B. A large phase index necessarily changes the real load resistance.

C. The frequency derivative relation becomes false solely because the phase is large.

D. The exact complex exponential is undefined for phase excursions above one radian.

Answer: A. The exact phase model remains meaningful, but truncating it to the carrier and two first-order terms can be inadequate. Model 6B does not claim an unchanged exact carrier amplitude at arbitrary index. Review: Equations 12H and 12I. Source: Equation 12H. Pointwise small-phase remainder (p. 3134)

Why the selected alternative fits: The retained approximation and its error are being used beyond the justified small-phase claim.

Distinguishing consideration: compare this with option B, “A large phase index necessarily changes the real load resistance”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Equation 12H. Pointwise small-phase remainder; Chapter 6 — Equation 12I. First-order sidebands for sinusoidal small phase.

Review: Chapter 6 — Equation 12H. Pointwise small-phase remainder; Chapter 6 — Equation 12I. First-order sidebands for sinusoidal small phase.

V011-C06-MCQ-080. Peak frequency deviation is 5 kHz and significant modulating content extends to 3 kHz. What Carson bandwidth estimate follows?

A. 6 kHz.

B. 8 kHz.

C. 10 kHz.

D. 16 kHz.

Answer: D. The estimate is twice the sum of peak deviation and the highest significant modulation frequency. Both inputs must use the same frequency unit.
Review: Equation 12J; Application 6B.9. Source: Equation 12J. Carson estimate and its stated inputs (p. 3135)
Why the selected alternative fits: 16 kHz.
Distinguishing consideration: compare this with option A, “6 kHz”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 6 — Equation 12J. Carson estimate and its stated inputs; Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response.
Review: Chapter 6 — Equation 12J. Carson estimate and its stated inputs; Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response.

V011-C06-MCQ-081. Why should a report define what significant modulating frequency means when applying Carson's estimate to a measured broadband message?

A. A bandwidth estimate uniquely determines all message-frequency amplitudes.

B. Any arbitrarily small spectral tail can be ignored without a stated criterion or consequence.

C. The selected upper message frequency is an input to the estimate and depends on the retained signal criterion.

D. The term always equals half the RF carrier frequency.

Answer: C. A broadband waveform may have no sharp finite spectral edge. A stated criterion and retained spectrum make the chosen planning input reproducible.

Review: Equation 12J and its stated inputs. Source: Equation 12J. Carson estimate and its stated inputs (p. 3135)

Why the selected alternative fits: The selected upper message frequency is an input to the estimate and depends on the retained signal criterion.

Distinguishing consideration: compare this with option A, "A bandwidth estimate uniquely determines all message-frequency amplitudes"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 6 — Equation 12J. Carson estimate and its stated inputs.

Review: Chapter 6 — Equation 12J. Carson estimate and its stated inputs.

V011-C06-MCQ-082. What does the chapter's Carson estimate establish about the exact fraction of power passed by a nominal IF width?

A. No exact passed fraction without the waveform spectrum and actual filter response.

B. Exactly 99 percent for every signal and every filter with that width label.

C. Exactly zero signal power whenever the nominal width is narrower.

D. Exactly all signal power whenever the nominal width exceeds the estimate.

Answer: A. A planning bandwidth does not specify spectral weighting or filter skirts. The archival IRIG discussion also distinguishes the estimate from a universal containment result. Review: Equation 12J; Application 6B.9; IRIG 106-05 Appendix A, section 5.2.3.3. Source: Equation 12J. Carson estimate and its stated inputs (p. 3135)

Why the selected alternative fits: No exact passed fraction without the waveform spectrum and actual filter response.

Distinguishing consideration: compare this with option B, "Exactly 99 percent for every signal and every filter with that width label"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 6 — Equation 12J. Carson estimate and its stated inputs; Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response; Chapter 6 — Model 6B: phase is the....

Review: Chapter 6 — Equation 12J. Carson estimate and its stated inputs; Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

V011-C06-MCQ-083. A 16 kHz Carson estimate is compared with IF labels of 12.5 kHz and 25 kHz. What is the appropriate next technical step?

A. Declare the 12.5 kHz setting has rejected exactly 3.5 kHz worth of uniformly distributed power.

B. Examine the actual transfer responses and recovered-waveform error under the intended settings.

C. Declare the 25 kHz setting distortion-free solely from its larger label.

D. Treat both width labels as ideal rectangular spectral masks by definition.

Answer: B. The label may describe a particular attenuation point while amplitude and phase response vary elsewhere. Suitability must be assessed against the actual waveform and measurand. Review: Application 6B.9. Source: §6.27 Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response (p. 3145)

Why the selected alternative fits: Examine the actual transfer responses and recovered-waveform error under the intended settings.

Distinguishing consideration: compare this with option A, “Declare the 12.5 kHz setting has rejected exactly 3.5 kHz worth of uniformly distributed power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response.

Review: Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response.

V011-C06-MCQ-084. A wider IF setting improves recovered deviation fidelity but admits more unwanted energy. Which selection principle follows?

A. Always maximize width because bandwidth has no measurement penalty.

B. Always minimize width because narrower paths cannot distort angle modulation.

C. Choose a response that meets the declared waveform-error criterion while evaluating its admitted noise and interference.

D. Select only by nominal carrier frequency and ignore the modulation spectrum.

Answer: C. Waveform fidelity and admitted energy are concurrent path properties. A suitable setting is justified by the intended quantity and tested operating domain, not by one universal width rule. Review: Application 6B.9; Analog Demodulator Verification. Source: §6.27 Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response (p. 3145)

Why the selected alternative fits: Choose a response that meets the declared waveform-error criterion while evaluating its admitted noise and interference.

Distinguishing consideration: compare this with option A, “Always maximize width because bandwidth has no measurement penalty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response; Chapter 6 — Analog Demodulator Verification.

Review: Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response; Chapter 6 — Analog Demodulator Verification.

V011-C06-MCQ-085. The Navy's historical FM discussion uses percent modulation relative to a stated allowed deviation. How should that be distinguished from the sinusoidal phase index?

A. Phase index is a universally fixed legal deviation limit.

B. Percent deviation uses a declared allowed-deviation reference; phase index divides actual deviation by modulation frequency.

C. A historical deviation example establishes today's allowed limit for every receiver task.

D. Both quantities are identical for every modulation frequency and service.

Answer: B. The ratios have different denominators and purposes. The chapter uses explicit phase and frequency quantities and does not import archival allocation examples as current requirements. Review: Equation 12B; NEETS Module 12, printed pages 2-12–2-13; chapter reference scope. Source: Equation 12B. Sinusoidal FM phase and modulation index (p. 3132)

Why the selected alternative fits: Percent deviation uses a declared allowed-deviation reference; phase index divides actual deviation by modulation frequency.

Distinguishing consideration: compare this with option A, "Phase index is a universally fixed legal deviation limit"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

Review: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

V011-C06-MCQ-086. An FM limiter reduces amplitude fluctuations before a discriminator. What cannot be concluded from that operation alone?

A. That the signal path now includes a nonlinear amplitude operation.

B. That the limiter has affected the amplitude delivered to the following stage.

C. That the limiter state belongs in the demodulator configuration record.

D. That weak-signal phase noise, interference, capture or loss of the desired component has been eliminated.

Answer: D. Amplitude limiting is not a universal recovery guarantee. The phase information can remain corrupted or dominated by another component even when output amplitude appears constant. Review: Frequency and Phase Modulation; Analog Demodulator Verification. Source: §6.31 Analog Demodulator Verification (p. 3152)

Why the selected alternative fits: That weak-signal phase noise, interference, capture or loss of the desired component has been eliminated.

Distinguishing consideration: compare this with option A, “That the signal path now includes a nonlinear amplitude operation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Analog Demodulator Verification; Chapter 6 — Frequency and Phase Modulation.

Review: Chapter 6 — Analog Demodulator Verification; Chapter 6 — Frequency and Phase Modulation.

V011-C06-MCQ-087. A strong nearby component dominates an FM output and a weaker component is not audible. What interpretation is strongest?

A. Capture or another receiver limitation may suppress the weaker component in that output; its absence from audio does not establish absence from RF.

B. The stronger component has physically removed the weaker transmission at its source.

C. Increasing audio normalization proves recovery of the original weak waveform.

D. The weaker external RF component cannot exist because no separate audio is heard.

Answer: A. The output reflects nonlinear and selective receiver behavior. A separate RF observation and a suitable challenge are needed to characterize the weaker component. Review: Frequency and Phase Modulation; Chapter Glossary: Capture effect. Source: §6.16 Frequency and Phase Modulation (p. 3128)

Why the selected alternative fits: Capture or another receiver limitation may suppress the weaker component in that output; its absence from audio does not establish absence from RF.

Distinguishing consideration: compare this with option B, “The stronger component has physically removed the weaker transmission at its source”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Frequency and Phase Modulation; Chapter 6 — CAPTURE EFFECT (glossary).

Review: Chapter 6 — Frequency and Phase Modulation; Chapter 6 — CAPTURE EFFECT (glossary).

V011-C06-MCQ-088. A demodulator passes a reference test at moderate carrier level. Why are low-level and strong-signal tests still relevant?

A. Any later failure can be assigned to the source without checking receiver state.

B. Only RF carrier frequency can affect recovered distortion.

C. A moderate-level test proves every level state because the modulation type is unchanged.

D. Different impairments can dominate near sensitivity limits and near overload limits.

Answer: D. Threshold behavior, noise, limiting, compression and control are level dependent. The verification domain must include the conditions used by the claimed measurement. Review: Analog Demodulator Verification. Source: §6.31 Analog Demodulator Verification (p. 3152)

Why the selected alternative fits: Different impairments can dominate near sensitivity limits and near overload limits.

Distinguishing consideration: compare this with option A, “Any later failure can be assigned to the source without checking receiver state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Analog Demodulator Verification.

Review: Chapter 6 — Analog Demodulator Verification.

V011-C06-MCQ-089. A frequency discriminator produces a large transient immediately after carrier recovery. What should be established before reporting it as intrapulse modulation?

A. The lock, limiter, filter and reference states during that transient.

B. A correction based solely on the average carrier power after the event.

C. An assumption that every post-trigger sample has settled because recording has begun.

D. Only that the final steady audio is intelligible.

Answer: A. Acquisition start and valid demodulation need not coincide. A recovery transient can arise inside the receiver and must be separated from a supported external waveform feature. Review: Preserve pulse and demodulator evidence across representations; Analog Demodulator Verification. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why the selected alternative fits: The lock, limiter, filter and reference states during that transient.

Distinguishing consideration: compare this with option B, “A correction based solely on the average carrier power after the event”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Analog Demodulator Verification.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Analog Demodulator Verification.

V011-C06-MCQ-090. A pulsed input has modest long-time average power but a high instantaneous peak. Which risk remains?

A. Guaranteed linearity because average power alone bounds every instantaneous level.

B. A requirement that peak envelope power equal average power for short events.

C. Automatic correction of any clipping by increasing observation duration.

D. Front-end compression or protection recovery during and after the pulse.

Answer: D. A short duty cycle can conceal high peaks in an average. The front end responds to its instantaneous operating conditions, and lost information is not recovered by a longer average. Review: Pulse, Radar, and Transient Reception.

Source: §6.29 Pulse, Radar, and Transient Reception (p. 3147)

Why the selected alternative fits: Front-end compression or protection recovery during and after the pulse.

Distinguishing consideration: compare this with option A, “Guaranteed linearity because average power alone bounds every instantaneous level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Pulse, Radar, and Transient Reception.

Review: Chapter 6 — Pulse, Radar, and Transient Reception.

V011-C06-MCQ-091. A pulse appears in a time capture but its peak is reduced by the selected narrow IF response. Which category best describes the problem?

A. A pure time-stamp error with no transfer-function involvement.

B. A pulse that necessarily occurred outside every acquisition window.

C. A captured but distorted observation.

D. Proof that the external source had no peak above the recorded value.

Answer: C. The event entered the record, but the path changed its waveform. This differs from a coverage failure in which no usable acquisition of the event occurred.

Review: Preserve pulse and demodulator evidence across representations; Model 15A cross-reference. Source: §15.2 Model 15A: calculate conditional event coverage from usable windows (p. 8677)

Why the selected alternative fits: A captured but distorted observation.

Distinguishing consideration: compare this with option A, “A pure time-stamp error with no transfer-function involvement”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 6 — Preserve pulse and demodulator evidence across representations.

V011-C06-MCQ-092. A burst occurs while a scanning receiver is tuned elsewhere and no usable samples are retained. Can changing the demodulator after the survey recover that burst?

A. Yes, because an audio export contains every RF event in the survey interval.

B. Yes, if the output is normalized to the expected peak.

C. Yes, provided the later detector has a narrower bandwidth.

D. No; the missing acquisition is not supplied by a different later demodulator.

Answer: D. Postprocessing can reinterpret retained samples but cannot create a missing valid observation. Coverage and waveform fidelity are distinct requirements. Review: Preserve pulse and demodulator evidence across representations; Model 15A cross-reference. Source: §15.2 Model 15A: calculate conditional event coverage from usable windows (p. 8677)

Why the selected alternative fits: No; the missing acquisition is not supplied by a different later demodulator.

Distinguishing consideration: compare this with option A, “Yes, because an audio export contains every RF event in the survey interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 15 — Model 15A: calculate conditional event coverage from usable windows; Chapter 6 — Preserve pulse and demodulator evidence across representations.

V011-C06-MCQ-093. A long-time spectrum and a pulse time trace are used together to identify intrapulse behavior. What link is essential?

A. Discarding the time trace once a repeated spectral feature is visible.

B. A common native record and documented time, window and processing conventions.

C. An assumption that equal carrier labels prove the two displays contain the same pulse.

D. Only matching nominal frequency spans, with independent acquisition intervals treated as interchangeable.

Answer: B. The views emphasize different aspects of the event. Their relationship is defensible when the acquisition and transformations can be traced to the same data and time support. Review: Preserve pulse and demodulator evidence across representations. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why the selected alternative fits: A common native record and documented time, window and processing conventions.

Distinguishing consideration: compare this with option A, “Discarding the time trace once a repeated spectral feature is visible”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations.

V011-C06-MCQ-094. A pulse-like feature appears on one receiver channel. Which challenge is appropriate before assigning it to an external RF source?

A. Use synchronized channels and applicable antenna or input substitutions to test internal, conducted and cross-channel explanations.

B. Treat any triggered display as conclusive source attribution.

C. Assume a stable repetition interval excludes local switching electronics.

D. Use audio intelligibility alone to eliminate analyzer sweep artifacts.

Answer: A. Local digital switching, power conversion, sweep behavior and coupling can produce pulse-like observations. Controlled changes can test these alternatives while preserving the original event record. Review: Pulse, Radar, and Transient Reception. Source: §6.29 Pulse, Radar, and Transient Reception (p. 3147)

Why the selected alternative fits: Use synchronized channels and applicable antenna or input substitutions to test internal, conducted and cross-channel explanations.

Distinguishing consideration: compare this with option B, “Treat any triggered display as conclusive source attribution”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Pulse, Radar, and Transient Reception.

Review: Chapter 6 — Pulse, Radar, and Transient Reception.

V011-C06-MCQ-095. An antenna-substitution challenge changes the pulse amplitude. What does that result establish by itself?

A. The exact remote transmitter identity and purpose.

B. That every internal coupling path has been excluded regardless of substitution details.

C. A dependence on the changed input condition, with its mechanism still requiring interpretation.

D. That the original receiver never experienced compression.

Answer: C. A useful challenge constrains explanations but does not automatically identify one unique cause. Document the substituted path, matching conditions, receiver state and temporal comparability. Review: Pulse, Radar, and Transient Reception; Chapter 1 evidence-boundary principles. Source: §6.29 Pulse, Radar, and Transient Reception (p. 3147)

Why the selected alternative fits: A dependence on the changed input condition, with its mechanism still requiring interpretation.

Distinguishing consideration: compare this with option A, “The exact remote transmitter identity and purpose”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Pulse, Radar, and Transient Reception; Chapter 1 — Receiver as a Measurement System; Chapter 1 — Evidence Record and Closing Verification.

V011-C06-MCQ-096. A receiver changes gain during a pulse and later regains stable lock. How should the affected data be retained?

A. As a silently removed segment followed by an apparently continuous splice.

B. As proof that all pre-transition and post-transition phase origins are identical.

C. As recoverable unclipped RF whenever the final gain value is known.

D. As an explicitly identified state interval, with continuity and validity limits preserved.

Answer: D. State transitions can alter scale, phase, filter history and validity. Keeping their boundaries visible avoids inventing a continuous calibrated waveform. Review: Preserve pulse and demodulator evidence across representations; Model 10E cross-reference. Source: §10.48 Model 10E for absolute sample continuity and retained processing state (p. 5744)

Why the selected alternative fits: As an explicitly identified state interval, with continuity and validity limits preserved.

Distinguishing consideration: compare this with option A, “As a silently removed segment followed by an apparently continuous splice”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Model 10E for absolute sample continuity and retained processing state; Chapter 6 — Preserve pulse and demodulator evidence across representations.

V011-C06-MCQ-097. A known carrier and independently calibrated modulation are available for receiver verification. Which sequence best supports localization of a demodulator error?

A. Change carrier, bandwidth and detector simultaneously without retaining the prior state.

B. Measure only one final output with no record of the applied reference waveform.

C. Adjust the final audio until it sounds correct and infer all upstream stages are valid.

D. Verify the RF path, then compare recovered quantities across applicable levels, bandwidths and demodulator states.

Answer: D. A staged comparison separates the admitted RF condition from subsequent processing. Controlled variation and recorded states help locate the mechanism rather than conceal it. Review: Analog Demodulator Verification. Source: §6.31 Analog Demodulator Verification (p. 3152)

Why the selected alternative fits: Verify the RF path, then compare recovered quantities across applicable levels, bandwidths and demodulator states.

Distinguishing consideration: compare this with option A, “Change carrier, bandwidth and detector simultaneously without retaining the prior state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 6 — Analog Demodulator Verification.

Review: Chapter 6 — Analog Demodulator Verification.

V011-C06-MCQ-099. A tested receiver configuration fails to recover modulation from a weak event. What is a defensible conclusion?

A. The transmitter necessarily emitted an unmodulated carrier.

B. All possible demodulators and acquisition settings would also fail.

C. The event can be excluded from the record because it produced no intelligible audio.

D. The stated method did not recover modulation under those recorded conditions; the external waveform's absence of modulation is not thereby proved.

Answer: D. A negative method result is bounded by coverage, sensitivity, path state and processing. It can be useful evidence without becoming an unlimited claim about the source. Review: Preserve pulse and demodulator evidence across representations; Chapter 1 bounded negative findings. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why the selected alternative fits: The stated method did not recover modulation under those recorded conditions; the external waveform's absence of modulation is not thereby proved.

Distinguishing consideration: compare this with option A, "The transmitter necessarily emitted an unmodulated carrier"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 1 — Frame a bounded finding from the completed observation.

V011-C06-FIB-006. Mean squared peak-envelope magnitude of 0.8 square volts across 50 ohms gives mean RF power _____ mW.

Answer: 8. Divide 0.8 by 100 to obtain 0.008 W, retaining the chapter's orthogonality or equivalent averaging conditions. Review: Equation 11B. Source: Equation 11B. Envelope power convention (p. 3113)

Why this term is required: "8" completes the stated technical proposition.

Question context: Mean squared peak-envelope magnitude of 0.8 square volts across 50 ohms gives mean RF power _____ mW

Basis and qualification: Chapter 6 — Equation 11B. Envelope power convention.

Review: Chapter 6 — Equation 11B. Envelope power convention.

Copyright 2026, James M. Atkinson

V011-C06-FIB-007. A peak envelope of 2 V across a 100-ohm real load gives peak envelope power _____ mW.

Answer: 20. The squared peak is 4 square volts. Divide by twice 100 ohms to obtain 0.020 W. Review: Equation 11B. Source: Equation 11B. Envelope power convention (p. 3113)

Why this term is required: “20” completes the stated technical proposition.

Question context: A peak envelope of 2 V across a 100-ohm real load gives peak envelope power _____ mW

Basis and qualification: Chapter 6 — Equation 11B. Envelope power convention.

Review: Chapter 6 — Equation 11B. Envelope power convention.

Copyright 2026, James M. Atkinson

V011-C06-FIB-008. The periodic mean-power simplification uses complete common periods or a justified _____ mean.

Answer: long-time. An arbitrary partial window may retain cross terms that the simplified relation excludes. Review: Equation 11B discussion. Source: Equation 11B. Envelope power convention (p. 3113)

Why this term is required: “long-time” completes the stated technical proposition.

Question context: The periodic mean-power simplification uses complete common periods or a justified _____ mean

Basis and qualification: Chapter 6 — Equation 11B. Envelope power convention.

Review: Chapter 6 — Equation 11B. Envelope power convention.

Copyright 2026, James M. Atkinson

V011-C06-FIB-009. A message bounded in magnitude by one and a conventional AM depth between zero and one guarantee a signed envelope that is _____.

Answer: nonnegative. The smallest possible bracket is one minus depth. A strictly positive minimum is not guaranteed at unit depth. Review: Equation 11C. Source: Equation 11C. Conventional AM and nonnegative-envelope condition (p. 3113)

Why this term is required: “nonnegative” completes the stated technical proposition.

Question context: A message bounded in magnitude by one and a conventional AM depth between zero and one guarantee a signed envelope that is _____

Basis and qualification: Chapter 6 — Equation 11C. Conventional AM and nonnegative-envelope condition.

Review: Chapter 6 — Equation 11C. Conventional AM and nonnegative-envelope condition.

V011-C06-FIB-010. Sinusoidal AM extrema of 3 V and 1 V imply a carrier peak of _____ V.

Answer: 2. Take the half-sum of the compatible nonnegative-envelope extrema.

Review: Equation 11D. Source: Equation 11D. Sinusoidal AM extrema and their inversion (p. 3113)

Why this term is required: “2” completes the stated technical proposition.

Question context: Sinusoidal AM extrema of 3 V and 1 V imply a carrier peak of _____ V

Basis and qualification: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Copyright 2026, James M. Atkinson

V011-C06-FIB-011. For sinusoidal AM extrema of 3 V and 1 V in the valid inverse-model domain, depth is _____.

Answer: 0.5. Divide the 2 V difference by the 4 V sum. The ratio is dimensionless.

Review: Equation 11D. Source: Equation 11D. Sinusoidal AM extrema and their inversion (p. 3113)

Why this term is required: “0.5” completes the stated technical proposition.

Question context: For sinusoidal AM extrema of 3 V and 1 V in the valid inverse-model domain, depth is _____

Basis and qualification: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Copyright 2026, James M. Atkinson

V011-C06-FIB-012. Carrier peak 2 V and sinusoidal depth 0.3 give a lower envelope extremum of _____ V.

Answer: 1.4. Multiply carrier peak by one minus depth: 2 times 0.7. Review: Equation 11D. Source: Equation 11D. Sinusoidal AM extrema and their inversion (p. 3113)

Why this term is required: “1.4” completes the stated technical proposition.

Question context: Carrier peak 2 V and sinusoidal depth 0.3 give a lower envelope extremum of _____ V

Basis and qualification: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Copyright 2026, James M. Atkinson

V011-C06-FIB-013. Carrier peak 2 V and sinusoidal depth 0.3 give an upper envelope extremum of _____ V.

Answer: 2.6. Multiply carrier peak by one plus depth: 2 times 1.3. Review: Equation 11D. Source: Equation 11D. Sinusoidal AM extrema and their inversion (p. 3113)

Why this term is required: “2.6” completes the stated technical proposition.

Question context: Carrier peak 2 V and sinusoidal depth 0.3 give an upper envelope extremum of _____ V

Basis and qualification: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion.

V011-C06-FIB-014. For carrier peak 1.5 V and sinusoidal depth 0.4, either RF sideband has peak voltage _____ V.

Answer: 0.3. Each sideband peak is half the modulation-scaled carrier peak: 1.5 times 0.4 divided by two. Review: Equation 11E. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why this term is required: “0.3” completes the stated technical proposition.

Question context: For carrier peak 1.5 V and sinusoidal depth 0.4, either RF sideband has peak voltage _____ V

Basis and qualification: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Copyright 2026, James M. Atkinson

V011-C06-FIB-015. At carrier power 20 mW and sinusoidal depth 0.4, either sideband contains _____ mW.

Answer: 0.8. Multiply carrier power by depth squared divided by four: 20 times 0.16 divided by four. Review: Equation 11E. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why this term is required: “0.8” completes the stated technical proposition.

Question context: At carrier power 20 mW and sinusoidal depth 0.4, either sideband contains _____ mW

Basis and qualification: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Copyright 2026, James M. Atkinson

V011-C06-FIB-016. At carrier power 20 mW and sinusoidal depth 0.4, total RF power is _____ mW.

Answer: 21.6. The two 0.8 mW sidebands add to the 20 mW carrier under the declared orthogonality conditions. Review: Equations 11E and 11F. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why this term is required: “21.6” completes the stated technical proposition.

Question context: At carrier power 20 mW and sinusoidal depth 0.4, total RF power is _____ mW

Basis and qualification: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers; Chapter 6 — Equation 11F. Total sinusoidal-AM power.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers; Chapter 6 — Equation 11F. Total sinusoidal-AM power.

Copyright 2026, James M. Atkinson

V011-C06-FIB-017. A verified sinusoidal AM sideband power ratio of 0.0225 relative to the carrier implies depth _____.

Answer: 0.3. Take the square root and multiply by two, retaining the linear symmetric AM assumptions. Review: Equation 11E. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why this term is required: “0.3” completes the stated technical proposition.

Question context: A verified sinusoidal AM sideband power ratio of 0.0225 relative to the carrier implies depth _____

Basis and qualification: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Copyright 2026, James M. Atkinson

V011-C06-FIB-018. Tripling sinusoidal AM depth while holding carrier power fixed multiplies either sideband power by _____.

Answer: nine. Sideband amplitude is linear in depth, so its power is quadratic. The comparison does not establish hardware linearity. Review: Equation 11E. Source: Equation 11E. Sinusoidal sideband amplitudes and powers (p. 3114)

Why this term is required: “nine” completes the stated technical proposition.

Question context: Tripling sinusoidal AM depth while holding carrier power fixed multiplies either sideband power by _____

Basis and qualification: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers.

Copyright 2026, James M. Atkinson

V011-C06-FIB-019. The one-half factor in sinusoidal AM total power is the mean square of a unit _____.

Answer: cosine. A different bounded message can have a different mean square despite the same peak bound. Review: Equations 11F and 11G. Source: Equation 11F. Total sinusoidal-AM power (p. 3114)

Why this term is required: “cosine” completes the stated technical proposition.

Question context: The one-half factor in sinusoidal AM total power is the mean square of a unit _____

Basis and qualification: Chapter 6 — Equation 11F. Total sinusoidal-AM power; Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Review: Chapter 6 — Equation 11F. Total sinusoidal-AM power; Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Copyright 2026, James M. Atkinson

V011-C06-FIB-020. For a zero-mean message of mean square 0.20 and AM scale 0.5, total-to-carrier power ratio is _____.

Answer: 1.05. One plus 0.5 squared times 0.20 equals 1.05. Use the actual message mean square. Review: Equation 11G. Source: Equation 11G. Power for a zero-mean nonsinusoidal message (p. 3114)

Why this term is required: “1.05” completes the stated technical proposition.

Question context: For a zero-mean message of mean square 0.20 and AM scale 0.5, total-to-carrier power ratio is _____

Basis and qualification: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Review: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Copyright 2026, James M. Atkinson

V011-C06-FIB-021. A nonzero message mean retains a squared-envelope expansion term _____ in the modulation scale.

Answer: linear. The term is twice the scale times the message mean. It disappears only under the stated zero-mean assumption. Review: Equation 11G. Source: Equation 11G. Power for a zero-mean nonsinusoidal message (p. 3114)

Why this term is required: “linear” completes the stated technical proposition.

Question context: A nonzero message mean retains a squared-envelope expansion term _____ in the modulation scale

Basis and qualification: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Review: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message.

Copyright 2026, James M. Atkinson

V011-C06-FIB-022. For unit carrier peak and depth 1.4, the signed sinusoidal envelope ranges down to _____ V.

Answer: minus 0.4. The lower extremum is one minus 1.4. Magnitude detection is a separate operation that loses this sign. Review: Equation 11H. Source: Equation 11H. Magnitude detection after envelope reversal (p. 3115)

Why this term is required: “minus 0” completes the stated technical proposition.

Question context: For unit carrier peak and depth 1.4, the signed sinusoidal envelope ranges down to _____ V

Basis and qualification: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal.

Review: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal.

Copyright 2026, James M. Atkinson

V011-C06-FIB-023. Taking the absolute value of a reversed AM envelope discards its _____ information.

Answer: sign. Negative portions fold upward, whereas a coherent complex representation can retain the reversal. Review: Equation 11H. Source: Equation 11H. Magnitude detection after envelope reversal (p. 3115)

Why this term is required: “sign” completes the stated technical proposition.

Question context: Taking the absolute value of a reversed AM envelope discards its _____ information

Basis and qualification: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal.

Review: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal.

Copyright 2026, James M. Atkinson

V011-C06-FIB-024. The unclipped algebraic RF product of one sinusoidal message and a carrier has _____ spectral terms even above unit modulation depth.

Answer: three. It contains a carrier and two sidebands. Physical clipping is a separate nonlinearity that can add components. Review: Application 6A.4. Source: §6.9 Application 6A.4: Show why an envelope-extrema estimate fails after reversal (p. 3121)

Why this term is required: “three” completes the stated technical proposition.

Question context: The unclipped algebraic RF product of one sinusoidal message and a carrier has _____ spectral terms even above unit modulation depth

Basis and qualification: Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

Review: Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

Copyright 2026, James M. Atkinson

V011-C06-FIB-025. A source-depth inference from receiver extrema must challenge compression, AGC and the relevant _____ response.

Answer: filter. Filtering can alter sideband balance and modulation-frequency transfer, so the received extrema need not describe the source alone. Review: Amplitude Modulation and Envelope Detection. Source: §6.2 Amplitude Modulation and Envelope Detection (p. 3108)

Why this term is required: “filter” completes the stated technical proposition.

Question context: A source-depth inference from receiver extrema must challenge compression, AGC and the relevant _____ response

Basis and qualification: Chapter 6 — Amplitude Modulation and Envelope Detection.

Review: Chapter 6 — Amplitude Modulation and Envelope Detection.

Copyright 2026, James M. Atkinson

V011-C06-FIB-026. The normalized real product detector multiplies by _____ times the LO cosine before sum-band rejection.

Answer: two. This compensates the half-amplitude coefficient of the retained difference product. Review: Equation 11I. Source: Equation 11I. Real coherent recovery with residual reference error (p. 3115)

Why this term is required: “two” completes the stated technical proposition.

Question context: The normalized real product detector multiplies by _____ times the LO cosine before sum-band rejection

Basis and qualification: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error.

Review: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error.

Copyright 2026, James M. Atkinson

V011-C06-FIB-027. At exact frequency agreement, a real envelope with a 180-degree coherent-reference error is multiplied by _____.

Answer: minus one. Cosine of 180 degrees is minus one. The output is sign inverted rather than absent. Review: Equation 11I. Source: Equation 11I. Real coherent recovery with residual reference error (p. 3115)

Why this term is required: “minus one” completes the stated technical proposition.

Question context: At exact frequency agreement, a real envelope with a 180-degree coherent-reference error is multiplied by _____

Basis and qualification: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error.

Review: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error.

Copyright 2026, James M. Atkinson

V011-C06-FIB-028. At exact frequency agreement, a real envelope with a 30-degree phase error has amplitude scale approximately _____.

Answer: 0.8660. Cosine of 30 degrees is square root three divided by two. The scale is constant only while the reference error is constant. Review: Equation 11I. Source: Equation 11I. Real coherent recovery with residual reference error (p. 3115)

Why this term is required: “0.8660” completes the stated technical proposition.

Question context: At exact frequency agreement, a real envelope with a 30-degree phase error has amplitude scale approximately _____

Basis and qualification: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error.

Review: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error.

V011-C06-FIB-051. A PM sensitivity of 0.5 radian per volt driven by a 2 V peak message gives phase excursion _____ radian.

Answer: 1. Multiply the sensitivity by the message peak. Frequency deviation additionally depends on the message rate. Review: Equation 12C. Source: Equation 12C. Sinusoidal PM and its frequency deviation (p. 3132)

Why this term is required: “1” completes the stated technical proposition.

Question context: A PM sensitivity of 0.5 radian per volt driven by a 2 V peak message gives phase excursion _____ radian

Basis and qualification: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

Review: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

Copyright 2026, James M. Atkinson

V011-C06-FIB-052. That 1-radian phase peak at a 3 kHz sinusoidal message frequency gives peak frequency deviation _____ kHz.

Answer: 3. Differentiating the sinusoid introduces message frequency after the two-pi factors cancel. Review: Equation 12C. Source: Equation 12C. Sinusoidal PM and its frequency deviation (p. 3132)

Why this term is required: “3” completes the stated technical proposition.

Question context: That 1-radian phase peak at a 3 kHz sinusoidal message frequency gives peak frequency deviation _____ kHz

Basis and qualification: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

Review: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

Copyright 2026, James M. Atkinson

V011-C06-FIB-053. Differentiating a cosine phase gives a _____ sine-shaped frequency offset under the chapter convention.

Answer: negative. The derivative sign matters when time-aligned phase and frequency traces are compared. Review: Equation 12C. Source: Equation 12C. Sinusoidal PM and its frequency deviation (p. 3132)

Why this term is required: “negative” completes the stated technical proposition.

Question context: Differentiating a cosine phase gives a _____ sine-shaped frequency offset under the chapter convention

Basis and qualification: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

Review: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

Copyright 2026, James M. Atkinson

V011-C06-FIB-054. A fixed PM phase peak of 0.4 radian at 5 kHz corresponds to frequency-deviation peak _____ kHz.

Answer: 2. Multiply phase peak by message frequency: 0.4 times 5 kHz. Review: Equation 12C. Source: Equation 12C. Sinusoidal PM and its frequency deviation (p. 3132)
Why this term is required: “2” completes the stated technical proposition.
Question context: A fixed PM phase peak of 0.4 radian at 5 kHz corresponds to frequency-deviation peak _____ kHz
Basis and qualification: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.
Review: Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation.

V011-C06-FIB-061. A finite unwrapped phase difference divided by its elapsed interval gives interval-_____ frequency.

Answer: average. It equals the average derivative over that interval under the model assumptions, not automatically a pointwise derivative. Review: Equation 12F.

Source: Equation 12F. Finite-interval frequency from unwrapped phase (p. 3133)

Why this term is required: “average” completes the stated technical proposition.

Question context: A finite unwrapped phase difference divided by its elapsed interval gives interval-_____ frequency

Basis and qualification: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Copyright 2026, James M. Atkinson

V011-C06-FIB-062. A phase increase of pi divided by two radians over 0.2 ms gives average offset _____ Hz.

Answer: 1250. One quarter cycle divided by 0.0002 second is 1250 Hz. Review: Equation 12F. Source: Equation 12F. Finite-interval frequency from unwrapped phase (p. 3133)

Why this term is required: “1250” completes the stated technical proposition.

Question context: A phase increase of pi divided by two radians over 0.2 ms gives average offset _____ Hz

Basis and qualification: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Copyright 2026, James M. Atkinson

V011-C06-FIB-063. Two adjacent equal intervals with frequency averages 100 Hz and 500 Hz have combined average _____ Hz.

Answer: 300. Equal durations give equal weights when the two phase changes are added. Review: Equation 12F. Source: Equation 12F. Finite-interval frequency from unwrapped phase (p. 3133)

Why this term is required: “300” completes the stated technical proposition.

Question context: Two adjacent equal intervals with frequency averages 100 Hz and 500 Hz have combined average _____ Hz

Basis and qualification: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Copyright 2026, James M. Atkinson

V011-C06-FIB-064. If those interval lengths differ, the combined average uses duration _____ rather than an unweighted mean.

Answer: weights. Add each frequency average times its duration and divide by total duration. Review: Equation 12F. Source: Equation 12F. Finite-interval frequency from unwrapped phase (p. 3133)

Why this term is required: “weights” completes the stated technical proposition.

Question context: If those interval lengths differ, the combined average uses duration _____ rather than an unweighted mean

Basis and qualification: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase.

