why this term is required: “two” completes the stated technical proposition.

Question context: Forward-Euler asymptotic stability requires a positive normalized interval strictly less than _____

Basis and qualification: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Copyright 2026, James M. Atkinson

V011-C05-FIB-071. A nonalternating Euler residual requires the positive normalized interval to be no greater than _____.

Answer: one. At one the approximation sets the residual to zero in a single step; below one its multiplier is positive. This condition is stricter than stability alone.

Review: Equation 10I. Source: Equation 10I. Forward-Euler residual and its validity range (p. 2524)

Why this term is required: “one” completes the stated technical proposition.

Question context: A nonalternating Euler residual requires the positive normalized interval to be no greater than _____

Basis and qualification: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Copyright 2026, James M. Atkinson

V011-C05-FIB-072. A negative Euler residual multiplier can create simulated target _____ absent from the physical one-pole trajectory.

Answer: crossings or alternation. The exact continuous residual keeps its sign. Numerical oscillation must be distinguished from measured loop behavior. Review: Equations 10H and 10I. Source: Equation 10H. Exact sampled-state recurrence (p. 2524)

Why this term is required: “crossings or alternation” completes the stated technical proposition.

Question context: A negative Euler residual multiplier can create simulated target _____ absent from the physical one-pole trajectory

Basis and qualification: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

V011-C05-FIB-075. Because the exponential coefficient is positive, initial-state interval propagation preserves voltage endpoint _____.

Answer: order. Each endpoint undergoes the same increasing affine transformation. A subsequent negative gain slope can reverse gain order. Review: Equation 10J. Source: Equation 10J. Propagation of an initial-state interval (p. 2524)
Why this term is required: “order” completes the stated technical proposition.
Question context: Because the exponential coefficient is positive, initial-state interval propagation preserves voltage endpoint _____
Basis and qualification: Chapter 5 — Equation 10J. Propagation of an initial-state interval.
Review: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Copyright 2026, James M. Atkinson

V011-C05-FIB-076. Initial voltage 0.2 through 0.4 V, target 0.8 V and factor 0.5 give the state interval _____ through _____ V.

Answer: 0.5; 0.6. Half the lower and upper initial displacements remain, giving 0.8 minus 0.3 and 0.8 minus 0.2 V. Review: Equation 10J. Source: Equation 10J. Propagation of an initial-state interval (p. 2524)

Why this term is required: “0” completes the stated technical proposition.

Question context: Initial voltage 0.2 through 0.4 V, target 0.8 V and factor 0.5 give the state interval _____ through _____ V

Basis and qualification: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Review: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Copyright 2026, James M. Atkinson

V011-C05-FIB-077. The propagated interval 0.5 through 0.6 V has width _____ V.

Answer: 0.1. Subtract the lower bound from the upper bound. This is a deterministic state width, not a standard deviation. Review: Equation 10J. Source: Equation 10J. Propagation of an initial-state interval (p. 2524)

Why this term is required: “0.1” completes the stated technical proposition.

Question context: The propagated interval 0.5 through 0.6 V has width _____ V

Basis and qualification: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Review: Chapter 5 — Equation 10J. Propagation of an initial-state interval.

V011-C05-FIB-083. A strong off-channel signal can suppress a desired weak signal through a _____ AGC path.

Answer: shared. The controlling detector may admit a wider band than the displayed channel. Display absence does not prove absence from the control input.

Review: Automatic Gain Control and Hidden State. Source: §5.16 Automatic Gain Control and Hidden State (p. 2536)

Why this term is required: “shared” completes the stated technical proposition.

Question context: A strong off-channel signal can suppress a desired weak signal through a _____ AGC path

Basis and qualification: Chapter 5 — Automatic Gain Control and Hidden State.

Review: Chapter 5 — Automatic Gain Control and Hidden State.

Copyright 2026, James M. Atkinson

V011-C05-FIB-084. RMS detection must remain within applicable bandwidth and _____-factor limits for the actual waveform.

Answer: crest. High peaks relative to RMS level can violate physical detector conditions even when the average input seems acceptable. Review: Logarithmic Amplifiers, Detectors, and Scaling. Source: §5.17 Logarithmic Amplifiers, Detectors, and Scaling (p. 2538)

Why this term is required: “crest” completes the stated technical proposition.

Question context: RMS detection must remain within applicable bandwidth and _____-factor limits for the actual waveform

Basis and qualification: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Review: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Copyright 2026, James M. Atkinson

V011-C05-FIB-085. Video bandwidth describes filtering after _____ or in the display path.

Answer: detection. Its smoothing can alter trace timing and peaks without an identical change to earlier RF or IF admission. Review: Chapter Glossary: Video bandwidth. Source: §8.1.6 Video bandwidth, smoothing, and averaging (p. 4381)

Why this term is required: “detection” completes the stated technical proposition.

Question context: Video bandwidth describes filtering after _____ or in the display path

Basis and qualification: Chapter 5 — VIDEO BANDWIDTH (glossary).

Review: Chapter 5 — VIDEO BANDWIDTH (glossary).

V011-C05-FIB-086. To compute physical mean power from changing dB levels, convert to _____ power before averaging.

Answer: linear. A mean of logarithms represents a different quantity. The temporal weights and applicable detector selection must also be defined. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why this term is required: “linear” completes the stated technical proposition.

Question context: To compute physical mean power from changing dB levels, convert to _____ power before averaging

Basis and qualification: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-FIB-087. Equal-duration levels of 10 mW and 100 mW have physical mean power _____ mW.

Answer: 55. The arithmetic mean is taken in the linear power domain. Its logarithmic level is approximately 17.40 dBm, not the 15 dBm mean of the two dBm levels. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why this term is required: “55” completes the stated technical proposition.

Question context: Equal-duration levels of 10 mW and 100 mW have physical mean power _____ mW

Basis and qualification: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-FIB-088. Equal-duration levels of 0 dBm and 10 dBm have mean power 5.5 mW, corresponding to approximately _____ dBm.

Answer: 7.404. Ten times the base-ten logarithm of 5.5 gives 7.4036 dBm. Averaging the two logarithmic levels would instead give 5 dBm. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why this term is required: “7.404” completes the stated technical proposition.

Question context: Equal-duration levels of 0 dBm and 10 dBm have mean power 5.5 mW, corresponding to approximately _____ dBm

Basis and qualification: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-FIB-089. A peak detector can retain a rare _____ that an averaging operation weights only briefly.

Answer: excursion. Peak and mean operations answer different questions about the waveform. Their results need not agree even when both are functioning properly. Review: Logarithmic Amplifiers, Detectors, and Scaling. Source: §5.17 Logarithmic Amplifiers, Detectors, and Scaling (p. 2538)

Why this term is required: “excursion” completes the stated technical proposition.

Question context: A peak detector can retain a rare _____ that an averaging operation weights only briefly

Basis and qualification: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Review: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Copyright 2026, James M. Atkinson

V011-C05-FIB-090. A sample trace can _____ a short event when its selection times do not capture the excursion.

Answer: miss. Absence in that trace is not proof of absence from the physical waveform. Dwell, selection and timing are relevant. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why this term is required: “miss” completes the stated technical proposition.

Question context: A sample trace can _____ a short event when its selection times do not capture the excursion

Basis and qualification: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-FIB-091. At the low end of a log detector's range, noise and _____ can dominate the response.

Answer: offsets. A high-level calibrated slope does not justify unlimited downward extrapolation. The actual floor and operating range must be known. Review: Logarithmic Amplifiers, Detectors, and Scaling. Source: §5.17 Logarithmic Amplifiers, Detectors, and Scaling (p. 2538)

Why this term is required: "offsets" completes the stated technical proposition.

Question context: At the low end of a log detector's range, noise and _____ can dominate the response

Basis and qualification: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Review: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Copyright 2026, James M. Atkinson

V011-C05-FIB-092. A flat output at high input can arise from AGC, limiting, clipping, log-detector _____ or software normalization.

Answer: saturation. The plateau alone does not distinguish those mechanisms. A known reference and controlled path observations help identify valid transfer.

Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why this term is required: “saturation” completes the stated technical proposition.

Question context: A flat output at high input can arise from AGC, limiting, clipping, log-detector _____ or software normalization

Basis and qualification: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-FIB-093. Calibrated gain telemetry cannot recreate signal information lost through _____.

Answer: clipping. The control-state record and the RF waveform are different observations. Noninvertible saturation destroys distinctions that a gain correction cannot restore. Review: Application 5A.3. Source: §5.8 Application 5A.3: Convert a control state into an output level (p. 2528)

Why this term is required: “clipping” completes the stated technical proposition.

Question context: Calibrated gain telemetry cannot recreate signal information lost through _____

Basis and qualification: Chapter 5 — Application 5A.3: Convert a control state into an output level.

Review: Chapter 5 — Application 5A.3: Convert a control state into an output level.

Copyright 2026, James M. Atkinson

V011-C05-FIB-094. The chapter's verification sequence begins with _____ gain before testing the intended automatic-control dynamics.

Answer: fixed. Holding avoidable state changes supports interpretation of tones, noise and bursts. Automatic mode is then tested under its own conditions. Review: Verify the detector and control path as part of the IF result. Source: §5.19 Verify the detector and control path as part of the IF result (p. 2541)

Why this term is required: "fixed" completes the stated technical proposition.

Question context: The chapter's verification sequence begins with _____ gain before testing the intended automatic-control dynamics

Basis and qualification: Chapter 5 — Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-FIB-095. Digital IF response can depend on sample clocks, coefficients, scaling and _____.

Answer: firmware. Digital implementation does not make its physical frequency mapping or numerical transfer permanently invariant. Review: IF Alignment, Calibration, and Failure Localization. Source: §5.18 IF Alignment, Calibration, and Failure Localization (p. 2540)

Why this term is required: “firmware” completes the stated technical proposition.

Question context: Digital IF response can depend on sample clocks, coefficients, scaling and _____

Basis and qualification: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Review: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Copyright 2026, James M. Atkinson

V011-C05-FIB-096. Regression tests should exercise automatic filter and gain _____ because behavior can change when a mode switches.

Answer: boundaries. A passing point far from a transition does not validate switching, carried state or the new path. Test the conditions affected by the change. Review: IF Acceptance and Regression Tests. Source: §5.20 IF Acceptance and Regression Tests (p. 2543)

Why this term is required: “boundaries” completes the stated technical proposition.

Question context: Regression tests should exercise automatic filter and gain _____ because behavior can change when a mode switches

Basis and qualification: Chapter 5 — IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

V011-C05-FIB-097. Authorized observations before and after an IF stage can help _____ a response defect.

Answer: localize. Different stimuli exercise frequency response, detection and dynamics. The observation planes and injected path must be retained. Review: IF Alignment, Calibration, and Failure Localization. Source: §5.18 IF Alignment, Calibration, and Failure Localization (p. 2540)

Why this term is required: “localize” completes the stated technical proposition.

Question context: Authorized observations before and after an IF stage can help _____ a response defect

Basis and qualification: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Review: Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Copyright 2026, James M. Atkinson

V011-C05-FIB-098. A passing center-frequency tone cannot by itself validate filter skirts, group delay or transient _____.

Answer: recovery. The path has more degrees of behavior than one amplitude point can test. Representative spectral and temporal cases are needed. Review: IF Acceptance and Regression Tests. Source: §5.20 IF Acceptance and Regression Tests (p. 2543)

Why this term is required: “recovery” completes the stated technical proposition.

Question context: A passing center-frequency tone cannot by itself validate filter skirts, group delay or transient _____

Basis and qualification: Chapter 5 — IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

V011-C05-FIB-099. A closing check assesses the functions it exercises at the _____ of that check.

Answer: time. It cannot alone establish uninterrupted validity during an earlier acquisition, especially across overload or state changes. Review: IF Acceptance and Regression Tests; Chapter 1 closing-verification qualification. Source: §5.20 IF Acceptance and Regression Tests (p. 2543)

Why this term is required: “time” completes the stated technical proposition.

Question context: A closing check assesses the functions it exercises at the _____ of that check

Basis and qualification: Chapter 5 — IF Acceptance and Regression Tests; Chapter 1 — Evidence Record and Closing Verification.

Review: Chapter 5 — IF Acceptance and Regression Tests; Chapter 1 — Evidence Record and Closing Verification.

Copyright 2026, James M. Atkinson

V011-C05-FIB-100. A release statement should retain the tested configurations, waveform domain, criteria and unresolved _____.

Answer: limits. Bounded capability is the defensible outcome of a finite acceptance matrix. A local fit does not establish every hidden state or possible waveform.

Review: IF Acceptance and Regression Tests. Source: §5.20 IF Acceptance and Regression Tests (p. 2543)

Why this term is required: “limits” completes the stated technical proposition.

Question context: A release statement should retain the tested configurations, waveform domain, criteria and unresolved _____

Basis and qualification: Chapter 5 — IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Acceptance and Regression Tests.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C05-ESSAY-001. Derive the constant-target solution of Model 5A from its state equation. Explain which measured behaviors would contradict one uninterrupted segment and which physical claims the solution does not establish.

- Opening: Present a thesis that answers this precise question: Derive the constant-target solution of Model 5A from its state equation. Identify which evidence would falsify the proposed conclusion Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)
- Core terminology and scope: Define solution, equation, contradict in the question's particular technical setting; explain how uninterrupted, segment, claims differ if that distinction would change the analysis of "Derive the constant-target solution of Model 5A from its state equation" Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define the residual as the control voltage minus the fixed target Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the constant-target solution of Model 5A from its state equation to the claimed result, following "Application 5A.5: Identify a time constant from two signed residuals"; name the intermediate states and measurable outputs Source: §5.10 Application 5A.5: Identify a time constant from two signed residuals (p. 2530)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for the constant-target solution of Model 5A from its state equation. Its derivative is minus the residual divided by the positive time constant Source: §5.10 Application 5A.5: Identify a time constant from two signed residuals (p. 2530)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation” that resolves the question about the constant-target solution of Model 5A from its state equation; derive the relevant result with units and stated validity conditions Source: §5.14 Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation (p. 2534)
- Evidence and method: Specify the native observations, control records and calculations that would resolve the constant-target solution of Model 5A from its state equation. Integration gives where is the initial residual; adding the target gives the voltage solution in Equation 10B Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)
- Worked application or illustrative case: Build a worked example of “the constant-target solution of Model 5A from its state equation”, addressing this associated condition: Explain which measured behaviors would contradict one uninterrupted segment and which physical claims.... Define the residual as the control voltage minus the fixed target Source: §5.10 Application 5A.5: Identify a time constant from two signed residuals (p. 2530)

Copyright 2026, James M. Atkinson

- Alternative explanations and failure modes: Construct two plausible technical explanations for “the constant-target solution of Model 5A from its state equation”. Using “Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation”, specify a discriminator and the result expected under each explanation Source: §5.14 Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation (p. 2534)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to the constant-target solution of Model 5A from its state equation, including the effect of missing measurements and inconsistent operating conditions Source: §5.15 Application 5A.10: Propagate an initial-state interval (p. 2535)
- Scholarly synthesis and implications: Explain what the result about the constant-target solution of Model 5A from its state equation authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)
- Closing: Conclude by answering “Derive the constant-target solution of Model 5A from its state equation” using only the demonstrated evidence; state the remaining decisive verification step Source: §5.4 Model 5A: an identified one-pole gain-control response (p. 2519)

V011-C05-ESSAY-004. A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V. The initial control is 0.2 V, the new target remains in range, and the identified time constant is 1.2 ms. Find the target, the control at 0.6 ms, and the remaining output rise. Explain the control-polarity check.

- Opening: Present a thesis that answers this precise question: A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V. Identify which evidence would falsify the proposed conclusion Source: §5.9 Application 5A.4: Check the required control polarity after a level step (p. 2529)
- Core terminology and scope: Define step, slope, target in the question's particular technical setting; explain how identified, remaining, rise differ if that distinction would change the analysis of "A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V" Source: §5.9 Application 5A.4: Check the required control polarity after a level step (p. 2529)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Restoring the previous output requires a gain change of minus 15 dB Source: §5.9 Application 5A.4: Check the required control polarity after a level step (p. 2529)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V to the claimed result, following "Application 5A.10: Propagate an initial-state interval"; name the intermediate states and measurable outputs Source: §5.15 Application 5A.10: Propagate an initial-state interval (p. 2535)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V. Dividing by minus 30 dB/V gives a positive 0.5 V target change, so the target is 0.7 V Source: §5.15 Application 5A.10: Propagate an initial-state interval (p. 2535)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 5A.2: Set a gain-error settling requirement” that resolves the question about A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V; derive the relevant result with units and stated validity conditions Source: §5.7 Application 5A.2: Set a gain-error settling requirement (p. 2527)
- Evidence and method: Specify the native observations, control records and calculations that would resolve A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V. At half a time constant the state is 0.3967347 V Source: §5.9 Application 5A.4: Check the required control polarity after a level step (p. 2529)
- Worked application or illustrative case: Build a worked example of “A 15 dB input step must be leveled by a gain map with slope minus 30 dB/V”, addressing this associated condition: The initial control is 0.2 V, the new target remains in range, and the identified time constant is 1.2 ms. Restoring the previous output requires a gain change of minus 15 dB Source: §5.15 Application 5A.10: Propagate an initial-state interval (p. 2535)

Discussion Questions

[Discussion instructions: For each discussion question, prepare approximately 500 spoken words for delivery over 2.5–3 minutes (approximately 167–200 words per minute). Address the ten subject prompts below in their stated order. Use the opening to frame the issue and the closing to synthesise the principal findings, conclusions and unresolved questions.]

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-001. Should a team choose the narrowest IF filter whenever the displayed noise floor improves?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Should a team choose the narrowest IF filter whenever the displayed noise floor improves?” Put this particular dispute to the panel: Should a team choose the narrowest IF filter whenever the displayed noise floor improves. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

- 02. Student A, terminology and scope: Agree the operational meanings of narrowest, filter, displayed and noise, floor, improves in “Should a team choose the narrowest IF filter whenever the displayed noise floor improves”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of whether a team choose the narrowest IF filter whenever the displayed noise floor improves; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Filter Shape, Selectivity, and Time Response”. A narrower response can reduce admitted noise while changing settling and the signal itself Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a team choose the narrowest IF filter whenever the displayed noise floor improves; explain what each record can establish State what the existing

Copyright 2026, James M. Atkinson

record establishes, what it does not establish, and which further measurement would change your opinion. Source: §5.13 Application 5A.8: Compare burst duration with control settling (p. 2533)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Filter Shape, Selectivity, and Time Response”. A narrower response can reduce admitted noise while changing settling and the signal itself Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Ask what quantity the observation must preserve: tone separation, channel power, modulation, onset time or peak Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving whether a team choose the narrowest IF filter whenever the displayed noise floor improves: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a team choose the narrowest IF filter whenever the displayed noise floor improves; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §5.13 Application 5A.8: Compare burst duration with control settling (p. 2533)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving whether a team choose the narrowest IF filter whenever the displayed noise floor improves: specify the altered receiver state or source condition, predicted

change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving whether a team choose the narrowest IF filter whenever the displayed noise floor improves, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving whether a team choose the narrowest IF filter whenever the displayed noise floor improves: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to

Copyright 2026, James M. Atkinson

retain, qualify or reject the conclusion. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for whether a team choose the narrowest IF filter whenever the displayed noise floor improves. Require a measured transfer or a representative stimulus for the intended quantity Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §5.13 Application 5A.8: Compare burst duration with control settling (p. 2533)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving whether a team choose the narrowest IF filter whenever the displayed noise floor improves, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §5.2 Filter Shape, Selectivity, and Time Response (p. 2514)

Copyright 2026, James M. Atkinson

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for whether a team choose the narrowest IF filter whenever the displayed noise floor improves. Require a measured transfer or a representative stimulus for the intended quantity Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §5.13 Application 5A.8: Compare burst duration with control settling (p. 2533)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about whether a team choose the narrowest IF filter whenever the displayed noise floor improves and Ask what quantity the observation must preserve: tone separation, channel power, modulation, onset time or…; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §5.24 Intermediate-frequency detector memory, settling and comparable measurement statistics (p. 2548)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “whether a team choose the narrowest IF filter whenever the displayed noise floor improves”, addressing “Ask

Copyright 2026, James M. Atkinson

what quantity the observation must preserve: tone separation, channel power, modulation, onset time or…"; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on "Should a team choose the narrowest IF filter whenever the displayed noise floor improves", specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of "Should a team choose the narrowest IF filter whenever the displayed noise floor improves". Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion. Source: §5.3 Choose an IF path for the quantity being measured (p. 2518)

Essay Guidance

V011-C05-ESSAY-001 — Define the residual as the control voltage minus the fixed target. Its derivative is minus the residual divided by the positive time constant. Integration gives $e(t)=e_0\exp(\frac{-t}{\tau})$, where e_0 is the initial residual; adding the target gives the voltage solution in Equation 10B. Retain voltage units for the state and matched time units in the dimensionless exponent. Since the exponential is positive and decreases from one, the residual keeps its sign and the voltage moves monotonically between the initial state and target. Overshoot, a delayed start, persistent oscillation or a sign reversal therefore cannot be explained by the same uninterrupted segment. They may indicate additional dynamics, a changed target, a hold state or measurement error; the equation alone does not select among those explanations. A voltage fit also does not supply RF gain without the calibrated signed local map. It neither identifies the full feedback topology nor validates clipping, slew or recovery outside its fitted domain. A sound answer separates the mathematical consequence from the empirical evidence needed to apply it. Review: Equations 10A–10C; Model 5A introduction.

Review: Chapter 5 — Equation 10A. Identified control-state equation; Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Model 5A: an identified one-pole gain-control response.

V011-C05-ESSAY-002 — Use consistent frequency units to obtain Q equal to 10.7 divided by 0.180, approximately 59.44. The stated width ratio is 720 divided by 180, or 4. Label its two attenuation levels explicitly; do not silently compare it with a shape factor defined using minus-6 dB width. These two scalars still omit passband ripple, the detailed skirts, transfer phase, group-delay variation and impulse response. A burst can be shorter than the path's settling time even when its nominal occupied spectrum seems to fit. The measured peak also depends on detector operation and the instant at which it is sampled. Establish the actual burst waveform, path response and observation timing, then verify peak transfer with an applicable calibrated transient. A continuous center-frequency gain correction is not enough. Equal loaded Q or equal width ratio in another filter does not guarantee equivalent temporal response or noise weighting. The report should retain the bandwidth definitions and the peak-specific verification separately. Review: Equation 9; Filter Shape, Selectivity, and Time Response; Hypothetical Case Adjudication.

Review: Chapter 5 — Equation 9. Loaded quality factor; Chapter 5 — Filter Shape, Selectivity, and Time Response; Chapter 5 — Hypothetical Case Adjudication: Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-003 — The elapsed ratio is 1.5, so the remaining voltage residual is minus 0.6 times exp of minus 1.5 V. The state is 0.6161219 V. Subtract the reference voltage and apply the signed slope to obtain 15.68573 dB gain; output is minus 56.31427 dBm. At the 0.75 V target, gain is 11 dB and output is minus 61 dBm. The initial gain-error magnitude relative to that target is 35 times 0.6, or 21 dB. The settling expression is 0.8 times ln of 105 ms, giving 3.72317 ms. The whole monotone voltage trajectory lies inside the stated calibration range, but the calculation additionally assumes fixed RF input and a valid signal path. It does not establish that an earlier stage avoids compression. The final gain must not be applied to all earlier samples; a time-resolved correction needs the calibrated control state aligned to the RF record. Retain the tolerance units and calibration uncertainty when converting this theoretical wait into an acceptance decision. Review: Equations 10B–10E; Applications 5A.2 and 5A.3.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement; Chapter 5 — Application 5A.3: Convert a control state into an output level.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-004 — Restoring the previous output requires a gain change of minus 15 dB. Dividing by minus 30 dB/V gives a positive 0.5 V target change, so the target is 0.7 V. At half a time constant the state is 0.3967347 V. Its 0.1967347 V rise reduces gain by 5.90204 dB, leaving an output rise of 9.09796 dB. This is also 15 times exp of minus 0.5 dB, the residual correction still required. A falling control voltage under this negative slope would increase gain and initially worsen the output rise. The remaining transient does not imply that the steady-state target is wrong. Check the whole control range, available gain range and RF-path validity before assigning the result to a real receiver. If another input transition occurs before settling, carry the actual state into the next segment. A changed detector or gain range can also require a different identified slope or time constant. Review: Equations 10C, 10D and 10G; Application 5A.4.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-005 — The two residuals have the same sign and decrease in magnitude. Their ratio is five over a 1.2 ms separation, giving a time constant of 1.2 divided by $\ln(5)$, or 0.7456019 ms. Extrapolating the first residual backward gives approximately minus 0.2243023 V at the time origin. From 1.5 to 2.1 ms, multiply minus 0.03 V by exp of minus 0.6 divided by the fitted time constant, giving approximately minus 0.0134164 V. An additional point should challenge that prediction using the measurement uncertainty and the validity of the common target. A material disagreement is evidence to investigate, not a reason to discard the point automatically. A wrong target, detector offset, slew-limited early interval or multiple dynamics can invalidate a single exponential. Retain the signed residuals, actual time reference and measured target. Two-point interpolation alone does not identify the loop's internal topology or justify transfer to other gain states and input excursions. Review: Equation 10F; Application 5A.5.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-006 — The first segment leaves the initial minus 0.8 V residual multiplied by exp of minus two thirds. Its terminal state is approximately 0.4892663 V. Use that value as the second initial state: the remaining displacement from 0.3 V is 0.1892663 V times exp of minus 0.8 divided by 1.5. The final state is approximately 0.4110324 V. Incorrectly restarting from 0.9 V would instead give approximately 0.6519877 V, an overestimate of about 0.2409554 V. The error arises from assuming an equilibrium that the first interval never reached. Explain that the state is continuous under this finite-rate model even though the target and time constant change. The result requires both segment parameters to be applicable and the transition time to be known. In repeated bursts, preserve enough history to determine the initial state or establish a validated periodic trajectory; a trigger does not reset the physical control. Review: Equation 10G; Application 5A.6.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-007 — Attack ends at approximately 0.6661219 V, calculated from a 1.5-time-constant segment. The explicitly stipulated hold retains that state for 0.4 ms. Release then lasts only 0.8 ms, half its own time constant, giving final state approximately 0.4827172 V. If release were incorrectly started immediately after attack, the full 1.2 ms remainder would be used and the predicted final state would be approximately 0.4201804 V. The two values differ by about 0.0625368 V because a hold is not equivalent to a slower exponential. State what event starts the timer, what quantity is held and when release begins. The constructed hold rule is part of this example, not a universal AGC behavior. A real receiver may reset or retrigger its timer on additional events, and that logic must be observed or specified. Separate attack, hold and release records make later weak-signal suppression interpretable. Review: Equation 10G discussion; Application 5A.7.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.7: Use separately identified attack and release constants.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-008 — The elapsed ratio is 0.0625, so step completion is one minus exp of minus 0.0625, approximately 6.05869 percent. The voltage reaches approximately 0.2424109 V. Its 0.0424109 V increase changes gain by minus 1.69643 dB, leaving an output rise of approximately 26.30357 dB under the valid small-signal model. The 95-percent time is 4 times $\ln(20)$, or 11.98293 ms, much longer than the burst. The final target would provide the required minus 28 dB gain correction, but it is not approached closely during this short event. These results predict only the identified control and gain response. The initial RF peak can exceed an earlier stage's valid range before control acts, and telemetry or detector bandwidth can hide that peak. Record a suitable signal-path observable as well as control state. Do not use the model to reconstruct clipped samples or claim successful transient protection from the eventual gain reduction. Review: Equations 10B–10E; Application 5A.8.

Review: Chapter 5 — Equation 10B. Control voltage and residual; Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.8: Compare burst duration with control settling.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-009 — The normalized interval is 1.5. The exact residual coefficient is exp of minus 1.5, approximately 0.2231302; after five steps the residual is 0.6 times exp of minus 7.5, approximately 0.000331851 V. Its sign stays positive and its magnitude decays monotonically. Euler instead uses one minus 1.5, or minus 0.5. Five steps give minus 0.01875 V. This Euler sequence is asymptotically stable because the coefficient magnitude is below one, but it alternates across the target and does not reproduce the stipulated physical one-pole samples. Stability alone is therefore not an accuracy or monotonicity certificate. At an interval ratio of two, Euler would have undamped sign alternation; above two its magnitude would grow. The exact recurrence avoids this approximation error for the stated model. If the implemented controller is physically discrete, identify that controller's actual update rather than assuming the continuous model is authoritative. Review: Equations 10H and 10I; Application 5A.9.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range; Chapter 5 — Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-010 — The exponential factor is exp of minus two. Mapping the initial endpoints gives approximately 0.5823324 through 0.5958659 V. The negative slope reverses endpoint order in gain, giving approximately 12.16536 through 12.70671 dB; its width is 0.541341 dB. Final gain at 0.65 V is 10 dB, so the largest error at 1 ms is 2.70671 dB. The largest initial voltage error is 0.5 V, corresponding to 20 dB. To cover the whole interval, use 0.5 times ln of 100 ms, giving 2.302585 ms. A midpoint calculation would not cover all allowed initial states. These are deterministic bounds with fixed target, time constant and slope, not a probabilistic confidence interval. A complete gain-correction uncertainty assessment also considers those parameters, calibration, timing alignment and any departures from the stipulated path. Do not describe contraction of the initial-state interval as removal of all measurement uncertainty. Review: Equations 10C, 10E and 10J; Application 5A.10.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Equation 10J. Propagation of an initial-state interval; Chapter 5 — Application 5A.10: Propagate an initial-state interval.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-011 — The linear power gains are 1, 10 and 100. With the stated durations, mean power gain is the weighted sum 1 plus 20 plus 100 divided by 4, or 30.25. Its logarithmic equivalent is approximately 14.80725 dB, so mean output is minus 45.19275 dBm. The time-weighted arithmetic mean gain is instead 10 dB, which would give minus 50 dBm and answers a different question. For a time-resolved input estimate, apply the calibrated gain corresponding to each actual signal sample or interval before forming the intended power statistic. Retain timing alignment, gain transitions and the detector's operation. A mean gain value cannot generally reverse a nonlinear averaging order. These calculations assume fixed input, valid linear transfer in each state and no missing clipped data. An AGC history may be useful for reconstruction, but it does not supply information destroyed by saturation or absent from the acquisition. Review: Equation 10D discussion; Verify the detector and control path as part of the IF result; Chapter 8 connection.

Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-012 — Convert the frequency span to angular-frequency span by multiplying 200000 Hz by two pi. The negative phase slope divided by that span gives positive group delay approximately 3 microseconds. State that the finite-difference calculation represents a constant slope only because linear phase has been stipulated. The amplitude variation still weights spectral components differently, so exact unchanged-copy behavior does not follow. Whether the distortion is acceptable depends on the waveform and its amplitude-fidelity tolerance; the given plus-or-minus 1 dB variation cannot simply be ignored. A single center-frequency delay would be weaker evidence than the full-band linear-phase condition supplied here. If the transfer becomes too small near a notch, phase and its derivative may also become ill-conditioned. Preserve the phase reference, unwrap procedure, frequency interval and response magnitude. The result is a frequency-domain descriptor with stated conditions, not a universal transit-time claim for arbitrary pulses. Review: Choose an IF path for the quantity being measured; Chapter Glossary: Group delay.

Review: Chapter 5 — Choose an IF path for the quantity being measured; Chapter 5 — GROUP DELAY (glossary).

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-013 — The farthest initial endpoint is 0.1 V, with 0.5 V error, giving a maximum initial gain error of 25 dB. The slowest admissible decay uses 1.2 ms. The conservative wait is therefore 1.2 times ln of 125 ms, approximately 5.79398 ms. Using the faster 0.8 ms endpoint would give approximately 3.86265 ms and would not cover the slower allowed case. The argument uses monotonic dependence of residual magnitude on the initial error magnitude and on the positive time constant for fixed elapsed time. It does not assign probabilities to the endpoints. The target and slope were held fixed, and the gain law and signal path were assumed valid throughout. Uncertainty in those quantities, telemetry timing, detector response and model adequacy remains outside this bound. If the target itself is uncertain, late-time convergence to a target does not remove uncertainty about its gain. Report the covered parameter domain explicitly. Review: Equations 10E and 10J; Application 5A.10 qualification.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Equation 10J. Propagation of an initial-state interval; Chapter 5 — Application 5A.10: Propagate an initial-state interval.

V011-C05-ESSAY-014 — Actual gain at 1 ms is 5 plus 20 times exp of minus one, approximately 12.35759 dB. The stale value from 0.8 ms is approximately 13.98658 dB. Subtracting that stale, larger gain from the actual output underestimates the input level by approximately 1.62899 dB. The sign matters: the software removes too much gain while the true gain is decreasing. This example isolates timing misalignment; it assumes the static gain calibration and the RF observations themselves are valid. A correction requires a measured relative delay or a synchronized record, with interpolation justified over the relevant dynamics. The final settled gain cannot repair the history, and fitting a control curve cannot reconstruct clipped or otherwise lost RF samples. Retain the physical time origin, telemetry timestamps and the applied alignment operation so the input-referred result can be reproduced. Review: Equation 10D; Application 5A.3.

Review: Chapter 5 — Equation 10D. Output level and gain-error magnitude; Chapter 5 — Application 5A.3: Convert a control state into an output level.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-015 — Begin with the actual path identity, reference planes, gain state and filter configuration. A swept or stepped calibrated tone can characterize passband amplitude and skirts and provides useful common response evidence. Tone amplitude needs the applicable frequency and level correction. Integrated channel power additionally needs the power weighting, effective bandwidth and detector or numerical integration convention across the occupied band. Burst peak requires a suitable impulse or step response, sufficient acquisition and detector bandwidth, known timing and peak-handling capability. A long-record energy agreement does not establish the original peak. Test fixed gain first to separate path response from control motion, then repeat relevant stimuli in the intended automatic mode. Preserve the stimulus waveform, reference measurements, response limits and uncertainty appropriate to each measurand. Do not treat one successful center-tone calibration or a shared bandwidth label as validation of all three quantities. The output should be a response matrix linked to specific measurement claims. Review: Filter Shape, Selectivity, and Time Response; Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Filter Shape, Selectivity, and Time Response.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-016 — Retain the actual transition time, range identity and control state. Apply the calibrated gain law belonging to each range over its valid voltage and signal interval; do not continue the old slope merely because the telemetry voltage is continuous. A range switch can produce an actual gain step, so continuity of RF gain is a measurement question rather than an automatic constraint. The control target and dynamic parameters can also change, requiring an applicable new segment with the actual carried state or the measured reset behavior. Synchronize the RF record with the state transition and mark any interval in which the transfer is not characterized. Verify the boundary using known stimuli on both sides and, where relevant, during the switch. Preserve correction-table identity and the observations supporting applicability. A numerically smooth corrected trace should not be manufactured by assuming away a physical discontinuity. Report any missing or invalid transition data explicitly. Review: Equations 10C and 10G; IF Acceptance and Regression Tests.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-017 — Maintain a known weak reference at the declared input plane and document the strong signal's delivered level and spectrum. Record control state and the path feeding the control detector, which may be wider than the displayed channel. Compare fixed-gain and intended automatic-gain operation while controlling other settings. If the weak response changes in accordance with calibrated control gain, that supports shared-control suppression, but verify that the reference remains measurable and the path remains linear. A fixed-gain result can still reveal overload or gain compression, so compare bounded strong-signal levels and appropriate attenuation or filtering with the desired reference preserved. Where accessible, observations before and after detection help localize the mechanism. A genuinely fixed injected weak reference removes source fading as the explanation for its own change, though it does not establish the behavior of a separate environmental source. Retain state, recovery and sensitivity limits, and avoid treating disappearance in the narrow display as proof that the blocker never reached the receiver. Review: Automatic Gain Control and Hidden State; Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Automatic Gain Control and Hidden State.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-018 — Each detector applies a different operation and often a different temporal selection. A peak can retain a rare excursion; a sample can miss it; a mean-square operation weights power over its stated interval; a mean of logarithmic levels gives another statistic. Burst duty, dwell, sample selection, averaging count and video filtering affect the comparison. RMS labeling does not remove bandwidth, level, crest-factor or recovery limits. Establish which physical quantity is required, then express the relevant detector operation and calibration under the actual waveform. Compare paths only after accounting for filter weighting and gain history. A quieter-looking trace is not inherently more accurate, and matching display units do not establish matching measurands. Retain raw or native observations when available so a valid alternate statistic can be reproduced. If a detector clips or misses the event, no change of averaging convention restores the absent information. Distinguish a legitimate difference in estimators from a failure of a device to meet its stated operating conditions. Review: Logarithmic Amplifiers, Detectors, and Scaling; Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-019 — A local fit identifies an observed response under the tested target, initial state, gain range, detector conditions and level excursion. It does not uniquely determine the internal architecture. Different systems can share one small-signal response while differing in integrating action, limits, hang rules, delays, windup and overdrive behavior. Use additional step sizes, initial conditions, time samples and state transitions to challenge the empirical model. Separate measured voltage response from calibrated gain and from the recovery of preceding RF stages. Retain the fit residuals and the conditions under which the model is accepted; do not hide systematic departures by selecting only convenient points. When internal documentation is unavailable, an observed input/output model with clear configuration and waveform limits remains useful. A strong-burst claim requires actual evidence for the relevant level, duration and recovery criterion. Neither the exponential equation nor the RMS detector label supplies a universal guarantee. Review: Model 5A introduction; Application 5A.5; Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals; Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-020 — A settled control state does not establish that every signal-path stage has recovered. A limiter, amplifier, detector or digital normalization step can retain a different disturbance; the reference measurement itself can also be bandwidth- or floor-limited. First establish that the weak reference is observable and that its injection point exercises the intended stages. Retain control and RF timing through the disturbance. Compare fixed-gain and automatic modes where available, use relevant pre- and post-detection observations, and vary pulse duration or level while controlling other conditions. A bypass or alternate path is informative only when the remaining chain stays within its valid range and the changed transfer is accounted for. Determine return to a declared reference amplitude and, where relevant, phase tolerance rather than merely return to a flat display. A later successful check assesses the functions exercised then; it cannot retroactively prove uninterrupted validity. Report the affected interval and the unresolved stage if localization remains incomplete. Review: Verify the detector and control path as part of the IF result; IF Alignment, Calibration, and Failure Localization.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — IF Alignment, Calibration, and Failure Localization.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-021 — Identify the exact revision and inspected pages, then separate the supported qualitative discussion from the disputed printed numerical expressions. The source supports a local single-pole response for small changes, integrating control, gain polarity and distinct large-change current-limited behavior. Page 13's printed Equation 4 has an intercept-sign conflict with its explanatory text, and the page 16 capacitance, slew and bandwidth example is internally inconsistent. Do not copy those expressions into an unqualified performance claim. The chapter's synthetic cases are derived from their declared state equation and calibrated local gain map; they are not measurements of that device. An independent dimensional calculation can expose a source inconsistency but does not establish the actual part's behavior across its operating conditions. A real equipment-specific use would need applicable authoritative clarification or direct validation. Preserve accurate source identity and the narrow qualification in References and Works Cited, while retaining the original source note and its legitimate scope. Review: Model 5A introduction; source notes 14 and 15; Chapter 5 References and Works Cited.

Review: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — Intermediate Frequency as a Controlled Band; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — References and Works Cited.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-022 — Retain the old and new firmware, coefficients, sample-rate interpretation, scaling, filter selection and correction identities. A common center label does not establish unchanged physical frequency weighting, gain or time response. Apply known tones across the passband and skirts, a calibrated noise case with an appropriate effective bandwidth, and representative bursts or modulation that exercise delay and settling. Include automatic filter boundaries and any gain-control paths whose detector admission may have changed. Compare the same declared reference planes and measurands under compatible detector operations. Preserve native observations and the processing steps that form the reported values. Differences should be assessed against applicable criteria or an approved baseline rather than removed by display renormalization. If a correction table remains in use, verify its applicability to the new physical and numerical transfer. State the tested domain and any transition interval for which response is not yet characterized. Review: IF Alignment, Calibration, and Failure Localization; IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Alignment, Calibration, and Failure Localization; Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-023 — Identify the local gain reference, signed slope, calibrated voltage interval and applicable RF levels. Include control-voltage measurement uncertainty, reference-gain and slope uncertainty, and the relative timing of telemetry and RF observations. If a dynamic fit is used between samples, include uncertainty and adequacy of its target, time constant, initial state and segmentation. An initial-state interval propagated through Equation 10J covers only one contribution; it is not the whole budget. Establish the detector operation, filter response and waveform conditions, including whether the burst is short relative to settling or telemetry response. Mark clipping, overdrive or gain-range transitions that invalidate a simple invertible correction. Apply the correction at the appropriate times before forming the intended physical-power statistic, and retain correlations where the adopted uncertainty method requires them. A bounded result can remain useful even if some intervals are excluded, but the exclusion and its effect on the claimed burst quantity must be explicit. Review: Equations 10C–10J; Applications 5A.3 and 5A.10; Chapter 14 connection.

Review: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — Application 5A.3: Convert a control state into an output level; Chapter 5 — Application 5A.10: Propagate an initial-state interval; Chapter 14 — Use covariance and model sensitivity deliberately; Chapter 14 — Model 14B: exact covariance and local uncertainty propagation; Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Equation 10J. Propagation of an initial-state interval.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-024 — Record exact configuration, reference planes, stimuli, correction method, environmental conditions relevant to the response and the acceptance criteria. Include several passband and skirt frequencies, applicable bandwidth and gain boundaries, a calibrated noise case, a short event and a recovery case. Use fixed gain to characterize the path and the intended automatic mode to exercise attack, release, hang and shared-channel loading. Observe an appropriate weak reference during the disturbance if continuing transfer is part of the claim. Compare with declared specifications or a compatible approved baseline and retain characteristic traces for future regression. A passing closing check establishes the functions and states actually exercised at that later time. It does not alone prove that earlier samples remained valid through a transient, nor does it cover untested configurations. The release statement should name the tested domain and any unresolved restriction, with enough evidence for another examiner to reproduce the comparison. Review: IF Acceptance and Regression Tests; Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

V011-C05-ESSAY-025 — Treat the three outputs as different paths until their filter, takeoff, detector, averaging and gain states are reconciled. The narrow trace may reduce a short peak through settling or selection, while the wider I/Q path can retain it and the audio path can exclude it. Moving telemetry adds a time-dependent gain factor; a final settled gain cannot correct the whole event. Preserve the native records and timing, determine whether any path clipped, and apply only validated corrections. Repeat a known representative burst with independently controlled duration and amplitude, first at fixed gain and then in the intended automatic mode. Retain a suitable weak reference and exercise relevant filter boundaries. A difference explained by receiver response is not automatically a propagation change, and an unresolved difference should not be assigned to an external source without discriminating evidence. The report should state which quantities are supported, which intervals or paths remain limited, and the specific observation that would resolve the leading alternatives. Review: Hypothetical Case Adjudication; Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 5 — Hypothetical Case Adjudication: Intermediate-Frequency Chains, Filters, AGC, Logarithmic Paths, and Detectors.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-C05-DISCUSSION-001 — Ask what quantity the observation must preserve: tone separation, channel power, modulation, onset time or peak. A narrower response can reduce admitted noise while changing settling and the signal itself. Require a measured transfer or a representative stimulus for the intended quantity. The discussion should produce a justified path choice and a declared limitation, rather than treating visual quietness as the acceptance criterion. Review: Filter Shape, Selectivity, and Time Response.

Review: Chapter 5 — Filter Shape, Selectivity, and Time Response.

V011-C05-DISCUSSION-002 — Separate the common center-to-width ratio from skirts, ripple, phase and impulse response. Determine whether the existing procedure depends on properties absent from Q. A substitution needs evidence for those properties and for detector timing under the same waveform. The useful outcome is a list of response equivalences actually established and the tests still needed. Review: Equation 9; Choose an IF path for the quantity being measured.

Review: Chapter 5 — Equation 9. Loaded quality factor; Chapter 5 — Choose an IF path for the quantity being measured.

V011-C05-DISCUSSION-003 — Examine transfer magnitude, measurement floor, phase coherence and unwrapping before accepting the derivative. Near a notch, uncertainty can dominate the phase slope. Even a valid local group delay does not establish unchanged transmission of an arbitrary pulse. The team should report the measurable frequency interval and the waveform-dependent limits of its interpretation. Review: Choose an IF path for the quantity being measured.

Review: Chapter 5 — Choose an IF path for the quantity being measured.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-004 — Translate the rule into the remaining fraction, approximately 4.98 percent, and compare that residual with the actual error tolerance. A large initial gain error can leave an unacceptable result after three time constants. Require compatible units, calibrated slope and an applicable model. The decision should be based on the declared error budget rather than the familiarity of the rule. Review: Equation 10E; Application 5A.2.

Review: Chapter 5 — Equation 10E. Settling time for a positive error tolerance; Chapter 5 — Application 5A.2: Set a gain-error settling requirement.

V011-C05-DISCUSSION-005 — Ask whether the target, state, acquisition or model changed. Overshoot is inconsistent with the uninterrupted monotone model, so it is evidence that deserves investigation. Establish measurement uncertainty and repeatability before deciding whether the point is erroneous. Preserve the original record and state the model's tested scope; a good fit elsewhere does not authorize deleting a meaningful departure. Review: Equation 10B and its monotonicity discussion.

Review: Chapter 5 — Equation 10B. Control voltage and residual.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-006 — Separate interpolation from model adequacy and internal identification. Favorable signs and decreasing residuals allow a positive time constant, but additional times, levels and states can reveal other dynamics. The team should identify the exact response supported by the two points and propose an independent challenge. A bounded empirical model is useful without claiming a unique internal circuit. Review: Equation 10F; Application 5A.5.

Review: Chapter 5 — Equation 10F. Two-point identification of the local time constant; Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

V011-C05-DISCUSSION-007 — Consider target error, detector offset, resolution and hold behavior before increasing model complexity. Examine whether the apparent floor is stable under changed references or input levels. A second pole is a hypothesis that needs discriminating evidence, not a mandatory interpretation of every departure from zero. Retain the simplest model adequate for the declared operating domain and the data. Review: Application 5A.5.

Review: Chapter 5 — Application 5A.5: Identify a time constant from two signed residuals.

V011-C05-DISCUSSION-008 — Require the signed local gain map and active gain range. A rising voltage reduces gain only for the appropriate negative slope; another circuit or mode can have the opposite polarity. Check the reference gain, valid voltage interval and RF response. The discussion should connect state direction with calibrated effect, rather than relying on a familiar control convention. Review: Equation 10C; Application 5A.4.

Review: Chapter 5 — Equation 10C. Local control-to-gain law; Chapter 5 — Application 5A.4: Check the required control polarity after a level step.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-009 — Regular repetition can produce a periodic trajectory that never reaches equilibrium. Carry the actual prior terminal state or establish the periodic initial state from sufficient history. Compare burst spacing with attack, hold and release behavior. The team should retain a justified initial-state rule, not a reset chosen because it simplifies arithmetic. Review: Equation 10G; Application 5A.6.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.6: Carry state across two target intervals.

V011-C05-DISCUSSION-010 — Compare the trajectories: a specified hold remains at its carried value before release, whereas a slow exponential moves immediately. The distinction can change a later weak-signal response. Define the timer trigger, retrigger rule and held quantity, then test them. A combined empirical approximation may be used only with its error and application interval stated. Review: Equation 10G discussion; Application 5A.7.

Review: Chapter 5 — Equation 10G. Carry state across a target change; Chapter 5 — Application 5A.7: Use separately identified attack and release constants.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-011 — Inspect the numerical recurrence and sample interval. Forward Euler can alternate or diverge even when the stipulated continuous system is stable. Compare with the exact sampled solution and distinguish stability from accuracy. If the real controller is discrete, obtain its actual update law rather than forcing either continuous or Euler behavior onto it. Review: Equations 10H and 10I; Application 5A.9.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range; Chapter 5 — Application 5A.9: Distinguish exact sampled state from an unstable Euler approximation.

V011-C05-DISCUSSION-012 — A stable alternating approximation can still misrepresent a monotone physical response. Compare residual values and acceptance crossings with the exact recurrence for this model. State numerical error where it matters to the tolerance. The desired result is a calculation accurate for the measurement decision, not merely a sequence whose magnitude eventually decreases. Review: Equations 10H and 10I.

Review: Chapter 5 — Equation 10H. Exact sampled-state recurrence; Chapter 5 — Equation 10I. Forward-Euler residual and its validity range.

V011-C05-DISCUSSION-013 — Identify which quantities were fixed during that propagation. Target, time constant, slope, gain reference and timing can still contribute. Contraction removes only sensitivity to the uncertain initial state under the stated model. The team should distinguish a deterministic partial bound from a complete uncertainty statement and add the missing contributions appropriately. Review: Equation 10J; Application 5A.10.

Review: Chapter 5 — Equation 10J. Propagation of an initial-state interval; Chapter 5 — Application 5A.10: Propagate an initial-state interval.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-014 — Telemetry assesses one control state and its calibrated relationship. An RF reference can expose independent compression or recovery in the actual exercised path. Neither is automatically sufficient alone. Define the relevant stages and ensure that the reference remains observable. The discussion should identify complementary evidence and the interval for which valid transfer is actually supported. Review: Application 5A.3; Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Application 5A.3: Convert a control state into an output level; Chapter 5 — Verify the detector and control path as part of the IF result.