V011-C06-FIB-084. Modest long-time average power does not exclude a high instantaneous pulse _____.

Answer: peak. A low duty factor can conceal peaks that compress the front end or activate protection. Review: Pulse, Radar, and Transient Reception. Source: §6.29 Pulse, Radar, and Transient Reception (p. 3147)

Why this term is required: “peak” completes the stated technical proposition.

Question context: Modest long-time average power does not exclude a high instantaneous pulse _____

Basis and qualification: Chapter 6 — Pulse, Radar, and Transient Reception.

Review: Chapter 6 — Pulse, Radar, and Transient Reception.

V011-C06-FIB-085. A pulse observed through a bandwidth-limited path may be captured yet _____.

Answer: distorted. The event entered the record but its shape or amplitude can be altered, unlike a missed acquisition. Review: Preserve pulse and demodulator evidence across representations. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why this term is required: “distorted” completes the stated technical proposition.

Question context: A pulse observed through a bandwidth-limited path may be captured yet _____

Basis and qualification: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Copyright 2026, James M. Atkinson

V011-C06-FIB-086. A burst outside all usable acquisition windows cannot be recreated by changing the later _____.

Answer: demodulator. Postprocessing works on retained observations and cannot supply RF samples that were not validly acquired. Review: Preserve pulse and demodulator evidence across representations. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why this term is required: “demodulator” completes the stated technical proposition.

Question context: A burst outside all usable acquisition windows cannot be recreated by changing the later _____

Basis and qualification: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Copyright 2026, James M. Atkinson

V011-C06-FIB-087. Complementary time and spectrum views of a pulse should be linked to the same native _____.

Answer: record. Retain windows, time basis and processing to avoid silently combining distinct events. Review: Preserve pulse and demodulator evidence across representations. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

Why this term is required: “record” completes the stated technical proposition.

Question context: Complementary time and spectrum views of a pulse should be linked to the same native _____

Basis and qualification: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations.

Copyright 2026, James M. Atkinson

V011-C06-FIB-088. A local switching transient is a competing explanation for an apparent received _____ event.

Answer: pulse. Synchronized channels and controlled input substitutions help test internal, conducted and external explanations. Review: Pulse, Radar, and Transient Reception. Source: §6.29 Pulse, Radar, and Transient Reception (p. 3147)

Why this term is required: “pulse” completes the stated technical proposition.

Question context: A local switching transient is a competing explanation for an apparent received _____ event

Basis and qualification: Chapter 6 — Pulse, Radar, and Transient Reception.

Review: Chapter 6 — Pulse, Radar, and Transient Reception.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C06-ESSAY-001. Derive the mean-power and peak-envelope-power relations for Model 6A. Explain why the factor of two and the averaging conditions are part of the result, and identify a plausible misuse of each relation.

- Opening: Present a thesis that answers this precise question: Derive the mean-power and peak-envelope-power relations for Model 6A. Identify which evidence would falsify the proposed conclusion Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)
- Core terminology and scope: Define relations, Model, factor in the question's particular technical setting; explain how averaging, conditions, relation differ if that distinction would change the analysis of "Derive the mean-power and peak-envelope-power relations for Model 6A" Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Begin with the real RF waveform as the real part of its translated complex peak-voltage envelope Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the mean-power and peak-envelope-power relations for Model 6A to the claimed result, following "Application 6A.8: Compare average power with peak envelope power for two SSB tones"; name the intermediate states and measurable outputs Source: §6.13 Application 6A.8: Compare average power with peak envelope power for two SSB tones (p. 3125)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for the mean-power and peak-envelope-power relations for Model 6A. Expanding its square produces one term proportional to the squared envelope magnitude and another oscillating around twice the carrier Source: §6.13 Application 6A.8: Compare average power with peak envelope power for two SSB tones (p. 3125)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 6A.10: Use message mean square rather than a sinusoidal shortcut” that resolves the question about the mean-power and peak-envelope-power relations for Model 6A; derive the relevant result with units and stated validity conditions Source: §6.15 Application 6A.10: Use message mean square rather than a sinusoidal shortcut (p. 3127)
- Evidence and method: Specify the native observations, control records and calculations that would resolve the mean-power and peak-envelope-power relations for Model 6A. Under the declared spectral separation and complete-period, long-time or carrier-cycle averaging convention, the latter term has zero relevant average Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)
- Worked application or illustrative case: Build a worked example of “the mean-power and peak-envelope-power relations for Model 6A”, addressing this associated condition: Explain why the factor of two and the averaging conditions are part of the result, and identify a.... Begin with the real RF waveform as the real part of its translated complex peak-voltage envelope Source: §6.13 Application 6A.8: Compare average power with peak envelope power for two SSB tones (p. 3125)

Copyright 2026, James M. Atkinson

- Alternative explanations and failure modes: Construct two plausible technical explanations for “the mean-power and peak-envelope-power relations for Model 6A”. Using “Application 6A.10: Use message mean square rather than a sinusoidal shortcut”, specify a discriminator and the result expected under each explanation Source: §6.15 Application 6A.10: Use message mean square rather than a sinusoidal shortcut (p. 3127)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to the mean-power and peak-envelope-power relations for Model 6A, including the effect of missing measurements and inconsistent operating conditions Source: §6.9 Application 6A.4: Show why an envelope-extrema estimate fails after reversal (p. 3121)
- Scholarly synthesis and implications: Explain what the result about the mean-power and peak-envelope-power relations for Model 6A authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)
- Closing: Conclude by answering “Derive the mean-power and peak-envelope-power relations for Model 6A” using only the demonstrated evidence; state the remaining decisive verification step Source: §6.4 Model 6A: preserve the complex envelope (p. 3112)

measurable outputs Source: §6.21 Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation (p. 3139)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for two hypothetical modulators at message frequencies 1 kHz and 4 kHz. The deviations are therefore 0.9 kHz and 3.6 kHz Source: §6.21 Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation (p. 3139)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 6B.2: Differentiate a sinusoidal PM phase” that resolves the question about two hypothetical modulators at message frequencies 1 kHz and 4 kHz; derive the relevant result with units and stated validity conditions Source: §6.20 Application 6B.2: Differentiate a sinusoidal PM phase (p. 3138)
- Evidence and method: Specify the native observations, control records and calculations that would resolve two hypothetical modulators at message frequencies 1 kHz and 4 kHz. For the stated FM law, integration makes the phase index equal to peak deviation divided by modulation frequency, giving 1.8 rad and 0.45 rad Source: §6.19 Application 6B.1: Convert a sinusoidal FM deviation into phase excursion (p. 3137)
- Worked application or illustrative case: Build a worked example of “two hypothetical modulators at message frequencies 1 kHz and 4 kHz”, addressing this associated condition: The PM case maintains peak phase 0.9 rad; the FM case maintains peak deviation 1.8 kHz. For the stated PM law, differentiation makes peak deviation equal to peak phase times modulation frequency Source: §6.21 Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation (p. 3139)

V011-C06-ESSAY-025. An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts. Write an integrated technical assessment that separates what the record establishes from what still requires a test.

- Opening: Present a thesis that answers this precise question: An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts. Identify which evidence would falsify the proposed conclusion Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)
- Core terminology and scope: Define asymmetric, sidebands, slowly in the question's particular technical setting; explain how drifting, integrated, separates differ if that distinction would change the analysis of "An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts" Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Begin with the retained RF or IF interval, reference plane and chain state Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts to the claimed result, following "Application 6A.9: Separate sideband filtering from source modulation depth"; name the intermediate states and measurable

Copyright 2026, James M. Atkinson

outputs Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts. Asymmetric sidebands may belong to the source or arise from unequal path transfer, interference or measurement error; a known coherent reference can test the relevant upper and lower responses Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Preserve pulse and demodulator evidence across representations” that resolves the question about An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts; derive the relevant result with units and stated validity conditions Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)
- Evidence and method: Specify the native observations, control records and calculations that would resolve An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts. Pitch drift may reflect modulation, LO or recovery error, or processing, so compare the uncorrected complex phase with a justified frequency reference and retain any correction Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

Copyright 2026, James M. Atkinson

- Worked application or illustrative case: Build a worked example of “An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts”, addressing this associated condition: Write an integrated technical assessment that separates what the record establishes from what still.... Begin with the retained RF or IF interval, reference plane and chain state Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)
- Alternative explanations and failure modes: Construct two plausible technical explanations for “An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts”. Using “Preserve pulse and demodulator evidence across representations”, specify a discriminator and the result expected under each explanation Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts, including the effect of missing measurements and inconsistent operating conditions Source: §6.8 Application 6A.3: Infer modulation depth from one resolved sideband (p. 3120)
- Scholarly synthesis and implications: Explain what the result about An observation contains asymmetric apparent AM sidebands, a slowly drifting audio pitch and occasional pulse-like dropouts authorises the investigator or engineer to claim, and what stronger

Discussion Questions

[Discussion instructions: For each discussion question, prepare approximately 500 spoken words for delivery over 2.5–3 minutes (approximately 167–200 words per minute). Address the ten subject prompts below in their stated order. Use the opening to frame the issue and the closing to synthesise the principal findings, conclusions and unresolved questions.]

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-001. Should a plausible modulation classification be reported as a source identification?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Should a plausible modulation classification be reported as a source identification?” Put this particular dispute to the panel: Should a plausible modulation classification be reported as a source identification. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

- 02. Student A, terminology and scope: Agree the operational meanings of modulation, classification, reported and source, identification, measurement in “Should a plausible modulation classification be reported as a source identification”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of whether a plausible modulation classification be reported as a source identification; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §6.44 Laboratory qualification of an analogue-demodulation measurement claim (p. 3177)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Laboratory qualification of an analogue-demodulation measurement claim”. Ask which observable features support the classification and whether the selected receiver path can create or suppress those features Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §6.44 Laboratory qualification of an analogue-demodulation measurement claim (p. 3177)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a plausible

Copyright 2026, James M. Atkinson

modulation classification be reported as a source identification; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Laboratory qualification of an analogue-demodulation measurement claim”. Ask which observable features support the classification and whether the selected receiver path can create or suppress those features Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §6.44 Laboratory qualification of an analogue-demodulation measurement claim (p. 3177)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Separate waveform evidence from identity, location and purpose Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving whether a plausible modulation classification be reported as a source identification: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a plausible modulation classification be reported as a source identification; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving whether a plausible modulation classification be reported as a source identification: specify the altered receiver state or source condition, predicted change, test

statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving whether a plausible modulation classification be reported as a source identification, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §6.44 Laboratory qualification of an analogue-demodulation measurement claim (p. 3177)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving whether a plausible modulation classification be reported as a source identification: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or

Copyright 2026, James M. Atkinson

reject the conclusion. Source: §6.1 Carrier, Sidebands, and Modulation Evidence (p. 3107)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for whether a plausible modulation classification be reported as a source identification. Identify independent evidence that would be needed for a source claim Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving whether a plausible modulation classification be reported as a source identification, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §6.44 Laboratory qualification of an analogue-demodulation measurement claim (p. 3177)

Copyright 2026, James M. Atkinson

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for whether a plausible modulation classification be reported as a source identification. Identify independent evidence that would be needed for a source claim Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §6.14 Application 6A.9: Separate sideband filtering from source modulation depth (p. 3126)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about whether a plausible modulation classification be reported as a source identification and Separate waveform evidence from identity, location and purpose; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §6.30 Preserve pulse and demodulator evidence across representations (p. 3150)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “whether a plausible modulation classification be reported as a source identification”, addressing “Separate waveform evidence from identity, location and purpose”;

Chapter 6 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C06-ESSAY-001 — Begin with the real RF waveform as the real part of its translated complex peak-voltage envelope. Expanding its square produces one term proportional to the squared envelope magnitude and another oscillating around twice the carrier. Under the declared spectral separation and complete-period, long-time or carrier-cycle averaging convention, the latter term has zero relevant average. Dividing by the positive real load resistance therefore gives mean RF power equal to the mean squared envelope magnitude divided by twice that resistance. Peak envelope power uses the maximum squared envelope magnitude with the same denominator. State that the envelope is a peak-voltage quantity, not an RMS voltage; omitting this convention invites a factor-of-two error. The peak is also defined over a stated observation interval or complete periodic waveform. An arbitrary short RF record need not satisfy the averaging cancellation. Moreover, the maximum instantaneous RF voltage squared divided by resistance is a different quantity from peak envelope power. A sound answer connects the representation, the load, the averaging interval and the requested measurand before applying either equation. Review: Equations 11A–11B; Model 6A voltage and averaging conventions.

Review: Chapter 6 — Equation 11A. Real RF waveform and its complex envelope; Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Model 6A: preserve the complex envelope.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-002 — The nonnegative envelope has extrema 0.5 V and 3.5 V. Carrier power is 40 mW. Each sideband has peak 0.75 V and power 5.625 mW, so total average power is 51.25 mW. Peak envelope power is 122.5 mW. Obtain the total both from the sum of the three orthogonal spectral powers and from the envelope mean square; the agreement is an independent check on the peak-voltage convention. The peak-envelope result uses the largest envelope magnitude and is not the largest instantaneous RF power. Require a linear path that passes both sidebands, a known 50 Ω reference plane and complete-period or equivalent averaging. Challenge the ideal symmetry by measuring both sideband transfers and by testing a known modulation reference at the same gain state. If one sideband is selectively attenuated, the measured output envelope no longer follows the assumed source model. A high average-power margin alone also does not prove that the 3.5 V envelope peak remains below the relevant chain limit. Review: Equations 11C–11F; Application 6A.1; Application 6A.8.

Review: Chapter 6 — Equation 11C. Conventional AM and nonnegative-envelope condition; Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion; Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers; Chapter 6 — Equation 11F. Total sinusoidal-AM power; Chapter 6 — Application 6A.1: Close the power accounting for sinusoidal AM; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-003 — Use the actual message mean square in Equation 11G. The two total-to-carrier power ratios are 1.32 and 1.128 respectively. The common modulation scale does not make their average powers equal, because the average of the squared message is different. The zero-mean condition removes the cross term between carrier and message; if the message has a nonzero mean, the carrier convention or the power expansion must be reconsidered explicitly. The stated mean squares do not establish the messages' maxima, crest factors, phase relations or spectral occupation. A common bound on message magnitude supplies a common conservative bound on the envelope, but that bound may not be attained. Consequently the two average powers do not determine the two peak envelope powers. Retain a reproducible message definition or record and the averaging interval. An answer that substitutes the sinusoidal half-mean-square shortcut for both messages loses the very distinction the question asks the reader to preserve. Review: Equation 11G; Application 6A.10.

Review: Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message; Chapter 6 — Application 6A.10: Use message mean square rather than a sinusoidal shortcut.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-004 — The half-sum gives a carrier peak of 1.8 V, while the normalized difference gives modulation depth 0.5. Carrier power is 21.6 mW, each sideband power is 1.35 mW, total average power is 24.3 mW and peak envelope power is 48.6 mW. The inference assumes the ordinary sinusoidal nonnegative envelope, linear calibrated transfer, compatible extrema and a positive real load. It is not an unrestricted inverse of every magnitude trace. Overmodulation can make the signed envelope cross zero, after which magnitude detection loses its sign. AGC changes between selected extrema, asymmetric sideband filtering, detector offsets, noise near a minimum and clipping can also invalidate the inference. Preserve the interval and detector state from which the extrema were selected. A reference modulation test should exercise the relevant amplitude and frequency range, rather than only the unmodulated carrier at the center of the passband. Report the inferred source parameters only within that verified path and model scope. Review: Equation 11D; Applications 6A.2 and 6A.4.

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion; Chapter 6 — Application 6A.2: Infer the conventional-AM envelope parameters; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-005 — The signed envelope ranges from −0.5 V to 2.5 V. It is negative when the modulation cosine is less than $-\frac{2}{3}$; the fraction of a complete period is $\arccos\left(\frac{2}{3}\right)$ divided by π, approximately 0.267720 or 26.7720 percent. The ideal algebraic RF waveform still has a 10 mW carrier and two 5.625 mW sidebands, giving 21.25 mW average power. Its largest envelope magnitude is 2.5 V, so peak envelope power is 62.5 mW. Magnitude detection folds the negative portion upward and reaches zero at the crossings. Applying the ordinary nonnegative-envelope inversion to extrema 2.5 V and zero would return depth 1 and carrier peak 1.25 V, neither of which recovers the stipulated signed model. Distinguish this information loss in the detector from physical transmitter clipping. The ideal waveform has only the original carrier and two RF sidebands; extra RF products require an additional mechanism. A properly phased coherent or complex record can preserve the sign needed to resolve the ambiguity. Review: Equations 11E–11H; Application 6A.4.

Review: Chapter 6 — Equation 11E. Sinusoidal sideband amplitudes and powers; Chapter 6 — Equation 11F. Total sinusoidal-AM power; Chapter 6 — Equation 11G. Power for a zero-mean nonsinusoidal message; Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-006 — The low-pass result is the real envelope multiplied by the cosine of the reference phase error. The recovered DC is approximately 0.919253 V and the sinusoidal message peak is approximately 0.551552 V. The message amplitude ratio to perfect phase alignment is cos(40°), corresponding to approximately −2.314921 dB. This loss is a projection loss under the stipulated normalization, not proof that the received RF power has fallen. At a 90° error the ideal real projection vanishes while the complementary quadrature contains the signal. A complex record preserves the rotation and can support correction when a measured reference or justified estimator establishes the phase. Rotating a record merely to maximize an expected output is a processing choice that must be declared; it is not independent evidence of the original phase. If the LO frequency is also wrong, the projection changes with time and the fixed-cosine scale no longer describes the complete output. Review: Equations 11I–11J; Applications 6A.5–6A.6.

Review: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error; Chapter 6 — Equation 11J. Complex coherent recovery; Chapter 6 — Application 6A.5: Measure phase-dependent coherent-AM recovery; Chapter 6 — Application 6A.6: Resolve the two tones caused by a DSB-SC tuning error.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-007 — The real detector multiplies the real message by the cosine of the residual 80 Hz rotation. Expanding the product gives components at 1420 Hz and 1580 Hz, each with peak 0.4 V under the declared detector normalization. This is a time-varying projection, not one 1500 Hz tone with a fixed gain error. A short segment may show beating or changing apparent level without resolving two spectral components; the analysis duration and window therefore belong with the interpretation. The result also depends on the assumed zero initial phase error, which controls the component phases even when their frequencies and amplitudes remain as stated. Retain the native or complex record, the reinsertion reference and the derived audio. Correcting a justified residual rotation in the time record can recover the intended detector relationship. Relabeling a displayed marker cannot undo the modulation imposed by the incorrect reference. Review: Equation 11I; Application 6A.6.

Review: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error; Chapter 6 — Application 6A.6: Resolve the two tones caused by a DSB-SC tuning error.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-008 — Over complete beat periods, the cross term averages to zero and the mean squared envelope magnitude is $0.9^2+0.5^2$, or 1.06 V^2. Average RF power is therefore 10.6 mW. When the components align, the envelope magnitude is 1.4 V and peak envelope power is 19.6 mW. The ratio is approximately 2.669502 dB. The peak statement requires an observation long enough to include the alignment, or an analytic statement about the complete periodic waveform; an arbitrary short captured interval may have a smaller observed maximum. Initial phases can shift the alignment time without changing the complete-period mean. Maintain the peak-voltage convention and the positive real load. A receiver judged only against 10.6 mW average input may still compress on a peak, so compare the appropriate peak quantity with the applicable chain limit and verify the waveform transfer. Do not substitute the peak instantaneous RF voltage-squared quantity for peak envelope power. Review: Equations 11A–11B and 11K; Application 6A.8.

Review: Chapter 6 — Equation 11A. Real RF waveform and its complex envelope; Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-009 — For these explicitly real coefficients, the in-phase component is 1 + 0.50 cos of the modulation angle, while the quadrature component is 0.20 sin of that angle. At $\frac{\pi}{2}$ the complex envelope is $1 + j\,0.20$ V. Its magnitude is approximately 1.019804 V and its phase is approximately 0.197396 radians. The nonzero quadrature term reveals a relation hidden by a magnitude-only display. The coefficient sum and difference follow from the full complex expansion; for generally complex coefficients, take the real and imaginary parts of the complete expression instead of treating the same real-coefficient formulas as universal. These output coefficients alone do not identify the original source depth, because the source and the two sideband transfers may both be unknown. A known input and coherent response measurements can separate those possibilities. The conclusion should concern the observed output unless the path evidence justifies a source-level inference. Review: Equation 11L; Application 6A.9.

Review: Chapter 6 — Equation 11L. In-phase and quadrature terms after unequal sideband response; Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-010 — The upper-sideband RF component is at carrier plus message frequency, so its signed complex baseband frequency is +2025 Hz. The lower-sideband component is at carrier minus message frequency, giving −2375 Hz. Both signed frequencies have been shifted by −175 Hz relative to ideal reinsertion. Their real-audio frequency magnitudes, however, are 2025 Hz and 2375 Hz, which conceal the signs and can encourage an incorrect claim that the tuning error acted in opposite algebraic directions. Preserve the sideband convention and complex orientation with the LO reference. A frequency adjustment made by ear can improve perceived intelligibility without establishing an accurate RF or baseband frequency scale. Report it as a documented processing choice unless a measured reference or specified estimator supports a stronger statement. A real-audio record alone generally cannot reconstruct the discarded analytic orientation. Review: Equation 11K; Application 6A.7.

Review: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes; Chapter 6 — Application 6A.7: Retain SSB sign when the reinsertion frequency is wrong.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-011 — For the stated PM law, differentiation makes peak deviation equal to peak phase times modulation frequency. The deviations are therefore 0.9 kHz and 3.6 kHz. For the stated FM law, integration makes the phase index equal to peak deviation divided by modulation frequency, giving 1.8 rad and 0.45 rad. Phase excursion, deviation magnitude and modulation rate are different quantities with different units or conventions. At one operating point, an appropriately chosen PM drive and FM drive can produce the same phase history, so the received waveform does not uniquely establish the internal modulator architecture. Compare controlled changes in message rate and amplitude only where the input relationship is known. Recovered loudness also depends on the demodulator transfer, filtering and de-emphasis. A sound answer derives the waveform relationships first and keeps the device-architecture inference conditional. Review: Equations 12B–12C; Applications 6B.2–6B.3.

Review: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation; Chapter 6 — Application 6B.2: Differentiate a sinusoidal PM phase; Chapter 6 — Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-012 — Integrate the frequency deviation in hertz over time in seconds and multiply the result by 2π. The first half is a negative triangle with area −4.5 cycles, so the additional phase at 3 ms is -9π radians. The positive second half contributes +4.5 cycles and brings the additional phase at 6 ms back to zero. The net endpoint increment is therefore zero even though the deviation is nonzero almost everywhere except the midpoint. A frequency estimate from the full-interval phase difference gives an average deviation of zero; it does not establish zero instantaneous deviation throughout the interval. Principal phase alone would discard whole turns and further obscure the trajectory. Preserve the continuous unwrapped phase or the properly supported integration model, the time interval and any resets. The example separates a cancellation in an integral from the local derivative that defines instantaneous frequency. Review: Equations 12D and 12F; Application 6B.5.

Review: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset; Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase; Chapter 6 — Application 6B.5: Integrate a linear frequency ramp without losing phase turns.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-013 — Differentiation and division by 2π give deviation components of $480\cos(2\pi \times 1200t)$ Hz and $480\cos(2\pi \times 3200t)$ Hz. The magnitude is bounded by 960 Hz. At $t=0$ both cosines equal one, so the positive bound is attained for this particular phase specification; the bound is not merely a loose inequality here. With the highest modulating frequency 3.2 kHz, Carson's engineering estimate is 2 times the sum of 960 Hz and 3200 Hz, or 8320 Hz. That estimate does not specify exact occupied power, individual sideband amplitudes or the performance of an 8.32 kHz IF filter. Different initial phases can change attainment without changing the componentwise triangle bound. A complete answer distinguishes the independently derived instantaneous-deviation result from the approximate bandwidth planning rule and identifies the actual spectrum and filter response needed for a containment or distortion claim. Review: Equations 12E and 12J; Application 6B.4.

Review: Chapter 6 — Equation 12E. Deviation from several phase components; Chapter 6 — Equation 12J. Carson estimate and its stated inputs; Chapter 6 — Application 6B.4: Bound and attain the deviation of a two-tone phase.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-014 — The principal interval is from −32 kHz inclusive to +32 kHz exclusive. The +43 kHz component therefore has representative −21 kHz, and the indistinguishable constant-frequency family is −21 kHz plus an integer multiple of 64 kHz. The principal phase increment is 2π times $-\frac{21}{64}$ radians, approximately −2.061670 radians. Additional decimal precision in that increment does not distinguish the family members. Selecting +43 kHz requires justified information beyond those samples alone, such as a known admitted RF band and conversion convention, a suitable prior frequency interval, or another independently informative acquisition. Merely unwrapping a constant principal sequence by assuming the desired sign embeds the answer in the processing rule. State the sampling, conversion, anti-alias and continuity assumptions, and preserve the original complex samples so the chosen branch can be reviewed. This constant-frequency example should not be generalized into a claim that every arbitrary time-varying waveform has the same simple pointwise alias description without further conditions. Review: Equation 12G; Application 6B.6.

Review: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Application 6B.6: Expose the ambiguity of sampled phase increments.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-015 — Divide each phase increment by 2π and by its 50 μs interval. The three average deviations are approximately 318.309886 Hz, 509.295818 Hz and 763.943727 Hz. The full 150 μs interval gives approximately 530.516477 Hz, which also equals the equally weighted mean of the three adjacent interval averages. These are exact interval-average consequences of the stipulated unwrapped, absolutely continuous phase; they are not automatically the derivatives at either endpoint or midpoint. A linear phase segment would make its interval average equal to its constant local derivative, but that additional shape assumption is not supplied. If an estimate is plotted at an interval midpoint, identify that placement as a display convention. Phase noise, amplitude nulls, resets, timing errors and branch choices need separate treatment before applying the same arithmetic to measured data. Preserve those qualifications instead of presenting the numerical precision as evidence that the underlying phase is valid. Review: Equation 12F; Application 6B.7.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase; Chapter 6 — Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-016 — The retained linear term gives sideband peak-amplitude magnitudes of $\frac{\beta}{2}$, or 0.06 relative to the unmodulated unit carrier. Each retained sideband power ratio is 0.0036, approximately −24.436975 dB relative to that stated unmodulated reference. The pointwise complex-envelope remainder is bounded by $\frac{\beta^2}{2}$, or 0.0072. The opposite signs of the two first-order exponential coefficients are part of the phase-modulation representation and should not be discarded when reconstructing the complex waveform. The remainder bound applies to the complex amplitude approximation, not directly to a claimed exact occupied bandwidth or to an identical numerical error in every spectral power. Nor does it justify treating the exact modulated carrier as unchanged for arbitrary index. State the approximation order, normalization and intended accuracy. If a stronger spectral or power claim is needed, evaluate the exact waveform or a separately justified expansion and compare it with the acquisition response. Review: Equations 12H–12I; Application 6B.8.

Review: Chapter 6 — Equation 12H. Pointwise small-phase remainder; Chapter 6 — Equation 12I. First-order sidebands for sinusoidal small phase; Chapter 6 — Application 6B.8: Bound a small-phase approximation before using it.

V011-C06-ESSAY-017 — The arithmetic gives an engineering bandwidth estimate of 16 kHz, but equality between that estimate and a nominal IF width does not establish adequate passage or a specified power-containment fraction. Ask which attenuation level defines the IF width, its ripple and phase response, and how the modulation energy is distributed. A nominal width also does not describe transition-band behavior or group delay. Retain the waveform and estimate the relevant spectrum or perform a calibrated transfer check across its significant components. Compare recovered deviation, message shape and any specified distortion metric against an appropriate wider or independently characterized reference path. Include receiver linearity and detector settings so the comparison does not confuse filtering with other transformations. The archival IRIG example supports treating the rule as a planning estimate, not as a universal exact mask. The final acceptance statement should name the quantity, tolerance, tested waveform and actual path state. Review: Equation 12J; Application 6B.9; IRIG 106-05 Appendix A, printed A-12.

Review: Chapter 6 — Equation 12J. Carson estimate and its stated inputs; Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-018 — The PM contribution has peak frequency deviation 0.6 times 2500 Hz, or 1500 Hz. Adding the +120 Hz residual offset yields a baseband frequency range from −1380 Hz to +1620 Hz. The constant −25° phase offset has zero derivative. Over 5 ms, the residual frequency offset alone advances phase by 0.6 cycle, or 216°; this is separate from the oscillatory PM phase. Correcting a justified frequency offset removes a linear phase trend, while a fixed phase rotation changes the phase origin. Neither operation authorizes bridging a phase reset or replacing an invalid branch. A fitted trend can absorb a slow genuine modulation component if the estimation interval or model is unsuitable. Retain the uncorrected record, the reference or training interval, the fitted parameters and the corrected result. A statement that the residual was removed should describe the estimation dependency rather than imply independent knowledge of the original carrier. Review: Equation 12K; Application 6B.10.

Review: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-019 — Specify the AM reference frequency, modulation rate and depth, carrier level, load and uncertainty relevant to the intended result. Exercise levels and gain states representative of the observation while keeping the reference below applicable peak and average limits. Verify both sidebands, not only the center-frequency carrier, and inspect complex or coherent response where asymmetry matters. Select maxima and minima within one stable state and declared interval; identify AGC transitions, detector offsets and noise-sensitive minima. Compare the envelope inversion with linear-power sideband accounting under the sinusoidal model. A disagreement calls for investigation of transfer, normalization or reference validity rather than averaging the answers blindly. State the acceptance tolerance before interpreting the result. A successful check establishes the functions and states actually exercised at the time of that check. It does not prove uninterrupted validity during a previous acquisition or the source identity of an unrelated signal. Preserve the settings and the reference evidence with the measured result. Review: Amplitude Modulation and Envelope Detection; Applications 6A.1–6A.3 and 6A.9.

Review: Chapter 6 — Application 6A.1: Close the power accounting for sinusoidal AM; Chapter 6 — Application 6A.2: Infer the conventional-AM envelope parameters; Chapter 6 — Application 6A.3: Infer modulation depth from one resolved sideband; Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth; Chapter 6 — Amplitude Modulation and Envelope Detection.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-020 — Separate the incoming waveform from the nonlinear and selective receiver operations. Limiting can reduce amplitude variation without preserving all multi-component information; capture can make one component dominate the demodulated output, and threshold behavior can produce abrupt changes or noise bursts as conditions vary. Clean audio therefore does not establish that the admitted RF contained only one source. Retain the complex RF or IF record and the state of the limiter, demodulator, filters, squelch and de-emphasis. Where authorized and technically appropriate, compare a characterized wider observation path, controlled level changes and a known two-signal reference. Check for front-end overload before attributing changes to the FM detector alone. Evaluate the weaker-component question with a stated sensitivity and selectivity scope. An absence statement should be bounded by the exercised chain, interval, bandwidth and detection criterion, not by the subjective cleanliness of the recovered audio. Review: Frequency and Phase Modulation; Carrier, Sidebands, and Modulation Evidence.

Review: Chapter 6 — Carrier, Sidebands, and Modulation Evidence; Chapter 6 — Frequency and Phase Modulation.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-021 — Treat acquisition continuity and waveform transfer as separate questions. Establish the expected or independently observed event timing, trigger operation, dwell or record coverage, sample continuity and any processing dead time. A gap can explain why a pulse was not acquired. For events known to have entered the retained record, examine IF bandwidth and transient response, gain control, limiting, detector time constants and output sampling. Those operations can broaden, suppress or reshape a pulse without deleting the corresponding acquisition interval. Use a representative calibrated pulse or independently timed reference to challenge the relevant path. Preserve peak, width, repetition and duty definitions, together with the level and state at which they were evaluated. Neither a quiet display nor a distorted audio trace alone distinguishes absence, missed capture and transfer distortion. The report should state which events were covered, which waveform properties were verified and which uncertainty remains. Review: Pulse, Radar, and Transient Reception; Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Pulse, Radar, and Transient Reception.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-022 — Possible explanations include a genuine modulation component in the admitted RF, an internal mixing or reference artifact, and a demodulator or processing response to noise or another signal. Begin by preserving native samples and all original settings. Compare whether the tone follows a predicted RF feature under a documented tuning change, whether it persists with a suitable terminated or reference input, and whether changing only the demodulator or derived-processing configuration changes the tone while native data remain fixed. These tests need known reference planes and stable states; a termination may bypass an antenna or external coupling path and therefore cannot test every part of the chain. Check overload and images before treating a tuning response as unique evidence. Interpret the outcomes against explicit predictions for each explanation, including cases where two mechanisms remain compatible. Avoid identifying a source or message solely from resemblance in audio. Keep the tested alternative, result and remaining ambiguity with every conclusion. Review: Single Sideband and Coherent Reception; Analog Demodulator Verification; Carrier, Sidebands, and Modulation Evidence.

Review: Chapter 6 — Carrier, Sidebands, and Modulation Evidence; Chapter 6 — Single Sideband and Coherent Reception; Chapter 6 — Analog Demodulator Verification.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-023 — Retain the native complex data with its sample rate, center or conversion frequency, clock and time basis, channel orientation, units or scaling, continuity information and capture interval. Record the exact extraction span, tuning correction, sideband convention, filter response, detector configuration, carrier or phase estimator, gain operation, limiting, squelch, de-emphasis and output resampling. Preserve software identity and configuration where they affect the transformation. Link the audio to the source interval and keep an unaltered original alongside any corrected product. A second analyst should be able to reproduce the transformation or identify which unavailable element prevents reproduction. Compare products generated from identical native data under controlled setting changes to isolate processing effects. Provenance establishes how a file was produced; it does not by itself calibrate amplitude, validate phase or establish metrological traceability of a result. The evidence package should make those distinctions explicit rather than relying on a file name or audible similarity. Review: Carrier, Sidebands, and Modulation Evidence; Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Carrier, Sidebands, and Modulation Evidence.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-024 — The Navy course supports the bounded carrier, sideband, envelope, modulation-rate and deviation relationships read in the identified pages. Its historical allocation examples and broad noise-immunity claims are not universal modern receiver specifications. The IRIG archive supports the stated Carson estimate and the dependence of its relation to power containment on modulating-energy distribution; it does not supply a current legal allocation, an exact spectrum mask or the response of the user's IF filter. Identify the edition and the pages actually inspected. The chapter independently derives its peak-voltage power, projection and phase-frequency equations under explicit assumptions, so a qualitative source citation is not being asked to certify every hypothetical numerical input. A useful answer distinguishes primary-source support for a claim from broader confidence in an issuing institution. When the proposed claim exceeds the inspected scope, obtain the applicable source or perform the necessary measurement rather than expanding the citation by implication. Review: Chapter source notes 16–19; NEETS Module 12, identified pages; IRIG 106-05 Appendix A, printed A-12.

Review: Chapter 6 — Carrier, Sidebands, and Modulation Evidence; Chapter 6 — Model 6A: preserve the complex envelope; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

Copyright 2026, James M. Atkinson

V011-C06-ESSAY-025 — Begin with the retained RF or IF interval, reference plane and chain state. Asymmetric sidebands may belong to the source or arise from unequal path transfer, interference or measurement error; a known coherent reference can test the relevant upper and lower responses. Pitch drift may reflect modulation, LO or recovery error, or processing, so compare the uncorrected complex phase with a justified frequency reference and retain any correction. Pulse-like dropouts may be real amplitude changes, acquisition gaps, squelch, AGC or demodulator behavior; inspect continuity and state records before assigning a mechanism. A phase derivative near an amplitude null may be invalid and should not become an apparent frequency excursion without qualification. Propose tests that discriminate these alternatives while preserving the original record. The conclusion should identify the supported waveform features, the transformations actually verified, and any unresolved source-level inference. Neither one modulation label nor apparently intelligible audio establishes transmitter identity or operational purpose. Review: Models 6A and 6B; Pulse, Radar, and Transient Reception; Analog Demodulator Verification; Chapter Summary.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 6 — Pulse, Radar, and Transient Reception; Chapter 6 — Analog Demodulator Verification.

Discussion Guidance

V011-C06-DISCUSSION-001 — Separate waveform evidence from identity, location and purpose. Ask which observable features support the classification and whether the selected receiver path can create or suppress those features. Identify independent evidence that would be needed for a source claim. A useful conclusion can be technically specific about the admitted waveform while leaving source identity unresolved; avoid treating uncertainty about identity as a reason to discard valid modulation measurements. Review: Carrier, Sidebands, and Modulation Evidence.