V011-C05-DISCUSSION-015 — Trace the signal admission to the control detector and vulnerable stages rather than using the display limits as a physical filter specification. A wider shared path can drive AGC. Use a controlled blocker and retained weak reference to distinguish gain control from overload or source changes. Report the actual admitted band and state evidence. Review: Automatic Gain Control and Hidden State.

Review: Chapter 5 — Automatic Gain Control and Hidden State.

V011-C05-DISCUSSION-016 — Define whether the intended result is a rare maximum, average power or another quantity. The traces perform different operations, and each has waveform-dependent bandwidth, crest-factor and recovery limits. A quieter appearance does not make an estimator appropriate. The team should select and validate the detector for the measurand and retain its acquisition conditions. Review: Logarithmic Amplifiers, Detectors, and Scaling.

Review: Chapter 5 — Logarithmic Amplifiers, Detectors, and Scaling.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-017 — Identify whether each trace averages linear power, logarithmic levels, selected samples or another detector output. Matching units can conceal different operations and time weights. Reconstruct a common intended statistic only when the retained data and calibration permit it. Preserve the original operation and avoid interpreting a change of label as a change of physical measurement. Review: Verify the detector and control path as part of the IF result; Chapter 8 connection.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

V011-C05-DISCUSSION-018 — Require control-state evidence, a calibrated gain relationship and a reference demonstrating valid signal transfer under the same conditions. Consider limiting, clipping, log-detector saturation and software normalization as alternative plateau mechanisms. The team should define an observable prediction that separates them, including recovery and weak-signal response, rather than accepting flatness alone. Review: Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-019 — Examine coefficient, clock, scaling, detector and automatic-selection changes. Center agreement can coexist with altered skirts, delay or transient behavior. Repeat the cases whose assumptions could have changed and verify correction applicability. The result should state the covered configurations and waveform domain, not treat software implementation as a guarantee of invariant transfer. Review: IF Alignment, Calibration, and Failure Localization; IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Alignment, Calibration, and Failure Localization; Chapter 5 — IF Acceptance and Regression Tests.

V011-C05-DISCUSSION-020 — Distinguish the specific inconsistent expressions from the supported material, retaining exact edition and page scope. Derive synthetic teaching cases independently and do not promote a guessed correction to a verified device specification. Document the qualification and seek clarification or measurement for equipment-specific use. Responsible source criticism can preserve useful evidence without repeating an error. Review: Chapter 5 References and Works Cited; source notes 14 and 15.

Review: Chapter 5 — Intermediate Frequency as a Controlled Band; Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — References and Works Cited.

V011-C05-DISCUSSION-021 — Relate the repair to the path properties and measurement claims that could have changed. Skirts, delay, gain boundaries, detection and recovery may require representative additional cases. Use declared criteria or an applicable baseline rather than expanding testing without a concrete purpose. The release should name what was verified and any remaining limitation. Review: IF Acceptance and Regression Tests.

Review: Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-022 — Keep the time scope explicit. The check assesses the functions exercised at its own time; it can reveal persistent change but does not establish uninterrupted earlier transfer. Contemporaneous references, clipping indicators and state records are needed for the burst interval. Preserve useful observations with their limits instead of silently transferring a later pass backward. Review: Verify the detector and control path as part of the IF result; Chapter 1 connection.

Review: Chapter 5 — Verify the detector and control path as part of the IF result; Chapter 1 — Evidence Record and Closing Verification.

V011-C05-DISCUSSION-023 — Ask whether a validated dynamic model and known initial state support interpolation for this regime. Without that evidence, the final value does not describe an unsettled burst. Even a valid control interpolation cannot recreate clipped RF peaks. The team should state the resulting amplitude limitation and design a faster or otherwise discriminating acquisition. Review: Application 5A.3; Application 5A.8.

Review: Chapter 5 — Application 5A.3: Convert a control state into an output level; Chapter 5 — Application 5A.8: Compare burst duration with control settling.

V011-C05-DISCUSSION-024 — Reconcile path origin, filter, detector, state and acquisition timing first. The outputs may represent different quantities, and sensitivity to one waveform does not validate another measurement. Choose the observation suited to the intended claim, retaining the others as complementary evidence. The adjudication should explain the differences or identify the next controlled test. Review: Verify the detector and control path as part of the IF result.

Review: Chapter 5 — Verify the detector and control path as part of the IF result.

Copyright 2026, James M. Atkinson

V011-C05-DISCUSSION-025 — State the tested model, configuration, level and time domain separately from the unresolved recovery behavior. Retain the event interval, references and competing explanations, and propose a specific additional observable or controlled perturbation. A bounded result is useful when its limits are explicit. Do not turn a convenient exponential fit into a complete internal or environmental explanation. Review: Model 5A introduction; IF Acceptance and Regression Tests.

Review: Chapter 5 — Model 5A: an identified one-pole gain-control response; Chapter 5 — IF Acceptance and Regression Tests.

Copyright 2026, James M. Atkinson

Chapter Glossary

ATTACK TIME CONSTANT: The positive time constant identified for a specified control response following an input change that calls for gain reduction. In Model 5A it describes one applicable exponential segment, with a calibrated gain polarity and declared target. It does not include an unmodeled detector delay, slew limit or hold rule, and it need not equal the release constant.

AUTOMATIC GAIN CONTROL: Feedback or feedforward process that changes receiver gain according to detected level or state.

CALIBRATED CONTROL INTERVAL: The voltage range over which a specified control-to-gain relationship is supported by calibration and applicable operating conditions. A model trajectory used for gain prediction must remain inside this interval or be segmented under separately justified mappings. Mathematical monotonicity of voltage does not validate gain extrapolation beyond the measured range.

CONTROL POLARITY: The direction in which a control-voltage change affects receiver gain in the active calibrated range. A negative local slope means increasing voltage reduces gain; a positive slope gives the opposite relationship. Polarity belongs to the gain map and must not be confused with the positive time constant or the sign of a residual.

Copyright 2026, James M. Atkinson

CONTROL RESIDUAL: The signed difference between actual control voltage and the target used for the current segment. Under the stipulated positive-time-constant one-pole law, a nonzero residual decays without changing sign. Its magnitude can be converted into gain-error magnitude only through an applicable gain slope. A target error or detector offset can create an apparent residual floor.

CONTROL TARGET: The equilibrium control voltage toward which a particular Model 5A segment relaxes. It is constant within that segment and is distinct from the voltage already reached. A new input, range or mode can change the target. Uncertainty in the target remains a separate contribution even after uncertainty in the initial state has decayed.

DETECTOR CREST-FACTOR LIMIT: An operating restriction on waveform peak relative to its RMS level for a detector or measurement path. Exceeding the applicable limit can invalidate an RMS or power indication even when average level appears acceptable. The limit depends on the specific detector and conditions; the name RMS does not establish unlimited peak-handling capability.

DETECTOR TAKEOFF: The physical or numerical point from which a detector receives its waveform. Its position relative to filters, gain stages, limiters and converters determines what it observes and which signals can influence control or indication. Audio, spectrum and recorded I/Q outputs can use different takeoffs; common receiver identity does not make their transfer functions equivalent.

Copyright 2026, James M. Atkinson

EXACT SAMPLED RECURRENCE: The discrete update obtained by evaluating a stipulated continuous model at successive sample times without numerical integration approximation. For Model 5A with fixed target over the interval, the residual multiplier is the exponential of the negative interval-to-time-constant ratio. Exactness belongs to that model; it does not establish that a physically discrete controller implements the same rule.

FILTER RINGING: A transient oscillatory response following a change or short excitation, determined by the filter's full dynamics. Ringing can extend an apparent event or alter a detected peak even when a continuous-tone amplitude is correct. Its relevance depends on the waveform and measurand; loaded Q or a single bandwidth label does not completely specify it.

FILTER SETTLING: The approach of an IF path's output to the response required by a stated stimulus and error criterion after a change. It depends on the full filter and observation chain, not merely the gain-control time constant. A burst shorter than the relevant settling interval can be measured before its steady response develops, changing peak or timing interpretation.

FORWARD-EULER APPROXIMATION: A first-order numerical update that advances a state using the derivative at the beginning of the interval. Applied to Model 5A, its residual coefficient is one minus the interval-to-time-constant ratio. This differs from the exact exponential coefficient and can introduce sign alternation or instability when the step is too large.

Copyright 2026, James M. Atkinson

FRACTIONAL SETTLING CRITERION: A requirement expressed as the permitted residual fraction of a specified nonzero initial step. For the chapter's one-pole law, a fixed fraction gives a fixed number of time constants, independent of step magnitude. A common absolute gain tolerance can instead require different waits for different initial errors. The chosen fraction must be tied to the measurement decision.

GAIN-ERROR MAGNITUDE: The nonnegative difference from the target gain attributable to the control residual under the chapter's calibrated local affine gain map. It equals the residual magnitude multiplied by the absolute gain slope and is expressed in decibels. It is distinct from signed gain change and does not include every calibration or signal-path error automatically.

GAIN-RANGE TRANSITION: A change between receiver gain ranges whose reference gain, control slope, limits or dynamics may differ. A continuous telemetry voltage does not prove continuous RF gain through the transition. Retain the active range and switch timing, use the applicable calibration for each segment, and verify any interval in which the transfer changes or becomes undefined for the intended correction.

GAIN-STATE TELEMETRY: A time-associated record of actual receiver gain settings or control behavior. For amplitude reconstruction it needs an applicable calibration, sufficient temporal resolution and alignment with the signal observations. A final gain value does not describe an unsettled burst, and telemetry cannot restore RF information lost through clipping or missing acquisition.

GROUP DELAY: Negative derivative of phase with angular frequency, used to describe delay of spectral components through a network.

Copyright 2026, James M. Atkinson

HANG STATE: A declared control mode that delays or modifies release after a specified event. A simple held-state example retains the attained control value for a defined duration before exponential release begins. The trigger, retrigger behavior and held quantity must be identified; replacing a hold with a larger release time constant changes the predicted trajectory.

IDENTIFIED CONTROL RESPONSE: A dynamic control-state law fitted or established within a declared operating interval and configuration.

INITIAL-STATE BOUND: A declared interval containing the control voltage at the start of a model segment without necessarily assigning a probability distribution. With fixed target and time constant, Model 5A maps both endpoints through an increasing affine transformation, contracting the interval width. The resulting bound covers initial-state uncertainty only, unless other parameter contributions are treated explicitly.

INTEGRATOR WINDUP: Accumulation or displacement of an integrating controller’s internal state when the requested output cannot be achieved within an actuator or gain limit. Return to ordinary operation can then require recovery of that state. This is a possible large-change control mechanism, not a universal explanation for every slow receiver response; its presence and limits require circuit or input/output evidence.

LOCAL GAIN MAP: A calibrated relationship between control state and receiver gain over a specified range.

LOGARITHMIC AMPLIFIER: Amplifier producing an output approximately proportional to the logarithm of input amplitude over a defined range.

Copyright 2026, James M. Atkinson

LOG-AVERAGE BIAS: The difference, under a stated probability model, between the expectation of an averaged logarithmic statistic and the logarithm of mean physical power. The related finite-record distinction is visible whenever the same varying levels are averaged before versus after logarithmic conversion. State the estimator and waveform assumptions; a common display unit does not make the two operations equivalent.

LOG-DETECTOR INTERCEPT: The reference offset in a specified calibrated relationship between a logarithmic detector's output and its input level. It is meaningful only with the stated slope, units, waveform conditions and operating range. An incorrect intercept creates a systematic level error, and a printed formula must be checked for consistency with its definitions before being used as a device-specific correction.

NONALTERNATING RESIDUAL: A residual sequence that does not repeatedly change sign about the specified target. The exact sampled one-pole solution has this property for positive time constant and interval. Forward Euler preserves it only for a positive normalized interval no greater than one, a stricter condition than its asymptotic-stability limit.

NUMERICAL STABILITY: The behavior of errors or perturbations under a numerical recurrence, distinct from the stability of the physical system being modeled. For the chapter's Euler residual update, asymptotic decay requires a positive interval-to-time-constant ratio below two. A stable approximation can still have substantial error or unphysical alternation, so stability alone does not validate a settling calculation.

Copyright 2026, James M. Atkinson

PASSBAND RIPPLE: Variation of transmission magnitude across the declared useful passband under a specified normalization. It can weight parts of a wide waveform differently even when the center-frequency gain is correct. The required flatness follows the intended amplitude or modulation measurand, and equal nominal bandwidth does not establish equal ripple.

POWER-AVERAGE ESTIMATOR: An arithmetic average of calibrated instantaneous powers with declared sample selection and time weights. A logarithmic level can be formed afterward, but averaging logarithmic levels first estimates a different quantity. With changing receiver gain, the appropriate time-resolved correction and validity conditions must be applied before interpreting the intended input-referred power statistic.

RELEASE TIME CONSTANT: The positive time constant identified for the applicable gain-return segment after the controlling condition changes. The actual state at the start of release is carried forward from prior activity. A release constant does not itself specify a preceding hang duration, a timer trigger or the recovery of other RF stages.

RESIDUAL FLOOR: An apparent nonzero limiting value in a residual record. It can arise from a wrong target, detector offset, measurement resolution, a hold state or additional physical dynamics. It should not automatically be fitted as a very slow pole. The residual definition, capability and competing mechanisms must be examined before assigning a physical cause.

SETTLING TOLERANCE: The positive permitted residual in a declared state or output quantity used to determine an acceptance time.

SHAPE FACTOR: Ratio of filter bandwidths measured at two specified attenuation levels.

Copyright 2026, James M. Atkinson

SHARED AGC DETECTOR: A level detector whose output controls gain used by more than one selected signal or observation path. Its admitted band can be wider than a displayed channel, allowing an off-channel signal to suppress a desired weak response. Interpretation requires the detector takeoff, admitted spectrum, gain distribution and control state, rather than the display span alone.

SLEW-LIMITED CONTROL: A regime in which the control state changes at an imposed maximum rate rather than following the small-change exponential law over the whole excursion. Limited charging or discharging current can produce an approximately linear voltage ramp. The applicable rate, transition and control range require their own evidence; a later exponential fit does not describe the earlier ramp automatically.

STATE CARRYOVER: Use of the actual ending state of one dynamic interval as the initial state of the next.

TIMING SKEW: Relative delay between nominally simultaneous channels, triggers or signal-path observations. In a control-based amplitude correction, skew can associate a calibrated gain with the wrong RF sample during a transient. The delay and its uncertainty should be measured or otherwise justified; static gain calibration alone does not establish temporal alignment.

TWO-POINT TIME-CONSTANT IDENTIFICATION: Estimation of a candidate one-pole time constant from two nonzero, same-sign residuals about one fixed target, with decreasing magnitude over a positive time separation. The elapsed time divided by the natural logarithm of their ratio gives the candidate constant. Additional observations are needed to establish model adequacy and its operating domain.

Copyright 2026, James M. Atkinson

UNWRAPPED PHASE: A phase branch that retains accumulated cycles over a declared valid interval instead of leaving principal-value jumps. In IF transfer measurements it supports a meaningful local phase slope and group-delay estimate only where the response is measurable and the reference coherent. Unwrapping cannot recover reliable phase from an unobservable transfer or establish missing phase information by itself.

VIDEO BANDWIDTH: Post-detection or display filtering bandwidth that controls trace smoothing and response time.

Chapter 6. Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals

Copyright 2026, James M. Atkinson

6.1 Carrier, Sidebands, and Modulation Evidence

Analog modulation places information in amplitude, frequency, phase, pulse parameters, or a combination of them. The receiver should preserve enough bandwidth and linearity to observe the relevant structure before demodulation. Carrier frequency, sideband symmetry, occupied bandwidth, deviation, pulse repetition, duty factor, and state changes can support classification. They do not by themselves prove the content, source, or purpose of the transmission.[1]

Modulation analysis begins with raw RF or IF data and a stated reference. Demodulated audio is a derived product whose fidelity depends on filter, detector, tuning, carrier recovery, de-emphasis, squelch, limiting, and recording settings. When the technical question concerns waveform identity or unintended information, the original complex or real-valued capture is preserved alongside any audio rendering.

1 United States Navy, Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles, NAVEDTRA 14189 (September 1998), 2-10–2-14, reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388–8392; title and edition at page 8345. These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

6.2 Amplitude Modulation and Envelope Detection

Conventional amplitude modulation produces a carrier and sidebands displaced by the modulating frequencies. Modulation depth affects envelope variation and sideband power. Overmodulation causes envelope reversal and distortion in a simple envelope detector. Suppressed-carrier and single-sideband signals require a coherent or product detector because the envelope alone does not preserve the original baseband relationship.

Receiver gain compression and AGC can alter measured modulation depth. Selective fading or multipath can unbalance sidebands. A narrow IF filter can attenuate high-frequency modulation, while detector time constants can introduce diagonal clipping or ripple. AM measurements should therefore include carrier level, sideband levels, bandwidth, detector mode, gain state, and a reference modulation test.

Figure 22. Analogue modulation and demodulation paths.

Copyright 2026, James M. Atkinson

6.3 Single Sideband and Coherent Reception

Single-sideband reception depends on accurate carrier reinsertion and sideband selection. Frequency error shifts recovered audio and can make speech unintelligible without changing the RF signal. Carrier and timing references can be obtained from residual pilots, external standards, known content, or estimators. The receiver should document whether the recovered frequency scale was measured or adjusted by ear.

Coherent detectors can also recover double-sideband suppressed-carrier and phase-related signals, but phase ambiguity and reference instability matter. Product-detector balance, I/Q mismatch, filter asymmetry, and LO phase noise can create residual carrier or opposite-sideband leakage. An apparently unusual modulation may therefore be a normal signal viewed through an improperly configured detector.

Copyright 2026, James M. Atkinson

TECHNICAL INTERPRETATION

A suppressed-carrier signal loses message polarity under envelope extraction. A phase-coherent product detector can recover it.

Figure 23. Envelope versus coherent detection.

6.4 Model 6A: preserve the complex envelope

An envelope is useful only after its voltage and frequency conventions have been fixed. Model 6A represents a real RF waveform as the real part of a complex peak-voltage envelope translated to a positive carrier. The envelope occupies a baseband narrower than the carrier frequency, so the positive and negative RF bands remain separated. This convention connects analog reception to the complex conversion in Model 4A and the sampled I/Q records in Chapter 10. It also makes clear which information is lost when a receiver retains only envelope magnitude or one real audio channel.

Equation 11A. Real RF waveform and its complex envelope

$$x(t)=\Re\left\{u(t)\exp\left(j2\pi f_c t\right)\right\}$$
$$supp\,U \subset [-B,B], 0 \le B < f_c$$

Here x and u are in volts, R is the positive load resistance in ohms, frequencies f_c, f_m and B are in hertz, and time is in seconds. The symbol U denotes the envelope spectrum. Angle brackets denote the declared time average, with the carrier and envelope terms satisfying the stated orthogonality; a peak is taken over the specified observation interval or complete periodic waveform. The imaginary unit j has square minus one. Modulation depth μ and the normalized message m are dimensionless.

At a positive real load resistance, the mean RF power under the stated carrier and message orthogonality convention equals the mean squared envelope magnitude divided by twice the resistance. For periodic examples, the mean is taken over complete common periods or as the long-time mean; carrier-cycle averaging gives the same envelope-power convention. Peak envelope power uses the largest squared envelope magnitude with that

Copyright 2026, James M. Atkinson

same factor. Instantaneous RF voltage squared has a different peak-to-average relation and should not be substituted without stating the change.

Equation 11B. Envelope power convention

$$P=\frac{\langle |u(t)|^2 \rangle}{2R}, R>0$$
$$P_{PEP}=\frac{max|u(t)|^2}{2R}$$

Conventional AM uses a real envelope consisting of a positive carrier amplitude plus a scaled real message. Bound the message magnitude by one and state its normalization. With modulation depth between zero and one, the signed envelope remains nonnegative. For a sinusoidal message, its extrema give the retained modulation-index formula. The Navy modulation course presents the carrier/sideband and envelope relationship in a directly inspectable form; the following derivation makes the peak-voltage and linear-path assumptions explicit.[2]

Equation 11C. Conventional AM and nonnegative-envelope condition

$$u(t)=A[1+\mu m(t)], A>0, \mid m(t) \mid \leq 1$$
$$0 \leq \mu \leq 1 \Rightarrow u(t) \geq 0$$

Equation 11D. Sinusoidal AM extrema and their inversion

$$E_{max}=A(1+\mu), E_{min}=A(1-\mu)$$
$$A=\frac{E_{max}+E_{min}}{2}, \mu=\frac{E_{max}-E_{min}}{E_{max}+E_{min}}$$
$$m(t)=\cos(2\pi f_m t), 0 \leq \mu \leq 1$$

2 Joint Committee for Guides in Metrology, International vocabulary of metrology: Basic and general concepts and associated terms, VIM3 online edition, entries 2.48, 2.49 and 2.53, https://jcgm.bipm.org/vim/en/2.48.html, https://jcgm.bipm.org/vim/en/2.49.html and https://jcgm.bipm.org/vim/en/2.53.html, read November 2, 2026. These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

Expanding the product of the message cosine and carrier cosine gives two sidebands, each with half the modulation-scaled carrier peak. Squaring their peak amplitudes and dividing by twice the load resistance produces the sideband powers. Over the orthogonality interval, the carrier and two sideband powers add. The resulting total-power expression is exact for this sinusoidal, linear AM model. It is not a universal correction for a voice waveform, an asymmetric channel response, or a transmitter whose amplitude law has clipped.

Equation 11E. Sinusoidal sideband amplitudes and powers

$$A_{+¿=A_{-}=\frac{A\mu}{2},P_c=\frac{A^2}{2R}¿}P_{+¿=P_{-}=\frac{P_c\mu^2}{4}}$$

$$¿$$

Equation 11F. Total sinusoidal-AM power

$$P_{total}=P_c\left(1+\frac{\mu^2}{2}\right)$$

For a different zero-mean message, use its actual mean square. The total-to-carrier power ratio then depends on the product of squared modulation scale and message mean square. This is one reason to retain the waveform or a reproducible message definition with a modulation-depth result. The same maximum excursion can accompany different average powers. A broadband message can also place appreciable energy in parts of the IF response that a center-frequency amplitude calibration never tested.

Equation 11G. Power for a zero-mean nonsinusoidal message

$$\langle m\rangle=0\Rightarrow P_{total}=P_c\left[1+\mu^2\langle m^2\rangle\right]$$

Use the declared averaging and spectral-separation conditions.

Overmodulation is a particularly useful boundary test. In the ideal algebraic waveform, the signed envelope becomes negative while the RF expression

Copyright 2026, James M. Atkinson

can still consist of only the original carrier and two sidebands. A magnitude-only detector replaces that signed envelope by its absolute value, losing the sign and distorting the recovered message. A physical transmitter that cannot realize the negative part may clip and generate additional RF components. Those are distinct mechanisms. The observed envelope alone does not establish which one occurred.

Equation 11H. Magnitude detection after envelope reversal

$$e_{mag}(t) = |\ A[1+\mu\cos(2\pi f_m t)]\ |$$

μ > 1: signed envelope reversal is lost in magnitude detection

A properly normalized real product detector multiplies by twice its LO cosine and removes the translated sum band. What remains is the real projection of the complex envelope after residual frequency and phase rotation. With exact frequency agreement, a real AM message is scaled by the cosine of the reference phase error. A 90-degree error can null that real output even though a quadrature recording retains the signal. Frequency error is more consequential than a fixed scale: the projection rotates with time, so an AM or suppressed-carrier message can be mixed with a residual low-frequency cosine.

Equation 11I. Real coherent recovery with residual reference error

$$y_R(t) = \Re\left\{u(t)\exp\left(j\left(2\pi(f_c - f_{LO})t - \theta_{LO}\right)\right)\right\}$$
$$f_{LO} = f_c, u\,real \Rightarrow y_R(t) = u(t)\cos\theta_{LO}$$

Equation 11J. Complex coherent recovery

$$y_C(t) = u(t)\exp\left(j\left(2\pi(f_c - f_{LO})t - \theta_{LO}\right)\right)$$

For the SSB examples, specify the envelope directly as a positive- or negative-frequency complex exponential, or as a finite sum of such components. This avoids ambiguity about which sideband has been

Copyright 2026, James M. Atkinson

retained. A general real message can be paired with its Hilbert transform to construct an analytic upper-sideband envelope under the same band-separation assumptions. The actual receiver may implement that operation with a filter, a phasing network, or digital processing; the model does not assume that its opposite-sideband rejection is perfect.