Review: Chapter 6 — Carrier, Sidebands, and Modulation Evidence.

V011-C06-DISCUSSION-002 — Compare the extraction interval, signed frequency convention, tuning correction, sideband choice, detector, filters, gain operation, de-emphasis, squelch and output resampling. Hold the native data fixed while changing one material processing choice at a time. A reproducible difference in derived output does not imply that the external signal changed. The team should identify the transformation responsible and state which product answers the intended technical question. Review: Carrier, Sidebands, and Modulation Evidence; Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Carrier, Sidebands, and Modulation Evidence.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-003 — Discuss the nonnegative conventional-AM domain in which magnitude retains the signed envelope, then contrast envelope reversal and unequal complex sideband response. A magnitude record can still answer a bounded amplitude question, but it may discard the sign or quadrature relation needed for a stronger inference. Decide what additional coherent or complex capture would resolve the specific ambiguity. Do not require I/Q by habit without explaining which information the intended conclusion needs. Review: Equations 11C–11L.

Review: Chapter 6 — Model 6A: preserve the complex envelope; Chapter 6 — Equation 11C. Conventional AM and nonnegative-envelope condition; Chapter 6 — Equation 11L. In-phase and quadrature terms after unequal sideband response.

V011-C06-DISCUSSION-004 — First test whether both estimates refer to the same source interval, gain state, reference plane, averaging convention and sinusoidal model. Investigate asymmetry, response, noise and clipping before combining them. A discrepancy can be evidence against a shared assumption rather than two independent random errors. Any combined result needs a justified measurement model and dependence treatment; numerical agreement obtained by averaging does not repair a failed model. Review: Applications 6A.1–6A.3 and 6A.9.

Review: Chapter 6 — Application 6A.1: Close the power accounting for sinusoidal AM; Chapter 6 — Application 6A.2: Infer the conventional-AM envelope parameters; Chapter 6 — Application 6A.3: Infer modulation depth from one resolved sideband; Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-005 — A minimum near zero is compatible with the boundary of nonnegative sinusoidal AM, but also with overmodulation after magnitude folding, destructive interference, fading, a detector offset or a noise-sensitive sample. Retain a stable interval and inspect the relevant signed or complex relationship. Ask whether the maximum and minimum belong to one calibrated state. The discussion should distinguish an observed output minimum from a justified inverse estimate of source depth. Review: Equation 11D; Application 6A.4.

Review: Chapter 6 — Equation 11D. Sinusoidal AM extrema and their inversion; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

V011-C06-DISCUSSION-006 — Use the ideal algebraic overmodulation example to separate the RF waveform from the magnitude detector. The signed envelope can reverse without adding RF terms to the linear product, while the absolute-value operation distorts the derived message. Physical clipping in a transmitter or receiver is an additional nonlinearity that can create other spectral components. Identify which side of the detector an observation describes before attributing a new component to the source. Review: Equation 11H; Application 6A.4.

Review: Chapter 6 — Equation 11H. Magnitude detection after envelope reversal; Chapter 6 — Application 6A.4: Show why an envelope-extrema estimate fails after reversal.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-007 — Maximizing a projection can be useful processing, but it does not independently establish the original phase or the complete calibration. Require a declared detector normalization and an applicable reference if amplitude is the result. Preserve the original complex record, the chosen rotation and the criterion used. Discuss cases in which noise or multiple components bias the maximizing phase. The correction should improve a defined estimate without erasing its dependency on the data. Review: Equations 11I–11J; Application 6A.5.

Review: Chapter 6 — Equation 11I. Real coherent recovery with residual reference error; Chapter 6 — Equation 11J. Complex coherent recovery; Chapter 6 — Application 6A.5: Measure phase-dependent coherent-AM recovery.

V011-C06-DISCUSSION-008 — Real-audio frequency magnitude discards the complex sign that distinguishes the two orientations. Apply one known LO offset to the signed upper and lower cases and compare the resulting magnitudes. Ask whether a stored sideband label supplies enough independent information to recover what was discarded. The appropriate record depends on the intended comparison, but an irreversible loss of orientation should be disclosed rather than reconstructed from expected speech content. Review: Equation 11K; Application 6A.7.

Review: Chapter 6 — Equation 11K. Explicit upper and lower single-sideband envelopes; Chapter 6 — Application 6A.7: Retain SSB sign when the reinsertion frequency is wrong.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-009 — Compare complete-period mean power with peak envelope power and the observation interval needed to encounter the peak. Determine whether the relevant hardware limit concerns average power, envelope peak, instantaneous voltage or another specified quantity. Use a representative waveform and state history to test linear transfer. A comfortable average margin can coexist with peak compression; the conclusion must follow the applicable limit rather than a convenient display statistic. Review: Equation 11B; Application 6A.8.

Review: Chapter 6 — Equation 11B. Envelope power convention; Chapter 6 — Application 6A.8: Compare average power with peak envelope power for two SSB tones.

V011-C06-DISCUSSION-010 — Unequal measured coefficients can motivate a path hypothesis, but source asymmetry and interference may remain alternatives. Examine both amplitudes and phases using a known input where possible. The full complex expansion shows how unequal sidebands create in-phase and quadrature terms; an envelope-only depth does not uniquely separate source and transfer. The discussion should end with a test that changes or characterizes the path while preserving the original observation. Review: Equation 11L; Application 6A.9.

Review: Chapter 6 — Equation 11L. In-phase and quadrature terms after unequal sideband response; Chapter 6 — Application 6A.9: Separate sideband filtering from source modulation depth.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-011 — The same phase history can be generated through different internal control laws when the drives are appropriately related. The waveform equations specify observable relationships, not a unique circuit architecture. A controlled change in known message rate or amplitude may discriminate a stated device hypothesis, but an unknown message does not provide that control. Keep waveform classification and architecture inference separate and identify the additional evidence needed for the latter. Review: Equations 12B–12C; Application 6B.3.

Review: Chapter 6 — Equation 12B. Sinusoidal FM phase and modulation index; Chapter 6 — Equation 12C. Sinusoidal PM and its frequency deviation; Chapter 6 — Application 6B.3: Distinguish fixed phase deviation from fixed frequency deviation.

V011-C06-DISCUSSION-012 — Require a meaningful nonzero complex representation, a justified continuous branch and adequate temporal resolution. At amplitude nulls or in unresolved mixtures, the phase can become unstable or represent an interference result rather than a unique component. Discuss exclusions, segmentation and alternative multi-component analysis. A smooth computed curve is not sufficient validation. State which signal model and intervals make the derivative interpretable. Review: Equation 12A; Model 6B phase-validity conditions.

Review: Chapter 6 — Equation 12A. Complex phase and instantaneous frequency; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-013 — An endpoint difference constrains only the net accumulated frequency offset. Positive and negative excursions can cancel. Preserve the trajectory and distinguish a principal phase display from an unwrapped branch. If the record lacks enough information to establish the intervening turns, report that ambiguity instead of inventing continuity. The team should identify whether the question concerns net phase, peak deviation or local frequency, because those require different evidence. Review: Equations 12D and 12F; Application 6B.5.

Review: Chapter 6 — Equation 12D. Integration of a general deterministic frequency offset; Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase; Chapter 6 — Application 6B.5: Integrate a linear frequency ramp without losing phase turns.

V011-C06-DISCUSSION-014 — An algorithm can impose continuity or choose a branch, but constant frequencies separated by integer sample rates can remain indistinguishable in the same samples. Ask what independent admitted-band, conversion or prior-frequency information supports the selected member. Verify that the assumption was applicable during the interval. The numerical output of an unwrapping routine should be reported with its branch rule and exclusions rather than as proof that ambiguity has disappeared. Review: Equation 12G; Application 6B.6.

Review: Chapter 6 — Equation 12G. Principal-increment frequency and its alias class; Chapter 6 — Application 6B.6: Expose the ambiguity of sampled phase increments.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-015 — Placement at an interval midpoint may be a useful convention, but the estimator remains an average over its specified interval. State the difference operator, span, overlap and any smoothing. Compare traces only after reconciling those choices and their timing. A shorter span can improve locality while increasing sensitivity to phase error. The discussion should preserve the distinction between a plotting coordinate and a demonstrated instantaneous derivative. Review: Equation 12F; Application 6B.7.

Review: Chapter 6 — Equation 12F. Finite-interval frequency from unwrapped phase; Chapter 6 — Application 6B.7: Report finite-interval frequency rather than an unsupported instantaneous value.

V011-C06-DISCUSSION-016 — Relate the pointwise complex-amplitude remainder bound to the quantity and tolerance actually being evaluated. An exact bound on the omitted complex amplitude does not automatically become the same bound on spectral power or distortion. The intended accuracy may permit the approximation or require the full exponential and a stronger calculation. Retain the unmodulated reference convention for the quoted first-order sideband powers and avoid extending it to arbitrary phase excursion. Review: Equations 12H–12I; Application 6B.8.

Review: Chapter 6 — Equation 12H. Pointwise small-phase remainder; Chapter 6 — Equation 12I. First-order sidebands for sinusoidal small phase; Chapter 6 — Application 6B.8: Bound a small-phase approximation before using it.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-017 — Use the estimate to guide which paths deserve evaluation. For acceptance, ask for the waveform spectrum, width definition, skirts, ripple, transfer phase and the permitted effect on the desired measurement. The same estimate can accompany different power distributions. A wider path may also admit more interference or noise. A useful decision names the tested waveform, chain state and quantity rather than declaring one nominal width universally correct. Review: Equation 12J; Application 6B.9.

Review: Chapter 6 — Equation 12J. Carson estimate and its stated inputs; Chapter 6 — Application 6B.9: Use Carson bandwidth as an estimate, then request the actual filter response.

V011-C06-DISCUSSION-018 — An estimated linear trend may remove carrier-reference error, but over an unsuitable interval it can also absorb a slow modulation component. Preserve the original phase and the source of the correction. Distinguish a fixed phase rotation, a frequency-offset correction and a phase reset. Ask whether an independent reference or a justified training interval supports the chosen parameters, and state the residual uncertainty instead of treating visual symmetry as validation. Review: Equation 12K; Application 6B.10.

Review: Chapter 6 — Equation 12K. Separate modulation, frequency offset and phase offset; Chapter 6 — Application 6B.10: Separate reference offset from a deterministic modulation.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-019 — The ideal phase-only model does not establish how a real limiter handles weak signals, multiple components, amplitude nulls, overload or recovery. Limiting can alter the evidence available for investigating those conditions even when it helps a particular demodulation task. Retain native data where possible and compare the relevant input and output behavior with a representative reference. The discussion should define what the limiter is permitted to change for the intended measurement. Review: Frequency and Phase Modulation; Model 6B phase-validity conditions.

Review: Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 6 — Frequency and Phase Modulation.

V011-C06-DISCUSSION-020 — Clean audio may be compatible with capture or other nonlinear selection, so it is insufficient evidence of a single-component RF input. Examine the native band, chain linearity and a stated weaker-signal detection criterion. A two-signal reference can test the actual configuration, but its levels, spacing and modulation must match the inference being made. Report the bounded detection scope rather than equating absence from audio with absence from the RF environment. Review: Frequency and Phase Modulation; Analog Demodulator Verification.

Review: Chapter 6 — Analog Demodulator Verification; Chapter 6 — Frequency and Phase Modulation.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-021 — Separate coverage from fidelity. Identify the usable interval, trigger timing, continuity and any dead time before characterizing the captured portion. A partial event may support some timing or amplitude observations while leaving the full width, peak or intrapulse structure unresolved. Do not splice separate stable fragments into a continuous event without a justified reconstruction model. State what was acquired and which properties could not be established. Review: Pulse, Radar, and Transient Reception; Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Pulse, Radar, and Transient Reception.

V011-C06-DISCUSSION-022 — Specify which stages and functions the stimulus actually traverses, its modulation and level range, and the time of the check. A reference injected downstream of an antenna cannot verify the bypassed antenna path. A successful check supports the exercised configuration at that time and cannot alone establish uninterrupted earlier validity. Choose complementary checks for competing hypotheses and keep the reference result distinct from source identification. Review: Analog Demodulator Verification; Preserve pulse and demodulator evidence across representations.

Review: Chapter 6 — Preserve pulse and demodulator evidence across representations; Chapter 6 — Analog Demodulator Verification.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-023 — It may be relevant to an authorized question, but it must be distinguished from calibrated amplitude, frequency, deviation or distortion. Record the processing needed to obtain it and avoid treating expected words as an independent frequency reference. Preserve the native technical record and minimize incidental content as the chapter directs. The discussion should state what an intelligibility observation can support and what additional objective evidence the report needs. Review: Analog Demodulator Verification; Hypothetical Case Adjudication.

Review: Chapter 6 — Analog Demodulator Verification; Chapter 6 — Hypothetical Case Adjudication: Analog Modulation Reception: AM, SSB, FM, PM, and Pulsed Signals.

V011-C06-DISCUSSION-024 — Identify the issuing body, edition and inspected pages, then attach the citation to the bounded claim actually supported. Preserve correct source identity and equipment or edition applicability. Do not extend a relationship about a historical architecture into a universal modern performance or regulatory statement. If a source contains a questionable example outside the relied-on scope, the qualification should be precise rather than discrediting all of its valid material. Review: Chapter source notes 16–19; Chapter References and Works Cited.

Review: Chapter 6 — Carrier, Sidebands, and Modulation Evidence; Chapter 6 — Model 6A: preserve the complex envelope; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 6 — Model 6B: phase is the quantity that frequency differentiates; Chapter 6 — References and Works Cited.

Copyright 2026, James M. Atkinson

V011-C06-DISCUSSION-025 — Require discriminating predictions and tests rather than selecting the most familiar story. A controlled processing change on the same native data can isolate some derived effects; a separately characterized acquisition may test overload, images or external coupling. If the available tests do not distinguish the remaining mechanisms, preserve the alternatives and narrow the conclusion. A reproducible bounded result is useful even when source identity or the exact internal mechanism remains unresolved. Review: Single Sideband and Coherent Reception; Analog Demodulator Verification.

Review: Chapter 6 — Single Sideband and Coherent Reception; Chapter 6 — Analog Demodulator Verification.

Copyright 2026, James M. Atkinson

Chapter Glossary

AMPLITUDE MODULATION: A representation in which a message changes the amplitude of a carrier-related waveform. Conventional AM in Model 6A uses a positive carrier term and a real normalized message. A magnitude envelope preserves that signed relationship only while the nonnegative-envelope condition and the applicable receiver transfer hold.

CAPTURE EFFECT: Tendency of an FM receiver to favor the stronger of two signals within its passband.

CARRIER POWER: The average power associated with the specified unmodulated carrier component at a declared reference plane. Under Model 6A's peak-voltage convention it is carrier peak squared divided by twice the positive real load resistance. Sideband powers, total average power and peak envelope power are separate quantities.

CARRIER REINSERTION: The introduction of a local carrier reference for coherent recovery of a suppressed-carrier or single-sideband signal. Its frequency and phase determine the recovered baseband orientation and projection. An adjustment made by ear is a processing choice; it does not independently calibrate the original RF frequency.

CARSON BANDWIDTH ESTIMATE: The engineering estimate twice the sum of peak frequency deviation and the highest declared modulating frequency, without an automatic exact-containment or filter-distortion claim.

COHERENT DETECTOR: Detector using a phase- and frequency-related reference to recover a modulated quantity.

COHERENT PROJECTION: Recovery of the component of a complex envelope aligned with a declared real reference phase.

Copyright 2026, James M. Atkinson

COMPLEX ENVELOPE: The complex baseband voltage function whose translation to a declared carrier and subsequent real part produce the modeled RF waveform. Its magnitude and phase retain information that a magnitude-only or one-axis record can discard. Model 6A uses a peak-voltage convention, spectral separation and a stated load and averaging interval for power calculations.

DE-EMPHASIS: A frequency-dependent operation in the recovered baseband path, commonly associated with an intended complementary emphasis characteristic. It changes the derived waveform and must be recorded with an audio result. Its presence alone does not establish the transmitter's characteristic or validate an amplitude or deviation measurement.

DEMODULATED AUDIO: An audio-band product formed by applying a declared tuning, detection and processing chain to an RF or IF record. It retains only the information admitted by that transformation. Reproducibility requires a link to the native interval and configuration; intelligibility alone does not calibrate the output or identify a source.

DEMODULATOR TRANSFER: The relationship between an admitted modulated waveform and a stated recovered output under a particular receiver configuration and state. It includes tuning, filtering, detector operation and relevant gain or conditioning behavior. Verification for one level, bandwidth or waveform does not automatically establish the relationship throughout the instrument's operating range.

DEVIATION: Peak or instantaneous departure of frequency from its unmodulated reference.

Copyright 2026, James M. Atkinson

DOUBLE-SIDEBAND SUPPRESSED CARRIER: An amplitude-modulated form retaining two message-related sidebands while suppressing the intended carrier component. Coherent reception needs a declared carrier reference. In the chapter's real product-detector example, a residual frequency error creates a rotating projection and can split a recovered sinusoidal message into two tones.

ENVELOPE DETECTOR: A detector that estimates a waveform's envelope magnitude through an applicable rectifying, magnitude or equivalent operation. Its bandwidth, time constants and nonlinear behavior affect the result. It loses the sign of an overmodulated real envelope and cannot generally substitute for coherent recovery of suppressed-carrier or single-sideband information.

ENVELOPE REVERSAL: A sign change of a real modulation envelope that magnitude detection cannot preserve.

FREQUENCY DISCRIMINATOR: A receiver operation that converts frequency variation into a baseband output according to its applicable transfer characteristic. Deviation scale, bandwidth, linear range and input conditions require verification. The term does not guarantee that amplitude nulls, multiple components or threshold behavior leave the recovered frequency unambiguous.

FREQUENCY MODULATION: A signal relation in which a specified message controls frequency deviation from a declared carrier reference. Phase follows by integration. For sinusoidal deviation, the peak phase index is peak deviation divided by positive modulation frequency; a constant offset instead produces a linear phase ramp.

Copyright 2026, James M. Atkinson

INSTANTANEOUS FREQUENCY: In Model 6B, the carrier reference plus the derivative of the stipulated unwrapped phase divided by two pi, wherever that derivative exists. The model requires a meaningful nonzero complex signal and an applicable continuous phase branch. A finite phase difference instead gives an interval average, and a phase reset requires separate treatment.

INTERVAL-AVERAGE FREQUENCY: The unwrapped phase change divided by two pi and the elapsed interval, with any included phase discontinuity explicitly identified.

LOWER SIDEBAND: The message-related spectral component or band below a declared carrier. In Model 6A's single-tone complex convention its envelope rotates at negative message frequency, and translation retains that sign before any conversion to real-audio magnitude. The label depends on the reference and conversion orientation.

MESSAGE MEAN SQUARE: The declared time average of the squared normalized message. For a zero-mean AM message it determines the additional average power through the squared modulation scale. A unit cosine has mean square one half, but a general bounded message need not; its peak bound alone does not establish this statistic.

MESSAGE NORMALIZATION: The stated scaling that relates a physical or mathematical message to the dimensionless waveform used in a modulation model. In Model 6A the message magnitude is bounded by one and the separate modulation scale sets its contribution to the envelope. Changing that normalization without changing the scale alters the modeled waveform and power.

Copyright 2026, James M. Atkinson

MODULATION FREQUENCY: The rate of a sinusoidal modulating component, expressed in hertz, or an explicitly identified frequency within a more general message. It differs from peak frequency deviation and peak phase excursion. A multicomponent waveform requires the component frequencies and, for a Carson estimate, the highest significant modulating frequency under a stated criterion.

MODULATION INDEX: Dimensionless ratio describing modulation excursion relative to a modulating frequency or carrier parameter.

OPPOSITE-SIDEBAND LEAKAGE: An unwanted retained component from the sideband that a receiver or conversion process was intended to reject. It can arise from finite filter rejection, I/Q mismatch, product-detector imbalance or other path imperfections. Its observation is a receiver-performance question unless independent evidence establishes that the component belongs to the source.

PEAK ENVELOPE POWER: The maximum squared envelope magnitude divided by twice the declared real load resistance under the peak-voltage convention.

PEAK-VOLTAGE ENVELOPE: A complex envelope scaled so that its magnitude is the local peak RF voltage under the stated band-separation convention.

PHASE-INCREMENT ALIAS CLASS: Frequencies separated by integer sample rates that produce the same principal sampled phase increment.

Copyright 2026, James M. Atkinson

PHASE MODULATION: A relation in which a specified message directly controls phase relative to a declared carrier. Differentiation gives frequency deviation. For a sinusoidal message with fixed peak phase, peak frequency deviation grows in proportion to message frequency; a received phase history alone does not uniquely identify the circuitry that generated it.

PHASE RESET: An event that changes the selected phase branch discontinuously or restarts its reference. It interrupts an analysis that assumes one absolutely continuous phase history. Preserve the event and segment the record; do not interpret an ideal jump as an ordinary finite instantaneous frequency or silently bridge it with a fitted trend.

PRINCIPAL PHASE INCREMENT: The argument of the product of one complex sample and the conjugate of its predecessor, restricted here to the interval from minus pi inclusive to plus pi exclusive. It records a rotation modulo a full turn. Frequency interpretation needs a sample interval and justified information to resolve possible whole-turn aliases.

RESIDUAL FREQUENCY OFFSET: The remaining frequency difference between the signal’s declared carrier reference and the local conversion or recovery reference. Under the chapter’s convention it is carrier minus LO frequency and adds a linear baseband phase trend. Estimating that trend from modulated data can absorb part of the modulation unless the estimation model and interval are justified.

Copyright 2026, James M. Atkinson

SIDEBAND COEFFICIENT: A complex peak-voltage coefficient assigned to an upper or lower spectral component in the envelope expansion. It carries phase as well as amplitude. After a path response, the sum and difference of the two coefficients contribute to the complete in-phase and quadrature expression; real-coefficient shortcuts do not apply to arbitrary complex coefficients.

SIDEBAND IMBALANCE: A difference between the applicable amplitudes or phases of corresponding upper and lower sideband responses. It can turn an originally real envelope into a complex one and bias a source-depth inference from output magnitude. Distinguishing source asymmetry from path distortion requires an appropriate reference or additional independent information.

SINGLE SIDEBAND: Amplitude-modulation form transmitting one sideband with reduced or suppressed carrier.

SMALL-PHASE APPROXIMATION: The retention of one plus j times phase as the first-order representation of the complex phase exponential. The chapter supplies an exact pointwise complex-amplitude remainder bound of half the squared real phase. First-order sideband amplitudes are approximate and use an unmodulated carrier reference; the bound does not itself specify exact spectral containment.

SQUELCH: A receiver operation that suppresses or gates a recovered output according to a defined or automatic condition. It can change the apparent presence and continuity of audio without proving that the RF waveform disappeared. Record its state and criterion when interpreting dropouts or comparing derived products.

Copyright 2026, James M. Atkinson

UNWRAPPED PHASE: A continuous phase branch retaining accumulated cycles on a declared valid interval, with reset events treated separately.

UPPER SIDEBAND: The message-related spectral component or band above a declared carrier. In Model 6A's single-tone complex convention its envelope rotates at positive message frequency. The signed baseband result also depends on LO frequency; folding it into real-audio magnitude can hide the orientation needed for a coherent comparison.

ZERO-MEAN MESSAGE: A message whose declared average is zero over the applicable averaging interval or limiting convention. In the conventional-AM power expansion this condition removes the carrier-message cross term. It does not imply zero mean square, absence of modulation, a specified peak value or a particular spectral distribution.

Annotation. Supports the bounded discussion of carrier, sideband and envelope relationships and the distinction among frequency deviation, modulation rate and modulation index. The chapter's peak-voltage, projection and phase-frequency calculations are independently derived under their stated assumptions. Historical allocation examples and broad noise-elimination or universal performance claims outside this scope are not adopted. Figure 1-38 on printed page 1-43 labels its lower sideband 94 kHz; the adjacent prose and the stated 100 kHz carrier minus 5 kHz modulation give 95 kHz. The figure label is not adopted. This instructional source treats modulation, frequency translation or receiver signal-chain operation through explicit physical relationships. Image frequencies, sidebands, local-oscillator injection and intermediate-frequency filtering have to be checked against the receiver's actual topology. Ideal mixer identities do not establish that a real component is free of compression, leakage, spurs or path-dependent calibration errors.

Range Commanders Council. Telemetry Standards, IRIG Standard 106-05. Appendix A, “Frequency Considerations for Telemetry,” 2005 archive edition. Section 5.2.3.3, printed page A-12, Equation A-4 and Figure A-7. https://irig106.org/docs/106-05/appendixA.pdf

Annotation. Supports use of Carson’s rule as an engineering estimate and the qualification that its relationship to a specified power-containment bandwidth depends on the distribution of modulating energy. The inspected archival passage does not establish a current allocation, a universal emissions mask or the transfer performance of a particular receiver filter. The source describes relationships among modulation parameters, occupied spectrum and instrument observations. Approximate bandwidth rules depend on the signal model and the chosen significance or emission-mask criterion, rather than constituting exact occupied-band measurements. The chapter should distinguish an engineering estimate from calibrated detection and should state the assumed modulation and detector conventions. In this chapter the citation should be read against the local receiver model and the expressly defined quantities, not as a general endorsement of every design choice.

Chapter 7. Digital Modulation Reception, Synchronization, EVM, and Error Metrics

Copyright 2026, James M. Atkinson

7.1 Constellations and Symbol Representation

Digital modulation maps discrete symbol values to amplitude, phase, frequency, time, code, or multicarrier states. The receiver must estimate carrier frequency, phase, symbol timing, gain, and sometimes channel response before symbols can be compared with their ideal locations. A constellation display is therefore the output of synchronization and equalization algorithms, not a direct image of the transmitted waveform.[1]

Binary and multilevel phase-shift keying, quadrature amplitude modulation, frequency-shift keying, minimum-shift keying, orthogonal frequency-division multiplexing, spread-spectrum methods, and pulsed schemes have different observables. Classification should consider cyclostationary structure, symbol rate, spectral shape, pilots, preambles, coding, and time behavior. A visual resemblance to a constellation is not sufficient when the receiver has imposed the assumed symbol timing and carrier.

1 United States Navy, Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles, NAVEDTRA 14189 (September 1998), 2-10–2-14, reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388–8392; title and edition at page 8345. These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

7.2 Carrier and Timing Synchronization

Frequency offset rotates a constellation and shifts matched-filter response. Phase offset changes symbol decision boundaries. Timing error samples the pulse away from its optimum point and can increase intersymbol interference. Practical receivers use acquisition and tracking loops, correlation with known sequences, timing-error detectors, and pilot-aided estimators. Loop bandwidth trades noise rejection against ability to follow drift and modulation.

Copyright 2026, James M. Atkinson

Figure 26. Carrier-offset and timing-error convergence.

Synchronization settings should be preserved with the result. A receiver can force a poor signal into an apparently stable display through narrow loops and long averaging, or can fail on a valid burst when acquisition range is too small. The practitioner records frequency and timing estimates, residual

Copyright 2026, James M. Atkinson

errors, lock indicators, slips, and the sections of data excluded from metrics. Held-out data provides a useful check against an estimator tuned to one capture.

Copyright 2026, James M. Atkinson

Figure 27. Digital modulation synchronisation and quality.

Copyright 2026, James M. Atkinson

7.3 Matched Filtering, Pulse Shaping, and Channel Effects

Pulse shaping controls occupied bandwidth and intersymbol interference. A matched filter maximizes signal-to-noise ratio for the assumed pulse in additive white Gaussian noise when timing and channel assumptions hold. Raised-cosine and root-raised-cosine filters are common, but implementation span, roll-off, sample rate, and scaling matter. Multipath and frequency-selective channels change the optimum response and may require equalization.

Equalizers can remove channel distortion while also hiding the physical condition being measured. A technical-security survey may need both pre-equalization and post-equalization metrics. If an equalizer with many degrees of freedom converts an unstable waveform into a tight constellation, the improvement is a processing result, not proof of a clean emission path. Coefficients, training intervals, convergence state, and regularization should be retained.

Copyright 2026, James M. Atkinson

7.4 Define the symbol experiment before fitting the constellation

A symbol-quality measurement begins with a reference relationship. Identify the transmitted or constructed reference sequence, its symbol rate, pulse shape, occupied interval, and mapping from labels to complex values. Then identify the receiver processing that makes an observed sample comparable with one reference symbol. Carrier recovery, timing selection, matched filtering, amplitude normalization, and equalization each change that comparison. A constellation plot omits much of this history, so it is a useful view of the result rather than a complete definition of the experiment.

Acquisition and tracking are separate parts of that history. A receiver can require a preamble or a sufficiently long carrier interval before its estimates become usable. Excluding that acquisition portion may be appropriate for a steady-state metric, but the excluded duration remains relevant to burst capture and packet success. Preserve both the acquisition result and the selected evaluation interval. A method that works only after most of the event has passed should not be described as though it characterized the entire event.

Pulse shaping and receive filtering determine which samples are symbol samples. State the filter coefficients or an unambiguous generation convention, span, roll-off or equivalent parameter, sample rate, delay, and initialization. A reference filter and a measurement filter may serve different purposes. Their names alone do not establish that an imported capture and a reconstructed ideal waveform are aligned. Check a known sequence with

Copyright 2026, James M. Atkinson

the same implementation and inspect the residual around transitions, where timing and filter-history errors are often clearest.

Equalization changes the question from the condition of an observed path to the condition after a specified compensation. Retain results before and after compensation when the physical channel is part of the investigation. Training length, coefficient count, regularization, adaptation interval, and held-out performance determine how much trust to place in the fitted result. An equalizer that follows each noisy sample can make a visually tight constellation without demonstrating a stable transferable channel model.

Copyright 2026, James M. Atkinson

7.5 Model 7A: a finite, declared EVM comparison

Model 7A develops the retained RMS EVM relation without introducing a probability law for symbol errors. The reference and observed vectors are finite disclosed data. Nonnegative weights identify the selected population, and the weighted reference energy must be positive. Timing, symbol mapping, filtering, and allowed corrections are fixed parts of the contract. Keysight's EVM documentation makes the symbol-location and normalization choices explicit, including differences for particular modulation formats. The model here states its own finite sample set so that no vendor-specific convention is implied.[2]

2 Joint Committee for Guides in Metrology, International vocabulary of metrology: Basic and general concepts and associated terms, VIM3 online edition, entries 2.48, 2.49 and 2.53, https://jcgm.bipm.org/vim/en/2.48.html, https://jcgm.bipm.org/vim/en/2.49.html and https://jcgm.bipm.org/vim/en/2.53.html, read November 2, 2026. These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

Illustrative RMS EVM = 14.0% (reference: ideal symbol RMS)

Important controls: common-phase correction, symbol alignment, reference constellation and fitting on held-out data.

Figure 28. QAM error vectors and RMS EVM.

Let s_k be the ideal complex symbol and y_k its observed counterpart at index k. The fixed comparison reference is t_k, which may equal s_k or a separately declared corrected reference. Their amplitude units must agree. The finite selected index set is S, and w_k are fixed nonnegative dimensionless weights.

Copyright 2026, James M. Atkinson

Training uses set T and held-out evaluation uses set H. E_s denotes weighted ideal-reference energy; the normalized EVM E is dimensionless. The fitted coefficient $\hat{a}$ is a dimensionless complex gain, and a star denotes complex conjugation.

Equation 13A. Finite reference energy and admissible weights

$$E_s = \sum_{k \in S} w_k |s_k|^2 > 0$$
$$w_k \geq 0, S\ finite$$

Equation 13B. Weighted fixed-reference error vector magnitude

$$E = \sqrt{\frac{\sum_{k \in S} w_k |y_k - t_k|^2}{\sum_{k \in S} w_k |t_k|^2}}$$
$$\sum_{k \in S} w_k |t_k|^2 > 0$$

The numerator is weighted squared residual distance in the complex plane, and the denominator is the corresponding reference energy. Their ratio is a power-like error ratio; taking its square root gives the amplitude-like EVM. Reporting a percentage multiplies that result by one hundred. Reporting decibels uses twenty times its logarithm. A zero residual has zero linear EVM and a limiting decibel value of minus infinity; it has no finite logarithm. A zero reference-energy record is undefined for this metric even if an instrument displays a convenient number.

Equation 13C. Percent and decibel reporting

$$E_{percent} = 100\,E$$
$$E_{dB} = 20 \log_{10}(E)\ for\ E > 0$$
$$E = 0 : limiting\ decibel\ value\ -\infty$$

An optional constant complex-gain fit can align amplitude and phase on a declared training set. Minimize the weighted sum of squared differences

Copyright 2026, James M. Atkinson

between the observations and a scaled reference. Expanding the squared magnitude separates the objective into a constant term and the reference energy multiplied by the squared distance from the fitted coefficient. The coefficient is therefore the weighted reference correlation divided by weighted reference energy. This derivation also identifies the required positive denominator.

Equation 13D. Optional complex-gain fit on a training set

$$\hat{a}=\frac{\sum_{k\in T} w_k y_k s_k^*}{\sum_{k\in T} w_k |s_k|^2}$$

$$E_{s,T}=\sum_{k\in T} w_k |s_k|^2>0$$

Equation 13E. Least-squares completion of the square

$$C=\sum_{k\in T} w_k y_k s_k^* \,,\hat{a}=\frac{C}{E_{s,T}}$$

$$J(a)=\sum_{k\in T} w_k |y_k - a s_k|^2$$

$$¿\sum_{k\in T} w_k |y_k|^2 - \frac{|C|^2}{E_{s,T}} + E_{s,T}|a-\hat{a}|^2$$

Two choices must then remain separate: which coefficient was fitted, and which reference normalizes the reported residual. If the evaluation reference is the fitted coefficient times the ideal symbols, that coefficient must be nonzero and the evaluation set must have positive ideal energy. A zero fitted coefficient can minimize residual energy while making this fitted-reference normalization undefined. Using the original ideal reference energy would be another valid declared metric, but it is not silently substituted here.

Copyright 2026, James M. Atkinson

Equation 13F. Held-out evaluation with a nonzero fitted reference

$$E_H = \sqrt{\frac{\sum_{k \in H} w_k \left| y_k - \hat{a}\, s_k \right|^2}{\left|\hat{a}\right|^2 \sum_{k \in H} w_k \left| s_k \right|^2}}$$

$$\hat{a} \neq 0,\ \sum_{k \in H} w_k \left| s_k \right|^2 > 0,\ H \cap T = \varnothing$$

A fit that reduces residual energy need not reduce every differently normalized EVM number. If the fitted reference has smaller energy, the denominator also falls. Report the coefficient, numerator, denominator, and selection when comparing results. This makes it possible to distinguish a physical improvement from a change in the metric definition. The same principle applies when a tool normalizes each trace independently before displaying it.

Constellation-maximum normalization uses a fixed ideal outer-point magnitude instead of the realized average reference magnitude. Keysight documents both choices and warns that trace normalization and error-summary normalization can differ. A multilevel constellation makes the distinction visible because its inner and outer symbols have different energies. The 16QAM example below deliberately includes every point once; a shorter or biased sequence can have a different realized average energy.[3]

3 Barry N. Taylor and Chris E. Kuyatt, Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results, NIST Technical Note 1297, 1994 edition (September 1994), Appendix A, A.1–A.5, https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. The functional and covariance framework is used within its stated scope; the synthetic ranges, examples and recoverability conclusions are original.

Copyright 2026, James M. Atkinson

Equation 13G. Average-reference and maximum-reference normalization

$$W=\sum_{k\in S} w_k, e_{rms}^2=\frac{\sum_{k\in S} w_k \left|y_k-t_k\right|^2}{W}$$

$$E_{avg}=\frac{e_{rms}}{\sqrt{\frac{\sum_{k\in S} w_k \left|t_k\right|^2}{W}}}$$

$$E_{max}=\frac{e_{rms}}{S_{max}}, S_{max}>0$$

Several simple impairment relations follow directly from the same residual definition. A constant real gain error gives the absolute gain departure from one. A fixed phase rotation gives a chord length on the unit circle. An additive offset survives a gain-only fit when the balanced reference sums to zero. A conjugate leakage term survives that fit when the reference sum of squares vanishes. These are controlled examples of nonunique causes: they show what a metric can measure, not how to diagnose an unknown record from one EVM value.

Equation 13H. Fixed gain and phase impairments

$$y_k=g\, s_k \Rightarrow E=\mid g-1 \mid$$

$$y_k=\exp\left(j\theta\right) s_k \Rightarrow E=2 \mid \sin\left(\frac{\theta}{2}\right) \mid$$

Equation 13I. Balanced-reference offset and conjugate terms

$$y_k=s_k+d \Rightarrow E=\frac{\left|d\right|}{\sqrt{\frac{\sum_{k\in S} w_k \left|s_k\right|^2}{\sum_{k\in S} w_k}}}$$

$$gain\, fit\, \hat{a}=1\, if \sum_{k\in S} w_k s_k=0$$

$$y_k=s_k+\beta\, s_k^{\,*} \Rightarrow E=\mid \beta \mid$$

$$gain\, fit\, \hat{a}=1\, if \sum_{k\in S} w_k s_k^{\,2}=0$$

Copyright 2026, James M. Atkinson

The sample selection is equally consequential. A complete burst, its settled payload, and a weighted transition region are different populations. Weights must be defined before judging the result and disclosed with it. A small subset cannot stand in for an entire recording merely because its constellation is cleaner. The largest residual, acquisition duration, excluded intervals, and continuity checks can complement EVM without being folded into an undocumented composite score.

Equation 13J. Residual sums for a disclosed selection

$$N_{err} = \sum_{k \in S} w_k \left| y_k - t_k \right|^2$$

$$D_{ref} = \sum_{k \in S} w_k \left| t_k \right|^2 > 0$$

$$E^2 = \frac{N_{err}}{D_{ref}}$$

Copyright 2026, James M. Atkinson

7.6 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

7.7 Application 7A.1: Show which error a fitted gain removes

Use the four unit-energy reference symbols 1, j, -1, and $-j$, and multiply every observed symbol by 1.08. Relative to the fixed reference, EVM is 0.08, or 8 percent and $-21.938200\ \mathrm{dB}$. A complex-gain fit returns 1.08 and leaves zero residual when the fitted reference is used.

The gain fit has removed exactly the impairment that the first result measures. Neither result is inherently contradictory. The fixed-reference value assesses absolute amplitude agreement, while the fitted value assesses what remains after that permitted correction. If amplitude calibration is the question, the fitted coefficient itself belongs in the acceptance result rather than disappearing behind the zero residual.

Copyright 2026, James M. Atkinson

7.8 Application 7A.2: Quantify a fixed phase error

A fixed 6-degree rotation of unit-energy symbols gives a chord distance of twice the sine of 3 degrees. The exact relation $2\sin(3^\circ)$ gives an EVM of approximately 0.10467191, equivalent to approximately 10.467191 percent or $-19.603397\ \mathrm{dB}$. No phase correction is fitted in this calculation.

The small-angle approximation would use the phase in radians, but the exact geometry is simple enough here to retain. A fitted phase could remove the rotation, provided that correction is part of the intended metric. A receiver phase-calibration test and a modulation-quality test after carrier recovery may therefore report different numbers from the same samples. Their correction permissions explain the difference.

Copyright 2026, James M. Atkinson

7.9 Application 7A.3: Preserve a DC impairment when fitting only complex gain

Add the same complex offset $0.04 + j\,0.03$ to the four balanced unit-energy references. Its magnitude is 0.05, so fixed-reference EVM is 5 percent. The reference symbols sum to zero, making their correlation with the constant offset vanish. A gain-only fit remains one and the EVM remains 5 percent.

Removing the estimated mean would eliminate this offset in the constructed case, but it would add another fitted parameter and change the measurement. A DC-removal step can also discard a real component when the signal definition permits nonzero mean. Preserve the reason for that operation, its training interval, and the uncorrected result. Do not label all removed mean as receiver leakage without an independent challenge.

Copyright 2026, James M. Atkinson

7.10 Application 7A.4: Expose a conjugate-image impairment

For the same four references, form each observation as its ideal symbol plus 0.06 times the conjugate of that symbol. The balanced reference has zero sum of squares, so the fitted ordinary complex gain remains one. Both fixed-reference and gain-fitted EVM are 6 percent. The residual changes direction with the symbol because it belongs to a conjugate path.

This is a bounded model of an image-like I/Q impairment, not proof that an unknown 6 percent EVM originates in I/Q imbalance. A calibration that estimates both direct and conjugate coefficients would be a different declared model with more parameters. Check its performance on an independent sequence before using it to correct an environmental recording. The original complex data remain necessary for that comparison.

Copyright 2026, James M. Atkinson

7.11 Application 7A.5: Compare RMS and constellation-maximum normalization

Use all sixteen square-16QAM points formed from real and imaginary coordinates -3, -1, 1, and 3. Their average energy is 10 and their maximum energy is 18. Add a fixed residual $0.2+j0.1$, with energy 0.05. RMS-reference normalization gives 7.071068 percent, while constellation-maximum normalization gives 5.270463 percent.

The observed residual has not changed. The smaller second number follows from its larger denominator. A threshold written for one normalization cannot be applied to the other without an explicit conversion and the correct reference population. This is why a report should name the normalization rather than treating a percent sign or an EVM label as a complete definition.

Copyright 2026, James M. Atkinson

7.12 Application 7A.6: Make selection and weighting visible

Four unit-reference symbols have residual magnitudes 0.30, 0.10, 0.02, and 0.02. Using all four equally gives 15.874508 percent EVM. Excluding the first two acquisition symbols gives 2 percent. Weights 0.1, 0.1, 1, and 1 instead give 7.006490 percent.

These values answer different questions about the same record. The settled-payload value can be useful, but it does not erase the acquisition errors. The weighted value expresses a chosen emphasis and is not automatically a standard-defined metric. Record the indices and weights, and preserve an unweighted complete-record result when the entire burst matters to the decision.

Copyright 2026, James M. Atkinson

7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols

Fit one training reference symbol 1 to one observation $1.2+j0.1$. The fitted gain is exactly $1.2+j0.1$ and the training residual is zero. Now apply that fitted reference to held-out ideal observations j, -1, and $-j$. Relative to the fitted reference, their EVM is 18.569534 percent. Relative to the true fixed reference it is zero.

The fit absorbed the entire error in a training set with no residual freedom for checking a complex gain. Its zero training EVM offers no assurance about other data. The example is deliberately small so that the failure is transparent. Longer training, a justified coefficient model, and held-out evaluation make the same issue observable in practical synchronization and equalization work.

Copyright 2026, James M. Atkinson

7.14 Application 7A.8: Keep a residual frequency rotation in a finite symbol record

A known unit pilot is sampled at 10,000 symbols per second for indices -10 through $+10$, while a residual 100 Hz offset rotates it. Phase spans -36 through $+36$ degrees. The in-sample constant-gain fit is approximately $0.92917367 + j0$. Fixed-reference EVM is 37.636773 percent; normalizing the fitted residual by the fitted-reference energy gives 39.781958 percent.

A constant coefficient cannot remove the time-dependent rotation. Its fitted magnitude is reduced because the rotating phasors partly cancel in their mean, which also changes the normalization denominator. A separately declared frequency-ramp fit could address that impairment, but it adds an estimation dependency and requires its own validation. The present result is an in-sample diagnostic, not a claim about held-out tracking performance.

Copyright 2026, James M. Atkinson

7.15 Application 7A.9: Separate constellation rotation from validated symbol mapping

Multiply the balanced QPSK reference sequence by j. Relative to its fixed labels, the EVM is the square root of two, or 141.421356 percent. A fitted complex gain j makes the residual zero. The same four constellation locations are occupied, but the association between observed points and the original labels has rotated.

A tight constellation after the fit does not resolve that label ambiguity. Known pilots, frame structure, or another justified reference may distinguish the intended mapping, and those checks should be retained. No bit error rate follows from the geometric EVM alone. This example separates successful numerical alignment from validation of the information represented by the symbols.

Copyright 2026, James M. Atkinson

7.16 Application 7A.10: Audit a complete finite residual vector

Take references $1+j$, $1-j$, $-1+j$, and $-1-j$. Their residuals are $0.02+j0.01$, $-0.01+j0.03$, $0.04-j0.02$, and $-0.02-j0.02$. The reference-energy sum is 8 and the residual-energy sum is 0.0043. The RMS EVM is 2.318405 percent, while the largest residual normalized to reference RMS is 3.162278 percent.

All inputs are disclosed, so the result can be recalculated without a proprietary constellation display. The larger peak residual does not contradict the RMS value; it supplies different information about this finite record. Retain both only when they serve the measurement question, and keep their normalization consistent. No statistical confidence interval or error-rate prediction is implied by four deterministic points.

Copyright 2026, James M. Atkinson

7.17 Error Vector Magnitude and Quality Metrics

Error vector magnitude compares measured symbol points with ideal references after stated normalization and synchronization. It aggregates noise, distortion, imbalance, phase noise, residual frequency error, timing error, compression, and channel effects. EVM is useful because it relates several impairments to demodulation quality, but it does not uniquely identify the cause. Different standards define averaging, normalization, included symbols, and reference reconstruction differently.

Bit error rate, packet error rate, modulation error ratio, adjacent-channel power, occupied bandwidth, and spectral regrowth answer different questions. A low error rate can coexist with high emissions because coding and margin compensate. A clean spectrum can coexist with poor data recovery if timing or protocol configuration is wrong. The metric set is selected from the engineering question and documented with test duration and confidence.

Copyright 2026, James M. Atkinson

7.18 Defensive Interpretation of Digital Signals

Digital receivers and software decoders can expose identifiers, service names, frame types, timing, and metadata. Those observations can support classification and asset inventory, but they may be spoofed, stale, relayed, encrypted, or unrelated to the physical source under examination. The practitioner separates protocol decoding from emitter location and authorization. Passive technical metadata is minimized according to the engagement authority.

Challenge tests include changing antenna position or polarization, using an independent receiver, altering sample rate and front-end gain, validating synchronization on a known reference, and correlating with authorized device state. A decoder that produces plausible but inconsistent frames under noise-only input is not evidence of a transmitter. The report states decoder version, checks, error indicators, and whether recovered fields were cryptographically or physically validated.

Copyright 2026, James M. Atkinson

7.19 Turn a quality metric into a reproducible acceptance record

A digital-reception acceptance record should bind the native sample segment to the reference sequence, time and frequency estimates, filtering, fitted parameters, selection, and final residual. Preserve intermediate residuals when several corrections are applied. A large improvement after equalization identifies dependence on that compensation; it does not by itself identify whether the original distortion came from the transmitter, propagation, the receiver, or the reference reconstruction. Controlled known-signal and bypass tests are needed to separate those paths.

Use independent checks that can fail for a different reason. A reference sequence with a known timing offset tests sample selection. A deliberately rotated mapping tests ambiguity handling. A noise-only or wrong-format record tests false lock. A held-out interval tests whether fitted coefficients transfer beyond their training set. A second implementation of the same finite EVM sum checks arithmetic, but it does not independently validate a shared wrong reference or shared synchronization estimate.

Equation 14 remains a rate-accounting identity under its stated exclusions. If a constructed 16QAM stream uses four coded bits per symbol, code rate 0.75, and a separately defined payload fraction 0.8 after framing and pilots, a 2.4 Mbit/s payload requires 1 Msymbol/s under those assumptions. The payload fraction and code rate describe different reductions. Do not count the same overhead twice, and do not infer either quantity from an observed constellation alone. This accounting reuses the retained relation rather than introducing a channel-error model.

Copyright 2026, James M. Atkinson

Report decoder results at the level supported by their validation. A passed checksum is a consistency check on a decoded structure, not a physical localization result or a cryptographic authentication claim. A failed check can arise from a wrong format assumption, synchronization, corruption, or a damaged path. Preserve error indicators and negative controls instead of selecting only plausible-looking outputs. The relationship between waveform classification, recovered fields, and external attribution remains the decision framework in Chapters 1 and 16.

Finally, retain acquisition failures alongside successful metrics. If the receiver locks only in some intervals, the EVM of the successful intervals is conditional on that selection. State the total observation time, attempted acquisitions, excluded segments, and reasons. This keeps a clean conditional metric from becoming an unsupported claim about uninterrupted receiver performance. Model 15A addresses observation opportunity; a complete demodulation success probability would require additional justified acquisition and decision behavior.

Copyright 2026, James M. Atkinson

7.20 Metric Validation and Held-Out Data

Digital quality metrics are validated on reference signals with known symbol rate, pulse shape, coding, frequency offset, and impairment. Processing parameters are selected from declared criteria rather than tuned until the result appears acceptable. A portion of the capture is held out from synchronization and equalizer fitting so that reported performance can be tested on data not used to build the model.

False-lock and noise-only tests are mandatory where a decoder produces rare events. The receiver is also challenged with altered sample rate, gain, and channel grid to verify that identifiers and checks move consistently with the physical signal. A technical report distinguishes raw observations, algorithmic estimates, decoded fields, validated checks, and external attribution.

7.21 Quantitative Model for Digital Modulation Reception, Synchronization, EVM, and Error Metrics

Equation 1. Root-mean-square EVM

$$\mathrm{EVM}_{\mathrm{RMS}} = \sqrt{\frac{\sum_k \left| S_{\mathrm{meas,k}} - S_{\mathrm{ref,k}} \right|^2}{\sum_k \left| S_{\mathrm{ref,k}} \right|^2}}$$

Root-mean-square error vector magnitude compares measured symbols $S_{\mathrm{meas},k}$ with reference symbols $S_{\mathrm{ref},k}$ after a stated normalization, synchronization, and symbol selection. The metric is dimensionless and is often reported as a percentage or in decibels.

Equation 2. Symbol-rate relation

$$R_s = \frac{R_b}{k_{\mathrm{bits}} r_{\mathrm{code}}}$$

Symbol rate R_{s} equals net bit rate R_{b} divided by bits per modulation symbol k_{bits} and code rate r_{code} when framing, pilots, retransmission, and other overhead are excluded. The actual transmitted symbol rate may differ when those terms are included.

Equation 13 is the equal-weight, positive-reference-energy case of Model 7A, whose ten applications distinguish reference choice, alignment, gain fit, and residual structure. Equation 14 is a rate-accounting identity. The payload-efficiency example above shows how additional overhead changes the denominator without introducing a new demodulation-error law.

7.22 Model 7B: finite rate accounting for symbols, coding and payload

Copyright 2026, James M. Atkinson

Figure 29. Finite-frame payload-rate accounting.

Equation 14 converts a declared information-bit rate into a modulation-symbol rate when its exclusions hold. A constellation supplies an alphabet, not a complete accounting of transmitted or delivered information. This development keeps the counts visible so that channel coding, pilots, framing, idle time and repeated payload cannot silently change the quantity

Copyright 2026, James M. Atkinson

called bit rate. It is one finite-count family, distinct from Model 7A's error-vector family. The examples below are independently constructed accounting cases, not protocol specifications or measurements of a commercial receiver. Unless a case gives an interval or alternative, its numerical counts, rates and durations are fixed stipulations. The examples do not represent measured observations or supply unreported timing or count uncertainties.[4] The finite-frame resource allocation is illustrated in Figure 29.

Choose a finite observation interval of duration T seconds, with T strictly positive. For the first construction, stipulate a uniform grid of N_{slot} nominal modulation opportunities. A slot may carry a data symbol, a pilot or a declared nonpayload use. Let N_{d} be the number of data-symbol slots; the two counts have units of slots and data symbols respectively. A guard or idle period belongs to this grid only when the grid has actually been defined through that period. The effective slot rate R_{slot} is N_{slot} divided by T. It must not be called the active transmitted-symbol rate when some of its opportunities contain no transmitted symbol.

Let k_{b} be the positive integer number of coded label bits assigned to each selected data symbol. For a specified power-of-two alphabet with an explicitly known binary labeling, k_{b} is the base-two logarithm of its cardinality. It counts label positions; it is not a claim about entropy, unique

These sources distinguish receiver noise from source and path contributions; the scalar assumptions and synthetic cases are stated in Model 2B.

Copyright 2026, James M. Atkinson

information, decoded correctness or stored ADC bits. Define N_c as the coded label-bit count and N_i as the input-information-bit count for the included complete coding blocks. The effective code rate r_c is N_i divided by N_c. Here the declared channel code adds redundancy without upstream compression, so the nondegenerate rate lies above zero and at most one. Puncturing, shortening, tails and boundary conventions belong in the actual finite counts.

Equation 14A. Count the distinct bit and slot populations

$$N_c = k_b N_d$$
$$r_c = \frac{N_i}{N_c}, \eta_b = \frac{N_p}{N_i}, \eta_s = \frac{N_d}{N_{slot}}$$
$$N_p = k_b r_c \eta_b \eta_s N_{slot}$$

N_p counts payload-bit instances represented by those transmissions under a stated framing rule; repeated instances are not yet deduplicated. The payload-bit fraction η_b removes declared nonpayload information bits, such as headers and padding, from N_i. The data-slot fraction η_s removes pilots or other nondata slots from N_{slot}. Both fractions lie between zero and one when their denominators are positive. These fractions operate on different populations and therefore can legitimately multiply. A single quoted efficiency that already combines those reductions must not be multiplied by either included reduction again. A code rate that already incorporates a particular termination cost must likewise not be penalized twice for that cost.

The count identity follows by cancellation, not by a channel-quality assumption: multiply the label bits per data symbol, information bits per coded bit, payload bits per information bit and data symbols per slot, then multiply by slots. Dividing both sides by the same T gives the fixed-mode

Copyright 2026, James M. Atkinson

rate law. R_{p} denotes payload bits per second, and the product $k_{\mathrm{b}}\, r_{\mathrm{c}}\, \eta_{\mathrm{b}}\, \eta_{\mathrm{s}}$ has the accounting meaning of payload bits per slot. With both overhead fractions equal to one and a fully occupied symbol grid, R_{p} is the net bit rate R_{b} of Equation 14 and R_{slot} is its R_{s}. No bandwidth, EVM or bit-error model is needed for this cancellation.

Equation 14B. Forward rate and the positive-target inverse

$$R_{\mathrm{slot}} = \frac{N_{\mathrm{slot}}}{T}$$

$$R_{\mathrm{p}} = \frac{N_{\mathrm{p}}}{T} = k_{\mathrm{b}}\, r_{\mathrm{c}}\, \eta_{\mathrm{b}}\, \eta_{\mathrm{s}}\, R_{\mathrm{slot}}$$

$$R_{\mathrm{slot}} = \frac{R_{\mathrm{p}}}{k_{\mathrm{b}}\, r_{\mathrm{c}}\, \eta_{\mathrm{b}}\, \eta_{\mathrm{s}}}\,;\, R_{\mathrm{p}} > 0\,,\, r_{\mathrm{c}}\, \eta_{\mathrm{b}}\, \eta_{\mathrm{s}} > 0$$

The empirical ratios in Equation 14A are defined only when their own denominator counts are positive. If no data slots occur, do not form an empirical code rate by dividing zero by zero; direct counting already gives no represented payload. A forward zero-throughput statement may use independently declared format factors, but it must identify their provenance. A positive payload target has no finite inverse under a zero useful-slot or zero payload fraction. For nonzero factors, a nominal inverse gives the required slot rate within the model; it does not establish that the transmitter, propagation path or receiver can realize that rate or meet an error requirement.

For successive modes, perform the accounting within each interval before combining results. If interval j has duration T_j and payload rate $R_{\mathrm{p},j}$, its payload count is $R_{\mathrm{p},j}\, T_j$. Add counts and divide by the sum of the durations. Do not average mode rates without time weights, and do not generally multiply separate averages of code rate and modulation order. Their joint

Copyright 2026, James M. Atkinson

variation determines the count. Simultaneous streams require a common time denominator and disjoint counted payload before their rates can simply be added.

Equation 14C. Combine counts before dividing by time

$$N_{\text{p,total}} = \sum_j R_{\text{p},j} T_j$$

$$R_{\text{p,total}} = \frac{\sum_j R_{\text{p},j} T_j}{\sum_j T_j}$$

$$|A \cup B| = |A| + |B| - |A \cap B|$$

The last relation in Equation 14C uses A and B as sets of identified payload-bit positions, not voltage or constellation amplitudes. It illustrates why duplicated copies cannot be counted twice when the stated result is unique delivered payload. Transmission counts, successfully decoded counts and distinct accepted delivery counts need different records. A checksum outcome alone neither identifies the physical sender nor supplies a delivery probability. In the examples, any delivery or duplicate count is explicitly stipulated as known; no probability of successful decoding is inferred from EVM or modulation order.

Finite framing introduces integer boundaries. Let U be the positive integer payload capacity of one complete fixed-length frame, S its positive integer total slot count and Q the positive integer payload demand. If the protocol sends only complete frames and pads unused final capacity, the minimum frame count is the ceiling of Q divided by U. The capacity FU can exceed the actual payload Q. Count the excess as padding under the stated rule, not as newly delivered information. For contiguous frames at a fixed positive slot rate, elapsed time is FS divided by R_{slot}. Additional interframe gaps must be added to the time denominator or explicitly included as slots.

Copyright 2026, James M. Atkinson

Equation 14D. Retain the integer frame boundary

$$F = \lceil \frac{Q}{U} \rceil, N_{\text{slot}} = F S$$

$$N_{\text{pad}} = F U - Q, T = \frac{F S}{R_{\text{slot}}}$$

$$R_{\text{p,actual}} = \frac{Q R_{\text{slot}}}{F S}$$

Uncertainty in the observation time can affect a rate even when the counted payload is exact. If T lies in a stated positive interval, the reciprocal is monotone and gives exact endpoint bounds for N_{p} divided by T. Those bounds describe the adopted timing enclosure; they are not a confidence interval without a probability model. If the count itself is ambiguous because framing or coding is unresolved, retain the discrete alternatives or a justified count enclosure instead of hiding the uncertainty in a nominal clock tolerance. No precision in a timestamp can repair a wrong population definition.

Equation 14E. Bound a rate with an exact count and uncertain positive duration

$$0 < T_{\min} \leq T \leq T_{\max}$$

$$\frac{N_{\text{p}}}{T_{\max}} \leq R_{\text{p}} \leq \frac{N_{\text{p}}}{T_{\min}}$$

7.22.1 Application 7B.1. Reconcile coded bits, information bits and modulation symbols

A constructed QPSK stream carries 4.000 Mbit/s of input information through a rate-one-half channel code. It uses two coded label bits per data symbol, has no headers, pilots, padding or idle time, and includes complete code blocks. The specified rate is an information-bit rate, not the coded bit rate and not a sample-file storage rate. Determine the required modulation-symbol rate and verify it using a 20.000 ms interval.

The coded bit rate follows by dividing 4.000 Mbit/s of information by code rate 0.5, giving 8.000 Mbit/s of coded bits. Dividing that coded rate by two coded label bits per data symbol gives 4.000 Msymbol/s. Equivalently, Equation 14 divides the information rate of 4.000 Mbit/s by the product of two coded label bits per data symbol and code rate 0.5, again giving 4.000 Msymbol/s. Each conversion retains its population label; applying the half-rate code as another multiplication would incorrectly halve the already net information rate.

Over 0.020000 s, the interval contains 80,000 data symbols, 160,000 coded bits and 80,000 information bits. The finite code ratio is $\frac{80{,}000}{160{,}000}=0.5$, and the data-symbol labeling supplies $\frac{160{,}000}{80{,}000}=2$ coded bits per symbol. Dividing the information count by the same duration returns 4.000 Mbit/s.

The agreement verifies the accounting under the stated complete-block and no-overhead assumptions. It does not predict occupied bandwidth, a receiver sample rate or delivered information after errors and repeats. If the quoted 4.000 Mbit/s had instead been the coded bit rate, the required

Copyright 2026, James M. Atkinson

symbol rate would be 2.000 Msymbol/s and the information rate 2.000 Mbit/s. The label on the given rate changes the problem before any arithmetic is performed.

Copyright 2026, James M. Atkinson

7.22.2 Application 7B.2. Separate two overhead populations without counting either twice

Use a 10.000 ms interval with 10,000 nominal slots. Exactly 9,000 slots carry 16QAM data symbols; the other 1,000 are known nondata slots. Each data symbol carries four coded label bits. The complete code blocks contain 27,000 information bits in 36,000 coded bits, and exactly 24,000 information bits are payload. Determine the slot rate, the two separate overhead fractions and the payload rate.

Dividing 10,000 nominal slots by 0.010000 s gives a slot rate of 1.000 Mslot/s. The data-slot fraction is $\frac{9,000}{10,000}=0.9$. The code rate is $\frac{27,000}{36,000}=0.75$. The payload-bit fraction is $\frac{24,000}{27,000}=\frac{8}{9}$. These fractions have different denominators: a slot count, a coded-bit count and an information-bit count. None is a substitute for the others.

Their product gives $4\times 0.75\times(\frac{8}{9})\times 0.9=2.4$ payload bits per nominal slot. At 1.000 Mslot/s, the payload rate is 2.400 Mbit/s. Dividing 24,000 payload bits by 0.010000 s gives 2,400,000 bit/s, the same 2.400 Mbit/s. The combined noncoding efficiency is $(\frac{8}{9})\times 0.9=0.8$, so the earlier concise 16QAM example with an explicitly combined 0.8 factor is recovered.

If an analyst uses that combined 0.8 and then applies the 0.9 data-slot fraction again, the predicted rate becomes 2.160 Mbit/s. The mismatch is double counting, not a receiver impairment. Retain the component counts even when a concise combined factor is reported. A different frame can have the same product 0.8 with a different division between pilots and

Copyright 2026, James M. Atkinson

information headers, and that distinction matters when the configuration changes.

Copyright 2026, James M. Atkinson

7.22.3 Application 7B.3. Count disjoint pilot and nonpayload slots explicitly

A synthetic frame has 100 slots. Twelve are pilots, and sixteen other slots are reserved for a distinct nonpayload use. These sets are explicitly disjoint. The remaining slots carry 16QAM under an effective code rate of 0.75, with every resulting information bit counted as payload. The slot rate is 3.000 Mslot/s, and successive frames are contiguous. Find payload per frame and the long-run rate for complete frames.

The data-slot count is $100-12-16=72$, giving $\eta_s=0.72$. Those symbols carry $72\times 4=288$ coded bits. The stipulated complete-block code supplies $0.75\times 288=216$ information bits, all payload. Dividing 100 slots by 3.000 million slots per second gives a frame duration of $\frac{100}{(3.000\times 10^6)}\ \mathrm{s}$, approximately 33.333333 μs.

The rate is 216 bits divided by that frame duration, giving 6.480 Mbit/s. The same result follows by multiplying the slot rate of 3.000 Mslot/s by four coded label bits per data symbol, code rate 0.75 and data-slot fraction 0.72. Multiplying the separate remaining fractions 0.88 and 0.84 would give 0.7392 instead of 0.72 and a wrong rate of 6.6528 Mbit/s. Those fractions were both defined against the original 100 slots, so sequential multiplication is unjustified.

If the two reserved sets instead overlapped in four slots, their union would contain 24 slots, leaving 76 data slots and giving 6.840 Mbit/s. That is a different stated allocation, not a rounding correction to the disjoint case. A framing record must identify whether categories overlap before an overhead calculation can be accepted. The calculation assumes complete

Copyright 2026, James M. Atkinson

frames and does not count partial boundary frames silently as complete ones.

Copyright 2026, James M. Atkinson

7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval

A burst contains exactly 4,000 data symbols sent at an active rate of 2.000 Msymbol/s. The selected alphabet is 64QAM, the complete-block code rate is two thirds and the payload-bit fraction is 0.9. No pilot slots occur inside the burst. A 0.500 ms silent guard follows each burst, and the reported wall-clock interval includes both burst and guard. Determine the payload count and both relevant rates.

Dividing 4,000 data symbols by the active rate of 2.000 Msymbol/s gives a burst duration of 0.002000 s. Six label bits per symbol give 24,000 coded bits, which represent 16,000 information bits. Multiplying by the payload-bit fraction yields 14,400 payload bits. Dividing by the active 2.000 ms gives 7.200 Mbit/s during the burst.

The complete repeating interval lasts 2.500 ms. Dividing 14,400 payload bits by 0.002500 s gives 5,760,000 bit/s, or 5.760 Mbit/s. The active-time fraction is $\frac{2.000}{2.500}=0.8$, so multiplying the active payload rate by 0.8 gives the same result. If a 0.500 μs opportunity grid is explicitly continued through the guard, it contains 5,000 nominal slots, of which 4,000 carry data; that equivalent slot accounting also gives 5.760 Mbit/s.

The physical active symbol rate remains 2.000 Msymbol/s. Calling 1.600 million transmitted symbols per wall-clock second the symbol clock would confuse an average event count with within-burst timing. Conversely, reporting 7.200 Mbit/s as the full-interval payload rate would omit the guard. State which interval and which event count define the rate before using it to compare a capture with a protocol or an equipment limit.

Copyright 2026, James M. Atkinson

7.22.5 Application 7B.5. Weight changing modes by their actual durations

A four-second record has two consecutive, fully known modes. During the first three seconds, a 2.000 Msymbol/s 16QAM stream uses code rate 0.75. During the last second, the same active symbol rate carries QPSK with code rate 0.5. Both intervals have no other overhead, idle time or duplicate payload. Calculate total information bits and the mean rate over all four seconds.

For the first mode, multiply 2.000 Msymbol/s by four coded label bits per symbol and code rate 0.75 to obtain 6.000 Mbit/s of information, hence 18.000 Mbit in three seconds. For the second mode, multiply 2.000 Msymbol/s by two coded label bits per symbol and code rate 0.5 to obtain 2.000 Mbit/s, hence 2.000 Mbit in one second. The total is 20.000 Mbit, and division by four seconds gives 5.000 Mbit/s.

An unweighted mean of the two mode rates would be 4.000 Mbit/s, which assigns the one-second mode the same time influence as the three-second mode. Even multiplying separately time-weighted factors can fail: the mean label count is 3.5 bits per symbol and the mean code rate is 0.6875, whose product with 2.000 Msymbol/s gives 4.8125 Mbit/s. Averaging the joint product is the required operation.

The mode change is part of the observation, so retain the interval boundaries and the factors belonging to each interval. A single average modulation order or code rate can be a descriptive statistic but cannot generally reconstruct the payload count. This example assumes the boundaries and durations are known and each interval contains valid

Copyright 2026, James M. Atkinson

complete blocks; uncertain transitions require separate counting or an explicit excluded interval.

Copyright 2026, James M. Atkinson

7.22.6 Application 7B.6. Remove duplicate payload before reporting unique throughput

Two simultaneous streams are recorded for the same 0.250 s interval. Their reported accepted-payload rates are 2.400 Mbit/s and 1.600 Mbit/s, with compatible bit definitions. Identity-linked delivery records establish that 100,000 payload-bit positions appear in both streams and that no other duplication occurs. Determine the sum of stream counts and the count of distinct delivered payload positions.

The first stream contributes 600,000 accepted payload-bit instances, and the second contributes 400,000. Their summed instance count is 1,000,000, corresponding to 4.000 Mbit/s when copies are counted separately. The declared overlap must be subtracted once: $600{,}000 + 400{,}000 - 100{,}000 = 900{,}000$ distinct delivered positions.

Dividing 900,000 distinct delivered payload bits by 0.250 s gives unique delivered throughput of 3,600,000 bit/s, or 3.600 Mbit/s. If the records instead established disjoint payload positions, simple addition would be justified and unique throughput would be 4.000 Mbit/s. The overlap information changes the counted population; it does not change either stream’s RF symbol clock or its coded-bit count.

The duplication record is an explicit premise in this constructed case. Modulation order, low EVM, a repeated identifier or one passed checksum cannot substitute for it. If overlap is unknown but each stream’s accepted count is trusted, the union count lies between the larger individual count and their sum. That coarse interval would give 2.400 through 4.000 Mbit/s,

Copyright 2026, James M. Atkinson

without assigning a probability or deciding which physical source sent the copies.

Copyright 2026, James M. Atkinson

7.22.7 Application 7B.7. Retain integer frames and last-frame padding

A fixed frame carries 800 input-information bits, including a 32-bit header, through a stipulated 800-to-1,000-bit channel code. QPSK sends the 1,000 coded bits in 500 data symbols. The protocol sends only complete contiguous frames at 1.000 Msymbol/s and fills unused final payload capacity with padding. A request contains exactly 10,000 original payload bits. Determine frame count, elapsed transmission time and the actual request-payload rate.

Each frame has capacity $800-32=768$ payload bits. Thirteen full payload capacities provide 9,984 bits, so they are short by 16 bits. The ceiling of $\frac{10{,}000}{768}$ is 14 frames. Their available capacity is $14\times 768=10{,}752$ bits, leaving 752 padding bits in the last frame. Padding is transmitted information for the coder but is not part of the original request payload.

Fourteen frames use 7,000 symbols and therefore 0.007000 s. Dividing 10,000 request-payload bits by 0.007000 s gives an actual request rate of approximately 1.428571 Mbit/s. The fully filled repeating-frame capacity rate instead divides 768 payload bits by 0.000500 s, giving 1,536,000 bit/s, or 1.536 Mbit/s. The finite request does not achieve that capacity rate because its last frame is mostly padding.

Check the complete count chain: the code sees $14\times 800=11{,}200$ information bits and produces 14,000 coded bits. The request-specific payload-bit fraction is $\frac{10{,}000}{11{,}200}$, approximately 0.8928571429, while the code rate remains 0.8. Multiplying 1.000 Msymbol/s by two label bits per symbol, code rate 0.8 and that exact payload fraction gives approximately 1.428571 Mbit/s. A

Copyright 2026, James M. Atkinson

request ending one frame earlier would save 0.500 ms but leave the final 16 requested bits unsent.

Copyright 2026, James M. Atkinson

7.22.8 Application 7B.8. Test a positive target against the declared rate limit

A constructed fixed mode uses 16QAM, code rate 0.75, data-slot fraction 0.8 and payload-bit fraction 0.9. It must represent at least 5.000 Mbit/s of payload. A separately stipulated configuration limit permits at most 2.000 Mslot/s. Ignore errors and retransmission in this accounting calculation, and determine whether the positive payload target is feasible within those premises.

The mode supplies $4 \times 0.75 \times 0.8 \times 0.9 = 2.16$ payload bits per nominal slot. The positive-target inverse requires a slot rate at least equal to the quotient of 5.000 Mbit/s and 2.16 payload bits per nominal slot. This required rate is approximately 2.314814815 Mslot/s. It exceeds the stipulated 2.000 Mslot/s limit, so no setting within this fixed mode meets the target.

At the limit of 2.000 Mslot/s, multiplying by 2.16 payload bits per nominal slot gives a maximum represented payload rate of 4.320 Mbit/s, leaving a 0.680 Mbit/s shortfall. This is an arithmetic incompatibility among stated target, fractions and slot-rate limit. A lower EVM does not alter the count identity. If another mode were available, its different code, framing and rate factors would have to be stated and checked separately.

If the useful-slot fraction were zero, direct counting would give no represented payload at any finite slot rate. The positive inverse would be undefined rather than zero. If a factor is only unknown, it must not be replaced by zero or one merely to obtain a number. Report the actual missing premise or a justified range; the hypothetical configuration limit here is not a published performance specification for any receiver.

Copyright 2026, James M. Atkinson

7.22.9 Application 7B.9. Propagate a positive timing enclosure through an exact count

Exactly 24,000 payload bits belong to an observed interval. Its duration is 10.000 ms with a deterministic timing enclosure from 9.995 ms to 10.005 ms. The payload count and its framing interpretation are stipulated exact. Calculate the nominal rate and an exact rate enclosure without assigning a probability distribution to the timing error.

Dividing 24,000 payload bits by the nominal duration of 0.010000 s gives 2,400,000 bit/s. Because the count is nonnegative and both time endpoints are positive, the smallest rate uses the largest duration. The exact lower endpoint divides 24,000 bits by 0.010005 s, giving approximately 2,398,800.5997 bit/s. The exact upper endpoint divides 24,000 bits by 0.009995 s, giving approximately 2,401,200.6003 bit/s.

The endpoint departures from nominal are approximately $-1{,}199.4003$ and $+1{,}200.6003\ \text{bit/s}$. A first-order magnitude estimate divides 24,000 bits by the square of 0.010000 s, then multiplies by 0.000005 s, giving 1,200 bit/s. It is close here, but its symmetric interval is not exactly the monotone reciprocal enclosure. Retain the exact endpoint quotients when that distinction matters.