Equation 11K. Explicit upper and lower single-sideband envelopes

$$u_{USB}(t)=A\exp(j2\pi f_m t),u_{LSB}(t)=A\exp(-j2\pi f_m t)$$
$$f_{BB,USB}=f_c+f_m-f_{LO}$$
$$f_{BB,LSB}=f_c-f_m-f_{LO}$$

An unequal response to the two AM sidebands generally turns a purely real envelope into a complex one. Its in-phase part and quadrature part then carry different combinations of the sidebands. A magnitude trace can hide that distinction. Compare the measured complex response with the known input before calling the resulting envelope variation the source modulation depth. Gain control and limiting add further transformations, so a detector output is accepted as a modulation measurement only within a verified path state.

Equation 11L. In-phase and quadrature terms after unequal sideband response

$$u=c_0+c_{+¿}\exp(j\omega t)+c_-\exp(-j\omega t)¿u=c_0+(c_{+¿}+c_-)\cos(\omega t)¿+j(c_{+¿}-c_-)\sin(\omega t)¿I=\Re(u),Q=\Im(u),\omega=2\pi f_m$$

In Equation 11L, c_0 is the complex carrier-envelope coefficient and c_+ and c_- are the complex upper- and lower-sideband coefficients after the path response, all in volts. Expanding the two exponentials into cosine and sine gives the second form directly. Taking its real and imaginary parts defines I and Q without assuming that the three coefficients are real or that the sideband responses are conjugate.

6.5 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

6.6 Application 6A.1: Close the power accounting for sinusoidal AM

A 1 MHz carrier has peak voltage 1 V across 50 Ω and is sinusoidally modulated at 2 kHz with depth 0.6. The envelope ranges from 0.4 to 1.6 V. Carrier power is 10.000 mW, each sideband is 0.900 mW, and total power is 11.800 mW. The corresponding levels are 10.0000, -0.4576, and 10.7188 dBm.

A spectrum-based check sums the three resolved line powers in linear units. An envelope-based check recovers the same depth from the extrema. Agreement tests the normalization only if the receiver has retained both sidebands, remains linear, and uses compatible reference planes. A lower sideband reading caused by IF attenuation would change the output waveform and would not prove that the source depth had changed.

Copyright 2026, James M. Atkinson

6.7 Application 6A.2: Infer the conventional-AM envelope parameters

A calibrated conventional-AM envelope has maximum 2.4 V and minimum 0.8 V. Their midpoint gives a carrier peak of 1.6 V, and their normalized difference gives depth 0.5. For a 75 Ω load and sinusoidal modulation, carrier power is 17.066667 mW, each sideband is 1.066667 mW, and total power is 19.200000 mW.

The estimate requires both extrema to belong to the same stable gain state. Selecting a maximum before AGC reduction and a minimum afterward can produce a depth that no single waveform had. Likewise, a noisy minimum near zero is sensitive to detector offset and bandwidth. Preserve the interval from which the extrema were selected and repeat the calculation on a known modulation reference using the same detector path.

Copyright 2026, James M. Atkinson

6.8 Application 6A.3: Infer modulation depth from one resolved sideband

One resolved sinusoidal-AM sideband is 18 dB below its carrier. Convert the power ratio to a peak-amplitude ratio before applying the sideband relation: the inferred modulation depth is $2 \times 10^{\frac{-18}{20}}$, or 0.251785. The total-to-carrier power ratio is 1.031698, corresponding to an increase of 0.135525 dB.

This calculation uses one sideband only because symmetry is an explicit assumption. Measure the other sideband to challenge that assumption. A difference can indicate source asymmetry, a filter response, coherent interference, or measurement error. The single-sideband estimate should then be reported as conditional rather than averaged into an apparently more precise depth without investigating the discrepancy.

Copyright 2026, James M. Atkinson

6.9 Application 6A.4: Show why an envelope-extrema estimate fails after reversal

Let the ideal signed envelope be $1+1.3\cos\backslash(\text{modulation angle}\backslash)$. Its extrema are −0.3 and 2.3 V. The observed magnitude envelope reaches zero at the sign crossings, so applying the ordinary extrema formula gives 1.0 instead of the true scale 1.3. The signed envelope is negative for 22.064 percent of each modulation period.

The failed inversion is caused by loss of sign. A complex or correctly phased coherent record can reveal the reversal, whereas a magnitude-only record cannot reconstruct it from the two extrema. This synthetic RF waveform has not been clipped by a transmitter. Additional RF sidebands would require another mechanism, such as a physical amplitude limit, and must not be attributed to the absolute-value detector after the RF record was already acquired.

Copyright 2026, James M. Atkinson

6.10 Application 6A.5: Measure phase-dependent coherent-AM recovery

A real coherent detector receives AM with carrier peak 0.8 V and depth 0.5, with exact frequency agreement but a 35-degree reference phase error. The recovered DC term is 0.655322 V, and the recovered message peak is 0.327661 V. Relative to perfect phase alignment, the message amplitude change is -1.732710 dB. At 90 degrees the ideal real message output is zero.

The null is not a loss of RF energy. It is a projection onto the wrong real axis. Recording both quadratures permits the phase rotation to be examined and, where an independent reference justifies it, corrected. A recovered-audio level is therefore not a direct RF modulation-depth measurement unless the phase and gain conventions of the detector are known.

Copyright 2026, James M. Atkinson

6.11 Application 6A.6: Resolve the two tones caused by a DSB-SC tuning error

Take a DSB-SC complex envelope equal to a 1 kHz cosine and a real coherent detector with a residual 50 Hz frequency offset. The recovered waveform is the product of those cosines. Expanding it gives tones at 950 and 1,050 Hz, each with peak 0.5 under the declared normalization. It does not give one unchanged 1 kHz tone with a constant amplitude error.

A short audio segment may sound like a changing level rather than two distinct tones because the observation is too brief to resolve their separation. Preserve the time record and analysis duration. Correcting the residual frequency from an independently established reference restores the intended projection; simply moving a displayed spectral marker does not correct the underlying time-domain waveform.

Copyright 2026, James M. Atkinson

6.12 Application 6A.7: Retain SSB sign when the reinsertion frequency is wrong

A 20 MHz carrier has a 1.5 kHz upper-sideband tone. Reinsertion at 20,000,120 Hz produces a signed complex audio frequency of +1,380 Hz. A separate lower-sideband tone under the same LO produces −1,620 Hz. If only real audio magnitudes are retained, these become 1,380 and 1,620 Hz and their orientation is lost.

The 120 Hz tuning error shifts the two signed examples in the same algebraic direction, but it changes their real-audio magnitudes differently. This is why an operator adjustment that improves apparent intelligibility is a processing choice requiring a record. The corrected frequency scale should be tied to a measured reference or a stated estimator, not reconstructed afterward from what the audio was expected to sound like.

Copyright 2026, James M. Atkinson

6.13 Application 6A.8: Compare average power with peak envelope power for two SSB tones

A two-tone SSB envelope contains 0.8 V at +1 kHz and 0.6 V at +2 kHz. Its mean squared magnitude is 1 V^2 under complete-period averaging, giving 10 mW average RF power in 50 Ω. When the two envelope components align, the peak is 1.4 V and peak envelope power is 19.6 mW. The peak-envelope-to-average ratio is 2.922561 dB.

A receiver can remain acceptable on average power while clipping that envelope peak. The appropriate headroom check therefore retains the waveform-dependent peak definition. Conversely, an instantaneous RF peak-voltage calculation would include the carrier oscillation and is not the same reported quantity as peak envelope power. State which limit the hardware specification and acceptance rule actually use.

Copyright 2026, James M. Atkinson

6.14 Application 6A.9: Separate sideband filtering from source modulation depth

An input depth of 0.8 produces ideal sideband peaks 0.4 relative to a unit carrier. Suppose the output retains the upper sideband at 0.4 but reduces the lower to 0.2, with their stated phases unchanged. Its complex envelope is $1+0.6\cos\backslash(\text{modulation angle}\backslash)+j\ \ 0.2\sin\backslash(\text{modulation angle}\backslash)$. The real message component is 0.6 rather than 0.8, a -2.498775 dB change.

The output magnitude extrema are 0.4 and 1.6, so a naive envelope-depth calculation gives 0.6. That number describes a distorted output and does not recover the source depth. The nonzero quadrature term is additional evidence of the asymmetric path. A coherent transfer measurement of the two sidebands can identify the response that a single envelope trace hides.

Copyright 2026, James M. Atkinson

6.15 Application 6A.10: Use message mean square rather than a sinusoidal shortcut

Use a message consisting of a 0.5-amplitude cosine at 1 kHz and a 0.25-amplitude cosine at 2 kHz, with modulation scale 0.8 and unit carrier peak. Its magnitude is bounded by 0.75, so the signed envelope is safely bounded below by 0.4 V. The mean message square is 0.15625, and total RF power is 1.10 times carrier power. The two sidebands associated with 1 kHz each have peak 0.2 V; the pair associated with 2 kHz each have peak 0.1 V.

The bound on envelope minimum is conservative and need not be attained, because the two message cosines do not reach every sign combination together. The power result uses their actual orthogonality over complete 1 ms message periods. Substituting the sinusoidal shortcut would give the wrong total because the message is not a unit-peak single cosine. This distinction is useful whenever an envelope statistic is used to infer total modulated power.

Copyright 2026, James M. Atkinson

6.16 Frequency and Phase Modulation

Frequency modulation encodes information in instantaneous frequency, while phase modulation encodes information in phase. Their spectra depend on modulation frequency, deviation or phase excursion, waveform, and index. Narrowband approximations are useful only when the index is sufficiently small. Wideband FM can occupy many significant sidebands, and Carson's rule provides an engineering estimate rather than an exact spectral boundary.

Copyright 2026, James M. Atkinson

Why it matters: demodulators recover different quantities;
waveform, phase continuity and frequency-deviation claims need separation.

Figure 24. AM, FM and PM signal characteristics.

FM receivers commonly use limiting to suppress amplitude variation, followed by a discriminator, quadrature detector, phase-locked loop, or digital estimator. Capture effect, threshold behavior, multipath, de-emphasis, and squelch can dramatically change recovered audio. A

Copyright 2026, James M. Atkinson

demodulator can produce noise bursts or tonal artifacts even when no intelligible information is present. Deviation and baseband bandwidth should be measured from calibrated data, not inferred only from loudness.

Copyright 2026, James M. Atkinson

6.17 Model 6B: phase is the quantity that frequency differentiates

A phase-based measurement begins with a complex signal whose phase has a defined continuous branch over the interval of interest. Model 6B uses a positive, constant amplitude and a declared unwrapped phase added to the carrier. The frequency deviation is the phase derivative divided by two pi wherever that derivative exists. The Navy modulation course distinguishes the amount of frequency deviation from the rate at which it varies; writing the phase equation prevents those two quantities from being confused.[3]

Equation 12A. Complex phase and instantaneous frequency

$$z(t) = A\exp\left(j\left(2\pi f_c t + \varphi(t)\right)\right), A > 0$$
$$f_{inst}(t) = f_c + \frac{1}{2\pi}\frac{d\varphi}{dt} \; almost\ everywhere$$

The nonzero complex amplitude A is in volts, carrier and modulation frequencies are in hertz, time is in seconds, and phase φ is in radians. Frequency offset δf is measured relative to f_c. A phase-modulator coefficient k_p has radians per unit of its specified message, while β is a dimensionless peak phase expressed in radians. A finite multi-tone expansion uses a positive integer count L, with each phase amplitude, frequency and initial phase explicitly assigned. The frequency derivative is a local statement; the phase branch and any reset must already be known.

The complex representation is a stipulated signal model. A noisy real waveform with several unresolved components does not automatically supply one physically meaningful instantaneous phase. Near zero amplitude, its phase estimate can become undefined or highly unstable. A limiter can suppress amplitude variation while retaining or introducing its own errors. Record how the complex signal was formed, its admitted bandwidth, any amplitude exclusions, and the phase-unwrapping convention before treating a derivative as frequency.

For a sinusoidal FM deviation, integration gives a sinusoidal phase whose amplitude equals peak deviation divided by modulation frequency. The modulation frequency must be positive for that expression; a constant offset instead gives a linear phase ramp. In PM, the message directly controls phase, so differentiation makes frequency deviation depend on both message amplitude and message frequency. A fixed phase excursion is therefore not equivalent to a fixed frequency excursion when the modulation rate changes.

Equation 12B. Sinusoidal FM phase and modulation index

$$\varphi(t)=\beta\sin(2\pi f_m t)+\varphi_0,\ \beta=\frac{\Delta f}{f_m}$$
$$f_{inst}(t)-f_c=\Delta f\cos(2\pi f_m t),\ f_m>0$$

Equation 12C. Sinusoidal PM and its frequency deviation

$$\varphi(t)=k_p M\cos(2\pi f_m t)$$
$$f_{inst}(t)-f_c=-k_p M f_m\sin(2\pi f_m t)$$
$$\Delta f_{peak}=|k_p|\,M f_m,\ M\geq 0$$

Equation 12D. Integration of a general deterministic frequency offset

$$\varphi(t)=\varphi(t_0)+2\pi\int_{t_0}^{t}\delta f(s)\,ds$$
$$f_{inst}(t)=f_c+\delta f(t)$$

Copyright 2026, James M. Atkinson

For a sum of differentiable phase components, their frequency deviations add. Bounding the sum by the sum of component magnitudes is always conservative, but the bound is attained only when the component phases permit it. This matters when a highest modulating frequency and a peak deviation are used together in a bandwidth estimate. They describe different aspects of the waveform and should be measured or stipulated independently rather than inferred from a single spectral peak.

Equation 12E. Deviation from several phase components

$$\varphi(t)=\sum_{\ell=1}^{L}\beta_\ell \sin(2\pi f_\ell t+\psi_\ell)$$

$$\delta f(t)=\sum_{\ell=1}^{L}\beta_\ell f_\ell \cos(2\pi f_\ell t+\psi_\ell)$$

$$|\,\delta f(t)\,| \le \sum_{\ell=1}^{L}\left|\beta_\ell f_\ell\right|$$

A sampled phase difference gives the average frequency over its interval when the phase is correctly unwrapped and absolutely continuous. It need not equal the instantaneous frequency at either endpoint or midpoint. The principal complex argument is periodic, so an observed increment is ambiguous by whole turns. A frequency estimate from it requires a justified interval of admissible frequencies and continuity assumptions. Increasing the number of displayed decimal places does not resolve an alias or recover a phase turn that the data cannot distinguish.

Equation 12F. Finite-interval frequency from unwrapped phase

$$f_{avg}=f_c+\frac{\varphi(t+\Delta t)-\varphi(t)}{2\pi\Delta t}$$

$$¿\frac{1}{\Delta t}\int_{t}^{t+\Delta t} f_{inst}(s)\,ds\,,\ \Delta t>0$$

Copyright 2026, James M. Atkinson

Equation 12G. Principal-increment frequency and its alias class

$$f_{principal} = \frac{f_s}{2\pi} Arg\left(z_{k+1} z_k^{*}\right)$$
$$Arg \in ¿$$
¿

A small-phase approximation can be useful, but its error should accompany it. The complex exponential equals one plus j times phase plus a remainder bounded pointwise by half the squared phase. For sinusoidal phase, the retained linear term gives two first-order sidebands. Their quoted power is relative to an unmodulated unit carrier; the exact modulated carrier amplitude is not silently treated as unchanged at arbitrary phase excursion. Chapter 11 uses the related remainder discipline when translating LO phase noise into admitted noise.

Equation 12H. Pointwise small-phase remainder

$$\exp(j\varphi) = 1 + j\varphi + r(\varphi)$$
$$|\, r(\varphi)\,| \le \frac{\varphi^2}{2}, \varphi \in \mathbb{R}$$

Equation 12I. First-order sidebands for sinusoidal small phase

$$\exp\left(j\beta \sin(\omega t)\right) \approx 1 + \frac{\beta}{2}\exp(j\omega t) - \frac{\beta}{2}\exp(-j\omega t)$$
$$\frac{P_{\pm,retained}}{P_{unmodulated}} = \frac{\beta^2}{4}, \; |\, r(t)\,| \le \frac{\beta^2}{2}$$

Carson's rule combines peak frequency deviation and the highest significant modulating frequency into a useful engineering estimate. It does not uniquely define the transmitted spectrum or an IF filter response. The IRIG telemetry appendix explicitly treats it as an estimate and shows that its relation to a stated power-containment bandwidth depends on how the modulation energy is distributed. This chapter uses the rule for planning

Copyright 2026, James M. Atkinson

and comparison, then requires the actual waveform and filter response for a distortion or containment decision.[4]

Equation 12J. Carson estimate and its stated inputs

$$B_C \approx 2\left(\Delta f_{peak} + f_{m,max}\right)$$

Engineering estimate; exact passed power requires spectrum and filter.

A frequency-reference offset adds a linear phase trend, while a constant phase-reference offset disappears on differentiation. A phase reset is different from either: it interrupts the continuous branch and must split the analysis into separately identified segments. Correcting an offset from the same weak data being evaluated also introduces an estimation dependency. Retain the uncorrected phase, the independent reference or training interval, and the corrected result so that the correction can be evaluated rather than assumed.

Equation 12K. Separate modulation, frequency offset and phase offset

$$\varphi_{BB}(t) = \varphi_{mod}(t) + 2\pi\,\delta f_{res}\,t + \theta_{res}$$

$$\delta f_{res} = f_c - f_{LO},\; f_{BB}(t) = \delta f_{res} + \frac{\varphi_{mod}'(t)}{2\pi}$$

6.18 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

6.19 Application 6B.1: Convert a sinusoidal FM deviation into phase excursion

A sinusoidal FM waveform has peak deviation 4.5 kHz at a 1.5 kHz modulation frequency. Its phase index is 3 radians. Differentiating that phase recovers the 4.5 kHz deviation, while Carson's estimate gives 12 kHz total bandwidth. The phase index is dimensionless, deviation is in hertz, and the rate of deviation is another frequency; the three quantities are not interchangeable.

A receiver check should verify both deviation scale and modulation-frequency scale with a known reference. The bandwidth estimate can guide an initial IF choice, but the accepted result still depends on the actual passband, phase response, and demodulator. A narrower path might bias the measured deviation before an obvious amplitude failure appears.

Copyright 2026, James M. Atkinson

6.20 Application 6B.2: Differentiate a sinusoidal PM phase

A PM sensitivity of 0.8 rad/V is driven by a 1.5 V peak, 2 kHz cosine. The phase peak is 1.2 radians. Its derivative produces a 2.4 kHz peak frequency deviation, with a sine-shaped sign convention determined by the derivative of the cosine. Using that deviation and 2 kHz message frequency gives an 8.8 kHz Carson estimate.

The phase and frequency records contain related information, but they are not pointwise copies of the message. A calibration that compares their peaks without their timing relationship can misidentify a quadrature shift as delay or distortion. Use the declared time reference and derive the expected waveform, including sign, before comparing the recovered phase and frequency channels.

Copyright 2026, James M. Atkinson

6.21 Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation

Hold phase excursion at 1.2 radians while changing a sinusoidal message from 1 to 4 kHz. The frequency-deviation peaks change from 1.2 to 4.8 kHz. Alternatively, hold FM deviation at 1.2 kHz over those two message frequencies; the phase indices become 1.2 and 0.3 radians. These are different stimulus families even though one of their operating points coincides.

A demodulator verification should say which quantity the generator holds fixed. Otherwise a changing frequency-deviation reading can be mistaken for detector error when it is the correct consequence of a fixed phase-modulation setting. Preserve the generator mode and its actual calibration alongside the receiver output, especially when a source offers both FM and PM controls with similar front-panel labels.

Copyright 2026, James M. Atkinson

6.22 Application 6B.4: Bound and attain the deviation of a two-tone phase

Let the unwrapped modulation phase be $0.3\sin[2\pi(1\ \text{kHz})t]+0.1\sin[2\pi(3\ \text{kHz})t]$, in radians. Differentiation gives frequency components of 300 Hz at each modulation frequency. Both cosine terms reach +300 Hz at the time origin and −300 Hz at 0.5 ms, so the attained peak deviation is 600 Hz. With highest message frequency 3 kHz, Carson's estimate is 7.2 kHz.

The attainable peak follows from the stated phases, not just from the two amplitudes. Changing relative phase can change the peak while preserving the component frequencies and powers. This is a useful reason to preserve the modulating waveform when a peak-deviation requirement matters. An averaged spectrum of the modulating signal can omit the relative phase needed for that decision.

Copyright 2026, James M. Atkinson

6.23 Application 6B.5: Integrate a linear frequency ramp without losing phase turns

A frequency offset ramps linearly from −2 to +2 kHz in 4 ms. Its slope is 1,000,000 Hz/s. Integrating from zero initial modulation phase gives -4π radians at the midpoint and zero again at the endpoint. The midpoint therefore lies two complete negative phase turns from the start even though the start and end phases agree.

An endpoint-only phase comparison would miss the excursion. Preserve the continuous trajectory or enough unambiguous samples to reconstruct it under a valid bandwidth model. A phase-wrap display can be useful for periodicity but cannot replace the unwrapped record when evaluating accumulated phase. The carrier remains a separate positive reference; the negative values here are deviations from it, not negative physical RF frequencies.

Copyright 2026, James M. Atkinson

6.24 Application 6B.6: Expose the ambiguity of sampled phase increments

At 48,000 samples per second, a +7 kHz complex offset advances by 0.916298 radians per sample, within the principal interval. A +31 kHz offset instead gives a principal increment -2.225295 radians, which is identical to −17 kHz at that sample rate. The principal-increment estimator therefore reports +7 and −17 kHz for the two cases.

No phase-unwrapping algorithm can select +31 kHz from those samples without additional prior information about the admitted band or a changed observation. The usual principal interval spans −24 to +24 kHz, with one endpoint excluded by convention. This is the same sampling-equivalence issue treated in Chapter 10, now expressed in phase increments rather than DFT bins.

Copyright 2026, James M. Atkinson

6.25 Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value

Four unwrapped phase observations are 0, 0.12, 0.29, and 0.51 radians, separated by 100 μs. Successive interval-average offsets are 190.986, 270.563, and 350.141 Hz. The centered two-interval average at the second observation is 230.775 Hz.

The interval-average derivatives follow exactly from the stipulated phase record, while the reported numerical values are rounded. Calling them instantaneous values requires a further local approximation that the four samples alone do not establish. A shorter difference interval can improve locality while increasing sensitivity to phase error. The acceptance record should name the difference operator and interval so that two frequency traces with different smoothing are not compared as if they were identical measurements.

Copyright 2026, James M. Atkinson

6.26 Application 6B.8: Bound a small-phase approximation before using it

A sinusoidal phase has peak 0.1 radian. The complex first-order approximation has a pointwise remainder no larger than 0.005000. Each retained first-order sideband has peak 0.05 relative to a unit unmodulated carrier, hence power ratio 0.0025, or -26.020600 dBc. The sideband calculation is approximate; the stated remainder bound is exact for real phase.

This distinction permits a bounded use of the approximation without pretending that it is a complete spectrum model. If the intended error tolerance is below the remainder bound, use the full complex exponential or a stronger analysis. A phase excursion larger than 0.1 radian is not automatically invalid, but it changes the bound and can make the retained terms inadequate for the decision being made.

Copyright 2026, James M. Atkinson

6.27 Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response

For 5 kHz peak deviation and significant message content through 3 kHz, Carson's estimate is 16 kHz. A nominal 12.5 kHz IF width has a half-width label of 6.25 kHz, while a 25 kHz width has 12.5 kHz. The estimate's half-width is 8 kHz. These comparisons identify which responses deserve examination; they do not determine an exact fraction of signal power passed by either filter.

The complete waveform spectrum and filter transfer function are missing. A nominal width may describe a −3 dB or −6 dB point, and the transition and phase response can differ between filters with similar labels. Measure the recovered waveform, deviation, and relevant distortion under the intended setting. The appropriate conclusion from the supplied numbers is that filter suitability remains to be established, rather than that clipping has already been proved.

Copyright 2026, James M. Atkinson

6.28 Application 6B.10: Separate reference offset from a deterministic modulation

A phase modulation of 0.75 radian at 2 kHz produces 1.5 kHz peak frequency deviation. Add a known +80 Hz carrier-minus-LO offset and a constant 35-degree phase offset. The positive residual follows Model 4A's baseband sign convention. The observed frequency deviation relative to the nominal reference spans −1,420 to +1,580 Hz. Over 2 ms, the residual offset contributes 0.16 cycle, or 57.6 degrees, while the constant phase contributes no frequency change.

Removing the independently measured 80 Hz offset restores a symmetric ±1.5 kHz deviation. Estimating it from a short portion of the modulated record can instead absorb part of the modulation, especially when the observation does not cover whole message periods. Keep the estimation interval and residual checks with the correction. A neat centered trace is not evidence that the chosen correction preserved the original modulation.