This timing bound does not characterize frame misidentification, omitted bits, duplicate delivery or an uncertain code rate. Those would change the counted quantity and require separate evidence. Nor does the enclosure imply 95 percent coverage: it follows from the stated deterministic duration limits. If the interval could include zero duration, the positive finite reciprocal bound would no longer be available.

7.22.10 Application 7B.10. Preserve discrete coding alternatives rather than inventing a single payload rate

A synthetic observation establishes a 1.000 Mslot/s grid, 16QAM data labels and a data-slot fraction of 0.8. The format is known to use exactly one of two code rates, 0.5 or 0.75, but the surviving record does not identify which. The payload-bit fraction is independently bounded from 0.9 to 1.0. No delivery or retransmission claim is requested. Determine the admissible represented-payload rates under these explicitly exhaustive alternatives.

For the half-rate alternative, multiply 1.000 Mslot/s by four coded label bits per data symbol, code rate 0.5 and data-slot fraction 0.8. This gives 1.600 Mbit/s before the payload-bit fraction is applied; its range from 0.9 to 1.0 therefore gives 1.440 through 1.600 Mbit/s. For code rate 0.75, the corresponding rate before the payload-bit fraction is 2.400 Mbit/s, giving 2.160 through 2.400 Mbit/s after that fraction. Positive monotonic factors place each alternative's extrema at the payload-fraction endpoints.

The admissible set is the union of those two intervals. A coarse overall enclosure from 1.440 to 2.400 Mbit/s is valid as an enclosure, but it includes rates between 1.600 and 2.160 Mbit/s that neither stated format permits. Taking the mean code rate and reporting one midpoint would invent a state or a probability weighting that the evidence has not supplied.

Retain the alternative-specific result and identify the missing coding evidence needed to select between them. The recognizable constellation alone does not resolve that gap. These are conditional represented-bit counts, not proof of correct decoder output, unique accepted delivery or transmitter identity. If the two code rates were merely examples rather than

Copyright 2026, James M. Atkinson

an exhaustive premise, even this two-interval admissible set would overstate what is known.

Table 1. Chapter 7 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Synchronization	Carrier offset, phase, timing, loop bandwidth, lock, slips, and residuals	Establishes the reference used for symbol metrics	Forced or overfit synchronization can conceal instability
Pulse shaping and equalization	Filter family, roll-off, span, channel estimate, taps, and training	Separates waveform design from channel distortion	Post-equalization quality is not the raw emission quality
EVM and MER	Normalization, included symbols, averaging, reference reconstruction, and units	Aggregates modulation impairments	Does not uniquely identify the physical cause
Decoder output	Software version, checks, error state, identifiers, timing, and validation	Supports classification and inventory	Plausible fields can result from false locks or spoofing

7.23 Hypothetical Applied Calculation: Digital Modulation Reception, Synchronization, EVM, and Error Metrics

A QPSK capture has normalized squared symbol error sum 2.4 and normalized reference energy sum 960. The RMS EVM is 5.0 percent, or about $-26.0\ \mathrm{dB}$. If the first 200 acquisition symbols are excluded, that exclusion and the synchronization settings must accompany the reported value.

Copyright 2026, James M. Atkinson

7.24 Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics

An SDR decoder reports intermittent valid-looking packets in a quiet band. A noise-only recording passed through the same decoder produces similar identifiers at a lower rate, and the reported checksums are inconsistent. Tightening synchronization and requiring independent CRC validation removes the events. The initial packet interpretation is unvalidated and consistent with false lock. The noise-only result establishes a decoder false-output mechanism; it does not establish that every original event had that mechanism or that no communications signal was present. Waveform detection, decoded fields, and source attribution remain separate claims.

Copyright 2026, James M. Atkinson

7.25 Digital-demodulation validation by error covariance and synchronisation-state segmentation

A single error-vector-magnitude percentage compresses several physically different impairments into one statistic. Carrier-frequency offset causes a phase slope; phase noise produces stochastic rotation; clock offset creates sampling-phase drift; IQ gain and quadrature errors generate image components; channel selectivity introduces symbol-dependent amplitude and phase distortion. For a known pilot sequence, define error $e_k = z_k - a s_k$ after applying a declared complex scaling a and permissible timing alignment, where z_k is the received symbol and s_k is the expected reference symbol. A conventional RMS error measure divides the sum of $|e_k|$ squared by an explicitly chosen reference-power sum. The method of estimating a, selecting pilot positions, and excluding invalid intervals changes the result. An EVM figure that hides extensive fitted corrections does not carry the same interpretation as one produced under fixed previously calibrated parameters.

A diagnostic decomposition benefits from preserving the temporal covariance of symbol errors rather than looking only at their overall RMS. A near-constant rotation across a burst suggests a different limitation than rapid phase excursions; periodic error linked to sample index can indicate interleaving or symbol-clock structure; isolated error clusters can coincide with front-end overload and recovery. However, these signatures are not uniquely identifying. To assess an alleged external waveform property, the test must first demonstrate that a known laboratory reference exhibits different impairment when the relevant receiver mechanism is changed.

Copyright 2026, James M. Atkinson

Performing a synchronisation fit on the same suspect burst used to claim excellent demodulation can remove the very defect under examination. Report the applied fitting degrees of freedom and repeat the test with frozen parameters on held-out records.

For a simple educational example, suppose four equal-energy reference symbols each have unit magnitude, with received errors of complex magnitudes 0.10, 0.20, 0.10 and 0.20 after a stipulated fixed alignment. The sum of squared error magnitudes is 0.10, and reference-energy sum is 4. The RMS EVM is sqrt(0.10/4) = 0.15811, or 15.81 percent. If an analyst re-estimates carrier rotation separately for every symbol, the resulting error may be made artificially small without establishing a receiver capable of independently tracking that rotation. This is an identifiability problem: more adjustable parameters can absorb distortions as well as signal structure. The measurement protocol must distinguish physically justified synchronisation from overfitting.

A multi-condition validation set should vary input amplitude, frequency offset, sample-clock error, reference phase noise, modulation type, burst duration and interferer level separately. Include deliberate missing samples and frequency excursions across the channeliser boundary, while recording which pilots and symbols were actually observed. Error-rate estimates need event definitions and sufficient independent test observations; repeated bits from one corrupted frame cannot be treated as separate field incidents. When proprietary frame content is outside authorised scope, use public or synthetic test waveforms rather than recovering protected payload. A defensible technical conclusion can describe a modulation-family

Copyright 2026, James M. Atkinson

classification or demodulator failure without claiming knowledge of individual-emitter ownership.

Copyright 2026, James M. Atkinson

7.26 Advanced technical expansion. EVM as an imperfect inverse problem

Error vector magnitude is frequently presented as a convenient scalar percentage, but its scientific meaning depends on the reference constellation, alignment, equalisation and normalisation used to construct the error vectors. Let r_k be an observed complex symbol and s_k the ideal symbol assigned to it under an explicitly declared mapping. For a population of N eligible symbols, a common RMS EVM measure is sqrt(sum |r_k - s_k| squared divided by sum |s_k| squared). The definition presupposes that timing, carrier offset, phase and gain transformations have been specified, and it must say whether a fitted complex gain or equaliser is permitted before residuals are calculated. Two laboratories can obtain different EVM values from the same native samples while both calculations are internally correct, because their allowed compensation and reference sequence differ.

A useful example separates impairments. Suppose a set of ideal unit-energy symbols is observed through a constant phase rotation, plus an independent additive complex noise whose mean-square magnitude is 0.01 relative to the reference energy. Without compensating the phase, the measured error contains both phase and noise contributions; after estimating a legitimate constant phase rotation from independent pilot symbols, the residual EVM attributable to the stipulated noise alone would be 10%. If the same pilot symbols were also used to tune a highly flexible equaliser, a smaller training residual could simply reflect overfitting rather than improved receiver fidelity. A separate held-out symbol sequence is therefore needed to evaluate the selected processing and its uncertainty.

Copyright 2026, James M. Atkinson

The example is mathematical and does not purport to reproduce a real modem test.

Carrier-frequency error produces a time-dependent phase trend rather than the constant rotation just described. Sampling-clock mismatch creates a gradually changing relationship between symbol epochs and the acquisition time base. Phase noise introduces correlated random rotations whose spectrum matters, while nonlinearity can distort constellation radii and produce memory effects. An examiner should inspect error-vector trajectories, error correlation, symbol-time dependence and response to level changes before summarising them in one RMS figure. A constellation plot can conceal transient failures if thousands of satisfactory symbols dominate a small number of bursts. For an intermittent surveillance-related signal, precisely those rare intervals may determine whether classification is supported.

Equalisation improves demodulation only under an identifiable channel model. A linear adaptive filter may remove some propagation-induced intersymbol interference, but it can also compensate for receiver amplitude or phase defects that should instead be reported as instrumental uncertainty. The analysis must distinguish a desired measurement of received waveform quality from an estimate of a hypothetical transmitter output corrected for propagation. The latter requires a channel model, pilot structure or independent calibration. Unconstrained blind adaptation may produce an attractive constellation while silently changing the question being answered. Recording adaptation coefficients and their time history prevents a later reader from treating the processed waveform as an untouched observation.

Copyright 2026, James M. Atkinson

Sampling uncertainty enters both EVM and error-rate measurement. A finite number of symbols yields an estimate whose precision depends on the covariance of error vectors and on whether consecutive errors arise from independent noise or shared bursts. Counting each correlated symbol as independent narrows confidence intervals unjustifiably. Zero observed symbol errors does not establish a zero error probability; a statistical upper bound requires a specified trial model and confidence convention. Likewise, an unusually low EVM on one favourable laboratory frame does not establish field performance under drifting oscillators, strong blockers or fading. The report should identify the tested population and the selection procedure used to choose evaluated frames.

A comprehensive verification programme uses calibrated reference modulations with controlled phase, frequency, timing, amplitude and interference impairments. The receiver should preserve raw complex samples, reference pilots, equaliser state, symbol decisions, rejected intervals and all post-processing parameters. Test both during steady operation and across mode transitions. Disclose where the signal model is uncertain: if the nominal constellation or coding is unknown, a recovered constellation resemblance may support a candidate modulation family but cannot justify an exact source-quality percentage. Expert interpretation requires explaining which impairments the processing compensated, which remained and what alternative receiver-generated mechanisms could explain the observed constellation structure.

Copyright 2026, James M. Atkinson

7.27 I/Q-derived modulation identity: distinguish discriminating features from unique source attribution

A complex-plane trace shows the coordinates produced by the measurement chain, not the transmitter's original constellation without qualification. Constant-envelope angle-modulated signals, quadrature amplitude modulation, offset constellations, frequency shifts and transient pulses can overlap in simple moment statistics once acquisition noise, carrier offset, I/Q imbalance and timing uncertainty are introduced. Even a mathematically correct estimate of error-vector magnitude requires a declared reference constellation, fitted nuisance parameters and channel equalisation convention. If a classifier has been trained on captured samples from one SDR front end, it may learn the gain ripple, DC offset or phase-noise structure of that instrument rather than the intended emission type.

A defensible feature workflow begins with classification-independent checks of sample continuity, sign convention and frame boundaries. Form candidate feature sets from amplitude distribution, unwrapped phase increments where magnitude permits, autocorrelation, spectral occupancy, cyclostationary periodicity and modulation-likelihood calculations. Each feature has an observation period and an uncertainty model. A short chirped pulse may appear as an FM-like instantaneous-frequency trajectory, but a general FM broadcast and one phase-coded radar pulse do not have the same prior time behaviour. Correlations with known laboratory templates should be labelled as template matches and checked against realistic alternatives. A withheld test set should contain overlapping signals,

Copyright 2026, James M. Atkinson

clock offsets, incomplete bursts and capture-state changes so the claimed classifier accuracy is not measured on a conveniently homogeneous dataset.

Preserve the raw I/Q because apparently small preprocessing choices can alter identification. Blind DC removal can eliminate genuine near-zero-frequency content. Automatic frequency correction can erase a diagnostically useful offset. Magnitude-only normalisation destroys absolute-amplitude relationships that could help distinguish noise, interference and gain-control artefacts. Resampling with an undocumented antialias filter can create or suppress spectral sidebands. The correct result is a reproducible processing graph whose derived features carry source sample indices, transformation parameters and bounded confidence. A probable modulation class is scientifically valuable, but the physical emitter, geographic position and lawful authority to extract content require separate evidence.

Chapter Summary

Digital modulation metrics depend on synchronization, reference reconstruction, filtering, equalization, and validation. Receiver software can create convincing structure, so raw samples and independent checks remain essential.

Model 7A defines the paired symbols, nonnegative weights, positive reference energy and permitted corrections before calculating EVM. Complex-gain fitting minimizes training residual energy; a changed denominator can still increase fitted-reference EVM. Held-out evaluation, residual vectors and declared normalization expose limitations hidden by a tight constellation or one scalar percentage.

Model 7B separates slots, coded bits, information bits and payload instances over a common positive duration. Overhead must be counted once. Bursts require an explicit time boundary, changing modes require count-based aggregation, complete frames require integer rounding, and unique throughput requires payload identities. Deterministic timing bounds and discrete format alternatives retain their stated limits.

A reproducible result preserves samples, reference construction, synchronization, filtering, fitted parameters, selected populations and intermediate sums or counts. Known-input challenges and negative controls test different failure mechanisms. Decoded consistency, acquisition coverage, physical attribution and authority remain separate questions; favorable quality or rate arithmetic cannot answer them without the relevant evidence.

Chapter 7 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C07-MCQ-001. A constellation becomes tight after carrier recovery and adaptive equalization. What has that display directly characterized?

A. The selected symbols after the declared synchronization and compensation operations.

B. The transmitter output independently of the propagation and receiving paths.

C. The correctness of every original information bit without a mapping check.

D. The unprocessed received waveform before any reference reconstruction.

Answer: A. The displayed points are products of receiver processing. Their interpretation requires the reference, timing, mapping, filtering and permitted corrections; visual concentration alone does not identify the physical path or validate labels. Review: Constellations and Symbol Representation; Define the symbol experiment before fitting the constellation. Source: §7.4 Define the symbol experiment before fitting the constellation (p. 3742)

Why the selected alternative fits: The selected symbols after the declared synchronization and compensation operations.

Distinguishing consideration: compare this with option B, “The transmitter output independently of the propagation and receiving paths”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Define the symbol experiment before fitting the constellation; Chapter 7 — Constellations and Symbol Representation.

Review: Chapter 7 — Define the symbol experiment before fitting the constellation; Chapter 7 — Constellations and Symbol Representation.

V011-C07-MCQ-002. Which pair most directly identifies the included population and normalization denominator of a finite-record EVM result?

A. The modulation name alone, provided both receivers report lock.

B. The occupied-band labels alone, provided both results are expressed as percentages.

C. The equalizer tap count and carrier-loop bandwidth alone.

D. The selected symbol population and the normalization reference used for each result.

Answer: D. EVM is a normalized residual on a defined population. Equal units or modulation labels do not establish equal denominators, processing permissions or included symbols. Review: Model 7A; Equations 13B and 13J. Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)

Why the selected alternative fits: The selected symbol population and the normalization reference used for each result.

Distinguishing consideration: compare this with option A, “The modulation name alone, provided both receivers report lock”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

V011-C07-MCQ-003. The observed and reference complex symbols are expressed in incompatible amplitude units. Which step is required before applying Equation 13B?

A. Use a percent sign to make the subtraction dimensionally meaningful.

B. Establish a justified common amplitude convention and preserve the conversion.

C. Increase the number of symbols until the unit mismatch averages away.

D. Take magnitudes first so that amplitude units disappear automatically.

Answer: B. The residual subtracts complex values, so their units and reference relation must agree before squaring or normalizing. Normalization cannot repair a physically undefined subtraction. Review: Model 7A symbol and unit definitions; Equation 13B. Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)

Why the selected alternative fits: Establish a justified common amplitude convention and preserve the conversion.

Distinguishing consideration: compare this with option A, “Use a percent sign to make the subtraction dimensionally meaningful”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

V011-C07-MCQ-004. What conditions on weights and reference energy define the chapter's admissible weighted EVM experiment?

A. Fixed nonnegative weights and strictly positive selected reference energy.

B. Arbitrary signed weights, provided their algebraic sum is nonzero.

C. A nonempty index set alone, even when every selected weight is zero.

D. Positive weight sum alone, even if all selected reference symbols are zero.

Answer: A. Nonnegative weights give squared-residual and reference-energy sums their stated meaning. A positive sum of weights does not guarantee positive reference energy if the corresponding references vanish. Review: Equations 13A and 13B. Source: Equation 13A. Finite reference energy and admissible weights (p. 3746)

Why the selected alternative fits: Fixed nonnegative weights and strictly positive selected reference energy.

Distinguishing consideration: compare this with option B, "Arbitrary signed weights, provided their algebraic sum is nonzero"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13A. Finite reference energy and admissible weights; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13A. Finite reference energy and admissible weights; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

V011-C07-MCQ-005. A finite record has squared-residual sum 2.4 and squared-reference sum 960 in compatible units. What is its RMS EVM?

A. 0.5 percent.

B. 0.25 percent.

C. 5.0 percent.

D. 25 percent.

Answer: C. The energy ratio is $\frac{2.4}{960}=0.0025$. Its square root is 0.05, and conversion to percent gives 5.0. Reporting the unsquared-root ratio would confuse an energy ratio with amplitude-like EVM. Review: Equation 13B; Hypothetical Applied Calculation. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: 5.0 percent.

Distinguishing consideration: compare this with option A, “0.5 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Hypothetical Applied Calculation: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Hypothetical Applied Calculation: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

V011-C07-MCQ-006. Using the chapter's EVM convention, what decibel value corresponds to a linear EVM of 0.05?

A. Approximately $-26.0206\ \mathrm{dB}$.

B. Approximately $-46.0206\ \mathrm{dB}$.

C. Approximately $+26.0206\ \mathrm{dB}$.

D. Approximately $-13.0103\ \mathrm{dB}$.

Answer: A. Apply $20\log_{10}$ to the linear amplitude-like ratio 0.05. Equivalently, apply $10\log_{10}$ to its squared value 0.0025. The percent numeral 5 must first be divided by 100. Review: Equation 13C. Source: Equation 13C. Percent and decibel reporting (p. 3746)

Why the selected alternative fits: Approximately.

Distinguishing consideration: compare this with option B, "Approximately"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13C. Percent and decibel reporting.

Review: Chapter 7 — Equation 13C. Percent and decibel reporting.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-007. A report gives 12.5 percent EVM. Which linear ratio belongs in Equation 13C?

A. 0.0125.

B. 1.25.

C. 0.125.

D. 12.5.

Answer: C. A percentage is one hundred times the linear EVM. Converting 12.5 percent to 0.125 avoids a 40 dB error from taking the logarithm of the percentage numeral as if it were the ratio. Review: Equation 13C. Source: Equation 13C. Percent and decibel reporting (p. 3746)

Why the selected alternative fits: 0.125.

Distinguishing consideration: compare this with option A, “0.0125”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13C. Percent and decibel reporting.

Review: Chapter 7 — Equation 13C. Percent and decibel reporting.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-008. What should a mathematically exact zero residual be assigned under the chapter's decibel convention?

A. A universal $-120\ \mathrm{dB}$ value independent of the instrument display floor.

B. Zero linear EVM and a decibel limit of negative infinity; no finite logarithm exists at zero.

C. Zero linear EVM and exactly 0 dB because no error is present.

D. Unit linear EVM and negative infinity decibels.

Answer: B. The logarithm is defined only for a positive EVM. A finite instrument floor or clipping rule may be reported separately, but it is not the mathematical logarithm of zero. Review: Equation 13C. Source: Equation 13C. Percent and decibel reporting (p. 3746)

Why the selected alternative fits: Zero linear EVM and a decibel limit of negative infinity; no finite logarithm exists at zero.

Distinguishing consideration: compare this with option A, "A universal value independent of the instrument display floor"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13C. Percent and decibel reporting.

Review: Chapter 7 — Equation 13C. Percent and decibel reporting.

V011-C07-MCQ-009. Every selected reference symbol is zero, and the selected observations are also zero. What does Equation 13B return?

A. A finite value determined only by how many zero samples were selected.

B. A valid zero EVM because numerator and denominator cancel.

C. A valid 100 percent EVM because the reference carries no signal.

D. An undefined normalized EVM because its denominator is zero.

Answer: D. The formula requires strictly positive reference energy. A zero residual does not make the indeterminate ratio zero divided by zero a valid normalized metric. Review: Equations 13A and 13B. Source: Equation 13A. Finite reference energy and admissible weights (p. 3746)

Why the selected alternative fits: An undefined normalized EVM because its denominator is zero.

Distinguishing consideration: compare this with option A, “A finite value determined only by how many zero samples were selected”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13A. Finite reference energy and admissible weights; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

V011-C07-MCQ-010. All nonnegative weights in a valid EVM record are multiplied by the same positive constant. What happens to EVM?

A. It decreases by the square root of that constant because averaging improves.

B. It becomes undefined unless the new weights sum to one.

C. It is unchanged because numerator and denominator scale by the same factor.

D. It increases by that constant because weighted energy is larger.

Answer: C. The positive common factor cancels in the energy ratio. The chapter does not require weights to sum to one, although changing relative weights changes the metric. Review: Equations 13B and 13J. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: It is unchanged because numerator and denominator scale by the same factor.

Distinguishing consideration: compare this with option A, “It decreases by the square root of that constant because averaging improves”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-011. A symbol has a nonzero residual but is assigned zero weight in the declared EVM calculation. Which statement is correct?

A. It proves that the corresponding physical interval was error-free.

B. It contributes only to the denominator because the reference is known.

C. It contributes to neither weighted sum, and its exclusion remains part of the reported population definition.

D. It still contributes to the numerator because every measured error must be counted.

Answer: C. A zero weight excludes that symbol from the weighted metric. It does not erase the original observation or establish performance in the excluded interval.
Review: Equation 13J; Application 7A.6. Source: Equation 13J. Residual sums for a disclosed selection (p. 3750)
Why the selected alternative fits: It contributes to neither weighted sum, and its exclusion remains part of the reported population definition.
Distinguishing consideration: compare this with option A, “It proves that the corresponding physical interval was error-free”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Equation 13J. Residual sums for a disclosed selection; Chapter 7 — Application 7A.6: Make selection and weighting visible.

V011-C07-MCQ-012. Why does using negative weights invalidate the chapter's squared-distance interpretation?

A. Negative weights necessarily change a complex symbol into its conjugate.

B. Negative terms can cancel positive squared residuals and destroy the nonnegative energy interpretation.

C. A negative weight is equivalent to a permitted timing correction.

D. Weights must be integers because symbols have discrete labels.

Answer: B. The derivation treats weights as fixed nonnegative dimensionless coefficients. Signed cancellation would define a different expression and can remove the positivity needed for the stated metric. Review: Equations 13A and 13B.

Source: Equation 13A. Finite reference energy and admissible weights (p. 3746)

Why the selected alternative fits: Negative terms can cancel positive squared residuals and destroy the nonnegative energy interpretation.

Distinguishing consideration: compare this with option A, "Negative weights necessarily change a complex symbol into its conjugate"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13A. Finite reference energy and admissible weights; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13A. Finite reference energy and admissible weights; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-013. A valid finite record is repeated exactly, with the same weights on every repeated copy. What happens to its EVM?

A. The EVM rises with total symbol count because the residual energy increases.

B. The EVM is unchanged; exact repetition does not by itself create new independent evidence.

C. The EVM becomes a confidence interval rather than a deterministic ratio.

D. The EVM falls as the inverse square root of the number of copies.

Answer: B. Both sums increase in the same proportion. Repeated storage of the same data is distinct from collecting independent observations under a probability model. Review: Equations 13B and 13J; Turn a quality metric into a reproducible acceptance record. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: The EVM is unchanged; exact repetition does not by itself create new independent evidence.

Distinguishing consideration: compare this with option A, “The EVM rises with total symbol count because the residual energy increases”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection; Chapter 7 — Turn a quality metric into a reproducible acceptance….

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-014. For two symbols with reference magnitudes 1 and 2, residual magnitudes 0.2 and 0.1, and weights 1 and 3, what energy ratio is used before the square root?

A. $\frac{0.13}{5}$.

B. $\frac{0.05}{5}$.

C. $\frac{0.07}{4}$.

D. $\frac{0.07}{13}$.

Answer: D. The weighted residual energy is 1(0.2 squared) + 3(0.1 squared) = 0.07. The weighted reference energy is 1(1 squared) + 3(2 squared) = 13. A weight sum is not the reference-energy denominator. Review: Equations 13B and 13J. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: option D contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

V011-C07-MCQ-015. A record has linear EVM 0.1. If the same residual energy is normalized by four times the original reference energy, what is the new EVM?

A. 0.4.

B. 0.05.

C. 0.2.

D. 0.025.

Answer: B. Multiplying the denominator energy by four divides the squared EVM by four, so EVM itself is halved. This is a normalization change, not evidence that the measured residual improved. Review: Equations 13B and 13G. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: 0.05.

Distinguishing consideration: compare this with option A, “0.4”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

V011-C07-MCQ-016. Which objective does the optional constant complex-gain estimate minimize?

A. Weighted squared residual energy on the declared training set.

B. Every possible EVM normalization on every future record.

C. The bit error probability without a symbol decision or channel model.

D. The physical transmitter error before propagation.

Answer: A. The least-squares fit minimizes one explicitly stated finite training objective. Its optimality does not extend automatically to differently normalized metrics, held-out data or an error-rate law. Review: Equations 13D and 13E. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: Weighted squared residual energy on the declared training set.

Distinguishing consideration: compare this with option B, “Every possible EVM normalization on every future record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-017. Which correlation appears in the numerator of the chapter's complex-gain estimate?

A. The weighted sum of each observation times the conjugate of its ideal reference.

B. The product of the unweighted mean observation and mean reference.

C. The weighted sum of observation magnitudes divided by reference magnitudes.

D. The weighted sum of each observation times the unconjugated reference.

Answer: A. Complex least squares uses the conjugated reference in the inner product. Omitting conjugation generally changes the estimated phase and no longer minimizes the stated objective. Review: Equations 13D and 13E. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: The weighted sum of each observation times the conjugate of its ideal reference.

Distinguishing consideration: compare this with option B, "The product of the unweighted mean observation and mean reference"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square.

V011-C07-MCQ-018. With positive weighted training reference energy, what establishes uniqueness of the constant complex-gain minimizer?

A. The objective is a constant plus positive reference energy times the squared distance from the fitted coefficient.

B. The fitted coefficient must be constrained to have unit magnitude.

C. The training references must have zero mean and zero sum of squares simultaneously.

D. The observed symbols must all have the same magnitude.

Answer: A. Completion of the square gives a strictly positive coefficient multiplying the distance term. Balanced references and unit-magnitude restrictions are not required for this unconstrained complex-gain fit. Review: Equation 13E. Source: Equation 13E. Least-squares completion of the square (p. 3747)

Why the selected alternative fits: The objective is a constant plus positive reference energy times the squared distance from the fitted coefficient.

Distinguishing consideration: compare this with option B, “The fitted coefficient must be constrained to have unit magnitude”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13E. Least-squares completion of the square.

Review: Chapter 7 — Equation 13E. Least-squares completion of the square.

V011-C07-MCQ-019. A positive-energy reference is fitted to observations that are all zero. Which pair of results follows?

A. The fitted gain is undefined because observation energy is zero.

B. The fitted gain is zero, while EVM normalized by that fitted reference is undefined.

C. The fitted gain is zero, and fitted-reference EVM is automatically zero.

D. The fitted gain is one, and fitted-reference EVM is zero.

Answer: B. The gain estimate has a valid reference-energy denominator and zero correlation numerator. However, scaling the evaluation reference by that zero gain makes its energy zero, violating the fitted-reference EVM domain. Review: Equations 13D and 13F. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: The fitted gain is zero, while EVM normalized by that fitted reference is undefined.

Distinguishing consideration: compare this with option A, “The fitted gain is undefined because observation energy is zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-020. Every selected observation is zero, and the unscaled ideal reference has positive weighted energy. What is fixed-reference EVM?

A. Undefined solely because the observations are zero.

B. 100 percent.

C. 50 percent.

D. 0 percent.

Answer: B. The residual is the negative reference, so residual energy equals reference energy. This valid fixed-reference value differs from the undefined zero-gain fitted-reference normalization. Review: Equations 13B and 13F. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: 100 percent.

Distinguishing consideration: compare this with option A, “Undefined solely because the observations are zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

V011-C07-MCQ-021. The weighted training correlation is $6+j8$ and weighted training reference energy is 10. What fitted gain follows?

A. $1+j0$.

B. $0.6+j0.8$.

C. $6+j8$.

D. $0.6-j0.8$.

Answer: B. Divide the complex correlation by the real positive reference energy. Its magnitude happens to be one, but the phase remains part of the fitted coefficient and cannot be discarded. Review: Equation 13D. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: option B contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

V011-C07-MCQ-022. An implementation mistakenly conjugates the observation instead of the reference in that fit. What is the consequence in general?

A. It changes only the number of selected symbols.

B. It conjugates the correlation and therefore generally reverses the estimated phase.

C. It always leaves the complex coefficient unchanged.

D. It guarantees a lower residual than the stated least-squares solution.

Answer: B. With real nonnegative weights, conjugating the opposite product conjugates the intended numerator. A purely real special case may hide the mistake, so a complex-phase reference is a useful check. Review: Equations 13D and 13E. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: It conjugates the correlation and therefore generally reverses the estimated phase.

Distinguishing consideration: compare this with option A, “It changes only the number of selected symbols”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square.

V011-C07-MCQ-023. Why should a phase-bearing known case accompany a purely real gain test of the fitting implementation?

A. A phase-bearing case removes the need to disclose symbol labels.

B. A real case can conceal a conjugation or phase-sign error that a complex coefficient exposes.

C. Only phase-bearing references permit any held-out evaluation.

D. A real case has zero reference energy by definition.

Answer: B. Different controlled cases exercise different algebraic features. A real fitted coefficient equals its conjugate, so it cannot alone detect the sign error in the complex correlation. Review: Equation 13D; Turn a quality metric into a reproducible acceptance record. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: A real case can conceal a conjugation or phase-sign error that a complex coefficient exposes.

Distinguishing consideration: compare this with option A, “A phase-bearing case removes the need to disclose symbol labels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-MCQ-024. A gain fit reduces residual energy, yet the reported fitted-reference EVM rises. Which explanation is possible?

A. The least-squares fit must necessarily have failed its own minimization objective.

B. Every EVM calculation must use the original reference denominator regardless of its declared convention.

C. The fitted-reference energy decreased enough to outweigh the numerator reduction.

D. The squared-residual sum must have become negative.

Answer: C. Least squares minimizes its numerator objective, not every ratio obtained with a parameter-dependent denominator. The report must retain both sums and the fitted gain to explain the change. Review: Equations 13E and 13F; Application 7A.8. Source: Equation 13E. Least-squares completion of the square (p. 3747)
Why the selected alternative fits: The fitted-reference energy decreased enough to outweigh the numerator reduction.
Distinguishing consideration: compare this with option A, “The least-squares fit must necessarily have failed its own minimization objective”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.8: Keep a residual frequency rotation….
Review: Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

V011-C07-MCQ-025. Which condition makes the evaluation in Equation 13F held out?

A. Its symbol indices are excluded from the training set used to estimate the applied gain.

B. Its samples are plotted in a separate window after the same indices were used for training.

C. Its EVM is smaller than the training EVM.

D. Its references have the same values as the training references, regardless of index overlap.

Answer: A. Held-out status concerns exclusion from parameter fitting, not display location or a favorable result. Reusing symbol values can be legitimate; reusing the evaluated observations for the same fit changes the claimed validation. Review: Equation 13F. Source: Equation 13F. Held-out evaluation with a nonzero fitted reference (p. 3748)

Why the selected alternative fits: Its symbol indices are excluded from the training set used to estimate the applied gain.

Distinguishing consideration: compare this with option B, “Its samples are plotted in a separate window after the same indices were used for training”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Review: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

V011-C07-MCQ-026. What additional nondegeneracy condition does fitted-reference EVM require beyond positive held-out ideal-reference energy?

A. The fitted complex gain must be nonzero.

B. The fitted gain must be exactly one.

C. The held-out reference mean must be zero.

D. Every observed symbol must have nonzero magnitude.

Answer: A. The fitted-reference denominator contains the squared gain magnitude. A zero gain makes that normalization undefined even when the unscaled held-out references have positive energy. Review: Equation 13F. Source: Equation 13F. Held-out evaluation with a nonzero fitted reference (p. 3748)

Why the selected alternative fits: The fitted complex gain must be nonzero.

Distinguishing consideration: compare this with option B, “The fitted gain must be exactly one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Review: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

V011-C07-MCQ-027. A single nonzero complex reference is fitted to one arbitrary complex observation using one unconstrained complex gain. What does a zero training residual demonstrate?

A. An independently established zero EVM for all future records.

B. A validated model of the complete propagation channel.

C. A proof that no noise or synchronization error affected the observation.

D. Exact interpolation of that one pair, with no residual freedom to test transfer to other symbols.

Answer: D. One complex coefficient can absorb the entire discrepancy in one nonzero reference pair. Held-out observations are needed to test whether that fitted relation transfers. Review: Application 7A.7. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

Why the selected alternative fits: Exact interpolation of that one pair, with no residual freedom to test transfer to other symbols.

Distinguishing consideration: compare this with option A, “An independently established zero EVM for all future records”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.7: Evaluate a fitted gain on held-out symbols.

Review: Chapter 7 — Application 7A.7: Evaluate a fitted gain on held-out symbols.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-028. Training uses reference 1 and observation $1.2+j0.1$. What gain is then applied to held-out references?

A. The real magnitude square root of 1.45 only.

B. $1+j0$ because the reference is ideal.

C. $1.2-j0.1$.

D. $1.2+j0.1$.

Answer: D. The training correlation equals the observation and the training reference energy is one. Replacing the complex coefficient by its magnitude would discard the fitted phase and define a different correction. Review: Application 7A.7; Equation 13D. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

Why the selected alternative fits: option D contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units. Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 7 — Application 7A.7: Evaluate a fitted gain on held-out symbols; Chapter 7 — Equation 13D. Optional complex-gain fit on a training set. Review: Chapter 7 — Application 7A.7: Evaluate a fitted gain on held-out symbols; Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-029. If the held-out observations in that case exactly equal their unscaled ideal references, what does their zero fixed-reference EVM imply?

A. The fixed and fitted denominators are necessarily identical.

B. Any nonzero fitted-reference EVM is impossible for those observations.

C. The fitted training coefficient must necessarily have been one.

D. They agree with the fixed reference, even though applying the noisy training fit can produce nonzero fitted-reference EVM.

Answer: D. The two metrics ask different questions. The noisy one-pair training fit can introduce disagreement relative to an otherwise exact held-out record. Review: Application 7A.7. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

Why the selected alternative fits: They agree with the fixed reference, even though applying the noisy training fit can produce nonzero fitted-reference EVM.

Distinguishing consideration: compare this with option A, “The fixed and fitted denominators are necessarily identical”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.7: Evaluate a fitted gain on held-out symbols.

Review: Chapter 7 — Application 7A.7: Evaluate a fitted gain on held-out symbols.

V011-C07-MCQ-030. Four balanced unit-energy references are all multiplied by 1.08. What is fixed-reference EVM?

A. Approximately 7.4074 percent.

B. 0.64 percent.

C. 108 percent.

D. 8 percent.

Answer: D. Each residual is 0.08 times its reference, so the normalized RMS error is 0.08. Dividing by 1.08 would instead introduce a different reference normalization.
Review: Equation 13H; Application 7A.1. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)
Why the selected alternative fits: 8 percent.
Distinguishing consideration: compare this with option A, “Approximately 7.4074 percent”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.1: Show which error a fitted gain removes.
Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.1: Show which error a fitted gain removes.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-031. A permitted complex-gain fit is applied to that exact 1.08-scaled record. Which result must accompany a zero residual?

A. A statement that the original absolute amplitude calibration was exact.

B. A replacement of the uncorrected record by the fitted reference alone.

C. A claim that all possible channel impairments have been independently excluded.

D. The fitted gain 1.08, because the fit has removed the amplitude discrepancy being assessed.

Answer: D. The zero residual is conditional on the permitted alignment. If absolute amplitude agreement matters, the fitted coefficient is evidence rather than a nuisance value to discard. Review: Application 7A.1. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

Why the selected alternative fits: The fitted gain 1.08, because the fit has removed the amplitude discrepancy being assessed.

Distinguishing consideration: compare this with option A, “A statement that the original absolute amplitude calibration was exact”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.1: Show which error a fitted gain removes.

Review: Chapter 7 — Application 7A.1: Show which error a fitted gain removes.

V011-C07-MCQ-032. For a fixed real gain of 0.92 with no permitted amplitude fit, what EVM follows?

A. 92 percent.

B. 8 percent.

C. Approximately 8.6957 percent.

D. 0.64 percent.

Answer: B. The chapter's fixed-reference relation is the absolute departure of gain from one. Positive and negative departures of equal magnitude give the same EVM in this bounded model. Review: Equation 13H. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)

Why the selected alternative fits: 8 percent.

Distinguishing consideration: compare this with option A, "92 percent"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-033. Why does a measured 8 percent EVM alone not identify whether a constant real gain is 0.92 or 1.08?

A. Both gains necessarily produce identical observed complex symbols.

B. The metric retains the magnitude of the gain departure, not its sign.

C. The two gains have equal power gain in linear units.

D. EVM always discards both reference and residual energy.

Answer: B. Different impairments can share one aggregate EVM. The original vectors or a separately retained gain estimate distinguish these two amplitude cases. Review: Equation 13H; Application 7A.1. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)

Why the selected alternative fits: The metric retains the magnitude of the gain departure, not its sign.

Distinguishing consideration: compare this with option A, “Both gains necessarily produce identical observed complex symbols”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.1: Show which error a fitted gain removes.

V011-C07-MCQ-034. A unit reference is rotated by a fixed 6 degrees without a fitted phase correction. Which expression gives the exact EVM?

A. Twice the absolute sine of 3 degrees.

B. Six as a dimensionless linear ratio.

C. Twice the cosine of 3 degrees.

D. The sine of 6 degrees without the factor of two.

Answer: A. The complex residual is the chord between two unit phasors separated by the rotation. The exact chord length is twice the absolute sine of half the angle.
Review: Equation 13H; Application 7A.2. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)
Why the selected alternative fits: Twice the absolute sine of 3 degrees.
Distinguishing consideration: compare this with option B, “Six as a dimensionless linear ratio”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.2: Quantify a fixed phase error.
Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.2: Quantify a fixed phase error.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-035. What is the approximate percentage EVM for that 6-degree rotation?

A. 104.67191 percent.

B. 5.233596 percent.

C. 10.467191 percent.

D. 6 percent.

Answer: C. Evaluate 2 sin(3 degrees) = 0.10467191 and multiply by 100. Degrees must not be substituted directly as a dimensionless small-angle value. Review: Application 7A.2. Source: §7.8 Application 7A.2: Quantify a fixed phase error (p. 3753)

Why the selected alternative fits: 10.467191 percent.

Distinguishing consideration: compare this with option A, “104.67191 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.2: Quantify a fixed phase error.

Review: Chapter 7 — Application 7A.2: Quantify a fixed phase error.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-036. When a small-angle approximation replaces the exact phase-error chord by the absolute phase error, which angular unit is required?

A. Any angular unit because EVM is dimensionless.

B. Degrees.

C. Cycles without conversion.

D. Radians.

Answer: D. The local approximation to sine uses a radian argument. Dimensionless output does not remove the conversion between degrees, cycles and radians.
Review: Equation 13H and the discussion in Application 7A.2. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)
Why the selected alternative fits: Radians.
Distinguishing consideration: compare this with option A, “Any angular unit because EVM is dimensionless”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.2: Quantify a fixed phase error.

V011-C07-MCQ-037. A balanced QPSK record is multiplied by j. What are its fixed-reference EVM and gain-fitted residual?

A. Approximately 141.421356 percent and zero, respectively.

B. Approximately 70.710678 percent and zero, respectively.

C. Zero and zero because the constellation point set is unchanged.

D. Exactly 100 percent and exactly 100 percent, respectively.

Answer: A. A quarter-turn changes each label-associated reference by a chord of square root two. A complex gain j aligns the points exactly, but that fit does not independently validate their original label association. Review: Application 7A.9.

Source: §7.15 Application 7A.9: Separate constellation rotation from validated symbol mapping (p. 3760)

Why the selected alternative fits: Approximately 141.421356 percent and zero, respectively.

Distinguishing consideration: compare this with option B, “Approximately 70.710678 percent and zero, respectively”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.9: Separate constellation rotation from validated symbol mapping.

Review: Chapter 7 — Application 7A.9: Separate constellation rotation from validated symbol mapping.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-038. Why does the gain-fitted zero residual in the quarter-turn QPSK example not establish zero bit error rate?

A. The fitted rotation can conceal a label ambiguity, while BER requires a validated mapping and decision comparison.

B. A fitted gain cannot be complex in a QPSK calculation.

C. A quarter-turn necessarily changes the symbol rate.

D. EVM is defined only for uncoded amplitude modulation.

Answer: A. Geometric alignment and correctness of recovered information are distinct. Known pilots, framing or another justified reference can resolve mapping, but the aggregate fitted EVM alone does not. Review: Application 7A.9; Defensive Interpretation of Digital Signals. Source: §7.15 Application 7A.9: Separate constellation rotation from validated symbol mapping (p. 3760)

Why the selected alternative fits: The fitted rotation can conceal a label ambiguity, while BER requires a validated mapping and decision comparison.

Distinguishing consideration: compare this with option B, “A fitted gain cannot be complex in a QPSK calculation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.9: Separate constellation rotation from validated symbol mapping; Chapter 7 — Defensive Interpretation of Digital Signals.

Review: Chapter 7 — Application 7A.9: Separate constellation rotation from validated symbol mapping; Chapter 7 — Defensive Interpretation of Digital Signals.

V011-C07-MCQ-039. The balanced unit references 1, j, -1 and $-j$ receive a common offset $0.04 + j\,0.03$. What fixed-reference EVM follows?

A. 0.25 percent.

B. 7 percent.

C. 1 percent.

D. 5 percent.

Answer: D. The offset magnitude is square root of 0.04 squared plus 0.03 squared, or 0.05. Every unit reference has the same residual magnitude, so RMS EVM is 5 percent. Review: Equation 13I; Application 7A.3. Source: Equation 13I. Balanced-reference offset and conjugate terms (p. 3749)

Why the selected alternative fits: 5 percent.

Distinguishing consideration: compare this with option A, “0.25 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

Review: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-040. Why does the gain-only fit remain one for that common-offset example?

A. A complex gain fit always removes any constant offset.

B. The weighted reference sum is zero, so the offset contributes zero to the gain-estimating correlation.

C. The offset has zero magnitude because its real and imaginary parts differ.

D. The reference sum of squared magnitudes is zero.

Answer: B. The offset contribution is the offset times the conjugate weighted reference sum. Balanced references remove that correlation term without removing the offset residual itself. Review: Equation 13I; Application 7A.3. Source: Equation 13I. Balanced-reference offset and conjugate terms (p. 3749)

Why the selected alternative fits: The weighted reference sum is zero, so the offset contributes zero to the gain-estimating correlation.

Distinguishing consideration: compare this with option A, “A complex gain fit always removes any constant offset”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

Review: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

V011-C07-MCQ-041. What changes if the analyst subtracts the fitted mean to remove that offset?

A. The operation proves that the removed term originated inside the receiver.

B. The original fixed-reference experiment is unchanged because means are never part of a waveform.

C. The operation is equivalent to a phase-only alignment for every constellation.

D. The analyst has added another permitted correction and must disclose its reason, training interval and uncorrected result.

Answer: D. Mean subtraction can eliminate the constructed offset, but it changes the comparison model and can remove a legitimate nonzero-mean signal component. Physical origin needs separate evidence. Review: Application 7A.3.

Source: §7.9 Application 7A.3: Preserve a DC impairment when fitting only complex gain (p. 3754)

Why the selected alternative fits: The analyst has added another permitted correction and must disclose its reason, training interval and uncorrected result.

Distinguishing consideration: compare this with option A, “The operation proves that the removed term originated inside the receiver”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

Review: Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

V011-C07-MCQ-042. For the same balanced unit references, observations are ideal symbols plus 0.06 times their conjugates. What EVM follows with a fixed reference?

A. 0.36 percent.

B. 6 percent.

C. 3 percent.

D. 12 percent.

Answer: B. Conjugation preserves each reference magnitude. Thus the residual energy is 0.06 squared times reference energy, giving a linear EVM of 0.06. Review: Equation 13I; Application 7A.4. Source: Equation 13I. Balanced-reference offset and conjugate terms (p. 3749)

Why the selected alternative fits: 6 percent.

Distinguishing consideration: compare this with option A, “0.36 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.4: Expose a conjugate-image impairment.

Review: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.4: Expose a conjugate-image impairment.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-043. Which balanced-reference property keeps the ordinary gain fit at one in that conjugate-leakage case?

A. The weighted sum of squared reference magnitudes is zero.

B. Every reference has zero imaginary part.

C. The weighted sum of the squared complex references is zero.

D. The conjugate coefficient is necessarily purely imaginary.

Answer: C. The conjugate residual enters the gain correlation through the conjugate of the weighted reference-square sum. This can vanish while reference energy remains positive. Review: Equation 13I; Application 7A.4. Source: Equation 13I. Balanced-reference offset and conjugate terms (p. 3749)

Why the selected alternative fits: The weighted sum of the squared complex references is zero.

Distinguishing consideration: compare this with option A, “The weighted sum of squared reference magnitudes is zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.4: Expose a conjugate-image impairment.

Review: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.4: Expose a conjugate-image impairment.

V011-C07-MCQ-044. What would estimating both direct and conjugate coefficients change?

A. It would identify the physical source of every observed I/Q error without additional tests.

B. It would make retention of the original complex symbols unnecessary.

C. It would introduce a different correction model whose parameter estimates and held-out performance need validation.

D. It would preserve exactly the same gain-only metric definition without disclosure.

Answer: C. Adding a conjugate branch enlarges the fitted model. Better in-sample residuals under that model do not establish a transferable calibration or a unique mechanism. Review: Application 7A.4. Source: §7.10 Application 7A.4: Expose a conjugate-image impairment (p. 3755)

Why the selected alternative fits: It would introduce a different correction model whose parameter estimates and held-out performance need validation.

Distinguishing consideration: compare this with option A, “It would identify the physical source of every observed I/ error without additional tests”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.4: Expose a conjugate-image impairment.

Review: Chapter 7 — Application 7A.4: Expose a conjugate-image impairment.

V011-C07-MCQ-045. All sixteen square-16QAM points with each coordinate in -3, -1, 1 and 3 occur once. What are their average and maximum symbol energies?

A. 5 and 9.

B. 10 and 18.

C. 8 and 16.

D. 18 and 10.

Answer: B. Each coordinate has average square 5, giving total average energy 10. The outer corners have energy 3 squared plus 3 squared, or 18. Review: Application 7A.5. Source: §7.11 Application 7A.5: Compare RMS and constellation-maximum normalization (p. 3756)

Why the selected alternative fits: 10 and 18.

Distinguishing consideration: compare this with option A, “5 and 9”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Review: Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-046. A fixed residual $0.2+j0.1$ is added to that complete 16QAM population. What residual energy does each symbol contribute before weighting?

A. 0.05.

B. 0.01.

C. 0.3.

D. 0.5.

Answer: A. Squared complex magnitude is the sum of squared real and imaginary components: $0.04+0.01=0.05$. Adding the components directly does not give energy. Review: Application 7A.5. Source: §7.11 Application 7A.5: Compare RMS and constellation-maximum normalization (p. 3756)

Why the selected alternative fits: 0.05.

Distinguishing consideration: compare this with option B, “0.01”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Review: Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-047. For the same complete 16QAM population and residual, what are RMS-reference and constellation-maximum EVM?

A. Exactly 0.5 percent and approximately 0.277778 percent.

B. Approximately 5.270463 percent and 7.071068 percent.

C. Approximately 7.071068 percent and 5.270463 percent.

D. Exactly 5 percent and 18 percent.

Answer: C. Take square roots of $\frac{0.05}{10}$ and $\frac{0.05}{18}$, respectively, then convert to percent. The different denominators explain the different numbers without any residual change. Review: Equation 13G; Application 7A.5. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why the selected alternative fits: Approximately 7.071068 percent and 5.270463 percent.

Distinguishing consideration: compare this with option A, “Exactly 0.5 percent and approximately 0.277778 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-048. For fixed residual RMS, which normalization gives the smaller EVM in that complete 16QAM example?

A. The normalization choices differ only in phase, so their magnitudes cancel.

B. Constellation maximum, because its reference amplitude exceeds the realized RMS reference amplitude.

C. Reference RMS, because averaging always lowers every normalized error.

D. Both must be equal because the constellation has sixteen points.

Answer: B. The denominator is square root 18 for the maximum convention and square root 10 for the average convention. This is a normalization comparison under the stated population, not a statement about measurement quality. Review: Equation 13G; Application 7A.5. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why the selected alternative fits: Constellation maximum, because its reference amplitude exceeds the realized RMS reference amplitude.

Distinguishing consideration: compare this with option A, “The normalization choices differ only in phase, so their magnitudes cancel”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

V011-C07-MCQ-049. A short 16QAM sequence contains inner points more often than the full uniform constellation. What should be checked before using the average energy 10?

A. Only whether a gain fit was estimated on the selected observations.

B. Only whether the EVM is expressed in decibels.

C. Only whether the outermost ideal coordinate is still 3.

D. Whether the selected reference population actually has that average energy.

Answer: D. The realized reference RMS depends on the selected sequence and weights. The full-constellation average of 10 is not a universal value for a biased finite population. Review: Equation 13G and its normalization discussion. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why the selected alternative fits: Whether the selected reference population actually has that average energy.

Distinguishing consideration: compare this with option A, “Only whether a gain fit was estimated on the selected observations”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-050. A threshold was specified for reference-RMS EVM, but a receiver reports constellation-maximum EVM. What is required before applying the threshold?

A. No conversion, because both values have percent units.

B. An explicit convention conversion using the correct reference population and normalization magnitudes.

C. Replacement of the measured residual by its largest symbol error.

D. A universal 3 dB adjustment for every modulation format and sequence.

Answer: B. A common label does not establish a common denominator. Conversion requires the ratio of the actual normalization amplitudes, which need not be constant across selected populations. Review: Equation 13G; Application 7A.5.

Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why the selected alternative fits: An explicit convention conversion using the correct reference population and normalization magnitudes.

Distinguishing consideration: compare this with option A, “No conversion, because both values have percent units”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

V011-C07-MCQ-051. Four unit-energy references have residual magnitudes 0.30, 0.10, 0.02 and 0.02 with equal weights. What is their RMS EVM?

A. Approximately 25.2 percent.

B. Exactly 30 percent.

C. Approximately 15.874508 percent.

D. Exactly 11 percent.

Answer: C. The residual energies sum to 0.1008 and reference energies to 4. The square root of 0.0252 is 0.15874508. Averaging the four magnitudes or reporting the maximum gives a different statistic. Review: Application 7A.6; Equation 13B.

Source: §7.12 Application 7A.6: Make selection and weighting visible (p. 3757)

Why the selected alternative fits: Approximately 15.874508 percent.

Distinguishing consideration: compare this with option A, “Approximately 25.2 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.6: Make selection and weighting visible; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

V011-C07-MCQ-052. If only the last two symbols of that four-symbol record are retained, what does the resulting 2 percent EVM describe?

A. A guarantee that acquisition was valid because the retained result is small.

B. The entire original four-symbol record after an equivalent re-expression.

C. An unbiased estimate of all transmitted symbols without any selection model.

D. The selected two-symbol population, with the larger acquisition errors explicitly excluded.

Answer: D. Both remaining residual magnitudes are 0.02 on unit references, so their EVM is 2 percent. The computation is valid for that subset, but its favorable value does not represent the excluded symbols. Review: Application 7A.6. Source: §7.12 Application 7A.6: Make selection and weighting visible (p. 3757)

Why the selected alternative fits: The selected two-symbol population, with the larger acquisition errors explicitly excluded.

Distinguishing consideration: compare this with option A, “A guarantee that acquisition was valid because the retained result is small”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.6: Make selection and weighting visible.

Review: Chapter 7 — Application 7A.6: Make selection and weighting visible.

V011-C07-MCQ-055. A receiver reports EVM only after successful lock. What additional information is needed to judge the whole acquisition experiment?

A. A claim that every excluded interval has the same EVM as the accepted population.

B. Only a smaller error threshold applied to the already selected locked intervals.

C. Only the mean EVM of successful intervals, because failures have no symbols to compare.

D. The attempted intervals, lock failures and selection rule, alongside the conditional locked-interval metric.

Answer: D. An EVM conditional on lock can be useful, but acquisition reliability and unobserved or rejected intervals are separate evidence. Omitting failures changes the population that the result can characterize. Review: Carrier and Timing Synchronization; Application 7A.6; reproducible acceptance record. Source: §7.12 Application 7A.6: Make selection and weighting visible (p. 3757)

Why the selected alternative fits: The attempted intervals, lock failures and selection rule, alongside the conditional locked-interval metric.

Distinguishing consideration: compare this with option A, “A claim that every excluded interval has the same EVM as the accepted population”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.6: Make selection and weighting visible; Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Application 7A.6: Make selection and weighting visible; Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-056. Which retained quantities permit exact recombination of compatible EVM blocks with different reference energies?

A. Only the largest error in each block and the modulation name.

B. Each block's residual-energy sum and reference-energy sum under the same declared convention.

C. Only the arithmetic mean of each block's symbol-error magnitudes.

D. Only each block's EVM percentage and its display update number.

Answer: B. The combined ratio is formed from the sum of residual energies divided by the sum of reference energies. Percentages alone lose the denominator weights needed for unequal-energy blocks. Review: Equation 13B; Turn a quality metric into a reproducible acceptance record. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: Each block's residual-energy sum and reference-energy sum under the same declared convention.

Distinguishing consideration: compare this with option A, "Only the largest error in each block and the modulation name"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-MCQ-057. A residual carrier offset is 100 Hz and the symbol rate is 10,000 symbols per second. What phase increment occurs per symbol?

A. 0.01 degrees.

B. 100 degrees.

C. 3.6 degrees.

D. 36 degrees.

Answer: C. The increment is $\frac{100}{10000} = 0.01$ cycles per symbol, equivalent to 3.6 degrees or 0.02π radians. Hertz must first be related to the symbol interval. Review: Application 7A.8. Source: §7.14 Application 7A.8: Keep a residual frequency rotation in a finite symbol record (p. 3759)

Why the selected alternative fits: 3.6 degrees.

Distinguishing consideration: compare this with option A, “0.01 degrees”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

Review: Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-058. Why can one constant complex gain not remove the entire residual of that frequency-offset record?

A. A complex coefficient can correct amplitude but cannot represent any phase.

B. A nonzero carrier offset makes the reference energy necessarily zero.

C. The phase changes with symbol time, while the fitted coefficient supplies only one constant amplitude and phase.

D. The fitting objective excludes complex-valued observations.

Answer: C. A fixed coefficient can approximate a finite phase arc but cannot equal distinct rotations at every retained time. The residual pattern and the declared correction model matter separately from the aggregate fit. Review: Equation 13D; Application 7A.8. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: The phase changes with symbol time, while the fitted coefficient supplies only one constant amplitude and phase.

Distinguishing consideration: compare this with option A, “A complex coefficient can correct amplitude but cannot represent any phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

V011-C07-MCQ-059. Ideal references $(1,1)$ produce observations $(1,-1)$ with equal weights. What happens to their constant-gain fit and fitted-reference EVM?

A. The gain magnitude is one because both observations have unit magnitude.

B. The gain is zero and fitted-reference EVM is zero.

C. The gain is one and fitted-reference EVM is zero.

D. The gain is zero and fitted-reference EVM is undefined.

Answer: D. The complex correlation cancels, although both observation magnitudes are one. The least-squares coefficient is zero, and its fitted reference has zero energy. Magnitude averaging would not implement this complex fit. Review: Equations 13D–13F; phase-cancellation boundary. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why the selected alternative fits: The gain is zero and fitted-reference EVM is undefined.

Distinguishing consideration: compare this with option A, “The gain magnitude is one because both observations have unit magnitude”; that competing statement does not meet the question’s stated requirement.

V011-C07-MCQ-060. For the chapter's symmetric 21-symbol frequency-offset record, why can gain-fitted EVM exceed fixed-reference EVM even though the fitted residual energy decreases?

A. The numerator of the fitted objective becomes larger than for every other constant gain.

B. The same denominator is retained and the only change is a smaller numerator.

C. The fitted gain magnitude is about 0.929174, reducing the fitted-reference denominator enough to raise the ratio.

D. The least-squares fit changes every nonnegative weight into a negative weight.

Answer: C. The chapter obtains approximately 37.636773 percent for the fixed reference and 39.781958 percent for the fitted reference. The fit minimizes squared residual, while the second metric also divides by the fitted gain magnitude. Review: Application 7A.8; Equations 13E and 13F. Source: §7.14 Application 7A.8: Keep a residual frequency rotation in a finite symbol record (p. 3759)

Why the selected alternative fits: The fitted gain magnitude is about 0.929174, reducing the fitted-reference denominator enough to raise the ratio.

Distinguishing consideration: compare this with option A, "The numerator of the fitted objective becomes larger than for every other constant gain"; that competing statement does not meet the question's stated requirement.

V011-C07-MCQ-061. For symmetric time indices and unit references, reversing the sign of that frequency offset can leave aggregate EVM unchanged. What remains necessary to distinguish the cases?

A. The signed phase history or equivalent retained complex record.

B. Only the EVM percentage, because it uniquely determines offset sign.

C. Only the reference-energy sum, because it changes sign with frequency.

D. Only the maximum constellation radius, because it identifies direction of rotation.

Answer: A. Conjugate phase arcs can have identical squared-distance sums. The scalar metric loses directional information that the complex time history retains.
Review: Application 7A.8; finite-record interpretation. Source: §7.14 Application 7A.8: Keep a residual frequency rotation in a finite symbol record (p. 3759)
Why the selected alternative fits: The signed phase history or equivalent retained complex record.
Distinguishing consideration: compare this with option B, “Only the EVM percentage, because it uniquely determines offset sign”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.
Review: Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

V011-C07-MCQ-062. The fitted coefficient for a symmetrically indexed phase arc is real. Does that establish zero residual carrier offset?

A. Yes; any real coefficient proves every symbol has zero phase error.

B. Yes; a carrier offset always produces a purely imaginary fitted coefficient.

C. No; opposite-time imaginary components can cancel in the mean while a phase ramp remains.

D. No, solely because real coefficients are excluded by the least-squares model.

Answer: C. A real aggregate coefficient is compatible with a symmetric nonzero phase evolution. Individual residuals and timing remain necessary to determine what the fit has averaged. Review: Application 7A.8. Source: §7.14 Application 7A.8: Keep a residual frequency rotation in a finite symbol record (p. 3759)

Why the selected alternative fits: No; opposite-time imaginary components can cancel in the mean while a phase ramp remains.

Distinguishing consideration: compare this with option A, “Yes; any real coefficient proves every symbol has zero phase error”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

Review: Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-063. In Application 7A.10, four references each have energy 2 and residual energies total 0.0043. What is RMS EVM?

A. Approximately 3.162278 percent.

B. Approximately 4.636809 percent.

C. Approximately 0.05375 percent.

D. Approximately 2.318405 percent.

Answer: D. The reference-energy sum is 8. Taking the square root of $\frac{0.0043}{8}$ gives 0.02318405. The approximately 3.162278 percent value is the largest individually normalized residual in this constructed record. Review: Application 7A.10. Source: §7.16 Application 7A.10: Audit a complete finite residual vector (p. 3761)

Why the selected alternative fits: Approximately 2.318405 percent.

Distinguishing consideration: compare this with option A, “Approximately 3.162278 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

Review: Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

V011-C07-MCQ-064. The third residual in that application has squared magnitude 0.002. What share of the total residual energy does it contribute?

A. Exactly 50 percent.

B. Exactly 25 percent.

C. Approximately 46.5116 percent.

D. Approximately 4.65116 percent.

Answer: C. Divide 0.002 by the total 0.0043. Equal reference magnitudes do not require equal residual-energy contributions, and the dominant residual can be concealed by one overall RMS statistic. Review: Application 7A.10. Source: §7.16 Application 7A.10: Audit a complete finite residual vector (p. 3761)

Why the selected alternative fits: Approximately 46.5116 percent.

Distinguishing consideration: compare this with option A, “Exactly 50 percent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

Review: Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

V011-C07-MCQ-065. What does exact agreement with the four-symbol arithmetic in Application 7A.10 establish about an implementation?

A. Agreement with that deterministic reference case, without a sampling-distribution or confidence claim.

B. A universal relation from EVM to bit error probability.

C. A 95 percent confidence bound for every later measurement.

D. Statistical independence of the four complex residuals.

Answer: A. A finite constructed case tests the specified arithmetic and conventions. A probability statement requires an additional justified statistical model and appropriate observations. Review: Application 7A.10; reproducible acceptance record. Source: §7.16 Application 7A.10: Audit a complete finite residual vector (p. 3761)

Why the selected alternative fits: Agreement with that deterministic reference case, without a sampling-distribution or confidence claim.

Distinguishing consideration: compare this with option B, “A universal relation from EVM to bit error probability”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.10: Audit a complete finite residual vector; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Application 7A.10: Audit a complete finite residual vector; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-MCQ-066. Both the observed and reference vectors are multiplied by the same unit-magnitude complex rotation. What happens to fixed-reference EVM?

A. It always becomes zero because any common rotation is a perfect correction.

B. It increases by the phase angle expressed in degrees.

C. It changes sign when the rotation exceeds 180 degrees.

D. It is unchanged because each residual magnitude and each reference magnitude are unchanged.

Answer: D. The common factor rotates each difference without changing its length. This invariance is about a coordinated representation change, not a phase correction applied only to observations. Review: Equation 13B; complex-magnitude invariance. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: It is unchanged because each residual magnitude and each reference magnitude are unchanged.

Distinguishing consideration: compare this with option A, “It always becomes zero because any common rotation is a perfect correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-067. Both observed and reference vectors are scaled by the same nonzero complex calibration factor. What can unchanged EVM fail to reveal?

A. The existence of any nonzero residual before the common scaling.

B. The algebraic cancellation of the common factor's squared magnitude.

C. A common absolute amplitude or phase calibration error shared by both vectors.

D. Whether the selected reference energy is positive before and after scaling.

Answer: C. Both energy sums receive the same positive scale factor, so the ratio remains invariant. A relative comparison can agree while both quantities share an incorrect absolute reference. Review: Equation 13B; receiver and reference validation. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: A common absolute amplitude or phase calibration error shared by both vectors.

Distinguishing consideration: compare this with option A, "The existence of any nonzero residual before the common scaling"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-068. Observed symbols, references and weights are permuted together. What remains unchanged, and what may be lost if the original order is discarded?

A. Aggregate EVM remains unchanged, while evidence of temporal drift or acquisition structure may be lost.

B. The symbol labels remain correct regardless of whether observations and references are paired.

C. The reference-energy sum becomes zero, while the residual history is unchanged.

D. Aggregate EVM necessarily doubles, while temporal information is preserved.

Answer: A. Finite sums are invariant to a common permutation of paired records. Time-dependent interpretation still requires the original sequence and timestamps; separately permuting only one vector changes the pairing. Review: Equation 13B; Error Vector Magnitude and Quality Metrics. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why the selected alternative fits: Aggregate EVM remains unchanged, while evidence of temporal drift or acquisition structure may be lost.
Distinguishing consideration: compare this with option B, “The symbol labels remain correct regardless of whether observations and references are paired”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Error Vector Magnitude and Quality Metrics.
Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Error Vector Magnitude and Quality Metrics.

V011-C07-MCQ-069. Training and evaluation use disjoint symbol indices from the same slowly varying channel record. What does disjointness alone establish?

A. Exclusion of evaluation indices from that fit, not statistical independence of the physical observations.

B. Independent channel realizations by definition.

C. A guarantee that the evaluation population represents every future channel state.

D. Zero covariance between all training and evaluation residuals.

Answer: A. Held-out indexing limits a fitting dependency, but temporal correlation and shared impairments can remain. Independence or generalization requires further assumptions and evidence. Review: Equation 13F; synchronization and validation scope. Source: Equation 13F. Held-out evaluation with a nonzero fitted reference (p. 3748)

Why the selected alternative fits: Exclusion of evaluation indices from that fit, not statistical independence of the physical observations.

Distinguishing consideration: compare this with option B, “Independent channel realizations by definition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Review: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

V011-C07-MCQ-070. Two records have equal RMS EVM but different residual histories. Which comparison best tests whether the same impairment mechanism is plausible?

A. Treat equal RMS values as proof of identical physical error sources.

B. Compare only the mean error vector while discarding its second moment and time dependence.

C. Replace each record by an independently shuffled set of residual magnitudes.

D. Compare complex error versus time and symbol state, together with the declared synchronization and corrections.

Answer: D. A scalar norm discards sign, direction, temporal ordering and state dependence. Structured residuals can test proposed mechanisms, although resemblance alone is not unique physical attribution. Review: Error Vector Magnitude and Quality Metrics; Applications 7A.1–7A.10. Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)

Why the selected alternative fits: Compare complex error versus time and symbol state, together with the declared synchronization and corrections.

Distinguishing consideration: compare this with option A, “Treat equal RMS values as proof of identical physical error sources”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Error Vector Magnitude and Quality Metrics; Chapter 7 — Application 7A.1: Show which error a fitted gain removes; Chapter 7 — Application….

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Error Vector Magnitude and Quality Metrics; Chapter 7 — Application 7A.1: Show which error a fitted gain removes; Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

V011-C07-MCQ-071. Two implementations use nominally the same pulse-shaping filter name but disagree near record boundaries. What should be compared first?

A. Actual coefficients, span, delay convention, initialization and the treatment of transient samples.

B. Only the final EVM percentage after discarding different edge intervals.

C. Only whether both implementations represent symbols as complex numbers.

D. Only the nominal roll-off label, because it uniquely determines every finite implementation.

Answer: A. A filter family name does not fix its finite realization or record-edge history. Different initialization and alignment rules can produce different sampled references even when steady-state labels agree. Review: Matched Filtering, Pulse Shaping, and Channel Effects. Source: §7.3 Matched Filtering, Pulse Shaping, and Channel Effects (p. 3741)

Why the selected alternative fits: Actual coefficients, span, delay convention, initialization and the treatment of transient samples.

Distinguishing consideration: compare this with option B, “Only the final EVM percentage after discarding different edge intervals”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Review: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-072. Under the conventional known-pulse, additive-white-noise model with a properly timed decision sample, what does a matched filter optimize?

A. The occupied bandwidth independently of the transmitted pulse.

B. Every receiver metric under arbitrary colored interference and unknown timing.

C. The signal-to-noise ratio at that specified decision sample.

D. Bit error probability without a decision rule or symbol mapping.

Answer: C. The matched-filter statement has a defined signal, noise and sampling model. It does not remove the need to specify timing, interference covariance, subsequent decisions or the quantity being assessed. Review: Matched Filtering, Pulse Shaping, and Channel Effects. Source: §7.3 Matched Filtering, Pulse Shaping, and Channel Effects (p. 3741)

Why the selected alternative fits: The signal-to-noise ratio at that specified decision sample.

Distinguishing consideration: compare this with option A, “The occupied bandwidth independently of the transmitted pulse”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Review: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-073. What tradeoff should be assessed when increasing a synchronization loop's bandwidth?

A. Every larger bandwidth guarantees lower residual error for every record.

B. Bandwidth changes only the displayed axes and cannot alter recovered symbols.

C. Faster tracking of changes may admit more noise or unwanted modulation into the estimate.

D. A wider loop necessarily resolves all symbol-label ambiguities.

Answer: C. Acquisition speed, tracking, jitter and disturbance rejection depend on the loop and signal conditions. A smaller selected EVM does not by itself justify a different permitted correction bandwidth. Review: Carrier and Timing Synchronization. Source: §7.2 Carrier and Timing Synchronization (p. 3737)

Why the selected alternative fits: Faster tracking of changes may admit more noise or unwanted modulation into the estimate.

Distinguishing consideration: compare this with option A, "Every larger bandwidth guarantees lower residual error for every record"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Carrier and Timing Synchronization.

Review: Chapter 7 — Carrier and Timing Synchronization.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-074. Why must filter group delay and symbol timing be handled consistently in reference reconstruction?

A. The residual must compare corresponding decision instants rather than differently delayed waveform locations.

B. Delay can be ignored whenever the reference and observation have equal total energies.

C. A delay correction proves the signal originated at the expected transmitter.

D. Any integer number of stored samples always equals one symbol interval.

Answer: A. Energy equality cannot establish temporal correspondence. Sample rate, symbol rate, filter delays and alignment conventions determine which values belong to the same intended symbol comparison. Review: Matched Filtering, Pulse Shaping, and Channel Effects; Model 7A experiment definition. Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)

Why the selected alternative fits: The residual must compare corresponding decision instants rather than differently delayed waveform locations.

Distinguishing consideration: compare this with option B, “Delay can be ignored whenever the reference and observation have equal total energies”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-075. A processing change excludes acquisition transients and lowers reported EVM. Which conclusion is warranted without additional evidence?

A. The physical receiver has necessarily acquired every signal faster.

B. The newly selected settled-interval metric is lower; whole-record acquisition performance has not thereby improved.

C. The deleted symbols can be treated as error-free because they no longer enter the sum.

D. The previous result was mathematically wrong solely because it included transients.

Answer: B. Both selection rules can produce valid but differently scoped metrics. Report the inclusion policy and failures rather than treating a changed denominator population as a physical improvement. Review: Application 7A.6; Carrier and Timing Synchronization. Source: §7.12 Application 7A.6: Make selection and weighting visible (p. 3757)

Why the selected alternative fits: The newly selected settled-interval metric is lower; whole-record acquisition performance has not thereby improved.

Distinguishing consideration: compare this with option A, “The physical receiver has necessarily acquired every signal faster”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Application 7A.6: Make selection and weighting visible; Chapter 7 — Carrier and Timing Synchronization.

Review: Chapter 7 — Application 7A.6: Make selection and weighting visible; Chapter 7 — Carrier and Timing Synchronization.

V011-C07-MCQ-076. A known signed frequency offset is injected to challenge a demodulator. Which result should be checked beyond a small final EVM?

A. Only whether the equalizer can fit a compact constellation after unlimited adaptation.

B. Only whether an unrelated checksum passes on one output frame.

C. Only whether the constellation centroid is at the origin.

D. The estimated offset sign and magnitude, phase progression and retained correction convention.

Answer: D. A controlled challenge should exercise the intended relationship. A flexible fit can hide a sign convention or reference mistake, so the intermediate estimate and uncorrected behavior belong in the check. Review: Define the symbol experiment before fitting the constellation; reproducible acceptance record. Source: §7.4 Define the symbol experiment before fitting the constellation (p. 3742)

Why the selected alternative fits: The estimated offset sign and magnitude, phase progression and retained correction convention.

Distinguishing consideration: compare this with option A, “Only whether the equalizer can fit a compact constellation after unlimited adaptation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Define the symbol experiment before fitting the constellation; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Define the symbol experiment before fitting the constellation; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-MCQ-077. What is the sound interpretation of pre-equalization and post-equalization EVM measured on the same observations?

A. A post-equalization result is invalid merely because compensation was applied.

B. They characterize different declared processing states and should be retained with the equalizer settings and purpose.

C. Their numerical difference uniquely identifies the transmitter's hardware impairment.

D. The smaller post-equalization value universally replaces the unprocessed result for every measurand.

Answer: B. Compensation can be appropriate for an operational demodulation question and inappropriate for isolating an uncompensated path. Neither result is meaningful without its measurement boundary and allowed corrections. Review: Matched Filtering, Pulse Shaping, and Channel Effects; Defensive Interpretation of Digital Signals. Source: §7.3 Matched Filtering, Pulse Shaping, and Channel Effects (p. 3741)

Why the selected alternative fits: They characterize different declared processing states and should be retained with the equalizer settings and purpose.

Distinguishing consideration: compare this with option A, "A post-equalization result is invalid merely because compensation was applied"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects; Chapter 7 — Defensive Interpretation of Digital Signals.

Review: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects; Chapter 7 — Defensive Interpretation of Digital Signals.