Copyright 2026, James M. Atkinson

6.29 Pulse, Radar, and Transient Reception

Pulsed signals require adequate instantaneous bandwidth, detector response, sample rate, and trigger strategy. Peak power, pulse width, rise and fall time, repetition interval, intrapulse modulation, and timing stability can be lost in an averaged or narrowband trace. Front-end protection and recovery are particularly important because a short pulse can compress a receiver whose average input power appears modest.

Copyright 2026, James M. Atkinson

Figure 25. Pulse bandwidth and filter memory.

A pulse observed in one channel should be challenged for local digital switching, power-converter transients, analyzer sweep artifacts, and cross-channel coupling. Synchronized multichannel capture, antenna substitution, polarization, blanking, and known-source tests help distinguish external RF

Copyright 2026, James M. Atkinson

from conducted or internal events. When pulse content or radar association is outside V011's ownership, the report cross-references V101 or V110 rather than duplicating their system analysis.

Copyright 2026, James M. Atkinson

6.30 Preserve pulse and demodulator evidence across representations

A pulse adds an event boundary to the modulation problem. A long-time spectrum can characterize its repeated frequency content while concealing which part of the pulse produced it. A time trace can reveal onset and recovery while omitting the filter that shaped them. Link both views to the same native record, use the finite-window conventions in Chapter 9, and use Model 15A to distinguish a missed acquisition from a captured but distorted waveform. A pulse that never entered the usable observation window cannot be restored by a different demodulator.

For analog demodulation, begin with a known carrier and independently calibrated modulation. Verify the RF path, then compare recovered amplitude, phase or frequency against the expected baseband under several levels and bandwidths. Preserve the limiter, squelch, de-emphasis, carrier-recovery and audio-normalization settings. Each of those operations can change the derived output without any change to the external signal. Where a setting is automatic, retain its state or identify the interval over which it can be treated as fixed.

A recovered audio product should carry a reproducible link to the original RF or IF samples, the tuning and phase convention, the chosen sideband, the processing version, and any excluded interval. Subjective intelligibility may help an authorized investigation, but it does not calibrate deviation or prove a source identity. A comparison with a known reference and a challenge using another plausible demodulator setting are more informative about whether the processing has preserved the signal relationship being claimed.

Copyright 2026, James M. Atkinson

When the receiver changes gain or loses lock during a burst, retain the affected segment as a separate state. Do not silently splice the stable pieces into an apparently continuous waveform. The continuity and filter-history rules in Model 10E apply before a phase derivative, envelope statistic, or audio export is trusted. A reproducible failure to recover an event can still be useful evidence about the receiver method; it should not be converted into an assertion that the external waveform lacked modulation.

Copyright 2026, James M. Atkinson

6.31 Analog Demodulator Verification

Demodulator verification uses calibrated carrier, modulation, and pulse references across the stated bandwidth and level range. Measurements include recovered amplitude, frequency response, distortion, residual carrier, sideband rejection, deviation accuracy, limiter threshold, squelch state, and transient response. The test is repeated near the sensitivity threshold and near the strong-signal limit because different impairments dominate those regions.

Audio or baseband recordings are linked to their RF or IF source file, demodulator configuration, de-emphasis, sample rate, and time basis. When intelligibility is reported, the method distinguishes objective technical quality from subjective listening. Incidental content is minimized, and the primary technical record remains the calibrated signal capture.

Copyright 2026, James M. Atkinson

6.32 Quantitative Model for Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals

Equation 1. AM modulation index

$$m_{\mathrm{AM}} = \frac{V_{\max} - V_{\min}}{V_{\max} + V_{\min}}$$

For a sinusoidal conventional AM envelope without overmodulation, modulation index m_{AM} is estimated from maximum and minimum envelope amplitudes. Receiver compression, selective fading, noise, and detector filtering bias the result.

Equation 2. Carson bandwidth estimate

$$B_{\mathrm{FM}} \approx 2\left(\Delta f_{\mathrm{peak}} + f_{\mathrm{m,max}}\right)$$

Carson's rule estimates occupied bandwidth for frequency modulation using peak deviation Δf_{peak} and highest significant modulating frequency $f_{m,\max}$. It is an engineering approximation, not an exact emissions mask or universal containment criterion.

The envelope assumptions behind Equation 11 are developed in Model 6A and Applications 6A.1–6A.10. Equation 12 is the bounded engineering estimate used in Model 6B and Applications 6B.1–6B.10. Neither a scalar modulation index nor the bandwidth estimate replaces examination of the admitted waveform and its receiver transfer.

Copyright 2026, James M. Atkinson

Table 1. Chapter 6 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
AM and sidebands	Carrier, sideband levels, modulation depth, IF bandwidth, and detector	Supports modulation classification and linearity assessment	AGC, fading, and filter asymmetry can distort the envelope
SSB or suppressed carrier	Sideband selection, carrier reference, frequency error, and opposite-sideband rejection	Supports coherent baseband recovery	Manual tuning can create misleading audio
FM or PM	Deviation, phase excursion, baseband bandwidth, limiter, discriminator, and de-emphasis	Characterizes instantaneous-frequency or phase behavior	Threshold and capture effects can hide weak components
Pulse or transient	Peak level, width, rise time, repetition, trigger, sample rate, and recovery	Preserves timing and intrapulse structure	Averaging or narrow filters can erase decisive features

6.33 Hypothetical Applied Calculation: Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals

An FM signal has measured peak deviation of 5.0 kHz and significant baseband content to 3.0 kHz. Carson's engineering estimate is about 16 kHz. Comparing 12.5 kHz and 25 kHz IF settings requires the actual waveform spectrum and filter transfer responses: the estimate alone does not establish passed power or distortion, even with the carrier centered. The wider setting can admit more noise and adjacent-channel energy according to its actual weighting. Model 6B develops this qualification.

Copyright 2026, James M. Atkinson

6.34 Hypothetical Case Adjudication: Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals

A narrowband receiver produces intelligible speech after an operator tunes 1.8 kHz below a weak component. Complex baseband analysis shows that the signal is ordinary upper-sideband voice with a suppressed carrier, not a novel low-frequency modulation. The recovered audio and the tuning offset are retained as derived evidence, while the original I/Q recording remains the primary record.

Copyright 2026, James M. Atkinson

6.35 Analogue demodulation as a source of systematic rather than merely random impairment

Demodulation changes which properties of the intercepted RF waveform survive in the output record. An amplitude detector discards much of the original carrier phase; an FM discriminator responds to instantaneous frequency under its own bandwidth and limiting assumptions; a product detector may translate phase or carrier-offset errors into audible or measurable low-frequency components. Thus a spectrum that shows a clean carrier cannot guarantee that a recovered analogue waveform reflects the original modulation without distortion. A receiver can produce apparently persuasive intelligibility while remaining outside its calibrated amplitude, timing or phase domain. For defensive measurement, the goal is usually to assess waveform structure and receiver validity, not to acquire unnecessary communications content. A lawful test should use synthetic modulation with known reference parameters and established collection boundaries.

A useful controlled comparison begins with a single-tone laboratory FM reference for which instantaneous phase is phi(t) = 2 pi f_c t + beta sin(2 pi f_m t), where carrier frequency f_c and modulation frequency f_m are in hertz and beta is dimensionless modulation index. The peak frequency deviation is beta f_m under that convention. For beta = 2.5 and f_m = 1 kHz, the stipulated peak deviation is 2.5 kHz. A discriminator's apparent output amplitude should track this deviation over the chosen passband and input-power range, within a separately measured uncertainty. A limiter that introduces recovery effects or a filter that suppresses significant sidebands can violate the result without shifting the displayed centre frequency. The

Copyright 2026, James M. Atkinson

numerical case is a stimulus definition, not a characterization of any field receiver.

AM and single-sideband reception require equally explicit analysis. A simple linear AM reference $s(t) = A[1 + mu \cos(2 pi f_m t)] \cos(2 pi f_c t)$ has conventional modulation depth mu when zero through unity; beyond that interval envelope detection no longer reproduces the baseband sinusoid in the ideal elementary form. A strong adjacent signal can alter detector operating point or gain, making a fixed external AM modulation appear to change. In SSB reception a beat-frequency oscillator misaligned with the transmitter shifts the audio spectrum. A tone moved by 30 Hz in the output is not proof that the remote source emitted a different audio tone; it may reflect the relative oscillator offset. Accordingly, reference-clock and demodulator calibration records must accompany any quantitative conclusion about original modulation.

A useful reporting table separates RF input observation, demodulator setting, recovered statistic and untested content assumptions. A lawful laboratory-generated waveform can be compared through alternate bandwidth, gain and oscillator states; the resulting error vector or distortion measure should be computed in the baseband only after demonstrating that the reference survives the analogue chain. A loud or smooth audio output is not a substitute for this comparison. The aim is to prevent useful diagnostic demodulation from being converted into an unsupported claim about source identity or an unauthorised interpretation of private communication, while still retaining the measurable impairments that reveal receiver failure.

Copyright 2026, James M. Atkinson

6.36 Advanced technical expansion. Complex envelopes, demodulation pathology and transient fidelity

An analogue receiver observing amplitude, phase or frequency modulation must distinguish the transmitted waveform from the transformations imposed by its own local oscillator, filter and detector. A real narrowband waveform may be represented by a complex envelope z(t) multiplying a carrier at an explicitly stated centre frequency. The instantaneous envelope magnitude describes an amplitude-related quantity, while the derivative of the unwrapped envelope phase describes frequency deviation relative to the chosen carrier convention. Neither is automatically the same as a transmitter's internal modulation variable, because propagation, phase noise, filtering and sampling can alter the observed envelope. For a professional measurement, the complex representation should therefore be retained before selecting AM, FM or PM demodulation, provided the acquisition and lawful-use scope permit its retention.

For an ideal frequency-modulated signal, a phase perturbation theta(t) produces instantaneous deviation delta_f(t) = (1/(2 pi)) d theta(t)/dt in hertz. This derivative amplifies high-frequency noise and becomes unstable near envelope nulls where phase is poorly determined. A phase trace that unwraps cleanly under strong-signal laboratory conditions may become a sequence of spurious frequency spikes near fades or interference cancellation. One must impose and record a validity mask based on signal amplitude, phase-estimation uncertainty and acquisition continuity. For a hypothetical linear phase increase of 0.4 radians over 200 microseconds, the mean deviation is approximately 318.31 Hz. That arithmetic does not

Copyright 2026, James M. Atkinson

establish an actual 318.31-Hz source modulation if the phase increase arose from LO drift, a reset, path movement or an unrecognised cycle slip.

Amplitude modulation measurements are similarly contingent on spectral symmetry. Unequal upper and lower sideband levels can originate in source modulation, asymmetric receiver passband gain, a nearby interferer or a drifting local oscillator. A receiver that reports accurate total power may nonetheless deliver a distorted recovered message because different sidebands experience different amplitude and phase transfer. To discriminate, inject a known double-sideband reference at the input plane, measure both sideband transfers, and repeat after a controlled carrier-frequency displacement within the same filter. A source effect follows the source, while a receiver filter artefact often follows position in the passband. The comparison requires enough sensitivity to observe the reference across the band and must account for any AGC response produced by the injection itself.

Pulsed modulation adds a time-frequency tradeoff. Multiplying an otherwise continuous waveform by a short gate spreads its spectrum, while finite filter settling modifies the pulse envelope in the time domain. A narrow IF filter can reduce broadband noise yet reject the high-frequency envelope components that define a sharp pulse onset. The operator should not claim a longer transmitted pulse merely because a detector output remained elevated after the input was removed. A useful laboratory challenge applies pulses of several known durations through the identical path and compares the returned envelope with the independently recorded input. Derive the convolutional response or characterise it empirically, and preserve the uncertainty of trigger time and filter state. Such a test may support

Copyright 2026, James M. Atkinson

deconvolution for a limited signal family, but cannot restore arbitrary waveform details that the acquisition never retained.

Multipath and fading deserve a distinct causal analysis. A coherent sum of delayed replicas can create amplitude nulls, rapid phase rotations and frequency-selective fading even when the transmitter is stable. Moving an antenna by a small fraction of a wavelength may change the resultant complex phasor substantially. One must distinguish the physics of the local propagation environment from the source modulation before assigning a fault or identifying a device. A set of spatially separated, phase-aware observations can help, but it must not be treated as independent confirmation when the sensors share a reference, antenna cable or demodulation implementation. The applicable error covariance and geometry belong in the report.

A defensible demodulation laboratory record contains source waveform identity, modulation index or deviation, occupied spectrum, input-plane power, receiver state, local-oscillator reference, digital processing version, complex samples and the recovered quantity with uncertainty. Verify source purity and instrument linearity. Compare coherent and noncoherent demodulators on held-out waveforms, especially near fading, overdeviation and pulse-edge conditions. Treat unintelligible audio as a limited result rather than evidence that no modulation existed; conversely, an intelligible recovered fragment does not establish ownership, intent or collection authority. The role of demodulation in a forensic argument is to add specific, reproducible waveform observations, not to convert apparent intelligibility into unsupported attribution.

Copyright 2026, James M. Atkinson

6.37 Analogue demodulation as a chain of estimators rather than a faithful copy of the transmitter

Analogue reception is often taught as a catalogue of modulation types. A postgraduate treatment must begin instead with the observable signal and the inverse operation proposed by the receiver. Let the real RF voltage at a declared port be $v(t)=\mathrm{Re}\{u(t)\exp(j2\pi f_c t)\}$, where $u(t)$ is the complex envelope in volts, f_c is a stipulated carrier frequency in hertz and the real-part operator converts the analytic representation to a physical waveform. Recovering a message from $v(t)$ requires decisions about carrier reference, observation bandwidth, amplitude scaling, phase continuity, filtering and noise. These decisions determine the result as surely as the transmitter's modulation law. A usable demodulation report therefore identifies whether the retained quantity is a physical input voltage, analytic IF samples, instantaneous phase, differentiated frequency, envelope magnitude or a post-filtered audio signal. These representations are not equivalent when clipping, loss of phase or inadequate sampling has occurred.

In a linear receive path, the complex envelope at the demodulator can be represented as $r(t)=h(t)*u(t)+n(t)$, after suitable carrier translation, where $*$ denotes convolution, $h(t)$ is a characterised complex impulse response and $n(t)$ is a residual whose statistics and dependence on $u(t)$ are not assumed without evidence. This expression is already a restricted model. Receiver automatic gain control makes h time dependent; limiting or saturation destroys linear superposition; a multipath channel introduces delayed replicas; a digital resampler contributes its own filtering and timing law. Derivations below state when the simple linear case applies and where they

Copyright 2026, James M. Atkinson

do not. The objective is not a pleasing recovered sound but a reproducible measurement of the modulation feature required by a lawful defensive question.

6.38 Amplitude modulation beyond the textbook envelope formula

For conventional double-sideband amplitude modulation with a single sinusoidal message, write $u(t)=A_c[1+\mu \cos(2\pi f_m t)]$, with carrier-envelope peak voltage A_c, modulation frequency f_m and dimensionless modulation index μ. For a matched resistance R, carrier mean power $P_c=A_c^2/(2R)$. With $0\leq\mu\leq1$, the envelope magnitude is proportional to $1+\mu \cos(2\pi f_m t)$, and an ideal envelope detector can recover the sinusoidal message up to scale and DC removal. At $\mu>1$ the signed envelope crosses zero. A magnitude-only detector loses that sign and folds the recovered waveform, so a familiar extrema formula derived for nonovermodulated AM becomes invalid. A coherent receiver with a maintained carrier reference can in principle retain the sign, subject to its filter, phase and operating-state limitations.

The two sinusoidal sidebands at $f_c\pm f_m$ each have power $P_c \mu^2/4$, while the total RF mean power is $P_c(1+\mu^2/2)$ under the stipulated matched sinusoidal model. This decomposition does not establish the envelope of a general programme, multitone transmission, or an interfered receive signal. For a multitone message the peak envelope may be governed by relative phases even where average modulation power is unchanged. A receiver whose detector measures mean-square power over an interval cannot automatically infer the maximum modulation depth. The analytical distinction matters when comparing an apparently narrow, quiet trace with a signal carrying short, high-envelope peaks. Preserve amplitude calibration and detector time constants before attempting an inversion.

Copyright 2026, James M. Atkinson

An envelope detector introduces a dynamical compromise. A simple diode-capacitor model charges rapidly near RF peaks and discharges through a load with time constant $\tau=RC$, where R is the effective load resistance in ohms and C is capacitance in farads. For plausible envelope recovery, the time constant must be long enough to suppress carrier ripple yet short enough to follow the falling message envelope; there may be no feasible τ if the carrier and modulation time scales are poorly separated. The familiar inequalities $1/f_c \ll \tau \ll 1/f_m$ are only rough design guides and conceal diode threshold, source impedance, droop curvature and large-signal behaviour. A quantitative acceptance should inject known envelope shapes, measure recovered delay and distortion, and verify behaviour at several carrier levels rather than relying on one nominal RC calculation.

Copyright 2026, James M. Atkinson

6.39 Coherent AM, suppressed carriers and single-sideband ambiguity

Synchronous detection multiplies the observed carrier by a locally generated reference and removes the high-frequency product. The recovered baseband of an ideal double-sideband AM signal is scaled by cos θ where θ is the phase error between receiver and desired carrier reference, assuming negligible frequency offset, adequate low-pass filtering and a suitable amplitude convention. A 90-degree reference error can null the desired in-phase component despite a strong RF carrier. If a receiver has both I and Q channels, the complex vector can preserve the rotated signal and enable later correction, but only if the two paths' gain, quadrature angle and timing mismatches are characterised. Magnitude formation removes much of this phase sensitivity while also discarding the sign information needed by some coherent interpretations.

A suppressed-carrier double-sideband transmission has no transmitted unmodulated carrier line from which a receiver can automatically recover the reference. Its recovered signal may have a polarity or phase ambiguity that is irrelevant for some audio-monitoring purposes and critical for others. A small carrier-frequency offset makes the recovered constellation or baseband rotate in time. Single-sideband reception brings a further sign convention: choosing upper instead of lower sideband changes whether the recovered baseband spectrum is mirrored. A sideband-selection error may produce intelligible but spectrally inverted output, while a small reinsertion-frequency error shifts every audio component. For forensic waveform

Copyright 2026, James M. Atkinson

classification, intelligibility alone cannot establish correct carrier placement or the identity of the original transmitted modulation.

The Hilbert-transform construction makes these distinctions explicit. If a real, appropriately bandlimited message is m(t) and its Hilbert transform is m_hat(t), an ideal analytic upper-sideband envelope may be written m(t)+j m_hat(t), whereas the lower sideband uses m(t)-j m_hat(t) under the chosen positive-frequency convention. Generating or recovering these forms in a finite filter introduces approximation error near band edges and transient boundaries. The implementer should verify sideband suppression and passband phase as functions of frequency, not infer them from one favourable tone. A transient burst can expose overshoot and phase settling that are invisible in a settled sinusoidal test. Preserve the filter coefficients, sample rate and edge handling for any offline reconstruction.

Copyright 2026, James M. Atkinson

6.40 Frequency modulation, phase modulation and the dangers of differentiation

For constant-envelope angle modulation write $u(t)=A \exp[j\varphi(t)]$, where $\varphi(t)$ is continuous phase in radians within the adopted convention. The instantaneous frequency is $f_{inst}(t)=f_c+(1/2\pi)d\varphi/dt$ where the derivative and sufficient observation bandwidth exist. For sinusoidal FM with peak deviation Δf and modulation frequency f_m, the phase is $\varphi(t)=(\Delta f/f_m)\sin(2\pi f_m t)$, making modulation index $\beta=\Delta f/f_m$. For sinusoidal PM with peak phase excursion β radians, differentiation instead gives peak frequency deviation $\Delta f=\beta f_m$. The distinction cannot be established by examining one bandwidth number alone. It requires the relationship between phase, frequency and the underlying message over a stated interval.

A practical FM discriminator is an estimator, not an exact derivative of an ideal noiseless phase. An arctangent phase detector applied to complex samples returns principal values; unwrapping attempts to construct a continuous phase history, but its success depends on signal-to-noise ratio, maximum phase change per sample and the absence of unrecorded gaps. A phase increment of more than π radians between samples is ambiguous modulo 2π unless other information resolves it. Even in valid intervals, differentiating phase increases the relative importance of high-frequency phase noise, and an output de-emphasis filter changes the final noise and waveform response. Narrowing the receiver passband can suppress some noise but distort wide-deviation or rapidly changing modulation.

Copyright 2026, James M. Atkinson

Consequently the measurement of frequency deviation must retain the actual IF filter, demodulator and reconstruction law.

Carson's widely used bandwidth estimate $B \approx 2(\Delta f + f_m)$ for a single-tone FM signal is a useful engineering approximation, not an exact emission boundary. The actual spectrum has infinitely many Bessel-function sidebands in the ideal sinusoidal FM model, with progressively smaller powers, and the practically relevant bandwidth depends on the chosen containment criterion. The phase-noise skirt, multipath, pre-emphasis and occupied-programme statistics can further affect a measured spectrum. For an independently reported peak deviation, the estimator must specify bandwidth, observation time and valid modulation conditions. The relevant ITU-R frequency-deviation measurement recommendation provides a useful formal reference for such monitoring measurements, but its apparatus requirements and scope must not be presumed to apply to every receiver configuration without checking the controlling version and conditions.

Copyright 2026, James M. Atkinson

6.41 Multipath, fading, capture and the physical limits of an apparently clean audio output

A narrowband multipath channel can be modelled as $h(t)=\sum_k a_k \exp(j\theta_k)\,\delta(t-\tau_k)$, with complex amplitudes $a_k \exp(j\theta_k)$, delays τ_k and an impulse δ. The frequency response $H(f)=\sum a_k \exp(j\theta_k)\exp(-j2\pi f\tau_k)$ varies with frequency and may include deep notches. A simple amplitude limiter can remove much of the received amplitude variation without removing the multipath-induced phase and frequency distortion. A recovered FM signal may therefore sound strong while exhibiting false discriminator excursions caused by rapid phasor rotation during fading. Conversely, selective fading can produce audible distortion that is mistakenly attributed to source modulation. Characterise the selected channel by moving or varying the receiver path only through controlled, recorded interventions, without conflating the changed propagation environment with a fixed source property.

The FM capture effect complicates dual-signal observations. With two cochannel emitters, a limiter and discriminator may favour the stronger received waveform rather than produce a straightforward linear sum of their audio signals. The transition can depend on instantaneous amplitudes, frequency offsets, filter response and noise. No universal capture ratio follows from the word FM. A controlled two-source laboratory test must vary desired and undesired level under fixed reference conditions, check the output metric and preserve competing hypotheses, including receiver limiting and source spectral overlap. An externally stable signal can appear intermittent in recovered audio if the receiver switches between competing

Copyright 2026, James M. Atkinson

cochannel components or experiences a deep multipath fade. Without sample-domain evidence, those alternatives are difficult to separate.

Copyright 2026, James M. Atkinson

6.42 Pulse shape and analogue information that filters irreversibly discard

A pulse-modulated carrier is not characterised solely by its nominal peak frequency or mean power. Multiplying a continuous carrier by an envelope gate spreads energy across frequency in accordance with the Fourier transform of the gate. A rectangular pulse of duration T has a sinc-shaped envelope transform, with its first zeros separated from the centre by 1/T in either direction under the ideal continuous model. Shortening T necessarily increases the width of its spectral features. A narrow IF filter may convert the sharp pulse into a delayed, rounded response whose observed peak is reduced even though the transmitter's original envelope remains unchanged. An AGC response or detector hold function can add further memory. Correct reporting therefore distinguishes source pulse width, input-plane waveform, IF-filtered pulse duration, detector-reported peak and any digitally reconstructed display.

For a controlled transient experiment, retain a simultaneously observed wide-enough reference waveform and the receiver output, with independent source and trigger timing. Measure delay to threshold, 10–90 percent rise time where that definition is applicable, peak response, ringing, recovery and noise under several input powers and pulse widths. Change bandwidth, gain and detector settings separately, because a single attractive recovered trace can conceal lost short events. The wideband reference is not automatically ground truth if it also clips or has insufficient analogue bandwidth. The acceptance table should identify which source-

Copyright 2026, James M. Atkinson

feature claims the measurement system can sustain and which are invalid once the signal has been filtered, clipped or averaged.

Copyright 2026, James M. Atkinson

6.43 Ten numerical worked examples under declared simplified models

Application 6C.1. A conventional AM signal has 1.000 mW carrier power and sinusoidal modulation index $\mu=0.60$. Each sideband carries $P_c \mu^2/4=0.0900$ mW and the total mean power is $P_c(1+\mu^2/2)=1.180$ mW, or approximately 0.718 dBm. The calculation assumes an ideal matched linear chain and a single sinusoidal message. It cannot be used as the peak envelope power or as a field-strength correction without additional data.