V011-C07-MCQ-078. An adaptive equalizer gains additional parameters and fits one short record extremely well. Which test most directly examines whether that fit transfers?

A. Infer physical channel uniqueness from the number of plotted constellation clusters.

B. Use only the training result and count fitted coefficients as independent observations.

C. Add more parameters until the same training residual is exactly zero.

D. Evaluate a separately reserved record under a declared fitting and validation policy.

Answer: D. Greater flexibility can absorb noise or incidental structure. Held-out evaluation and controlled cases test transfer under stated conditions; they do not create universal validity automatically. Review: Matched Filtering, Pulse Shaping, and Channel Effects; Equation 13F validation principle. Source: Equation 13F. Held-out evaluation with a nonzero fitted reference (p. 3748)

Why the selected alternative fits: Evaluate a separately reserved record under a declared fitting and validation policy.

Distinguishing consideration: compare this with option A, “Infer physical channel uniqueness from the number of plotted constellation clusters”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

V011-C07-MCQ-079. Two implementations agree exactly on EVM while sharing the same wrongly mapped reference symbols. What has their agreement failed to validate?

A. The correctness of the reference mapping and its relation to the intended transmitted symbols.

B. The fact that both implementations use the same numerical input records.

C. The arithmetic equality of the reported values.

D. The possibility of checking the common convention with a known reference.

Answer: A. Independent arithmetic does not remove a shared model or input error. Reference construction, label mapping and acquisition conditions need their own tests. Review: Defensive Interpretation of Digital Signals; reproducible acceptance record. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

Why the selected alternative fits: The correctness of the reference mapping and its relation to the intended transmitted symbols.

Distinguishing consideration: compare this with option B, “The fact that both implementations use the same numerical input records”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Defensive Interpretation of Digital Signals; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Defensive Interpretation of Digital Signals; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-MCQ-080. A noise-only input sometimes produces plausible recovered symbol clusters. What should this control establish in the report?

A. That real digital transmissions cannot produce the same constellation geometry.

B. That every previously observed signal was necessarily noise.

C. That the numerical EVM formula should be abandoned for all records.

D. That the tested processing can generate such structure under that control, requiring additional validation of candidate locks.

Answer: D. The control exposes a possible false-lock mechanism under its actual conditions. It does not retroactively classify every other observation; the candidate record still needs its own discriminating evidence. Review: Carrier and Timing Synchronization; Hypothetical Case Adjudication. Source: §7.2 Carrier and Timing Synchronization (p. 3737)

Why the selected alternative fits: That the tested processing can generate such structure under that control, requiring additional validation of candidate locks.

Distinguishing consideration: compare this with option A, “That real digital transmissions cannot produce the same constellation geometry”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

Review: Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

V011-C07-MCQ-081. A coded QPSK stream carries 4 Mbit/s of information at code rate one half, with no other overhead or idle time. What symbol rate is required?

A. 2 Msymbol/s.

B. 8 Msymbol/s.

C. 4 Msymbol/s.

D. 1 Msymbol/s.

Answer: C. QPSK carries two coded bits per data symbol. The information rate is two times one half times the symbol rate, so the required symbol rate is 4 million symbols per second. Review: Equation 14; Model 7B rate accounting. Source: Equation 14. Symbol-rate relation (p. 3767)

Why the selected alternative fits: 4 Msymbol/s.

Distinguishing consideration: compare this with option A, “2 Msymbol/s”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 14. Symbol-rate relation; Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Equation 14. Symbol-rate relation; Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-082. A 16QAM link has code rate 0.75 and data-slot fraction 0.8. Every information bit is payload, with no additional overhead. What symbol-slot rate supports 2.4 Mbit/s of payload under this model?

A. 0.8 Msymbol-slot/s.

B. 1 Msymbol-slot/s.

C. 0.6 Msymbol-slot/s.

D. 1.25 Msymbol-slot/s.

Answer: B. Each useful slot carries four coded bits and therefore three information bits before the separate slot fraction. Payload rate is $4 \times 0.75 \times 0.8$ times the slot rate, so 2.4 Mbit/s requires 1 million slots per second. Review: Turn a quality metric into a reproducible acceptance record; Model 7B. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: 1 Msymbol-slot/s.

Distinguishing consideration: compare this with option A, “0.8 Msymbol-slot/s”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-083. Why must a code rate and a separate payload-overhead factor have explicitly disjoint definitions?

A. Because multiplying two dimensionless factors is mathematically prohibited.

B. Because a code rate is measured in hertz while an overhead fraction is measured in bits.

C. Otherwise the same overhead can be counted twice or assigned to incompatible bit and symbol populations.

D. Because any two efficiency factors must always have numerically equal values.

Answer: C. The product is useful only when each factor represents a different declared conversion in the count chain. A reported payload fraction that already includes coding must not be multiplied by that coding reduction again. Review: Equation 14 limitations; Model 7B count definitions. Source: Equation 14. Symbol-rate relation (p. 3767)

Why the selected alternative fits: Otherwise the same overhead can be counted twice or assigned to incompatible bit and symbol populations.

Distinguishing consideration: compare this with option A, “Because multiplying two dimensionless factors is mathematically prohibited”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Equation 14. Symbol-rate relation; Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Equation 14. Symbol-rate relation; Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

V011-C07-MCQ-084. A uniform 64QAM stream has slot rate 2 Msymbol-slot/s, code rate two thirds and data-slot fraction 0.9. Every information bit is payload, with no additional overhead. What payload rate follows?

A. 10.8 Mbit/s.

B. 18 Mbit/s.

C. 7.2 Mbit/s.

D. 1.2 Mbit/s.

Answer: C. There are six coded bits per 64QAM data symbol. Multiply 2 million slots per second by 6, by two thirds and by 0.9. Each factor has a stated role; coding does not create extra information bits. Review: Model 7B fixed-mode rate identity. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: 7.2 Mbit/s.

Distinguishing consideration: compare this with option A, “10.8 Mbit/s”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

V011-C07-MCQ-085. A calculation counts all transmitted payload-bearing bits, including repeats of the same packet. What additional evidence is needed to report unique delivered payload throughput?

A. A delivery and duplication rule with packet outcomes or equivalent identity-linked counts.

B. Only the nominal code rate, because it already includes all retransmission outcomes.

C. Only EVM, converted through a universal bit-error formula.

D. Only the modulation order, because every transmitted label necessarily delivers new information.

Answer: A. The physical transmission rate and the rate of distinct accepted payload are different populations. Repeat and delivery accounting needs its own observations and convention. Review: Turn a quality metric into a reproducible acceptance record; Model 7B scope. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: A delivery and duplication rule with packet outcomes or equivalent identity-linked counts.

Distinguishing consideration: compare this with option B, “Only the nominal code rate, because it already includes all retransmission outcomes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-MCQ-086. A 100-slot frame reserves 12 slots for pilots and 16 other disjoint slots for nonpayload use. The remaining slots carry 16QAM with code rate 0.75 at 3 million slots per second; every resulting information bit is payload. What payload rate follows?

A. 8.64 Mbit/s.

B. 6.48 Mbit/s.

C. 9 Mbit/s.

D. 2.16 Mbit/s.

Answer: B. There are 72 useful slots per 100, so the usable fraction is 0.72. Multiply 3 million by 4 coded bits per symbol, 0.75 information fraction and 0.72 useful-slot fraction. Review: Model 7B finite-frame count example. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: 6.48 Mbit/s.

Distinguishing consideration: compare this with option A, “8.64 Mbit/s”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

V011-C07-MCQ-087. A receiver identifies a 16QAM-like constellation but has not established coding or framing. What payload-rate conclusion is justified from constellation order alone?

A. Four coded label bits can be assigned per such symbol, but payload rate still needs rate, coding and overhead definitions.

B. Payload rate is necessarily four times the RF carrier frequency.

C. All observed symbols necessarily contain four distinct accepted payload bits.

D. The code rate must be one because there are sixteen states.

Answer: A. Constellation cardinality describes an alphabet under a mapping, not the full protocol or delivery population. Coding, pilots, headers, duty and outcome accounting remain separate. Review: Equation 14 and its limitations; Defensive Interpretation of Digital Signals. Source: Equation 14. Symbol-rate relation (p. 3767)
Why the selected alternative fits: Four coded label bits can be assigned per such symbol, but payload rate still needs rate, coding and overhead definitions.
Distinguishing consideration: compare this with option B, “Payload rate is necessarily four times the RF carrier frequency”; that competing statement does not meet the question’s stated requirement.
Basis and limitation: Chapter 7 — Equation 14. Symbol-rate relation; Chapter 7 — Defensive Interpretation of Digital Signals.
Review: Chapter 7 — Equation 14. Symbol-rate relation; Chapter 7 — Defensive Interpretation of Digital Signals.

V011-C07-MCQ-088. Two simultaneous, disjoint payload streams deliver 2.4 Mbit/s and 1.6 Mbit/s over the same declared wall-clock interval. What aggregate payload rate follows?

A. 2.0 Mbit/s, because parallel streams must be averaged rather than added.

B. 3.84 Mbit/s, because rates combine by multiplication.

C. The larger stream's 2.4 Mbit/s, regardless of the second stream's payload.

D. 4.0 Mbit/s, provided their counted payload is disjoint and the rate definitions agree.

Answer: D. Counts of disjoint delivered payload over a common interval add. Duplicated diversity copies or incompatible time bases would require a different accounting before addition. Review: Model 7B aggregate count identity. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: 4.0 Mbit/s, provided their counted payload is disjoint and the rate definitions agree.

Distinguishing consideration: compare this with option A, "2.0 Mbit/s, because parallel streams must be averaged rather than added"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-089. A link delivers 6 Mbit/s for 3 seconds and 2 Mbit/s for 1 second, with no other interval. What is its payload rate over the complete 4 seconds?

A. 5 Mbit/s.

B. 8 Mbit/s.

C. 3 Mbit/s.

D. 4 Mbit/s.

Answer: A. The payload count is 18 million plus 2 million bits. Divide by 4 seconds. An unweighted mean of the two mode rates would incorrectly give the shorter mode equal time weight. Review: Model 7B duration-weighted mode accounting.

Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: 5 Mbit/s.

Distinguishing consideration: compare this with option B, “8 Mbit/s”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-090. Under the finite-slot model, the usable-symbol fraction is zero while a positive payload rate is required. What does the inverse rate calculation imply?

A. The code rate can be ignored to avoid the zero denominator.

B. The receiver may replace the zero fraction by one without changing the model.

C. No finite slot rate satisfies that positive payload requirement within the stated zero-useful-slot model.

D. The required symbol rate is zero because the usable fraction is zero.

Answer: C. A zero useful-slot factor makes the modeled payload count zero at every finite slot rate. The positive-target inverse is outside its domain, so the premises or requirement must change. Review: Model 7B inverse-domain boundary.

Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why the selected alternative fits: No finite slot rate satisfies that positive payload requirement within the stated zero-useful-slot model.

Distinguishing consideration: compare this with option A, “The code rate can be ignored to avoid the zero denominator”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-091. A decoded frame passes its declared cyclic-redundancy check. What does that fact alone fail to establish?

A. Consistency with that particular implemented check rule.

B. Authenticity, emitter location or lawful acquisition authority.

C. The possibility of preserving the frame and decoder configuration for review.

D. The existence of the observed check outcome in the retained decoder record.

Answer: B. A check result is evidence about a defined code relation under a decoder. It does not by itself authenticate a sender, locate an emitter or establish authority for the acquisition. Review: Defensive Interpretation of Digital Signals.

Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

Why the selected alternative fits: Authenticity, emitter location or lawful acquisition authority.

Distinguishing consideration: compare this with option A, “Consistency with that particular implemented check rule”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Defensive Interpretation of Digital Signals.

Review: Chapter 7 — Defensive Interpretation of Digital Signals.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-092. A noise-only control also produces a passing short check on one trial. Which inference is defensible?

A. The control demonstrates a false-accept possibility under the tested search and check procedure, not universal invalidity of every candidate.

B. All real frames must now be rejected regardless of independent evidence.

C. The probability of any future false acceptance is exactly the fraction from that one trial without further assumptions.

D. A check pass guarantees a true signal because the control was unexpected.

Answer: A. Search multiplicity, trial definitions and the control population matter. One event can disprove an absolute impossibility claim but does not by itself supply a transferable false-accept rate. Review: Hypothetical Case Adjudication; decoder validation limits. Source: §7.24 Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics (p. 3794)

Why the selected alternative fits: The control demonstrates a false-accept possibility under the tested search and check procedure, not universal invalidity of every candidate.

Distinguishing consideration: compare this with option B, “All real frames must now be rejected regardless of independent evidence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

Review: Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

V011-C07-MCQ-093. A candidate component shifts in a repeatable way when only the sampling rate or digital grid is changed. What should be investigated?

A. Only the final EVM threshold, with all rate metadata discarded.

B. Only the transmitter location, because processing cannot move a displayed component.

C. An assumption that every rate-dependent component is necessarily malicious.

D. Sampling, alias, reference and processing dependencies before treating the display as a fixed external emission.

Answer: D. A controlled receiver-state challenge tests whether the observation behaves as the proposed physical signal should. The result can implicate a processing mechanism without uniquely identifying it or establishing intent. Review: Defensive Interpretation of Digital Signals; Hypothetical Case Adjudication. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

Why the selected alternative fits: Sampling, alias, reference and processing dependencies before treating the display as a fixed external emission.

Distinguishing consideration: compare this with option A, “Only the final EVM threshold, with all rate metadata discarded”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Defensive Interpretation of Digital Signals; Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

Review: Chapter 7 — Defensive Interpretation of Digital Signals; Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

V011-C07-MCQ-094. Why is agreement between two decoders insufficient when both import the same incorrect sample-rate metadata?

A. A shared metadata error is automatically removed by RMS normalization.

B. Sample-rate metadata cannot affect any digital demodulation result.

C. They can share the same time-axis and synchronization error despite separate implementations.

D. Different implementations can never produce numerically equal results.

Answer: C. Independence must be assessed at the level of assumptions, references and inputs as well as code. A known time/frequency reference can expose a shared metadata error that duplicate processing preserves. Review: Carrier and Timing Synchronization; reproducible acceptance record. Source: §7.2 Carrier and Timing Synchronization (p. 3737)

Why the selected alternative fits: They can share the same time-axis and synchronization error despite separate implementations.

Distinguishing consideration: compare this with option A, “A shared metadata error is automatically removed by RMS normalization”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-095. Which record best supports a later reviewer's evaluation of failed acquisition attempts?

A. Only the final accepted constellation with failed intervals replaced by zero errors.

B. Only screenshots from successful locks, labeled as representative of all attempts.

C. Native samples where retained, timestamps, attempted settings, state evidence and explicit failure outcomes under the declared retention policy.

D. Only the decoder's nominal modulation list without the attempted settings.

Answer: C. The acquisition population includes attempted and excluded intervals. Reproducible records distinguish a valid negative observation, an unobserved interval and a processing failure. Review: Carrier and Timing Synchronization; record and acceptance discussion. Source: §7.2 Carrier and Timing Synchronization (p. 3737)

Why the selected alternative fits: Native samples where retained, timestamps, attempted settings, state evidence and explicit failure outcomes under the declared retention policy.

Distinguishing consideration: compare this with option A, "Only the final accepted constellation with failed intervals replaced by zero errors"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Carrier and Timing Synchronization; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-096. What does preserving a processing script's file hash establish directly?

A. That the file was necessarily executed on every reported record.

B. The identity of that retained file, with execution, configuration and metrological validity requiring additional evidence.

C. That every physical reference used by the receiver is traceable to an appropriate standard.

D. That the script implements the correct reference mapping for every signal format.

Answer: B. A file identity check supports provenance. It does not prove execution or correctness, and it is distinct from the evidence supporting a measurement result and its reference chain. Review: Turn a quality metric into a reproducible acceptance record; Chapter 1 traceability boundary. Source: §7.19 Turn a quality metric into a reproducible acceptance record (p. 3764)

Why the selected alternative fits: The identity of that retained file, with execution, configuration and metrological validity requiring additional evidence.

Distinguishing consideration: compare this with option A, "That the file was necessarily executed on every reported record"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Turn a quality metric into a reproducible acceptance record; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Review: Chapter 7 — Turn a quality metric into a reproducible acceptance record; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C07-MCQ-097. Which retained material is most useful for reproducing the chapter's finite-record EVM result?

A. The paired complex observations and references, selected indices and weights, fitted parameters, processing versions and both energy sums.

B. Only the final percentage and the modulation name.

C. Only the receiver's nominal maximum sample rate.

D. Only a constellation screenshot after automatic scaling.

Answer: A. These records expose the numerator, denominator and transformations that produced the metric. A scalar or image alone generally cannot reconstruct the selected finite experiment. Review: Equations 13A–13J; reproducible acceptance record. Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)

Why the selected alternative fits: The paired complex observations and references, selected indices and weights, fitted parameters, processing versions and both energy sums.

Distinguishing consideration: compare this with option B, "Only the final percentage and the modulation name"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Turn a quality metric into a reproducible acceptance record; Chapter 7 — Equation 13A. Finite reference energy and admissible weights;....

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Turn a quality metric into a reproducible acceptance record; Chapter 7 — Equation 13A. Finite reference energy and admissible weights; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

V011-C07-MCQ-098. A monitoring task authorizes spectral characterization but does not establish permission for content recovery. What should the analyst establish before expanding processing?

A. The actual authorized scope for the proposed acquisition, recovery, retention and reporting operations.

B. That a low EVM itself grants permission to recover content.

C. That successfully decoded bits can always be retained because they were technically accessible.

D. That a modulation label alone resolves every acquisition and retention boundary.

Answer: A. Technical capability and task authority are separate conditions. The chapter requires an explicit boundary for the operation being proposed rather than inferring permission from successful processing. Review: Defensive Interpretation of Digital Signals; Chapter 1 mission scope. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

Why the selected alternative fits: The actual authorized scope for the proposed acquisition, recovery, retention and reporting operations.

Distinguishing consideration: compare this with option B, “That a low EVM itself grants permission to recover content”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Defensive Interpretation of Digital Signals; Chapter 1 — Mission Authority and Collection Boundaries.

Review: Chapter 7 — Defensive Interpretation of Digital Signals; Chapter 1 — Mission Authority and Collection Boundaries.

V011-C07-MCQ-099. Why can an RF spectral-emission result and a decoded-content result require different validation records?

A. Because a common input cable forces both results to have identical uncertainty and authority requirements.

B. Because a spectral measurement is always independent of receiver configuration.

C. They concern different quantities and propositions, with different receiver operations and success conditions.

D. Because decoded content automatically validates all earlier amplitude and bandwidth measurements.

Answer: C. Shared hardware does not make the measurement questions identical. Each result needs its own processing boundary, relevant reference, validity evidence and claim limits. Review: Defensive Interpretation of Digital Signals; receiver-system boundary. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

Why the selected alternative fits: They concern different quantities and propositions, with different receiver operations and success conditions.

Distinguishing consideration: compare this with option A, “Because a common input cable forces both results to have identical uncertainty and authority requirements”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 7 — Defensive Interpretation of Digital Signals.

Review: Chapter 7 — Defensive Interpretation of Digital Signals.

V011-C07-MCQ-100. A vendor demodulator's documented normalization differs from the chapter's explicitly defined finite-record convention. What is the correct comparison policy?

A. Treat matching percentage units as sufficient proof that the thresholds are interchangeable.

B. Preserve both definitions, compute any justified conversion explicitly and validate applicability to the actual format and selected population.

C. Assume the chapter formula silently replaces every documented vendor convention.

D. Assume every format uses the same constellation-maximum denominator.

Answer: B. The chapter's model is a declared mathematical experiment. Actual implementations can use format-dependent reference and sample conventions, so comparison requires a stated relation rather than an assumed universal EVM label.
Review: Model 7A normalization scope; Keysight EVM and EVM Normalization Reference help. Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)
Why the selected alternative fits: Preserve both definitions, compute any justified conversion explicitly and validate applicability to the actual format and selected population.
Distinguishing consideration: compare this with option A, "Treat matching percentage units as sufficient proof that the thresholds are interchangeable"; that competing statement does not meet the question's stated requirement.
Basis and limitation: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Model 7A: a finite, declared EVM comparison.

V011-C07-FIB-018. A fourfold increase in residual energy with unchanged positive reference energy multiplies EVM by _____.

Answer: 2. EVM scales as the square root of its numerator energy. The result is not a fourfold EVM increase. Review: Equation 13B. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why this term is required: “2” completes the stated technical proposition.

Question context: A fourfold increase in residual energy with unchanged positive reference energy multiplies EVM by _____

Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-FIB-019. If reference energy alone increases ninefold, EVM becomes _____ of its original value.

Answer: one third. The denominator change divides squared EVM by nine. Its square root divides EVM by three, even though the residual itself has not improved.
Review: Equations 13B and 13G. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)
Why this term is required: “one third” completes the stated technical proposition.
Question context: If reference energy alone increases ninefold, EVM becomes _____ of its original value
Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.
Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

V011-C07-FIB-020. An 8 percent EVM must enter the decibel expression as the linear ratio _____.

Answer: 0.08. Taking the logarithm of the percentage numeral 8 would introduce a 40 dB offset relative to taking the logarithm of 0.08. Review: Equation 13C. Source: Equation 13C. Percent and decibel reporting (p. 3746)

Why this term is required: “0.08” completes the stated technical proposition.

Question context: An 8 percent EVM must enter the decibel expression as the linear ratio _____

Basis and qualification: Chapter 7 — Equation 13C. Percent and decibel reporting.

Review: Chapter 7 — Equation 13C. Percent and decibel reporting.

Copyright 2026, James M. Atkinson

V011-C07-FIB-021. In the complex-gain fit, the reference factor in the weighted correlation is complex _____.

Answer: conjugated. The correlation is the weighted sum of observation times conjugated ideal reference. Conjugating the other factor instead generally reverses the fitted phase. Review: Equation 13D. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why this term is required: “conjugated” completes the stated technical proposition.

Question context: In the complex-gain fit, the reference factor in the weighted correlation is complex _____

Basis and qualification: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Copyright 2026, James M. Atkinson

V011-C07-FIB-022. A training correlation of $4 - j3$ and reference energy of 5 give fitted gain _____.

Answer: $0.8 - j0.6$. Divide the complex numerator by the real positive denominator. The coefficient has unit magnitude but a nonzero phase. Review: Equation 13D. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why this term is required: "Divide the complex numerator by the real positive denominator" completes the stated technical proposition.

Question context: A training correlation of and reference energy of 5 give fitted gain _____

Basis and qualification: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Copyright 2026, James M. Atkinson

V011-C07-FIB-023. A training correlation of $2+j2$ and reference energy of 8 give fitted gain _____.

Answer: $0.25+j0.25$. The real and imaginary correlation components are each divided by eight. Replacing that coefficient by its magnitude would define a different correction. Review: Equation 13D. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)

Why this term is required: "The real and imaginary correlation components are each divided by eight" completes the stated technical proposition.

Question context: A training correlation of and reference energy of 8 give fitted gain _____

Basis and qualification: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set.

Copyright 2026, James M. Atkinson

V011-C07-FIB-024. With observation energy 10, correlation magnitude squared 25 and reference energy 5, the minimized training residual energy is _____.

Answer: 5. Completion of the square gives the minimum as 10 minus $\frac{25}{5}$, which equals 5 in the squared-amplitude convention of the input sums. Review: Equation 13E. Source: Equation 13E. Least-squares completion of the square (p. 3747)

Why this term is required: “5” completes the stated technical proposition.

Question context: With observation energy 10, correlation magnitude squared 25 and reference energy 5, the minimized training residual energy is _____

Basis and qualification: Chapter 7 — Equation 13E. Least-squares completion of the square.

Review: Chapter 7 — Equation 13E. Least-squares completion of the square.

Copyright 2026, James M. Atkinson

V011-C07-FIB-025. If training reference energy is 5 and a trial gain differs from the minimizer by magnitude 0.2, its excess residual energy is _____.

Answer: 0.2. The completed-square penalty is reference energy times squared gain displacement: 5 times 0.04 equals 0.2. Review: Equation 13E. Source: Equation 13E. Least-squares completion of the square (p. 3747)

Why this term is required: “0.2” completes the stated technical proposition.

Question context: If training reference energy is 5 and a trial gain differs from the minimizer by magnitude 0.2, its excess residual energy is _____

Basis and qualification: Chapter 7 — Equation 13E. Least-squares completion of the square.

Review: Chapter 7 — Equation 13E. Least-squares completion of the square.

Copyright 2026, James M. Atkinson

V011-C07-FIB-026. A positive-energy training reference with zero weighted observation-reference correlation has fitted gain _____.

Answer: zero. The gain estimate is defined, but using that zero gain to form an EVM normalization reference would create a zero denominator. Review: Equations 13D and 13F. Source: Equation 13D. Optional complex-gain fit on a training set (p. 3747)
Why this term is required: “zero” completes the stated technical proposition.
Question context: A positive-energy training reference with zero weighted observation-reference correlation has fitted gain _____
Basis and qualification: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.
Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Copyright 2026, James M. Atkinson

V011-C07-FIB-027. Evaluation indices excluded from the parameter-estimation set are described as _____ data.

Answer: held-out. The exclusion limits reuse of the evaluated observations for fitting. It does not by itself establish physical or statistical independence. Review: Equation 13F. Source: Equation 13F. Held-out evaluation with a nonzero fitted reference (p. 3748)

Why this term is required: “held-out” completes the stated technical proposition.

Question context: Evaluation indices excluded from the parameter-estimation set are described as _____ data

Basis and qualification: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Review: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Copyright 2026, James M. Atkinson

V011-C07-FIB-028. For a fitted-reference EVM, positive ideal-reference energy is insufficient if the fitted gain is _____.

Answer: zero. The denominator also includes the squared magnitude of the fitted coefficient. Its vanishing makes the fitted-reference metric undefined. Review: Equation 13F. Source: Equation 13F. Held-out evaluation with a nonzero fitted reference (p. 3748)

Why this term is required: “zero” completes the stated technical proposition.

Question context: For a fitted-reference EVM, positive ideal-reference energy is insufficient if the fitted gain is _____

Basis and qualification: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Review: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Copyright 2026, James M. Atkinson

V011-C07-FIB-029. Completion of the square establishes a unique complex-gain minimizer when the training reference energy is strictly _____.

Answer: positive. That positive coefficient multiplies the squared distance from the minimizing gain. A zero reference-energy case lacks this uniqueness argument and lies outside the stated fit. Review: Equation 13E. Source: Equation 13E. Least-squares completion of the square (p. 3747)

Why this term is required: “positive” completes the stated technical proposition.

Question context: Completion of the square establishes a unique complex-gain minimizer when the training reference energy is strictly _____

Basis and qualification: Chapter 7 — Equation 13E. Least-squares completion of the square.

Review: Chapter 7 — Equation 13E. Least-squares completion of the square.

Copyright 2026, James M. Atkinson

V011-C07-FIB-030. A fit minimizes the declared training residual _____, not every later normalized error ratio.

Answer: energy. A denominator depending on the fitted gain can change even while the numerator decreases. Held-out records also have a different objective from the fitted training record. Review: Equations 13E–13F; Application 7A.8. Source: Equation 13E. Least-squares completion of the square (p. 3747)

Why this term is required: “energy” completes the stated technical proposition.

Question context: A fit minimizes the declared training residual _____, not every later normalized error ratio

Basis and qualification: Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.8: Keep a residual frequency rotation in….

Review: Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

V011-C07-FIB-031. A real gain of 1.12 applied to every reference without a permitted gain fit produces _____ percent fixed-reference EVM.

Answer: 12. The residual is 0.12 times each reference, so the normalized RMS magnitude is 0.12. Review: Equation 13H. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)

Why this term is required: “12” completes the stated technical proposition.

Question context: A real gain of 1.12 applied to every reference without a permitted gain fit produces _____ percent fixed-reference EVM

Basis and qualification: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Copyright 2026, James M. Atkinson

V011-C07-FIB-032. A real gain of 0.88 produces the same fixed-reference EVM as gain 1.12 because EVM retains the _____ of the gain departure.

Answer: magnitude. Both departures from one have magnitude 0.12. The scalar result alone does not preserve whether the amplitude is high or low. Review: Equation 13H. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)

Why this term is required: “magnitude” completes the stated technical proposition.

Question context: A real gain of 0.88 produces the same fixed-reference EVM as gain 1.12 because EVM retains the _____ of the gain departure

Basis and qualification: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Copyright 2026, James M. Atkinson

V011-C07-FIB-033. A constant phase rotation of 60 degrees gives exactly _____ percent fixed-reference EVM.

Answer: 100. The chord is twice sin of 30 degrees, which is one. Percentage conversion gives 100, despite unchanged individual reference magnitudes. Review: Equation 13H. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)
Why this term is required: “100” completes the stated technical proposition.
Question context: A constant phase rotation of 60 degrees gives exactly _____ percent fixed-reference EVM
Basis and qualification: Chapter 7 — Equation 13H. Fixed gain and phase impairments.
Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Copyright 2026, James M. Atkinson

V011-C07-FIB-034. A constant phase reversal of 180 degrees gives a linear fixed-reference EVM of _____.

Answer: 2. Each observation is the negative of its reference, making the residual negative twice the reference. EVM need not be bounded by one. Review: Equation 13H. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)

Why this term is required: “2” completes the stated technical proposition.

Question context: A constant phase reversal of 180 degrees gives a linear fixed-reference EVM of _____

Basis and qualification: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments.

Copyright 2026, James M. Atkinson

V011-C07-FIB-035. The small-angle approximation to phase-only EVM uses the phase error in _____.

Answer: radians. The local sine approximation requires a radian argument. Degrees and cycles need explicit conversion. Review: Equation 13H; Application 7A.2. Source: Equation 13H. Fixed gain and phase impairments (p. 3749)

Why this term is required: “radians” completes the stated technical proposition.

Question context: The small-angle approximation to phase-only EVM uses the phase error in _____

Basis and qualification: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.2: Quantify a fixed phase error.

Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.2: Quantify a fixed phase error.

Copyright 2026, James M. Atkinson

V011-C07-FIB-036. A common offset of $0.06 + j\,0.08$ on balanced unit-energy references gives _____ percent fixed-reference EVM.

Answer: 10. The offset magnitude is 0.10, obtained from the square root of 0.06 squared plus 0.08 squared. Unit reference RMS gives EVM 0.10. Review: Equation 13I. Source: Equation 13I. Balanced-reference offset and conjugate terms (p. 3749)

Why this term is required: “10” completes the stated technical proposition.

Question context: A common offset of on balanced unit-energy references gives _____ percent fixed-reference EVM

Basis and qualification: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms.

Review: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms.

Copyright 2026, James M. Atkinson

V011-C07-FIB-037. For a common offset, a zero weighted reference _____ prevents that offset from changing the gain-fit correlation.

Answer: sum. The offset contribution is the offset multiplied by the conjugate of that sum. The offset residual can remain even when its contribution to the gain estimate vanishes. Review: Equation 13I; Application 7A.3. Source: Equation 13I. Balanced-reference offset and conjugate terms (p. 3749)

Why this term is required: “sum” completes the stated technical proposition.

Question context: For a common offset, a zero weighted reference _____ prevents that offset from changing the gain-fit correlation

Basis and qualification: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

Review: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain.

V011-C07-FIB-043. A selected record using only the four inner square-16QAM points has reference energy _____ per symbol.

Answer: 2. Each inner point has coordinates of magnitude one, so each symbol has energy 1 plus 1. The full-alphabet average energy 10 does not apply to this selected record. Review: Equation 13G finite-population normalization. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why this term is required: “2” completes the stated technical proposition.

Question context: A selected record using only the four inner square-16QAM points has reference energy _____ per symbol

Basis and qualification: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Copyright 2026, James M. Atkinson

V011-C07-FIB-044. For those inner points, a fixed residual magnitude 0.1 gives reference-RMS EVM of approximately _____ percent.

Answer: 7.071068. The residual energy per symbol is 0.01 and the reference energy per symbol is 2. The square root of $\frac{0.01}{2}$ times one hundred gives the stated value.

Review: Equation 13G. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why this term is required: “7.071068” completes the stated technical proposition.

Question context: For those inner points, a fixed residual magnitude 0.1 gives reference-RMS EVM of approximately _____ percent

Basis and qualification: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Copyright 2026, James M. Atkinson

V011-C07-FIB-045. The same inner-point residual normalized to the 16QAM maximum magnitude gives approximately _____ percent EVM.

Answer: 2.357023. Use maximum reference energy 18 in the denominator: one hundred times the square root of $\frac{0.01}{18}$ is approximately 2.357023. The residual is unchanged. Review: Equation 13G. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why this term is required: “2.357023” completes the stated technical proposition.

Question context: The same inner-point residual normalized to the 16QAM maximum magnitude gives approximately _____ percent EVM

Basis and qualification: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Copyright 2026, James M. Atkinson

V011-C07-FIB-046. For the inner-point record, reference-RMS EVM is _____ times its constellation-maximum EVM.

Answer: 3. The maximum normalization magnitude is the square root of 18, while the realized RMS magnitude is the square root of 2. Their ratio is three. Review: Equation 13G. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why this term is required: “3” completes the stated technical proposition.

Question context: For the inner-point record, reference-RMS EVM is _____ times its constellation-maximum EVM

Basis and qualification: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Copyright 2026, James M. Atkinson

V011-C07-FIB-047. A threshold and a measured EVM can share percent units while having different normalization _____.

Answer: references. Matching unit labels do not establish a common denominator, selected population or correction policy. An explicit conversion is needed before comparing thresholds. Review: Equation 13G; implementation comparison. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why this term is required: “references” completes the stated technical proposition.

Question context: A threshold and a measured EVM can share percent units while having different normalization _____

Basis and qualification: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Copyright 2026, James M. Atkinson

V011-C07-FIB-048. If the same nonzero complex factor scales both observations and references, the residual-energy and reference-energy sums receive the same positive _____.

Answer: scale factor. The factor is the squared magnitude of the common complex multiplier. It cancels from EVM, which is why common absolute errors can remain hidden. Review: Equation 13B invariance. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why this term is required: “scale factor” completes the stated technical proposition.

Question context: If the same nonzero complex factor scales both observations and references, the residual-energy and reference-energy sums receive the same positive _____

Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-FIB-049. A common permutation preserves EVM only when observations, references and weights keep their original _____.

Answer: pairing. A finite sum is unchanged by rearranging paired terms. Permuting only one vector can create different residuals and a different experiment. Review: Equation 13B. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why this term is required: “pairing” completes the stated technical proposition.

Question context: A common permutation preserves EVM only when observations, references and weights keep their original _____

Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-FIB-050. A constellation-maximum denominator is based on the declared alphabet convention, while a reference-RMS denominator depends on the selected reference _____.

Answer: population. The realized symbol occurrence counts and weights can change its RMS value. A full uniform constellation average is not universal for short or biased records. Review: Equation 13G. Source: Equation 13G. Average-reference and maximum-reference normalization (p. 3749)

Why this term is required: “population” completes the stated technical proposition.

Question context: A constellation-maximum denominator is based on the declared alphabet convention, while a reference-RMS denominator depends on the selected reference _____

Basis and qualification: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

Copyright 2026, James M. Atkinson

V011-C07-FIB-051. Four unit-energy references have only one nonzero residual, of magnitude 0.2. Their RMS EVM is _____ percent.

Answer: 10. Residual energy is 0.04 and reference energy is 4. The square root of 0.01 gives 10 percent, while the peak individually normalized residual is 20 percent. Review: Equation 13B; peak versus RMS interpretation. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why this term is required: “10” completes the stated technical proposition.

Question context: Four unit-energy references have only one nonzero residual, of magnitude 0.2. Their RMS EVM is _____ percent

Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-FIB-052. For that one-error, four-symbol record, peak individually normalized error is _____ times RMS EVM.

Answer: 2. The peak is 0.2 and the RMS value is 0.1. A largest-error metric retains information that one overall RMS value does not. Review: Application 7A.10 principle. Source: §7.16 Application 7A.10: Audit a complete finite residual vector (p. 3761)
Why this term is required: “2” completes the stated technical proposition.
Question context: For that one-error, four-symbol record, peak individually normalized error is _____ times RMS EVM
Basis and qualification: Chapter 7 — Application 7A.10: Audit a complete finite residual vector.
Review: Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

V011-C07-FIB-055. Two compatible blocks have reference energies 100 and 900 and linear EVM values 0.1 and 0.2. Their combined residual energy is _____.