Application 6C.2. An ideal nonovermodulated AM signal has envelope extrema 1.6 V and 0.4 V, measured in the same voltage convention without noise. The extrema estimator gives $\mu=(E_{max}-E_{min})/(E_{max}+E_{min})=1.2/2.0=0.60$. If the signal is actually overmodulated, taking only envelope magnitude can fold the negative signed envelope and produce misleading extrema. The original index should then be determined by a different calibrated measurement.

Application 6C.3. A coherent AM detector has a 30-degree carrier reference phase error. Under the simple in-phase product law, the desired recovered component is multiplied by $\cos 30°=0.866025$, a $20\log10(0.866025)=-1.249$ dB amplitude reduction. A change in recovered level alone is therefore not evidence of a changed RF source amplitude unless the local-reference state is controlled.

Application 6C.4. A coherent demodulator averages a complex tone over $T=40$ ms with residual frequency error $\Delta f=15$ Hz. The normalised complex-average magnitude is $|\sin(\pi\Delta fT)/(\pi\Delta fT)|=|\sin(0.6\pi)/(0.6\pi)|=0.50455$, or -5.94 dB in amplitude. The effect comes from rotation during integration, not a

Copyright 2026, James M. Atkinson

measured fall in source power. Retaining the complex samples permits a different frequency correction when the assumptions and data support it.

Application 6C.5. A sinusoidal FM signal has peak deviation 6.0 kHz and message frequency 2.0 kHz. Its modulation index is $\beta=6/2=3$, and the Carson estimate is $B\approx 2(6+2)=16$ kHz. This approximate bandwidth is not a guaranteed signal-containment interval or a validated channel-filter requirement for a different message waveform.

Application 6C.6. A sinusoidal PM signal has phase excursion 0.50 rad and message frequency 10 kHz. Its peak frequency deviation is $\beta f_m=5.0$ kHz. Keeping the phase excursion fixed while doubling f_m doubles the frequency deviation, unlike the construction in which an FM transmitter's peak frequency deviation is fixed.

Application 6C.7. An ideal single-pole de-emphasis filter with time constant $\tau=75$ microseconds has magnitude $|H(f)|=1/\mathrm{sqrt}[1+(2\pi f\tau)^2]$. At 1 kHz, $|H|\approx 0.9046$, or -0.87 dB. At 10 kHz it is approximately 0.2076, or -13.65 dB. These are deliberately chosen filter-model values; real receivers need measured transfer and any corresponding pre-emphasis convention.

Application 6C.8. A rectangular envelope pulse lasts 10 microseconds. Its first ideal sinc-spectrum zeros occur at frequency offsets $\pm 1/T=\pm 100$ kHz from the carrier. A receive channel whose useful response spans only 20 kHz about its centre cannot reproduce the sharp rectangular edges. This geometric bandwidth argument does not specify the precise distorted output peak, which depends on the complete filter impulse response and detector law.

Copyright 2026, James M. Atkinson

Application 6C.9. Under a stipulated phasor model two equal-amplitude received replicas arrive at the same narrowband frequency with relative phase 180 degrees. Their vector sum is zero even though each replica separately has nonzero power. A slight change of relative path phase moves the result away from the null. The observation demonstrates the nonuniqueness of source-power inference from one received amplitude, not a guarantee that all broadband components share that null.

Application 6C.10. A synthetic SINAD test gives total signal-plus-noise-plus-distortion power 10.0 mW and residual noise-plus-distortion power 0.10 mW after the defined notch procedure. Their ratio is 100, or 20.0 dB SINAD. The implied recovered fundamental signal power is 9.90 mW, and S/(N+D)=99, or 19.956 dB. The distinction is small here but conceptually important: SINAD includes the original residual in its numerator, and the result belongs to the specified weighting and detector conditions.

Copyright 2026, James M. Atkinson

6.44 Laboratory qualification of an analogue-demodulation measurement claim

The final acceptance should include a defined reference-plane source, independently verified modulation, representative signal powers, known reference frequency, filter and detector settings, and a record of actual sample continuity. For each intended inference establish suitable tests: amplitude index for AM, carrier phase error for coherent reception, sideband suppression and signed orientation for SSB, deviation and discriminator linearity for FM and PM, and impulse response for pulsed emissions. Repeat representative tests under noise and bounded blockers, including states where automatic gain or limiting may alter the result. Distinguish a tested detection of a waveform family from recovery of communications content, which may require separate lawful authority. The record must permit a reviewer to reproduce both the reported statistic and its limits without substituting intelligibility or display neatness for scientific validity.

Copyright 2026, James M. Atkinson

6.45 Pulse modulation as a measurable time-frequency process and not merely on-off keying

A pulse-modulated radio signal has a physical time history before it has an attractive frequency-domain representation. A finite radio-frequency burst can be described by a carrier, a complex amplitude envelope, an instantaneous phase law, and a sequence of intervals in which the transmitter enters different states. Pulse duration, pulse-repetition interval, repetition-frequency stability, rise and fall times, duty factor, centre frequency, chirp slope, intra-pulse phase code, and amplitude overshoot are different observables. A detector can recover some of them without recovering the others. For example, an envelope detector may report the presence and approximate width of a burst while destroying the sign of frequency offset and much of the intra-pulse phase structure. Conversely, a narrow frequency discriminator can report a stable carrier during a pulse while missing the leading edge entirely. The examiner must identify the acquisition operation that supports each claimed pulse characteristic, particularly when a proposed device identity is inferred from the pattern rather than established by an independently tested physical link.

Let a real RF waveform be $r(t)=\mathrm{Re}\{u(t)\exp(j\,2\pi f_c t)\}$, where f_c is a carrier in hertz, j is the positive imaginary unit, and $u(t)=a(t)\exp(j\varphi(t))$ is the complex envelope. The magnitude $a(t)$ is nonnegative and has the voltage units chosen by the measurement system; $\varphi(t)$ is measured in radians. With this convention, the instantaneous frequency departure from the carrier is $\Delta f(t)=(1/2\pi)d\varphi(t)/dt$ when the phase derivative exists and the signal magnitude is sufficiently above noise. A pulse with constant complex phase

Copyright 2026, James M. Atkinson

and approximately rectangular a(t) is fundamentally unlike a pulse in which the amplitude remains constant but φ(t) varies quadratically. The latter may implement linear frequency modulation, or chirp; its spectrum, correlation properties and required receive bandwidth differ substantially, even when the two bursts have identical start and stop times. No frequency plot can recover which phase law occurred unless the retained complex measurement preserves the relevant timing and phase references.

For an ideal rectangular complex-envelope pulse of amplitude A between time zero and duration τ, its Fourier-transform magnitude has the familiar sinc envelope $A\tau|\mathrm{sinc}(f\tau)|$, where $\mathrm{sinc}(x)=\sin(\pi x)/(\pi x)$. The first zeros occur at $\pm 1/\tau$ relative to its centre frequency and the null-to-null main-lobe width is $2/\tau$. This is not an occupied-bandwidth specification for a practical transmitter with finite edge time, chirp, modulation or spectral masks; it is a diagnostic limiting model. Abrupt edges imply extended spectral sidelobes, whereas shaped edges can redistribute sidelobe energy and broaden the principal transition. If a receiver's analog preselector removes the high-frequency components associated with an edge, subsequent digital deconvolution cannot be assumed to recover that edge, especially when the filter has deep stopband zeros or an uncertain group-delay response. This is precisely why pulse-fidelity tests must use the complete installed receive path rather than a nominal converter sampling rate alone.

A pulse train introduces a second scale. For constant pulse-repetition interval T_r, pulse-repetition frequency $f_r=1/T_r$ and duty factor $D=\tau/T_r$ for a nonoverlapping rectangular train. In a perfectly periodic and infinitely long model, discrete spectral lines are spaced by f_r under a broad pulse-envelope weighting. Real finite recordings, missed pulses, deliberate jitter

Copyright 2026, James M. Atkinson

and varying modulation replace that ideal comb with a measurement-limited statistical pattern. A line spacing near a claimed repetition frequency is not unique evidence of one emitting device; switch-mode power supplies, oscillator clocks, gating artifacts and internal receiver sampling structures can also create quasi-periodic features. Periodicity must be checked against native timestamped event lists and an independent receiver configuration before source identity is inferred.

A narrow 30 Hz spectrum bin can be useful for a stable carrier but is poorly matched to an isolated microsecond pulse if treated as a complete detector. Resolution is not the only problem: a filter with approximately 30 Hz noise bandwidth generally has response memory on a scale of many milliseconds, while the original event may last a millionth of a second. The display can show an attenuated, delayed, broadened response governed by the filter impulse response rather than the pulse envelope. Preserve a parallel wideband, time-resolved signal path or a hardware event trigger alongside the narrowband integration. The narrow path can subsequently quantify a persistent carrier or slow repetition feature; it must not be cited as though its temporal output were the true burst width. Where both products are made from one raw I/Q stream, their common origin and their different digital filters must be explicit in the processing record.

Noise complicates the location of pulse edges. A threshold crossing occurs where the filtered amplitude, noise and criterion meet, not necessarily where the transmitting device switches. For a finite slope $s=d\,a/dt$ expressed in volts per second, a small additive amplitude disturbance δa changes an isolated threshold-crossing time approximately by $\delta t \approx \delta a/s$, provided the linear local approximation and monotonic edge assumptions hold. Strong

Copyright 2026, James M. Atkinson

prefilter ringing can create multiple crossings; detector hysteresis can create different leading and trailing delays; gain control can change the slope. The error is therefore not generally a constant trigger latency removable from all observations by one offset. Report the threshold, hysteresis, filter state, sampling interval, observed rise/fall slopes and threshold-jitter evidence. When a sequence of bursts is used for attribution, a systematic pulse-timing bias can be more damaging than a small amount of random amplitude noise.

Pulse width is also representation-dependent. Width measured between half-power crossings of a detected envelope, between ten-percent amplitude crossings of an RF pulse, and between digital trigger events are three different quantities. A displayed width can increase after video filtering even though the RF energy interval has not changed. An envelope detector that compresses or saturates during the pulse may produce a long decay. A phase discriminator may lose lock during the leading edge and report its reacquisition transient as a chirp. A coherent matched filter intentionally compresses a longer coded or chirped pulse into a short correlation response. That correlation response is a useful range or timing statistic, not a claim that the transmitter emitted an equally short physical pulse. The manuscript must preserve the original and transformed durations as separately labelled quantities.

The engineering release test should include a known pulse source and an independently characterised observation channel. Vary pulse width, rise time, amplitude, intra-pulse phase code, chirp slope, repetition regularity and relative start phase with respect to the sample clock. Record both the transmitted reference and the receiving system's native samples. Measure

Copyright 2026, James M. Atkinson

edge bias, width bias, missed-event probability, false triggers, ringing, recovery dead time and variation across frequency slices. Challenge the acquisition with two overlapping bursts, a weak burst beside a blocker, and a burst straddling a retune or buffer handover. A clean plot of selected successes does not establish the performance of a system tasked with discovering rare unknown events. The distribution of failed conditions belongs in the acceptance evidence.

Copyright 2026, James M. Atkinson

6.46 Ten worked examples for pulse characterisation, ambiguity and false temporal precision

Application P6.1. For a rectangular 4 microsecond pulse, $\tau=4\times10^{-6}$ seconds; the ideal complex-envelope main-lobe nulls lie at ±250 kHz and its null-to-null width is 500 kHz. The 30 Hz analysis filter cannot be used to claim direct resolution of its edge. The calculation concerns a rectangular complex envelope, not a specification for all practical edge shapes.

Application P6.2. A transmitter emits 2 microsecond pulses every 2 milliseconds. The pulse-repetition frequency is 500 Hz, and duty factor is 0.001, or 0.1 percent. A swept receiver that only observes the frequency during a 100 microsecond dwell has no guarantee of intercept from these averages unless the relationship between dwell phase, sweep period and pulse start times is specified.

Application P6.3. A pulse contains 20 microseconds of linear chirp over 10 MHz. The nominal slope is $10^7/(20\times10^{-6})=5\times10^{11}$ Hz per second. The duration-bandwidth product is 200. A matched-filter correlation may yield a much narrower response than 20 microseconds, but the stored I/Q waveform must still show the emitted 20 microsecond chirped event and the filter used to produce the compressed response.

Application P6.4. A laboratory source produces pulses 50 microseconds long at 200 pulses per second. The period is 5 milliseconds and duty factor is 1 percent. An averaged full-time power level can lie about 20 dB below the pulse-on average power when the off interval contains negligible signal energy, because $10\log10(0.01)=-20$ dB. Peak and average powers must not be used interchangeably for front-end survivability.

Copyright 2026, James M. Atkinson

Application P6.5. An analogue detector has a one-pole response with 1 millisecond time constant. After one time constant a step response reaches $1-e^{-1}\approx 63.2$ percent of its final value. In a 5 microsecond pulse, its response reaches only $1-\exp(-0.005)\approx 0.499$ percent before the pulse ends under the simplified model. The small display response cannot be attributed to low transmitter pulse power without considering filter settling.

Application P6.6. A 100 mV amplitude perturbation is superimposed on a monotonic edge rising at 10^5 volts per second. The linearised crossing-time displacement is 0.0001/100000=1 nanosecond. The result assumes the local slope remains constant and ignores repeated crossings; a changing automatic-gain state invalidates those premises.

Application P6.7. A 10 MHz I/Q channel sampled at 12.5 million complex samples per second contains 62.5 samples across a 5 microsecond pulse. Finite sample placement implies that an un-interpolated edge index alone has a grid spacing of 80 nanoseconds. A finer reported edge time requires a justified interpolating estimator and a measurement uncertainty, not extra displayed decimals.

Application P6.8. A 1 microsecond pulse has a characteristic envelope spectral scale near 1 MHz. Converting its trace into a 30 Hz averaged-frequency representation replaces the original event with a much longer windowed spectral summary. For a 33.33 millisecond window, the pulse occupies only about 0.003 percent of the window time. This time fraction does not predict a universal 45 dB detection loss, because the outcome depends on coherent integration, energy, windowing and detector law.

Copyright 2026, James M. Atkinson

Application P6.9. A pulse-to-pulse phase rotation of 45 degrees at a 1 millisecond interval can be consistent with a constant 125 Hz frequency offset modulo the 1 kHz pulse-sampling alias interval, because 45/360 divided by 0.001=125 Hz. A fitted offset is ambiguous by integer multiples of the pulse-sampling frequency unless extra continuity or reference information is available.

Application P6.10. A recorded burst has a 2 microsecond leading-edge transient, 18 microseconds stable carrier, and a 4 microsecond trailing response. Reporting a single 24 microsecond width conceals three mechanisms. A calibrated comparison should report edge criteria, settled duration and the installed filter's impulse response. If an alternative preselector shortens the trailing response without changing the emitted reference, the result supports receive-path memory rather than a transmitter-length change.

Copyright 2026, James M. Atkinson

Chapter Summary

Analog demodulation is a configured inference from RF or IF data. Bandwidth, reference recovery, gain, detector, and processing settings must accompany any claim about modulation or recovered information.

Model 6A declares a complex peak-voltage envelope, load and averaging convention. Mean power follows envelope mean square; peak envelope power follows its maximum. Sinusoidal AM inversion requires a nonnegative signed envelope. General messages need their actual mean square, while magnitude detection loses reversal sign and unequal sideband transfer can introduce quadrature structure.

Coherent recovery depends on the frequency and phase reference. Preserve complex rotation and signed SSB orientation before audio folding. Model 6B relates valid unwrapped phase to frequency: finite differences give interval averages, principal increments leave aliases, nulls can invalidate phase, and resets require segmentation. FM and PM relate excursion and modulation rate differently.

The small-phase remainder bounds a specified approximation; Carson’s estimate does not certify filter suitability or exact containment. Preserve native samples, processing states and evidence for corrections. Verify modulation across applicable levels and bandwidths, and distinguish pulse coverage from waveform fidelity. Classification and intelligibility do not independently establish source identity.

Chapter 6 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C06-MCQ-001. A receiver measures a carrier with symmetric sidebands and a stable spacing. What can these observations establish without additional evidence?

A. They prove the received envelope is unaffected by the selected IF filter.

B. They can support a modulation classification within the verified receiver response.

C. They uniquely identify the transmitter and its operational purpose.

D. They establish the original message even if the detector phase is unknown.

Answer: B. Spectral structure is technical evidence about the admitted waveform. Source identity, message reconstruction and path fidelity require different evidence and cannot be inferred from symmetry alone. Review: Carrier, Sidebands, and Modulation Evidence. Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

Why the selected alternative fits: They can support a modulation classification within the verified receiver response.

Distinguishing consideration: compare this with option A, “They prove the received envelope is unaffected by the selected IF filter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Carrier, Sidebands, and Modulation Evidence.

Review: Chapter 6 — Carrier, Sidebands, and Modulation Evidence.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-002. An audio export changes after de-emphasis is enabled while the retained RF samples are identical. Which interpretation is supported?

A. Identical RF samples require identical audio for every demodulator configuration.

B. De-emphasis can be treated as a time stamp correction with no amplitude effect.

C. The transmitter must have changed its modulation during the export.

D. The processing path has changed the derived product without demonstrating an external signal change.

Answer: D. The detector, tuning, filtering and de-emphasis help define the audio transfer. Their configuration belongs with the derived recording and must be reconciled before comparing outputs. Review: Carrier, Sidebands, and Modulation Evidence; Preserve pulse and demodulator evidence across representations. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why the selected alternative fits: The processing path has changed the derived product without demonstrating an external signal change.

Distinguishing consideration: compare this with option A, “Identical RF samples require identical audio for every demodulator configuration”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Carrier, Sidebands, and Modulation Evidence.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Carrier, Sidebands, and Modulation Evidence.

V011-C06-MCQ-003. What voltage convention does Model 6A assign to its complex envelope?

A. An RMS-voltage envelope that already includes every factor of square root two.

B. A peak-voltage envelope whose real translated waveform is the physical RF voltage.

C. A dimensionless analytic envelope independent of any load or calibration.

D. An instantaneous power envelope expressed directly in watts.

Answer: B. The peak-voltage convention fixes the factor of two in the power equations. Changing to RMS normalization is possible but requires a consistent change in all associated formulas. Review: Equations 11A and 11B. Source: Equation 11A. Real RF waveform and its complex envelope (p. 3112)

Why the selected alternative fits: A peak-voltage envelope whose real translated waveform is the physical RF voltage.

Distinguishing consideration: compare this with option A, “An RMS-voltage envelope that already includes every factor of square root two”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11A. Real RF waveform and its complex envelope; Chapter 6 — Equation 11B. Envelope power convention.

Review: Chapter 6 — Equation 11A. Real RF waveform and its complex envelope; Chapter 6 — Equation 11B. Envelope power convention.

V011-C06-MCQ-004. Why does Model 6A require the envelope bandwidth to be smaller than the positive carrier frequency?

A. To keep the translated positive and negative RF bands separated under the stated representation.

B. To guarantee that an arbitrary IF filter passes the entire modulation unchanged.

C. To force the envelope to be real for every modulation type.

D. To make the carrier power equal to total power for all messages.

Answer: A. Spectral separation supports the selected complex-envelope and averaging convention. It does not impose a real envelope, a receiver response or a particular power distribution. Review: Equation 11A. Source: Equation 11A. Real RF waveform and its complex envelope (p. 3112)

Why the selected alternative fits: To keep the translated positive and negative RF bands separated under the stated representation.

Distinguishing consideration: compare this with option B, “To guarantee that an arbitrary IF filter passes the entire modulation unchanged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11A. Real RF waveform and its complex envelope.

Review: Chapter 6 — Equation 11A. Real RF waveform and its complex envelope.

V011-C06-MCQ-005. Under the stated orthogonality and averaging conditions, a peak-voltage envelope has mean squared magnitude 1.2 square volts across 50 ohms. What is the mean RF power?

A. 24 mW.

B. 120 mW.

C. 6 mW.

D. 12 mW.

Answer: D. Divide mean squared envelope magnitude by twice the resistance: 1.2 divided by 100 equals 0.012 W. The factor of two follows the peak-voltage convention. Review: Equation 11B. Source: Equation 11B. Envelope power convention (p. 3113)

Why the selected alternative fits: 12 mW.

Distinguishing consideration: compare this with option A, “24 mW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11B. Envelope power convention.

Review: Chapter 6 — Equation 11B. Envelope power convention.

V011-C06-MCQ-006. Two captures have the same mean squared envelope magnitude but different envelope maxima. What follows under otherwise identical power conventions?

A. Their instantaneous RF voltage peaks must occur at the same times.

B. They necessarily have the same peak envelope power because their means agree.

C. They have the same mean RF power but can have different peak envelope powers.

D. Their carrier powers must be equal even when one waveform has no carrier.

Answer: C. The mean and maximum are different functionals of the envelope. Equality of one does not constrain the other, or establish a particular spectral decomposition. Review: Equation 11B; Application 6A.8. Source: Equation 11B. Envelope power convention (p. 3113)

Why the selected alternative fits: They have the same mean RF power but can have different peak envelope powers.

Distinguishing consideration: compare this with option A, “Their instantaneous RF voltage peaks must occur at the same times”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Review: Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

V011-C06-MCQ-007. A mean-power calculation averages a periodic carrier and message over an arbitrary fraction of their common period. Which condition needs attention?

A. Whether the maximum envelope magnitude must equal its RMS magnitude.

B. Whether the omitted cross terms actually vanish over the selected interval.

C. Whether the voltage convention automatically eliminates all finite-window effects.

D. Whether resistance can be removed from the calculation because the waveform is periodic.

Answer: B. The compact envelope-power relation is used with its declared orthogonality, carrier-cycle or justified long-time averaging convention. A partial interval may retain cross terms that the derivation excluded. Review: Equation 11B and its averaging assumptions. Source: Equation 11B. Envelope power convention (p. 3113)

Why the selected alternative fits: Whether the omitted cross terms actually vanish over the selected interval.

Distinguishing consideration: compare this with option A, “Whether the maximum envelope magnitude must equal its RMS magnitude”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11B. Envelope power convention.

Review: Chapter 6 — Equation 11B. Envelope power convention.

V011-C06-MCQ-008. A conventional AM envelope has positive carrier amplitude, a real message bounded in magnitude by one and modulation depth between zero and one. What is guaranteed?

A. The signed envelope is nonnegative.

B. The receiver output cannot be compressed at high input level.

C. The upper and lower received sidebands remain equal after any channel.

D. The message mean square is exactly one half.

Answer: A. The smallest possible bracket is one minus the depth, which is nonnegative. The result is a transmitter-model statement, not a guarantee about message statistics or the receiver. Review: Equation 11C. Source: Equation 11C. Conventional AM and nonnegative-envelope condition (p. 3113)

Why the selected alternative fits: The signed envelope is nonnegative.

Distinguishing consideration: compare this with option B, “The receiver output cannot be compressed at high input level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11C. Conventional AM and nonnegative-envelope condition.

Review: Chapter 6 — Equation 11C. Conventional AM and nonnegative-envelope condition.

V011-C06-MCQ-009. For sinusoidal conventional AM within the nonnegative-envelope domain, extrema are 1.8 V and 0.6 V. What carrier peak and modulation depth follow?

A. 0.6 V and 2.

B. 1.2 V and 0.667.

C. 2.4 V and 0.5.

D. 1.2 V and 0.5.

Answer: D. The carrier peak is the half-sum of the extrema, while depth is their difference divided by their sum. These are separate inversions with compatible peak-voltage inputs. Review: Equation 11D. Source: Equation 11D. Sinusoidal AM extrema and their inversion (p. 3113)

Why the selected alternative fits: 1.2 V and 0.5.

Distinguishing consideration: compare this with option A, “0.6 V and 2”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

V011-C06-MCQ-010. The maximum and minimum of a magnitude-only envelope are 2.3 V and zero. Why does the extrema formula alone not establish the original depth?

A. The half-sum formula remains an exact carrier estimator for every reversed envelope.

B. A zero minimum uniquely proves exactly 100 percent modulation before every receiver impairment.

C. An overmodulated signed envelope can cross zero and lose its negative part under magnitude detection.

D. The maximum alone fixes the carrier amplitude independently of the message.

Answer: C. A magnitude minimum at zero occurs for both a boundary case and many reversed envelopes. The nonnegative signed-envelope assumption must be established before using the inverse formula. Review: Equations 11D and 11H; Application 6A.4. Source: Equation 11D. Sinusoidal AM extrema and their inversion (p. 3113)

Why the selected alternative fits: An overmodulated signed envelope can cross zero and lose its negative part under magnitude detection.

Distinguishing consideration: compare this with option A, “The half-sum formula remains an exact carrier estimator for every reversed envelope”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion; Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate….

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion; Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

V011-C06-MCQ-011. A sinusoidal AM carrier has 1.2 V peak across 75 ohms and depth 0.5. What is the carrier power?

A. 10.8 mW.

B. 19.2 mW.

C. 9.6 mW.

D. 0.6 mW.

Answer: C. Carrier power is the squared carrier peak divided by twice the resistance: 1.44 square volts divided by 150 ohms gives 0.0096 W. Total power and either sideband power are different quantities. Review: Equation 11E. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why the selected alternative fits: 9.6 mW.

Distinguishing consideration: compare this with option A, “10.8 mW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

V011-C06-MCQ-014. Both sidebands of a verified sinusoidal AM signal are 20 dB below the carrier in power. What depth follows?

A. 0.4.

B. 0.1.

C. 0.2.

D. 0.02.

Answer: C. A minus-20 dBc sideband has power ratio 0.01. Taking its square root and multiplying by two gives depth 0.2; using a power ratio directly as an amplitude ratio loses the square root. Review: Equation 11E; Application 6A.3. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why the selected alternative fits: 0.2.

Distinguishing consideration: compare this with option A, “0.4”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers; Chapter 6 — Application 6A.3: Infer modulation depth from one resolved sideband.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers; Chapter 6 — Application 6A.3: Infer modulation depth from one resolved sideband.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-015. Only one sideband is measured at minus 20 dBc and the other lies outside the acquisition band. What is the warranted inference about AM depth?

A. A depth of 0.2 is conditional on a sinusoidal, symmetric, linear AM model that the missing sideband has not yet verified.

B. The observed sideband alone proves the carrier was suppressed.

C. The original depth is exactly 0.2 for every possible asymmetric channel.

D. The unseen sideband must have zero power because it was not recorded.

Answer: A. One sideband supports a conditional estimate. Selective filtering, fading or a different modulation can break the assumptions, so the missing evidence remains explicit. Review: Application 6A.3; Amplitude Modulation and Envelope Detection. Source: §6.8 Application 6A.3: Infer modulation depth from one resolved sideband (p. 3120)

Why the selected alternative fits: A depth of 0.2 is conditional on a sinusoidal, symmetric, linear AM model that the missing sideband has not yet verified.

Distinguishing consideration: compare this with option B, “The observed sideband alone proves the carrier was suppressed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6A.3: Infer modulation depth from one resolved sideband; Chapter 6 — Amplitude Modulation and Envelope Detection.

Review: Chapter 6 — Application 6A.3: Infer modulation depth from one resolved sideband; Chapter 6 — Amplitude Modulation and Envelope Detection.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-016. A sinusoidal AM depth increases from 0.25 to 0.5 while carrier power remains fixed. What happens to either sideband power?

A. It increases by a factor of two, approximately 3.01 dB.

B. It increases by a factor of sixteen, approximately 12.04 dB.

C. It increases by a factor of four, approximately 6.02 dB.

D. It remains fixed because carrier power is fixed.

Answer: C. Sideband amplitude is proportional to depth, but sideband power is proportional to its square. Doubling depth therefore quadruples either sideband power. Review: Equation 11E. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why the selected alternative fits: It increases by a factor of four, approximately 6.02 dB.

Distinguishing consideration: compare this with option A, “It increases by a factor of two, approximately 3.01 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-017. A zero-mean bounded AM message has mean square 0.25 and the modulation scale is 0.8. What total-to-carrier power ratio follows?

A. 1.32.

B. 1.64.

C. 1.16.

D. 1.20.

Answer: C. Use the actual mean square: one plus 0.8 squared times 0.25 is 1.16. Substituting the unit-cosine mean square of one half would give a different, unjustified value. Review: Equation 11G. Source: Equation 11G. Power for a zero-mean nonsinusoidal message (p. 3114)

Why the selected alternative fits: 1.16.

Distinguishing consideration: compare this with option A, “1.32”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Review: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-018. Two zero-mean AM messages have equal maximum magnitude and equal modulation scale but different mean squares. What can differ even in a perfect linear chain?

A. Their total mean powers relative to the same carrier.

B. The stipulated positive carrier amplitude solely because the message peaks agree.

C. The load resistance required by the peak-voltage definition.

D. The numerical value of the stated modulation scale itself.

Answer: A. Peak normalization does not fix a waveform's time distribution. The mean-square message term determines its contribution to average power. Review: Equation 11G; Application 6A.10. Source: Equation 11G. Power for a zero-mean nonsinusoidal message (p. 3114)

Why the selected alternative fits: Their total mean powers relative to the same carrier.

Distinguishing consideration: compare this with option B, "The stipulated positive carrier amplitude solely because the message peaks agree"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message; Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

Review: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message; Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

V011-C06-MCQ-019. The arbitrary-message AM power relation is applied to a message whose mean is not zero. Which omitted term must be reconsidered?

A. A compulsory negative sideband power that restores the zero-mean formula.

B. A correction that makes peak envelope power equal mean power.

C. The term proportional to twice the modulation scale times the message mean.

D. A factor that removes all dependence on the message mean square.

Answer: C. Expanding the squared real envelope gives a constant term, a term linear in the message and a squared-message term. The linear term vanishes only under the stated zero-mean condition. Review: Equation 11G and its zero-mean assumption. Source: Equation 11G. Power for a zero-mean nonsinusoidal message (p. 3114)

Why the selected alternative fits: The term proportional to twice the modulation scale times the message mean.

Distinguishing consideration: compare this with option A, “A compulsory negative sideband power that restores the zero-mean formula”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Review: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

V011-C06-MCQ-020. The ideal algebraic envelope is one plus 1.3 times a cosine, with no transmitter clipping. Which spectrum statement is correct?

A. The original carrier disappears whenever the signed envelope is negative.

B. The real RF product still contains the original carrier and two sinusoidal sidebands.

C. The two sidebands cease to be separated from the carrier by the message frequency.

D. Envelope reversal alone necessarily creates an unlimited set of new RF harmonics.

Answer: B. A linear product with one cosine expands into three RF terms at any scale. Rectifying the envelope or physically clipping the transmitter is a separate nonlinear operation. Review: Equation 11H; Application 6A.4. Source: Equation 11H. Magnitude detection after envelope reversal (p. 3115)

Why the selected alternative fits: The real RF product still contains the original carrier and two sinusoidal sidebands.

Distinguishing consideration: compare this with option A, “The original carrier disappears whenever the signed envelope is negative”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

Review: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

V011-C06-MCQ-021. Why does a simple magnitude detector distort an overmodulated AM message?

A. It preserves the signed envelope but necessarily changes the RF carrier frequency.

B. It removes the carrier and both sidebands without producing any output.

C. It replaces negative signed-envelope portions by their magnitudes and therefore loses sign information.

D. It performs exact complex rotation with a known phase reference.

Answer: C. The absolute-value operation folds the reversed portions upward. That nonlinear baseband operation is distinct from coherent recovery of the original signed envelope. Review: Equation 11H. Source: Equation 11H. Magnitude detection after envelope reversal (p. 3115)

Why the selected alternative fits: It replaces negative signed-envelope portions by their magnitudes and therefore loses sign information.

Distinguishing consideration: compare this with option A, “It preserves the signed envelope but necessarily changes the RF carrier frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal.

Review: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal.

V011-C06-MCQ-022. Additional RF components appear when an actual transmitter clips an intended overmodulated waveform. How should they be related to Model 6A?

A. They are required by any negative signed envelope even without clipping.

B. They prove the three-term cosine product identity is mathematically false.

C. They reflect a physical nonlinearity outside the unclipped algebraic AM expression.

D. They can be removed from the measured RF record by relabeling the depth.

Answer: C. The algebraic identity and the hardware transfer are different claims. A clipped amplitude law changes the waveform and can generate components absent from the ideal linear expression. Review: Equation 11H discussion; Application 6A.4.

Source: Equation 11H. Magnitude detection after envelope reversal (p. 3115)

Why the selected alternative fits: They reflect a physical nonlinearity outside the unclipped algebraic AM expression.

Distinguishing consideration: compare this with option A, “They are required by any negative signed envelope even without clipping”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

Review: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

V011-C06-MCQ-023. A measured AM envelope flattens at its peaks as receiver input rises. Which check most directly challenges a receiver-created depth error?

A. Keep the overloaded gain state and correct depth only from its maximum.

B. Repeat the same known modulation over applicable attenuation and gain states while retaining the raw waveform.

C. Infer a transmitter depth change from the flattened audio alone.

D. Assume the extrema ratio cancels every nonlinear transfer.

Answer: B. Compression and control can alter the envelope shape. A controlled level challenge helps distinguish path distortion from a source change; ratio formation does not cancel an arbitrary nonlinearity. Review: Amplitude Modulation and Envelope Detection; Analog Demodulator Verification. Source: §6.2 Amplitude Modulation and Envelope Detection (p. 3108)

Why the selected alternative fits: Repeat the same known modulation over applicable attenuation and gain states while retaining the raw waveform.

Distinguishing consideration: compare this with option A, “Keep the overloaded gain state and correct depth only from its maximum”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Amplitude Modulation and Envelope Detection; Chapter 6 — Analog Demodulator Verification.

Review: Chapter 6 — Amplitude Modulation and Envelope Detection; Chapter 6 — Analog Demodulator Verification.

V011-C06-MCQ-024. A narrow IF response attenuates high-frequency AM sidebands more strongly than low-frequency sidebands. What must accompany a reported modulation-depth result?

A. Only the nominal IF width, with all skirt and phase properties treated as equivalent.

B. The relevant path response and the message spectrum or reference modulation used to establish applicability.

C. A claim that equal input depth forces equal output depth for all message frequencies.

D. Only the center-frequency carrier calibration, assumed to cover every sideband.

Answer: B. Depth measured after a frequency-dependent path can depend on the modulation spectrum. A carrier point alone does not establish waveform fidelity across the sidebands. Review: Amplitude Modulation and Envelope Detection; Equation 11G discussion. Source: Equation 11G. Power for a zero-mean nonsinusoidal message (p. 3114)

Why the selected alternative fits: The relevant path response and the message spectrum or reference modulation used to establish applicability.

Distinguishing consideration: compare this with option A, “Only the nominal IF width, with all skirt and phase properties treated as equivalent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message; Chapter 6 — Amplitude Modulation and Envelope Detection.

V011-C06-MCQ-026. Why is the real product detector normalized with twice the LO cosine in Model 6A?

A. The factor compensates the one-half coefficient of the selected difference-frequency product.

B. It guarantees perfect opposite-sideband rejection in every hardware detector.

C. It removes all dependence on LO phase and frequency error.

D. It doubles the physical RF input power before any mixing operation.

Answer: A. Multiplication of two cosines produces half-amplitude sum and difference terms. The normalization defines unity amplitude for the intended difference term after the sum band is rejected. Review: Equation 11I; Model 4A conversion convention. Source: Equation 11I. Real coherent recovery with residual reference error (p. 3115)

Why the selected alternative fits: The factor compensates the one-half coefficient of the selected difference-frequency product.

Distinguishing consideration: compare this with option B, “It guarantees perfect opposite-sideband rejection in every hardware detector”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error; Chapter 4 — Model 4A: a declared conversion map.

V011-C06-MCQ-029. A residual carrier-minus-LO frequency error remains during real coherent recovery. How does its effect differ from a constant phase error?

A. It rotates the envelope continuously with time and can mix the message with a residual low-frequency oscillation.

B. It changes only the receiver time stamp without changing recovered frequencies.

C. It always produces only one constant amplitude scale for the full record.

D. It vanishes when a real output is retained instead of complex I/Q.

Answer: A. The residual frequency appears in a time-dependent exponential. A fixed projection of that rotating envelope cannot generally be represented by a single constant gain. Review: Equations 11I and 11J; Application 6A.6. Source: Equation 11I. Real coherent recovery with residual reference error (p. 3115)

Why the selected alternative fits: It rotates the envelope continuously with time and can mix the message with a residual low-frequency oscillation.

Distinguishing consideration: compare this with option B, “It changes only the receiver time stamp without changing recovered frequencies”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error; Chapter 6 — Equation 11J. Complex coherent recovery; Chapter 6 — Application 6A.6: Resolve the two tones caused by a DSB-SC....

V011-C06-MCQ-030. A suppressed-carrier real envelope is a 1 kHz cosine and the real coherent detector has a 50 Hz residual rotation with zero initial phase. Which output tones result?

A. Only 1 kHz at the full original envelope peak.

B. Only 1050 Hz at the full original envelope peak.

C. 50 Hz and 2 kHz with equal original peaks.

D. 950 Hz and 1050 Hz, each with half the original envelope peak.

Answer: D. The recovered real product is the 1 kHz cosine multiplied by the 50 Hz cosine. The product-to-sum identity gives the two half-amplitude components.

Review: Application 6A.6. Source: §6.11 Application 6A.6: Resolve the two tones caused by a DSB-SC tuning error (p. 3123)

Why the selected alternative fits: 950 Hz and 1050 Hz, each with half the original envelope peak.

Distinguishing consideration: compare this with option A, “Only 1 kHz at the full original envelope peak”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6A.6: Resolve the two tones caused by a DSB-SC tuning error.

Review: Chapter 6 — Application 6A.6: Resolve the two tones caused by a DSB-SC tuning error.

V011-C06-MCQ-031. Under Model 6A, which operation preserves both signed baseband orientation and residual phase rotation for later analysis?

A. Retain the calibrated complex I/Q output and its reference convention.

B. Replace every negative baseband frequency with its absolute value.

C. Discard quadrature after adjusting the audio to sound plausible.

D. Retain only the magnitude of one real audio spectrum.

Answer: A. Complex data retain information that a real projection or magnitude folding can discard. The reference and calibration are still required to interpret that retained information. Review: Equations 11J and 11K. Source: Equation 11J. Complex coherent recovery (p. 3115)

Why the selected alternative fits: Retain the calibrated complex I/Q output and its reference convention.

Distinguishing consideration: compare this with option B, “Replace every negative baseband frequency with its absolute value”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11J. Complex coherent recovery; Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes.

Review: Chapter 6 — Equation 11J. Complex coherent recovery; Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-032. For a 10 MHz reference carrier, a 2 kHz upper-sideband tone and an LO at 10.0003 MHz, what signed complex baseband frequency follows?

A. Positive 2300 Hz.

B. Negative 1700 Hz.

C. Negative 2300 Hz.

D. Positive 1700 Hz.

Answer: D. The upper-sideband RF frequency is carrier plus message frequency. Subtracting the LO gives 10,002,000 minus 10,000,300 Hz, or positive 1700 Hz.

Review: Equation 11K. Source: Equation 11K. Explicit upper and lower single-sideband envelopes (p. 3116)

Why the selected alternative fits: Positive 1700 Hz.

Distinguishing consideration: compare this with option A, “Positive 2300 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes.

Review: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes.

V011-C06-MCQ-033. For the same carrier and LO, what signed complex baseband frequency follows for the 2 kHz lower-sideband tone?

A. Positive 2300 Hz.

B. Positive 1700 Hz.

C. Negative 2300 Hz.

D. Negative 1700 Hz.

Answer: C. The lower-sideband RF frequency is carrier minus message frequency. Subtracting the LO gives 9,998,000 minus 10,000,300 Hz, or negative 2300 Hz.

Review: Equation 11K. Source: Equation 11K. Explicit upper and lower single-sideband envelopes (p. 3116)

Why the selected alternative fits: Negative 2300 Hz.

Distinguishing consideration: compare this with option A, “Positive 2300 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes.

Review: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-034. A real audio magnitude spectrum folds the preceding positive 1700 Hz and negative 2300 Hz results to positive frequencies. What information is then absent from that magnitude display alone?

A. The ability to distinguish 1700 Hz from 2300 Hz as magnitudes.

B. The original signed baseband orientation of each component.

C. The fact that the display has a frequency coordinate.

D. The two displayed absolute tone frequencies themselves.

Answer: B. A real magnitude display can retain absolute frequencies while losing their complex orientation. That loss can conceal sideband inversion or confuse the sign of a tuning correction. Review: Equation 11K; Application 6A.7. Source: Equation 11K. Explicit upper and lower single-sideband envelopes (p. 3116)

Why the selected alternative fits: The original signed baseband orientation of each component.

Distinguishing consideration: compare this with option A, “The ability to distinguish 1700 Hz from 2300 Hz as magnitudes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes; Chapter 6 — Application 6A.7: Retain SSB sign when the reinsertion frequency is wrong.

Review: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes; Chapter 6 — Application 6A.7: Retain SSB sign when the reinsertion frequency is wrong.

V011-C06-MCQ-035. An operator tunes an SSB signal until speech is intelligible. What remains necessary for a measured recovered-frequency claim?

A. A claim that tuning changes the transmitted RF waveform itself.

B. An assumption that any intelligible SSB setting exactly restores the suppressed carrier.

C. A documented carrier-reference method and its frequency accuracy, separate from subjective intelligibility.

D. Only a statement that the chosen audio sounds natural.

Answer: C. Intelligibility can guide a listening task but does not establish metrological accuracy. The retained LO/reference state determines the recovered frequency scale. Review: Single Sideband and Coherent Reception. Source: §6.3 Single Sideband and Coherent Reception (p. 3110)

Why the selected alternative fits: A documented carrier-reference method and its frequency accuracy, separate from subjective intelligibility.

Distinguishing consideration: compare this with option A, “A claim that tuning changes the transmitted RF waveform itself”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Single Sideband and Coherent Reception.

Review: Chapter 6 — Single Sideband and Coherent Reception.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-036. A two-tone SSB envelope has peak coefficients 0.6 V and 0.8 V at distinct harmonically related frequencies, observed over complete periods across 50 ohms. What mean RF power follows?

A. 20 mW.

B. 19.6 mW.

C. 10 mW.

D. 14 mW.

Answer: C. The cross term averages to zero, leaving 0.6 squared plus 0.8 squared, or 1 square volt. Divide by twice 50 ohms to obtain 10 mW. Review: Equation 11B; Application 6A.8. Source: Equation 11B. Envelope power convention (p. 3113)

Why the selected alternative fits: 10 mW.

Distinguishing consideration: compare this with option A, “20 mW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Review: Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-037. The two SSB components in the preceding case align in phase within the observation interval. What peak envelope power follows?

A. 39.2 mW.

B. 10 mW.

C. 9.8 mW.

D. 19.6 mW.

Answer: D. Their aligned envelope peak is 1.4 V. Squaring and dividing by 100 ohms gives 19.6 mW; the coherent maximum is not the sum of separately averaged powers. Review: Application 6A.8. Source: §6.13 Application 6A.8: Compare average power with peak envelope power for two SSB tones (p. 3125)

Why the selected alternative fits: 19.6 mW.

Distinguishing consideration: compare this with option A, “39.2 mW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Review: Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-038. Why must an SSB peak envelope power calculation state its observation interval or attainable phase alignment?

A. The load resistance changes automatically with the observation length.

B. A maximum is always identical to the long-time mean for multitone signals.

C. The complex envelope ceases to be defined when an interval is finite.

D. A maximum depends on the retained time domain and may not attain the sum of component magnitudes within an arbitrary finite interval.

Answer: D. The sum of magnitudes is a useful upper bound. Equality requires simultaneous phase alignment within the domain over which the maximum is taken. Review: Equation 11B; Application 6A.8. Source: Equation 11B. Envelope power convention (p. 3113)

Why the selected alternative fits: A maximum depends on the retained time domain and may not attain the sum of component magnitudes within an arbitrary finite interval.

Distinguishing consideration: compare this with option A, “The load resistance changes automatically with the observation length”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Review: Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

V011-C06-MCQ-039. An AM path leaves a unit real carrier coefficient and real sideband coefficients 0.4 and 0.2. What complex envelope follows?

A. A purely real envelope of one plus 0.8 times the cosine.

B. A real part of one plus 0.6 times the cosine and an imaginary part of 0.2 times the sine.

C. A constant envelope magnitude of one for every message phase.

D. A real part of one plus 0.2 times the cosine and an imaginary part of 0.6 times the sine.

Answer: B. The cosine coefficient is the sum of the sideband coefficients and the imaginary sine coefficient is their difference. Unequal sideband transfer therefore introduces a quadrature component. Review: Equation 11L; Application 6A.9. Source: Equation 11L. In-phase and quadrature terms after unequal sideband response (p. 3116)

Why the selected alternative fits: A real part of one plus 0.6 times the cosine and an imaginary part of 0.2 times the sine.

Distinguishing consideration: compare this with option A, “A purely real envelope of one plus 0.8 times the cosine”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11L. In-phase and quadrature terms after unequal sideband response; Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth.

Review: Chapter 6 — Equation 11L. In-phase and quadrature terms after unequal sideband response; Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth.

V011-C06-MCQ-040. For that unequal-sideband example, a real detector reports a cosine modulation coefficient 0.6 instead of the input value 0.8. What is the correct attribution?

A. The quadrature component proves that the input was necessarily phase modulated.

B. The source must have changed its modulation depth by exactly 0.2.

C. The magnitude trace uniquely identifies which sideband the path attenuated.

D. The observed change includes the asymmetric path response and cannot be assigned to the original source depth alone.

Answer: D. A known real input can acquire a complex envelope after unequal filtering. The received scalar depth is a property of the combined source and path under the selected detector. Review: Application 6A.9. Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)

Why the selected alternative fits: The observed change includes the asymmetric path response and cannot be assigned to the original source depth alone.

Distinguishing consideration: compare this with option A, “The quadrature component proves that the input was necessarily phase modulated”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth.

Review: Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth.

V011-C06-MCQ-041. Equation 11L permits complex carrier and sideband coefficients. Which extraction remains valid without assuming those coefficients are real?

A. Replace the lower-sideband coefficient by the conjugate of the upper one without checking the path.

B. Call the complete coefficient sum the real component even if it is complex.

C. Take the real and imaginary parts of the entire reconstructed complex envelope.

D. Discard every coefficient phase before computing the waveform.

Answer: C. The algebraic expansion is valid for complex coefficients, but identifying physical I and Q still requires real and imaginary extraction of the complete expression. Review: Equation 11L and coefficient definitions. Source: Equation 11L. In-phase and quadrature terms after unequal sideband response (p. 3116)

Why the selected alternative fits: Take the real and imaginary parts of the entire reconstructed complex envelope.

Distinguishing consideration: compare this with option A, “Replace the lower-sideband coefficient by the conjugate of the upper one without checking the path”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11L. In-phase and quadrature terms after unequal sideband response.

Review: Chapter 6 — Equation 11L. In-phase and quadrature terms after unequal sideband response.

V011-C06-MCQ-042. A residual opposite-sideband component appears after a practical coherent detector. Which receiver mechanism belongs in the challenge?

A. A guaranteed new modulation type whenever the rejection is finite.

B. Only a change in the remote transmitter, because local conversion cannot create leakage.

C. An automatic cancellation of phase noise by the existence of two channels.

D. I/Q imbalance, filter asymmetry or imperfect product-detector balance.

Answer: D. Practical conversion can produce residual carrier or opposite-sideband leakage. The interpretation must include verified receiver rejection and reference behavior. Review: Single Sideband and Coherent Reception. Source: §6.3 Single Sideband and Coherent Reception (p. 3110)

Why the selected alternative fits: I/Q imbalance, filter asymmetry or imperfect product-detector balance.

Distinguishing consideration: compare this with option A, “A guaranteed new modulation type whenever the rejection is finite”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Single Sideband and Coherent Reception.

Review: Chapter 6 — Single Sideband and Coherent Reception.

V011-C06-MCQ-043. A message is one half of a 1 kHz cosine plus one quarter of a 2 kHz cosine, with a common averaging period. What is its mean square?

A. 0.15625.

B. 0.5625.

C. 0.3125.

D. 0.75.

Answer: A. Each squared cosine contributes one half of its squared coefficient, and the distinct-frequency cross term averages to zero. The result is one half of 0.25 plus one half of 0.0625. Review: Equation 11G; Application 6A.10. Source: Equation 11G. Power for a zero-mean nonsinusoidal message (p. 3114)

Why the selected alternative fits: 0.15625.

Distinguishing consideration: compare this with option B, “0.5625”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message; Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

Review: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message; Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

V011-C06-MCQ-044. For that message at modulation scale 0.8, what total-to-carrier mean-power ratio follows?

A. 1.32.

B. 1.10.

C. 1.05.

D. 1.40.

Answer: B. Multiply the message mean square 0.15625 by the squared scale 0.64, then add one. The result is 1.10 under the stated averaging conditions. Review: Application 6A.10. Source: §6.15 Application 6A.10: Use message mean square rather than a sinusoidal shortcut (p. 3127)

Why the selected alternative fits: 1.10.

Distinguishing consideration: compare this with option A, “1.32”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

Review: Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

V011-C06-MCQ-045. The triangle inequality bounds the magnitude of that two-cosine message by 0.75. What does this establish for an AM envelope with unit carrier and scale 0.8?

A. An exact measured minimum of 0.4 V at every combination of message phases.

B. A total mean power equal to the square of the lower envelope bound.

C. A requirement that both cosines reach minus one simultaneously.

D. A conservative lower bound of 0.4 V on the signed envelope, without proving that bound is attained.

Answer: D. The message bound gives one minus 0.8 times 0.75. It proves nonnegativity but can be loose because component extrema need not coincide.

Review: Application 6A.10. Source: §6.15 Application 6A.10: Use message mean square rather than a sinusoidal shortcut (p. 3127)

Why the selected alternative fits: A conservative lower bound of 0.4 V on the signed envelope, without proving that bound is attained.

Distinguishing consideration: compare this with option A, “An exact measured minimum of 0.4 V at every combination of message phases”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

Review: Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-046. A receiver limiter is inserted before an intended AM-depth measurement. Which limitation must be addressed?

A. Limiter output alone provides the original carrier-to-sideband power ratio for every input.

B. A limiter automatically restores signed envelope portions lost to magnitude detection.

C. The limiter can remove or alter amplitude information needed by the measurand.

D. Limiting preserves all envelope extrema because carrier frequency is unchanged.

Answer: C. An operation useful for suppressing amplitude variation in an angle-modulation path can destroy the amplitude relationship required by AM analysis. The appropriate path depends on the measurand. Review: Amplitude Modulation and Envelope Detection; Analog Demodulator Verification. Source: §6.2 Amplitude Modulation and Envelope Detection (p. 3108)

Why the selected alternative fits: The limiter can remove or alter amplitude information needed by the measurand.

Distinguishing consideration: compare this with option A, “Limiter output alone provides the original carrier-to-sideband power ratio for every input”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Amplitude Modulation and Envelope Detection; Chapter 6 — Analog Demodulator Verification.

Review: Chapter 6 — Amplitude Modulation and Envelope Detection; Chapter 6 — Analog Demodulator Verification.

V011-C06-MCQ-047. Two candidate demodulator configurations produce plausible audio from the same stored RF capture. What is the stronger technical discriminator?

A. Average the two audio waveforms and call the result the original message.

B. Compare each output with known waveform relationships and calibrated reference tests under its recorded configuration.

C. Treat plausible audio as evidence that filter and tuning states are immaterial.

D. Accept whichever output sounds more familiar as proof of the transmitter type.

Answer: B. Multiple processing choices can produce plausible derived signals. A reproducible relationship to the native capture and a verified transfer provide stronger evidence than familiarity alone. Review: Preserve pulse and demodulator evidence across representations. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why the selected alternative fits: Compare each output with known waveform relationships and calibrated reference tests under its recorded configuration.

Distinguishing consideration: compare this with option A, “Average the two audio waveforms and call the result the original message”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations.

V011-C06-MCQ-048. What additional condition makes the phase derivative in Model 6B a well-defined local frequency relation?

A. A supported unwrapped, absolutely continuous phase branch for the stipulated nonzero-amplitude complex signal.

B. Only a list of wrapped angles with no continuity or time basis.

C. A zero-amplitude sample at every point so that phase is unrestricted.

D. An arbitrary real audio magnitude spectrum with all phase discarded.

Answer: A. The derivative relation uses the continuous phase of the defined complex signal and holds almost everywhere under the stated regularity. An undefined or unsupported phase does not become physical frequency merely by numerical differentiation. Review: Equation 12A and Model 6B assumptions. Source: Equation 12A. Complex phase and instantaneous frequency (p. 3131)

Why the selected alternative fits: A supported unwrapped, absolutely continuous phase branch for the stipulated nonzero-amplitude complex signal.

Distinguishing consideration: compare this with option B, “Only a list of wrapped angles with no continuity or time basis”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12A. Complex phase and instantaneous frequency; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

Review: Chapter 6 — Equation 12A. Complex phase and instantaneous frequency; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-049. Why is a dramatic phase-derived frequency excursion near a signal null not automatically evidence of a transmitter chirp?

A. Numerical phase differentiation cannot respond to noise or interference.

B. Every phase derivative is exactly zero whenever amplitude varies.

C. The phase estimate can become ill-conditioned when amplitude is near zero or multiple components are unresolved.

D. A null guarantees an infinitely precise carrier-frequency estimate.

Answer: C. The single supported phase branch is a model condition. Near a null, noise or component cancellation can dominate the phase estimate and invalidate a simple physical-frequency interpretation. Review: Model 6B assumptions; Frequency and Phase Modulation. Source: §6.17 Model 6B: phase is the quantity that frequency differentiates (p. 3131)

Why the selected alternative fits: The phase estimate can become ill-conditioned when amplitude is near zero or multiple components are unresolved.

Distinguishing consideration: compare this with option A, “Numerical phase differentiation cannot respond to noise or interference”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 6 — Frequency and Phase Modulation.

Review: Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 6 — Frequency and Phase Modulation.

V011-C06-MCQ-051. A sinusoidal FM signal has 4.5 kHz peak deviation at a 1.5 kHz modulation frequency. What is its phase index?

A. 6.75 radians.

B. 0.333 radian.

C. 3000 radians.

D. 3 radians.

Answer: D. The phase index is deviation divided by modulation frequency with matching units. The ratio is dimensionless, customarily reported as a phase excursion in radians. Review: Equation 12B; Application 6B.1. Source: Equation 12B. Sinusoidal FM phase and modulation index (p. 3132)

Why the selected alternative fits: 3 radians.

Distinguishing consideration: compare this with option A, “6.75 radians”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Application 6B.1: Convert a sinusoidal FM deviation into phase excursion.

Review: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Application 6B.1: Convert a sinusoidal FM deviation into phase excursion.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-052. The peak frequency deviation of a sinusoidal FM signal remains fixed while its modulation frequency doubles. How does the phase index change?

A. It halves.

B. It remains fixed.

C. It becomes zero regardless of deviation.

D. It doubles.

Answer: A. The index divides a fixed deviation by modulation frequency. This differs from a PM experiment in which phase excursion is held fixed. Review: Equation 12B; Application 6B.3. Source: Equation 12B. Sinusoidal FM phase and modulation index (p. 3132)

Why the selected alternative fits: It halves.

Distinguishing consideration: compare this with option B, “It remains fixed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation.

Review: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-053. A sinusoidal PM experiment holds peak phase excursion fixed while modulation frequency increases from 1 kHz to 4 kHz. What happens to peak frequency deviation?

A. It increases by a factor of four.

B. It decreases by a factor of four.

C. It remains fixed.

D. It becomes a constant carrier-frequency offset.

Answer: A. Frequency offset is the phase derivative divided by two pi. Differentiating a fixed-amplitude sinusoidal phase introduces the modulation frequency. Review: Equation 12C; Application 6B.3. Source: Equation 12C. Sinusoidal PM and its frequency deviation (p. 3132)

Why the selected alternative fits: It increases by a factor of four.

Distinguishing consideration: compare this with option B, “It decreases by a factor of four”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation; Chapter 6 — Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation.

V011-C06-MCQ-055. A constant 35-degree phase-reference offset is added to an otherwise correct continuous phase record. What frequency offset does that constant contribute?

A. 35 times the sample rate in hertz.

B. Zero.

C. One complete cycle per observation interval.

D. 35 Hz.

Answer: B. The derivative of a constant phase offset is zero. A constant phase error can matter to coherent projection while contributing no frequency error. Review: Equation 12K; Application 6B.10. Source: Equation 12K. Separate modulation, frequency offset and phase offset (p. 3135)

Why the selected alternative fits: Zero.

Distinguishing consideration: compare this with option A, “35 times the sample rate in hertz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

Review: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-056. A known positive 80 Hz carrier-minus-LO offset persists for 2 ms. What additional phase accumulation does it produce?

A. 0.16 cycle, or 57.6 degrees.

B. 160 cycles, or 57,600 degrees.

C. 0.04 cycle, or 14.4 degrees.

D. Zero because it is a constant frequency offset.

Answer: A. Cycles equal frequency offset times elapsed seconds: 80 times 0.002. A constant frequency error produces a linear phase trend, unlike a constant phase error. Review: Equation 12K; Application 6B.10. Source: Equation 12K. Separate modulation, frequency offset and phase offset (p. 3135)

Why the selected alternative fits: 0.16 cycle, or 57.6 degrees.

Distinguishing consideration: compare this with option B, “160 cycles, or 57,600 degrees”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

Review: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

V011-C06-MCQ-057. A frequency-reference offset is estimated from a short segment of the same modulated record and then removed. What dependency should be retained?

A. A short interval necessarily spans complete periods of every modulation component.

B. The estimate can absorb part of the modulation, depending on the segment and estimator.

C. Any centered corrected trace proves that the original modulation was preserved.

D. The correction is independent of the signal because it is expressed in hertz.

Answer: B. A fitted trend can confound reference error with genuine low-frequency or incomplete-period modulation. Preserve the original record, fit interval and independent reference evidence. Review: Equation 12K discussion; Application 6B.10. Source: Equation 12K. Separate modulation, frequency offset and phase offset (p. 3135)

Why the selected alternative fits: The estimate can absorb part of the modulation, depending on the segment and estimator.

Distinguishing consideration: compare this with option A, “A short interval necessarily spans complete periods of every modulation component”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

Review: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

V011-C06-MCQ-058. A carrier-recovery algorithm resets phase after losing lock. How should a phase derivative be handled across that boundary?

A. Assume that an arbitrary integer-cycle correction is uniquely determined by the reset alone.

B. Differentiate the jump as proof of an instantaneous physical frequency spike.

C. Treat the reset as a segment boundary and establish any intersegment relationship separately.

D. Delete the reset samples and splice the stable portions into an apparently continuous record.

Answer: C. A reference reset is not the same as continuous signal phase evolution. Bridging it without a justified relationship creates an unsupported frequency history. Review: Equation 12K discussion; Preserve pulse and demodulator evidence across representations. Source: Equation 12K. Separate modulation, frequency offset and phase offset (p. 3135)

Why the selected alternative fits: Treat the reset as a segment boundary and establish any intersegment relationship separately.

Distinguishing consideration: compare this with option A, “Assume that an arbitrary integer-cycle correction is uniquely determined by the reset alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Preserve pulse and demodulator evidence across representations.

V011-C06-MCQ-059. A linear frequency offset ramps from minus 2 kHz to plus 2 kHz over 4 ms. Its net phase change is zero. What does that endpoint result establish?

A. The unwrapped phase could not have made an intermediate excursion.

B. The waveform had zero frequency offset at every time.

C. Every receiver filter must produce an unchanged waveform because the endpoints agree.

D. The signed frequency-offset integral cancels, not that frequency or phase remained unchanged throughout.

Answer: D. Equal positive and negative areas can cancel over the full interval. Endpoint phase differences alone do not reveal the intermediate trajectory. Review: Equation 12D; Application 6B.5. Source: Equation 12D. Integration of a general deterministic frequency offset (p. 3132)

Why the selected alternative fits: The signed frequency-offset integral cancels, not that frequency or phase remained unchanged throughout.

Distinguishing consideration: compare this with option A, “The unwrapped phase could not have made an intermediate excursion”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset; Chapter 6 — Application 6B.5: Integrate a linear frequency ramp without losing phase turns.

Review: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset; Chapter 6 — Application 6B.5: Integrate a linear frequency ramp without losing phase turns.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-060. A frequency offset ramps linearly from minus 3 kHz to plus 3 kHz over 6 ms, starting at zero phase. What is the accumulated phase at the midpoint?

A. Minus 9 pi radians.

B. Zero radians.

C. Minus 18 pi radians.

D. Positive 9 pi radians.

Answer: A. Over the first 3 ms, the average offset is minus 1.5 kHz, giving minus 4.5 cycles. Multiplication by two pi gives minus 9 pi radians; the second half later cancels this accumulation. Review: Equation 12D; Application 6B.5 method. Source: Equation 12D. Integration of a general deterministic frequency offset (p. 3132)

Why the selected alternative fits: Minus 9 pi radians.

Distinguishing consideration: compare this with option B, “Zero radians”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset; Chapter 6 — Application 6B.5: Integrate a linear frequency ramp without losing phase turns.

Review: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset; Chapter 6 — Application 6B.5: Integrate a linear frequency ramp without losing phase turns.

V011-C06-MCQ-061. Phase consists of 0.3 radian times a 1 kHz sine plus 0.1 radian times a 3 kHz sine, with aligned phases. What peak frequency deviation is attained at time zero?

A. 1200 Hz.

B. 600 Hz.

C. 0.4 Hz.

D. 400 Hz.

Answer: B. Differentiation gives cosine components of 300 Hz each. Both equal their positive maxima at time zero, so their sum attains the 600 Hz triangle bound.

Review: Equation 12E; Application 6B.4. Source: Equation 12E. Deviation from several phase components (p. 3133)

Why the selected alternative fits: 600 Hz.

Distinguishing consideration: compare this with option A, “1200 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12E. Deviation from several phase components; Chapter 6 — Application 6B.4: Bound and attain the deviation of a two-tone phase.

Review: Chapter 6 — Equation 12E. Deviation from several phase components; Chapter 6 — Application 6B.4: Bound and attain the deviation of a two-tone phase.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-062. For several sinusoidal phase terms with arbitrary relative phases, what does the sum of the absolute individual frequency-deviation peaks establish?

A. A conservative upper bound whose attainability requires compatible phase alignment.

B. An exact maximum for every set of phases and every observation interval.

C. A lower bound that every instantaneous deviation must exceed.

D. An exact RMS deviation independent of correlations.

Answer: A. The triangle inequality bounds the sum, but equality requires the component extrema to align with the necessary signs. That condition is not automatic. Review: Equation 12E. Source: Equation 12E. Deviation from several phase components (p. 3133)

Why the selected alternative fits: A conservative upper bound whose attainability requires compatible phase alignment.

Distinguishing consideration: compare this with option B, “An exact maximum for every set of phases and every observation interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12E. Deviation from several phase components.

Review: Chapter 6 — Equation 12E. Deviation from several phase components.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-063. A constant frequency offset of 75 Hz lasts for 20 ms on a continuous phase branch. What phase accumulation follows?

A. 1500 cycles.

B. 0.15 cycle, or 0.3 pi radian.

C. 1.5 cycles, or 3 pi radians.

D. 75 radians independently of duration.

Answer: C. Integrate frequency offset over time: 75 times 0.020 gives 1.5 cycles. The conversion to radians multiplies by two pi. Review: Equation 12D. Source: Equation 12D. Integration of a general deterministic frequency offset (p. 3132)

Why the selected alternative fits: 1.5 cycles, or 3 pi radians.

Distinguishing consideration: compare this with option A, “1500 cycles”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset.

Review: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset.

V011-C06-MCQ-064. A phase sensitivity is specified in radians per volt and the message peak in volts. What is the unit of their product before differentiating the phase?

A. Radians of phase excursion.

B. Watts of RF power.

C. Hertz of frequency deviation without any time dependence.

D. Volts per radian.

Answer: A. The voltage units cancel, leaving a phase excursion. Frequency deviation additionally depends on the message time derivative or, for a sinusoid, its modulation frequency. Review: Equation 12C. Source: Equation 12C. Sinusoidal PM and its frequency deviation (p. 3132)

Why the selected alternative fits: Radians of phase excursion.

Distinguishing consideration: compare this with option B, “Watts of RF power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

Review: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

V011-C06-MCQ-065. At 48,000 complex samples per second, a constant positive 31 kHz offset gives which principal-increment frequency?

A. Negative 17 kHz.

B. Negative 31 kHz.

C. Positive 31 kHz.

D. Positive 17 kHz.

Answer: A. Subtract one 48 kHz sampling-rate interval to place the frequency in the selected principal interval. The resulting minus 17 kHz has the same sampled complex progression. Review: Equation 12G; Application 6B.6. Source: Equation 12G. Principal-increment frequency and its alias class (p. 3134)

Why the selected alternative fits: Negative 17 kHz.

Distinguishing consideration: compare this with option B, “Negative 31 kHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Application 6B.6: Expose the ambiguity of sampled phase increments.

Review: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Application 6B.6: Expose the ambiguity of sampled phase increments.

V011-C06-MCQ-066. The principal argument convention is minus pi inclusive to plus pi exclusive. At a 48 kHz complex sample rate, how is the half-rate boundary represented?

A. Positive 24 kHz is included and negative 24 kHz is excluded.

B. Both boundaries are excluded and the interval is narrower than 48 kHz.

C. Negative 24 kHz is included and positive 24 kHz is excluded.

D. Both positive and negative 24 kHz are separate distinguishable endpoints.

Answer: C. The chosen argument branch determines which equivalent boundary value is retained. The two half-rate signs produce the same sampled exponential and are not distinct observations. Review: Equation 12G. Source: Equation 12G. Principal-increment frequency and its alias class (p. 3134)

Why the selected alternative fits: Negative 24 kHz is included and positive 24 kHz is excluded.

Distinguishing consideration: compare this with option A, “Positive 24 kHz is included and negative 24 kHz is excluded”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class.

Review: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class.

V011-C06-MCQ-067. Why can phase unwrapping alone not distinguish a constant positive 31 kHz offset from negative 17 kHz at a 48 kHz complex sample rate?

A. An unwrapping algorithm always selects the physically positive frequency.

B. The correct alias is uniquely determined by the final sample index.

C. A larger integer number of phase wraps necessarily has greater measured amplitude.

D. The sampled complex values are identical, so selecting an alias needs additional band information or a changed observation.

Answer: D. Unwrapping does not create information absent from the samples. An admitted-band constraint, additional reference or changed sampling condition can supply the missing evidence. Review: Equation 12G; Application 6B.6. Source: Equation 12G. Principal-increment frequency and its alias class (p. 3134)

Why the selected alternative fits: The sampled complex values are identical, so selecting an alias needs additional band information or a changed observation.

Distinguishing consideration: compare this with option A, “An unwrapping algorithm always selects the physically positive frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Application 6B.6: Expose the ambiguity of sampled phase increments.

Review: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Application 6B.6: Expose the ambiguity of sampled phase increments.

V011-C06-MCQ-069. An unwrapped phase increment of pi divided by four radians is observed over 50 microseconds. What interval-average frequency offset follows?

A. 1250 Hz.

B. 15,708 Hz.

C. 5000 Hz.

D. 2500 Hz.

Answer: D. Divide the phase increment by two pi and by the elapsed interval in seconds. The increment is one eighth of a cycle, giving 2500 cycles per second over 50 microseconds. Review: Equation 12F. Source: Equation 12F. Finite-interval frequency from unwrapped phase (p. 3133)

Why the selected alternative fits: 2500 Hz.

Distinguishing consideration: compare this with option A, “1250 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Copyright 2026, James M. Atkinson

V011-C06-MCQ-070. A finite difference of unwrapped phase is labeled instantaneous frequency at its midpoint. What further condition is needed for that label?

A. A declaration that carrier frequency is positive.

B. A justified local approximation relating the interval average to the midpoint derivative.

C. An arbitrary choice of midpoint with no smoothness or error consideration.

D. Only a nonzero time interval, which makes all averages equal instantaneous values.

Answer: B. The phase difference divided by interval is exactly an average derivative under the stated assumptions. Equality or approximation to a point value needs additional information about variation within the interval. Review: Equation 12F; Application 6B.7. Source: Equation 12F. Finite-interval frequency from unwrapped phase (p. 3133)

Why the selected alternative fits: A justified local approximation relating the interval average to the midpoint derivative.

Distinguishing consideration: compare this with option A, “A declaration that carrier frequency is positive”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase; Chapter 6 — Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value.

V011-C06-MCQ-071. A shorter phase-difference interval is chosen to improve temporal locality. What tradeoff must also be assessed?

A. Conversion of a wrapped phase record into a uniquely known continuous branch.

B. Automatic elimination of all alias ambiguity.

C. Greater sensitivity of the frequency estimate to phase measurement error for a fixed phase-error scale.

D. Guaranteed reduction of both time averaging and all noise at every sample.

Answer: C. The same phase error divided by a shorter time can produce a larger frequency error. Locality, phase quality and sampling assumptions must be considered together. Review: Application 6B.7. Source: §6.25 Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value (p. 3143)

Why the selected alternative fits: Greater sensitivity of the frequency estimate to phase measurement error for a fixed phase-error scale.

Distinguishing consideration: compare this with option A, “Conversion of a wrapped phase record into a uniquely known continuous branch”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value.

Review: Chapter 6 — Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value.

V011-C06-MCQ-072. Two adjacent equal-duration intervals have average offsets 200 Hz and 400 Hz. What is the average offset over their combined interval?

A. 600 Hz.

B. 300 Hz.

C. 200 Hz.

D. A uniquely established instantaneous 300 Hz at their shared boundary.

Answer: B. Add their phase changes and divide by the combined duration. Equal durations give the arithmetic mean, but this does not establish a pointwise derivative at the boundary. Review: Equation 12F. Source: Equation 12F. Finite-interval frequency from unwrapped phase (p. 3133)

Why the selected alternative fits: 300 Hz.

Distinguishing consideration: compare this with option A, “600 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

V011-C06-MCQ-073. An unknown but constant complex phase rotation multiplies every sample in a valid segment. What happens to adjacent phase-increment products?

A. The common rotation cancels in each sample times the conjugate of its predecessor.

B. It changes the sample interval and therefore the declared sampling rate.

C. It doubles in the increment because both samples contain it.

D. It adds a different arbitrary frequency offset to every interval.

Answer: A. The rotation and its complex conjugate multiply to one. This cancellation applies to a constant phase factor, not a time-varying reference or a reset. Review: Equation 12G; Equation 12K. Source: Equation 12G. Principal-increment frequency and its alias class (p. 3134)

Why the selected alternative fits: The common rotation cancels in each sample times the conjugate of its predecessor.

Distinguishing consideration: compare this with option B, “It changes the sample interval and therefore the declared sampling rate”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset.

Review: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset.

V011-C06-MCQ-074. A phase record has a missing interval and reacquires with an independently chosen phase origin. What should a frequency trace do at that gap?

A. Choose an integer wrap that makes the graph smooth and call it a verified correction.

B. Preserve the discontinuity in coverage and avoid an unsupported derivative across the two origins.

C. Fill the gap with a straight line and report the interpolated derivative as observed.

D. Remove the gap from the time axis so adjacent retained samples appear contiguous.

Answer: B. Continuity and reference identity are prerequisites to the derivative interpretation. Interpolation or branch selection can be a model, but it is not an observation of the missing interval. Review: Preserve pulse and demodulator evidence across representations; Model 10E cross-reference. Source: §10.48 Model 10E for absolute sample continuity and retained processing state (p. 5744)

Why the selected alternative fits: Preserve the discontinuity in coverage and avoid an unsupported derivative across the two origins.

Distinguishing consideration: compare this with option A, “Choose an integer wrap that makes the graph smooth and call it a verified correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Model 10E for absolute sample continuity and retained processing state; Chapter 6 — Preserve pulse and demodulator evidence across representations.

Review: Chapter 10 — Model 10E for absolute sample continuity and retained processing state; Chapter 6 — Preserve pulse and demodulator evidence across representations.

V011-C06-MCQ-076. A real phase excursion is bounded in magnitude by 0.2 radian. What pointwise bound does Model 6B give for the error of the first-order complex exponential approximation?

A. 0.02 in normalized complex amplitude.

B. 0.01 Hz.

C. Exactly zero because 0.2 is smaller than one.

D. 0.2 in normalized power.

Answer: A. The remainder magnitude is bounded by half the squared phase. The largest stated bound is 0.2 squared divided by two, and it concerns complex-amplitude error, not a power probability. Review: Equation 12H. Source: Equation 12H. Pointwise small-phase remainder (p. 3134)

Why the selected alternative fits: 0.02 in normalized complex amplitude.

Distinguishing consideration: compare this with option B, “0.01 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12H. Pointwise small-phase remainder.

Review: Chapter 6 — Equation 12H. Pointwise small-phase remainder.

V011-C06-MCQ-078. A small-phase remainder bound is 0.005 in normalized complex amplitude. Which claim does that bound support?

A. The receiver has a 0.005 probability of missing any event.

B. The pointwise approximation error cannot exceed the stated bound under the model assumptions.

C. The actual error is exactly 0.005 at every time.

D. Exactly 0.5 percent of the signal power lies outside the retained spectrum.

Answer: B. A deterministic amplitude-error bound differs from an attained error, an integrated spectral-power fraction and a detection probability. Its scope must remain attached to the quantity bounded. Review: Equations 12H and 12I; Application 6B.8. Source: Equation 12H. Pointwise small-phase remainder (p. 3134)

Why the selected alternative fits: The pointwise approximation error cannot exceed the stated bound under the model assumptions.

Distinguishing consideration: compare this with option A, “The receiver has a 0.005 probability of missing any event”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12H. Pointwise small-phase remainder; Chapter 6 — Equation 12I. First-order sidebands for sinusoidal small phase; Chapter 6 — Application 6B.8: Bound a small-phase approximation before….