Answer: 37. The first residual energy is 100 times 0.1 squared, or 1. The second is 900 times 0.2 squared, or 36. Add these energies to obtain 37. Review: Equation 13B block combination. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why this term is required: “37” completes the stated technical proposition.

Question context: Two compatible blocks have reference energies 100 and 900 and linear EVM values 0.1 and 0.2. Their combined residual energy is _____

Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-FIB-056. Those two blocks have combined reference energy 1,000, so their union EVM is approximately _____ percent.

Answer: 19.235384. Take the square root of $\frac{37}{1000}$ and multiply by one hundred. An unweighted average of 10 and 20 percent would incorrectly ignore the unequal reference energies. Review: Equation 13B block combination. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why this term is required: “19.235384” completes the stated technical proposition.

Question context: Those two blocks have combined reference energy 1,000, so their union EVM is approximately _____ percent

Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-FIB-057. Copies of the same finite record do not by themselves increase the number of _____ observations.

Answer: independent. Duplicating stored samples repeats their information and scales both EVM sums together. Statistical independence needs a justified observation model. Review: Equation 13B; validation scope. Source: Equation 13B. Weighted fixed-reference error vector magnitude (p. 3746)

Why this term is required: “independent” completes the stated technical proposition.

Question context: Copies of the same finite record do not by themselves increase the number of _____ observations

Basis and qualification: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude.

Copyright 2026, James M. Atkinson

V011-C07-FIB-058. An EVM reported only after lock is a metric _____ on successful acquisition.

Answer: conditional. The included population has been selected by the lock outcome. Whole-experiment reporting also needs attempted acquisitions, failures and exclusions. Review: Carrier and Timing Synchronization; Application 7A.6.

Source: §7.12 Application 7A.6: Make selection and weighting visible (p. 3757)

Why this term is required: “conditional” completes the stated technical proposition.

Question context: An EVM reported only after lock is a metric _____ on successful acquisition

Basis and qualification: Chapter 7 — Application 7A.6: Make selection and weighting visible; Chapter 7 — Carrier and Timing Synchronization.

Review: Chapter 7 — Application 7A.6: Make selection and weighting visible; Chapter 7 — Carrier and Timing Synchronization.

V011-C07-FIB-090. The logarithm base two of a known power-of-two constellation cardinality counts coded _____ positions per symbol.

Answer: label-bit. That count does not establish entropy, delivered unique information or a stored ADC-bit rate. The binary labeling and selected symbol type must be declared. Review: Model 7B label and count definitions. Source: §7.22 Model 7B: finite rate accounting for symbols, coding and payload (p. 3768)

Why this term is required: “label-bit” completes the stated technical proposition.

Question context: The logarithm base two of a known power-of-two constellation cardinality counts coded _____ positions per symbol

Basis and qualification: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

V011-C07-FIB-091. A CRC pass is a check on the decoded code relation and is not, by itself, cryptographic _____.

Answer: authentication. A passed consistency check does not prove who originated the signal or where it was transmitted. The validation claim must match the check actually performed. Review: Defensive Interpretation of Digital Signals. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

Why this term is required: “authentication” completes the stated technical proposition.

Question context: A CRC pass is a check on the decoded code relation and is not, by itself, cryptographic _____

Basis and qualification: Chapter 7 — Defensive Interpretation of Digital Signals.

Review: Chapter 7 — Defensive Interpretation of Digital Signals.

V011-C07-FIB-092. Preserving only a final EVM percentage generally prevents full _____ of the selected finite experiment.

Answer: reproduction. The paired observations and references, selection, weights, fitted parameters and both energy sums are needed to reconstruct the calculation and its conventions. Review: Turn a quality metric into a reproducible acceptance record. Source: §7.19 Turn a quality metric into a reproducible acceptance record (p. 3764)

Why this term is required: “reproduction” completes the stated technical proposition.

Question context: Preserving only a final EVM percentage generally prevents full _____ of the selected finite experiment

Basis and qualification: Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Review: Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-FIB-094. Converting EVM into a bit-error probability requires an additional justified channel, _____ and coding model.

Answer: decision. The metric alone does not define how observations become labels or bits. Different impairments and mappings can produce the same EVM with different decision outcomes. Review: Error Vector Magnitude and Quality Metrics.

Source: §7.17 Error Vector Magnitude and Quality Metrics (p. 3762)

Why this term is required: “decision” completes the stated technical proposition.

Question context: Converting EVM into a bit-error probability requires an additional justified channel, _____ and coding model

Basis and qualification: Chapter 7 — Error Vector Magnitude and Quality Metrics.

Review: Chapter 7 — Error Vector Magnitude and Quality Metrics.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C07-ESSAY-001. Develop the weighted finite-record EVM definition from paired complex observations and references. State the admissible weights, units, normalization domain, percentage and decibel conventions, and what changes when some symbols receive zero weight.

- Opening: Present a thesis that answers this precise question: Develop the weighted finite-record EVM definition from paired complex observations and references. Identify which evidence would falsify the proposed conclusion Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)
- Core terminology and scope: Define paired, admissible, weights in the question's particular technical setting; explain how percentage, conventions, weight differ if that distinction would change the analysis of "Develop the weighted finite-record EVM definition from paired complex observations and references" Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Start with a finite set of paired observations and references in compatible complex-amplitude units Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the weighted finite-record EVM definition from paired complex observations and references to the claimed result, following "Application 7A.10: Audit a complete finite residual vector"; name the intermediate states and measurable outputs Source: §7.16 Application 7A.10: Audit a complete finite residual vector (p. 3761)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for the weighted finite-record EVM definition from paired complex observations and references. Subtract each reference from its observation, square the complex magnitude, multiply by a fixed nonnegative dimensionless weight and sum Source: §7.16 Application 7A.10: Audit a complete finite residual vector (p. 3761)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 7A.3: Preserve a DC impairment when fitting only complex gain” that resolves the question about the weighted finite-record EVM definition from paired complex observations and references; derive the relevant result with units and stated validity conditions Source: §7.9 Application 7A.3: Preserve a DC impairment when fitting only complex gain (p. 3754)
- Evidence and method: Specify the native observations, control records and calculations that would resolve the weighted finite-record EVM definition from paired complex observations and references. Divide by the correspondingly weighted reference-energy sum, which must be strictly positive, and take the square root Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)
- Worked application or illustrative case: Build a worked example of “the weighted finite-record EVM definition from paired complex observations and references”, addressing this associated condition: State the admissible weights, units, normalization domain, percentage and decibel conventions, and what.... Start with a finite set of paired observations and references in compatible complex-

amplitude units Source: §7.16 Application 7A.10: Audit a complete finite residual vector (p. 3761)

- Alternative explanations and failure modes: Construct two plausible technical explanations for “the weighted finite-record EVM definition from paired complex observations and references”. Using “Application 7A.3: Preserve a DC impairment when fitting only complex gain”, specify a discriminator and the result expected under each explanation Source: §7.9 Application 7A.3: Preserve a DC impairment when fitting only complex gain (p. 3754)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to the weighted finite-record EVM definition from paired complex observations and references, including the effect of missing measurements and inconsistent operating conditions Source: §7.25 Digital-demodulation validation by error covariance and synchronisation-state segmentation (p. 3795)
- Scholarly synthesis and implications: Explain what the result about the weighted finite-record EVM definition from paired complex observations and references authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)
- Closing: Conclude by answering “Develop the weighted finite-record EVM definition from paired complex observations and references” using only the demonstrated evidence; state the remaining decisive verification step Source: §7.5 Model 7A: a finite, declared EVM comparison (p. 3744)

V011-C07-DISCUSSION-001. Should the smallest available EVM value be selected as the receiver's headline quality result?

- 01. Moderator, opening proposition: Introduce the exact dispute, "Should the smallest available EVM value be selected as the receiver's headline quality result?" Put this particular dispute to the panel: Should the smallest available EVM value be selected as the receiver's headline quality result. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

- 02. Student A, terminology and scope: Agree the operational meanings of smallest, available, value and receiver, headline, quality in "Should the smallest available EVM value be selected as the receiver's headline quality result"; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of whether the smallest available EVM value be selected as the receiver's headline quality result; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in "Application 7A.7: Evaluate a fitted gain on held-out symbols". A smaller number may follow from a changed denominator, greater fitting freedom or removal of difficult intervals Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether the smallest available

EVM value be selected as the receiver's headline quality result; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §7.9 Application 7A.3: Preserve a DC impairment when fitting only complex gain (p. 3754)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in "Application 7A.7: Evaluate a fitted gain on held-out symbols". A smaller number may follow from a changed denominator, greater fitting freedom or removal of difficult intervals Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Compare the questions answered by fixed-reference, fitted-reference, post-equalization and selected-interval metrics Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving whether the smallest available EVM value be selected as the receiver's headline quality result: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether the smallest available EVM value be selected as the receiver's headline quality result; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §7.9 Application 7A.3: Preserve a DC impairment when fitting only complex gain (p. 3754)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving whether the smallest available

Copyright 2026, James M. Atkinson

EVM value be selected as the receiver's headline quality result: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §7.7 Application 7A.1: Show which error a fitted gain removes (p. 3752)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving whether the smallest available EVM value be selected as the receiver's headline quality result, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §7.13 Application 7A.7: Evaluate a fitted gain on held-out symbols (p. 3758)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving whether the smallest available EVM value be selected as the receiver's headline quality result: specify the altered receiver state or source condition, predicted change, test statistic and rejection

what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Metric Validation and Held-Out Data”. A pass can strengthen confidence in a particular decoded structure under the tested assumptions, while identity or physical-origin claims need different evidence Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §7.20 Metric Validation and Held-Out Data (p. 3766)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Separate the decoded consistency relation from authentication and localization Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §7.19 Turn a quality metric into a reproducible acceptance record (p. 3764)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §7.19 Turn a quality metric into a reproducible acceptance record (p. 3764)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter: specify

Copyright 2026, James M. Atkinson

the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §7.19 Turn a quality metric into a reproducible acceptance record (p. 3764)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §7.20 Metric Validation and Held-Out Data (p. 3766)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or

Copyright 2026, James M. Atkinson

reject the conclusion. Source: §7.19 Turn a quality metric into a reproducible acceptance record (p. 3764)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter. Discuss replay, relaying, spoofed fields and common-format reuse as possibilities only where relevant, without claiming that they occurred Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §7.20 Metric Validation and Held-Out Data (p. 3766)

Copyright 2026, James M. Atkinson

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter. Discuss replay, relaying, spoofed fields and common-format reuse as possibilities only where relevant, without claiming that they occurred Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §7.18 Defensive Interpretation of Digital Signals (p. 3763)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about whether a passed CRC permit an analyst to attribute a frame to a specific physical emitter and Separate the decoded consistency relation from authentication and localization; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §7.22.10 Application 7B.10. Preserve discrete coding alternatives rather than inventing a single payload rate (p. 3791)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “whether a passed CRC permit an analyst

V011-C07-DISCUSSION-021. Should a deterministic rate enclosure be reported with a confidence percentage?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Should a deterministic rate enclosure be reported with a confidence percentage?” Put this particular dispute to the panel: Should a deterministic rate enclosure be reported with a confidence percentage. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §7.22.9 Application 7B.9. Propagate a positive timing enclosure through an exact count (p. 3790)

- 02. Student A, terminology and scope: Agree the operational meanings of deterministic, rate, enclosure and reported, confidence, percentage in “Should a deterministic rate enclosure be reported with a confidence percentage”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §7.22.9 Application 7B.9. Propagate a positive timing enclosure through an exact count (p. 3790)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of whether a deterministic rate enclosure be reported with a confidence percentage; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval (p. 3782)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Application 7B.4. Distinguish active-burst rate from rate over the full interval”. Exact count divided by a positive duration enclosure yields endpoint bounds, but no coverage probability follows without a justified uncertainty or statistical construction Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §7.22.4 Application 7B.4. Distinguish active-burst rate from rate over the full interval (p. 3782)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to

Chapter 7 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C07-ESSAY-001 — Start with a finite set of paired observations and references in compatible complex-amplitude units. Subtract each reference from its observation, square the complex magnitude, multiply by a fixed nonnegative dimensionless weight and sum. Divide by the correspondingly weighted reference-energy sum, which must be strictly positive, and take the square root. The result is dimensionless; percentage reporting multiplies it by one hundred. For positive EVM, use twenty times its base-ten logarithm, equivalently ten times the logarithm of the energy ratio. Zero residual energy gives zero linear EVM and a negative-infinity decibel limit, not a finite logarithm. A zero denominator leaves the metric undefined. Zero weights remove those pairs from the effective population, so the selection and its reason belong to the result. The formula is a deterministic description of the disclosed record. It supplies neither a probability distribution nor an error-rate prediction without additional justified models. Review: Model 7A; Equations 13A–13C and 13J.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Equation 13A. Finite reference energy and admissible weights; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13C. Percent and decibel reporting; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-002 — Write the training objective as the weighted sum of squared magnitudes of observation minus a times ideal reference. Define C as the weighted sum of observation times conjugated reference, and $E_{\mathrm{s},T}$ as the weighted ideal-reference energy. Expansion gives observation energy minus twice the real part of $a^{*}C$ plus $|a|^{2}E_{\mathrm{s},T}$. Completing the square gives observation energy minus $\frac{|C|^{2}}{E_{\mathrm{s},T}}$ plus $E_{\mathrm{s},T}\left|a-\frac{C}{E_{\mathrm{s},T}}\right|^{2}$. When $E_{\mathrm{s},T}$ is positive, the last term is nonnegative and vanishes uniquely at $a=\frac{C}{E_{\mathrm{s},T}}$.

Conjugating the observation instead would generally reverse the fitted phase and would not minimize the stated objective. The estimator minimizes the training numerator. If a fitted reference also supplies the normalization, its energy depends on the coefficient; a smaller numerator therefore need not produce a smaller normalized EVM. A zero fitted coefficient can be the unique least-squares answer while making that fitted-reference EVM undefined. Evaluation on excluded data is a separate calculation. Review: Equations 13D–13F.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-003 — The residuals are $(0.1+j0.05, -0.05+j0.2, -0.2+j0.1, 0.1-j0.1)$. Their weighted squared magnitudes are 0.0125, 0.085, 0.05 and 0.01, totaling 0.1575. Weighted reference energy is $1+2+4+2=9$, so fixed-reference EVM is the square root of $\frac{0.1575}{9}$, or approximately 13.228757 percent. The weighted observation-reference correlation is $9.2+j0.45$, giving fitted gain $1.022222+j0.05$. Weighted observation energy is 9.5575; subtracting $\frac{|9.2+j0.45|^2}{9}$ yields minimized residual energy approximately 0.13055556. These quantities use the stated finite weights, which are not sample probabilities. If a fitted-reference EVM is also reported, its denominator must use the squared magnitude of this nonzero fitted coefficient times nine. Do not silently retain the old denominator while giving the result the fitted-reference name. Neither fit nor finite sum establishes a physical cause or a confidence interval. Review: Equations 13B, 13D–13F; Application 7A.10.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-004 — The fixed residuals are zero and minus one. Their energy is one and the reference energy is two, giving fixed-reference EVM approximately 70.710678 percent. The correlation is one, so the fitted gain is 0.5. The fitted residuals are 0.5 and -0.5, reducing the residual-energy sum from one to 0.5. However, the fitted references are both 0.5 and their total energy is also 0.5. The fitted-reference EVM is therefore 100 percent. No optimization failure has occurred: the fit minimized residual energy, while the reported ratio also changed its denominator. This is an in-sample demonstration, not held-out validation. State both energy sums, the fitted coefficient and the allowed correction when comparing the results. The zero observation also does not, by itself, identify a dropout mechanism; the example supplies numerical observations without a physical fault history. Review: Equations 13D–13F; normalization distinction after Equation 13F.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-005 — The training correlation is 2.2 and its ideal energy is two, so the fitted gain is 1.1 and the training residual is zero. On the evaluation set, the fixed references agree exactly with the observations, giving zero fixed-reference EVM. The fitted references are -1.1 and $-j1.1$; each residual has magnitude 0.1. The evaluation numerator is therefore 0.02 and the fitted-reference denominator is 2 times 1.1 squared, or 2.42. Their square-root ratio is approximately 9.090909 percent. A zero training residual did not guarantee useful transfer to the excluded symbols. The example is deliberately deterministic and supplies no distribution from which to estimate a general failure probability. Separating training and evaluation prevents direct reuse of those evaluation pairs for this fit, but does not establish statistical independence, correct reference generation or common physical conditions. Those premises need their own evidence. Review: Equation 13F; Application 7A.7.

Review: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.7: Evaluate a fitted gain on held-out symbols.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-006 — The references have unit energy, zero sum and zero sum of complex squares. The offset contribution to the gain correlation vanishes because the conjugated references sum to zero; the conjugate-leakage contribution also vanishes because their conjugate squares sum to zero. The ordinary fitted gain therefore remains one. Each residual is the offset d plus β multiplied by the conjugated reference. Summing its squared magnitude eliminates the cross terms on this balanced set, giving average residual energy $|d|^2+|\beta|^2=0.0025+0.0036=0.0061$. Unit average reference energy gives EVM approximately 7.810250 percent. The residual mean retains d, while the direction-dependent component retains the conjugate relationship. The scalar discards that distinction: a different impairment can have the same aggregate energy. An offset-removal or direct-plus-conjugate fit would add parameters and change the declared measurement. The constructed coefficients are supplied premises, not an inference that a similarly sized unknown EVM has those causes. Review: Equation 13I; Applications 7A.3–7A.4.

Review: Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain; Chapter 7 — Application 7A.4: Expose a conjugate-image impairment.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-007 — Subtract the unrotated reference from its rotated observation. The common reference magnitude factors out of the residual-to-reference ratio, leaving $|\exp(j\theta)-1|$. Multiplying by a unit-magnitude half-angle factor or using the cosine identity gives $2\left|\sin\left(\frac{\theta}{2}\right)\right|$. At 30 degrees, the exact linear value is approximately 0.51763809, or 51.763809 percent. The small-angle approximation uses θ in radians, giving $\frac{\pi}{6}$, or approximately 52.359878 percent. Its excess is about 0.596069 percentage points, so it should not be treated as exact at this angle. EVM is not limited to 100 percent; a 180-degree reversal reaches 200 percent under the same fixed-reference convention. Permitting a constant phase fit could remove the stipulated rotation entirely. That result would assess the residual after the allowed correction, while the fitted phase would remain evidence of the original alignment discrepancy. Review: Equation 13H; Application 7A.2.

Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Application 7A.2: Quantify a fixed phase error.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-008 — The selected reference-energy sum is six times two plus two times eighteen, or 48; with eight equal weights, its mean is six. Each residual has energy 0.02, so reference-RMS EVM is the square root of $\frac{0.02}{6}$, approximately 5.773503 percent. The declared square-16QAM maximum energy is eighteen, giving constellation-maximum EVM approximately 3.333333 percent. Substituting the full-alphabet mean energy ten would give approximately 4.472136 percent, which is a different denominator from the realized selected record. The correct answer must preserve the supplied symbol multiplicities rather than assume uniform use of every constellation point. The two legitimate normalization results describe the same residual under distinct conventions; the smaller value does not indicate a cleaner waveform. None of these calculations estimates symbol probabilities or changes the permitted synchronization and correction policy. Review: Equation 13G; Application 7A.5.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Application 7A.5: Compare RMS and constellation-maximum normalization.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-009 — The equal-weight residual-energy sum is $0.0625+0.0225+0.0025+0.0025=0.09$. Dividing by four and taking the square root gives 15 percent. The last two symbols alone have energy sum 0.005 and reference energy two, giving 5 percent. With the stated weights, the numerator is $0.0125+0.0045+0.0025+0.0025=0.022$ and the denominator is 2.4, giving approximately 9.574271 percent. These are three defined populations or emphases, not three physical improvements to the same observations. If acquisition is excluded from the settled metric, preserve its duration, attempted captures, errors and selection rule. Choosing weights after looking for a favorable result must be disclosed as a different exploratory procedure. The four fixed magnitudes supply no sampling distribution, and a clean settled subset cannot establish that the receiver characterized the entire burst. Review: Equation 13J; Application 7A.6; acquisition record.

Review: Chapter 7 — Equation 13J. Residual sums for a disclosed selection; Chapter 7 — Application 7A.6: Make selection and weighting visible.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-010 — Convert the percentages to linear values before reconstructing residual energies. The first block contributes 40 times 0.05 squared, or 0.1; the second contributes 160 times 0.15 squared, or 3.6. The combined energy ratio is $\frac{3.7}{200}$, giving pooled EVM approximately 13.601471 percent. Averaging the two percentages would give 10 percent and would not reproduce the finite pooled energy ratio. The weighting is by reference energy, not merely block count or duration. If each block has its own fitted gain, their sums can still describe a declared piecewise-corrected record, but that record is not automatically equivalent to one common-gain experiment. A common fit must be estimated from its declared training population and evaluated consistently. Preserve the coefficients and denominator conventions before claiming a single whole-record measure. Review: Equations 13B, 13D–13F and 13J.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Equation 13J. Residual sums for a disclosed selection.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-011 — The three observed phasors sum to two, so the correlation is two and the ideal-reference energy is three. The fitted constant gain is therefore $\frac{2}{3}$ with zero imaginary part. The fixed residual energies are one, zero and one, giving fixed-reference EVM equal to the square root of $\frac{2}{3}$, approximately 81.649658 percent. Observation energy is three; the minimized residual energy is $3-\frac{4}{3}=\frac{5}{3}$. The fitted-reference energy is $\left(\frac{2}{3}\right)$ squared times three, or $\frac{4}{3}$, giving fitted-reference EVM equal to the square root of $\frac{5}{4}$, approximately 111.803399 percent. Symmetric phase contributions cancel in the imaginary part of their mean, despite the persistent phase ramp. A phase advance of 60 degrees per symbol corresponds to one sixth of the symbol rate in this constructed unwrapped interpretation. A separate frequency estimator would add a model and would need validation; the present results are in-sample diagnostics. Review: Equations 13D–13F; Application 7A.8.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-012 — Every reference has energy two, so their sum is eight and reference RMS magnitude is the square root of two. Residual energies are 0.0025, zero, 0.01 and zero, totaling 0.0125. RMS EVM is the square root of $\frac{0.0125}{8}$, approximately 3.952847 percent. The largest residual has magnitude 0.1, so its normalization by reference RMS gives approximately 7.071068 percent. The third symbol supplies $\frac{0.01}{0.0125}=0.8$, or 80 percent of the residual energy. The peak and concentration identify features hidden by the average, without contradicting it. Four disclosed deterministic pairs are sufficient to reproduce these arithmetic statements, but provide no asserted random sampling scheme, repeated-trial model or confidence procedure. Any uncertainty claim must identify its actual sources and coverage construction instead of attaching an unsupported probability to this finite record. Review: Equations 13B and 13J; Application 7A.10.

Review: Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13J. Residual sums for a disclosed selection; Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-013 — Begin with disclosed complex vectors whose squared distances and reference energies can be calculated independently, including a nonzero fit, a zero residual and an inadmissible zero denominator. This checks arithmetic and domain handling. Then use a known sequence with an imposed timing displacement and a separately known symbol rate to challenge sample selection and clock metadata. A deliberately rotated mapping tests whether label ambiguity survives a tight constellation. Preserve the training interval and apply fixed fitted parameters to excluded data to test transfer. Noise-only and wrong-format records challenge false structure, with the number of attempts and exclusions recorded. A second implementation of the same sum can detect coding mistakes, but agreement under a shared wrong reference or timing estimate does not validate those premises. Report the actual outcomes and coverage of each challenge; a planned validation sequence is not evidence that the checks have passed. Review: Metric Validation and Held-Out Data; reproducible acceptance record.

Review: Chapter 7 — Metric Validation and Held-Out Data; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-014 — The observations show that the selected parameterization fits the training record better but transfers less well under the stated evaluation. Check that the evaluation uses fixed coefficients, compatible reference normalization and an interval excluded from fitting; otherwise the two values may describe different experiments. Retain pre-equalization and post-equalization residuals, tap count, training length, regularization, convergence state and adaptation policy. Reduce or challenge model flexibility only against declared criteria, then test the revised model on data not used for that choice. Known-signal and bypass comparisons can separate processing dependence from physical-path effects. The training improvement can arise from fitting noise, nonstationary behavior or a wrong reconstruction premise, so it does not uniquely locate an impairment. A defensible conclusion identifies dependence on the compensation and the limits of demonstrated transfer while leaving unresolved causes explicit. Review: Matched Filtering, Pulse Shaping, and Channel Effects; Model 7A training and evaluation.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-015 — The stated matched-filter benefit assumes the relevant known pulse and additive white Gaussian noise, with the timing and channel relationship required for the comparison. It is not a universal claim that any filter carrying that label is optimal in an unknown channel or colored interference. Specify coefficients or a reproducible generation convention, roll-off, span, sample rate, scaling, delay, initialization and treatment of unavailable samples at the record edges. Confirm the same symbol decision instants and reference construction with a known sequence. Two truncated realizations can differ around transitions and boundaries even when their family names agree. If equalization follows, preserve its coefficients and permitted role separately. For reception quality, compensation may be useful; for the original path condition, its effects must remain visible in pre-compensation results. The comparison should reproduce the declared experiment rather than choose whichever implementation yields the smallest displayed EVM. Review: Matched Filtering, Pulse Shaping, and Channel Effects; definition of the symbol experiment.

Review: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects; Chapter 7 — Define the symbol experiment before fitting the constellation.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-016 — The slot rate is $\frac{20{,}000}{0.020} = 1{,}000{,}000$ slots per second. The data-slot fraction is $\frac{16{,}000}{20{,}000} = 0.8$. Coded label bits total 16,000 times four, or 64,000; the 0.75 complete-block code rate gives 48,000 input-information bits. Payload-bit fraction is $\frac{36{,}000}{48{,}000} = 0.75$. Multiplying slot rate, four label bits, code rate 0.75, data-slot fraction 0.8 and payload-bit fraction 0.75 gives 1.8 Mbit/s, matching $\frac{36{,}000}{0.020}$ directly. The combined noncoding efficiency is 0.8 times 0.75, or 0.6. If that combined factor is used and the data-slot reduction is then applied again, the erroneous result becomes 1.44 Mbit/s. Keep count populations and reductions separate; the stipulated values are not measured uncertainties or inferred format properties. The numerator counts represented payload instances and has not established unique successful delivery. Review: Equations 14A–14B; Application 7B.2.

Review: Chapter 7 — Equation 14A. Count the distinct bit and slot populations; Chapter 7 — Equation 14B. Forward rate and the positive-target inverse; Chapter 7 — Application 7B.2. Separate two overhead populations without counting either twice.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-017 — The burst carries 20,000 coded bits, 16,000 input-information bits and 14,400 payload bits. Five thousand symbols at 5 Msymbol/s occupy 1 ms, giving an active-interval payload rate of 14.4 Mbit/s. Including the supplied 0.2 ms guard gives a total interval of 1.2 ms and payload rate 12 Mbit/s. A deliberately continued nominal grid at the active clock would contain 6,000 opportunities over that interval, with data-slot fraction $\frac{5{,}000}{6{,}000}=\frac{5}{6}$; the complete rate product then gives the same 12 Mbit/s. This is a stated accounting convention, not evidence that physical symbols were transmitted during the guard. The wall-interval average of transmitted data-symbol instances is $\frac{5{,}000}{0.0012}$, which differs from the active clock. Do not reduce for the guard both in the duration and again through a redundant efficiency. Actual acquisition success and unique delivery require separate observations. Review: Equations 14A–14B; Application 7B.4.

Review: Chapter 7 — Equation 14A. Count the distinct bit and slot populations; Chapter 7 — Equation 14B. Forward rate and the positive-target inverse; Chapter 7 — Application 7B.4. Distinguish active-burst rate from rate over the full interval.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-018 — The first mode represents 1 Mbit/s and contributes 2 Mbit over two seconds. The second represents 4 Mbit/s and contributes 4 Mbit over one second. Total payload is therefore 6 Mbit in three seconds, giving 2 Mbit/s. The duration-weighted mean label-bit count is $\frac{2\times 2+1\times 6}{3}=\frac{10}{3}$. The duration-weighted mean code rate is $\frac{2\times 0.5+1\times \frac{2}{3}}{3}=\frac{5}{9}$. Multiplying those separate means by 1 Msymbol/s gives $\frac{50}{27}\ \mathrm{Mbit/s}$, approximately 1.851852 Mbit/s, which is incorrect. The factors change jointly, so average their realized products through interval counts. The result uses the stipulated durations and complete-block rates, with no additional transition cost or other overhead. It does not license treating an unobserved mode distribution as a probability model. Review: Equation 14C; Application 7B.5.

Review: Chapter 7 — Equation 14C. Combine counts before dividing by time; Chapter 7 — Application 7B.5. Weight changing modes by their actual durations.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-019 — One frame uses 1,240 input-information bits, 1,550 coded bits and 775 symbols. The ceiling of $\frac{5{,}000}{1{,}200}$ requires five complete frames. They provide 6,000 payload positions, so 1,000 positions are padding and the final frame carries 200 original request bits. Five frames use 3,875 symbols and take $\frac{3{,}875}{2{,}500{,}000} = 0.00155$ seconds. Actual request-payload rate is $\frac{5{,}000}{0.00155}$, approximately 3.225806 Mbit/s. The repeating full-frame capacity rate is 1,200 times $\frac{2{,}500{,}000}{775}$, approximately 3.870968 Mbit/s. The request spans 6,200 input-information bits, so its realized payload-bit fraction is $\frac{5{,}000}{6{,}200}$, approximately 0.80645161. The capacity result assumes every payload position is useful; it must not count the padded final positions as request data. These complete-frame counts are exact stipulations, with no unspecified gaps or retransmissions inserted. Review: Equation 14D; Application 7B.7.

Review: Chapter 7 — Equation 14D. Retain the integer frame boundary; Chapter 7 — Application 7B.7. Retain integer frames and last-frame padding.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-020 — Rate is the fixed count divided by positive duration, so its minimum uses 20.02 ms and its maximum uses 19.98 ms. The exact bounds are approximately 1,998,001.998 and 2,002,002.002 bit/s. The central 20 ms value is 2,000,000 bit/s. Its departures are therefore about $-1{,}998.002$ and $+2{,}002.002\ \text{bit/s}$, slightly asymmetric. Linearizing the reciprocal at 20 ms gives a magnitude of 40,000 times 0.00002 divided by 0.020 squared, or 2,000 bit/s, which is an approximation rather than the exact endpoint result. The supplied enclosure assigns no probability distribution or coverage level. If the payload count, population boundary or format is also uncertain, the premises of this one-variable bound change and those effects must be assessed explicitly. Do not import an unreported timer accuracy or treat the nominal center as a measured unbiased estimate. Review: Equation 14E; Application 7B.9.

Review: Chapter 7 — Equation 14E. Bound a rate with an exact count and uncertain positive duration; Chapter 7 — Application 7B.9. Propagate a positive timing enclosure through an exact count.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-021 — Before code and payload-bit reductions, the product is 1.5 times four times 0.75, or 4.5 Mbit/s. Code rate 0.5 gives the interval from 4.5 times 0.5 times 0.8 to 4.5 times 0.5, namely 1.8 to 2.25 Mbit/s. Code rate 0.8 gives 2.88 to 3.6 Mbit/s. The admissible set is the union of those two closed intervals. The proposed 2.6 Mbit/s lies in their gap and is not represented by any stipulated alternative, even though it falls inside the coarser enclosure from 1.8 to 3.6 Mbit/s. A mean code rate would invent an unsupported intermediate configuration unless an actual time-sharing schedule were supplied and accounted for separately. The interval premise allows the payload fraction independently across the stated range; a dependence constraint would require a narrower admissible set. No probabilities are assigned to the two formats. Review: Equations 14B and 14C; Application 7B.10.

Review: Chapter 7 — Equation 14B. Forward rate and the positive-target inverse; Chapter 7 — Equation 14C. Combine counts before dividing by time; Chapter 7 — Application 7B.10. Preserve discrete coding alternatives rather than inventing a single payload rate.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-022 — Adding stream instances gives 1,600,000 accepted instances over half a second, or 3.2 Mbit/s. For unique positions, apply inclusion and exclusion to the stated identity sets: 900,000 plus 700,000 minus 250,000 equals 1,350,000 positions, giving 2.7 Mbit/s. The overlap is defined by common payload identities, not by equal binary values or similar waveforms. If only the two stream counts are known, overlap can range from zero to 700,000 under the supplied no-internal-duplicates premise. Unique counts then range from 900,000 to 1,600,000, giving 1.8 to 3.2 Mbit/s. A narrower result requires evidence of the common positions. Time bases and acceptance rules must match before aggregation. The finite accepted-position count still does not identify the original emitter or establish that every intended request bit was delivered. Review: Equation 14C; Application 7B.6.

Review: Chapter 7 — Equation 14C. Combine counts before dividing by time; Chapter 7 — Application 7B.6. Remove duplicate payload before reporting unique throughput.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-023 — First compare the exact paired symbol population, permitted corrections, reference reconstruction and denominator. The cited implementation documents a choice between reference-RMS and constellation-maximum normalization, and warns that trace normalization can differ from error-summary normalization. Particular formats can also use special sampling or normalization rules, so retain the selected mode and documented software scope. Recalculate the chapter's finite numerator and denominator from the exported pairs, then reproduce the implementation convention only where its actual rules and exported data support that reconstruction. A shared capture filename or percent unit does not establish equivalent experiments. Avoid converting one threshold using a generic constellation factor when the selected reference population or a special format changes that factor. State the implementation version or help edition actually inspected and the bounded sections used. A documented difference can explain the discrepancy without establishing which convention answers the user's measurement question. Review: Equation 13G; cited EVM Normalization Reference and EVM (Digital Demod) help.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Model 7A: a finite, declared EVM comparison.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-024 — Keep the raw waveform observation separate from algorithmic synchronization, decoded fields and any external source claim. Record decoder version, format assumptions, search alternatives, attempted intervals, exclusions and the actual checks performed. The noise-only control demonstrates that the tested process can produce false structure; it does not establish that every original candidate has that origin or that no signal exists. Recheck candidates with independently justified timing, reference structure and validation rules, and preserve failures as well as apparent successes. A CRC pass supports a consistency relation but is not cryptographic authentication or physical localization. Without a declared trial model, dependence structure and relevant null behavior, the rarity of a few outputs cannot be converted into a numerical false-alarm probability. Further content recovery, retention and reporting must remain within the engagement authority. Report the narrowest supported finding and the unresolved alternatives. Review: Defensive Interpretation of Digital Signals; Hypothetical Case Adjudication.

Review: Chapter 7 — Defensive Interpretation of Digital Signals; Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

Copyright 2026, James M. Atkinson

V011-C07-ESSAY-025 — Bind the sample segment and timing metadata to its reference sequence, mapping, processing version, filters, synchronization estimates, weights, training and evaluation sets, allowed corrections and residuals. Retain the fitted coefficients and both EVM energy sums so the scalar can be reconstructed. For rate accounting, record the positive time interval, slot convention, data symbols, coded bits, complete-block information bits, payload instances, exclusions and any identified duplicate positions. Derive rates from those common counts and distinguish full-frame capacity from actual request data. Preserve acquisition attempts, failures, lock gaps and reasons for omitted intervals alongside successful metrics. A low residual tests the declared symbol comparison; a rate identity tests internally consistent populations and time. Neither supplies source attribution, proof of every interval's validity or evidence that repeated payload instances are unique delivery. Add independent known-signal, bypass, timing and authorized device-state checks where those broader claims are required, and state their actual scope. Review: Reproducible acceptance record; Models 7A–7B.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

Discussion Guidance

V011-C07-DISCUSSION-001 — Compare the questions answered by fixed-reference, fitted-reference, post-equalization and selected-interval metrics. A smaller number may follow from a changed denominator, greater fitting freedom or removal of difficult intervals. The group should agree on the measurement purpose before selecting the primary result, then retain the permitted correction policy, coefficients and population. A useful report can include several clearly defined metrics when each supports a different decision. Reject an unqualified ranking based solely on the smallest percentage, while recognizing that an appropriately compensated metric can be the relevant reception measure. Review: Model 7A; Equations 13B–13G.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Equation 13B. Weighted fixed-reference error vector magnitude; Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization.

V011-C07-DISCUSSION-002 — Distinguish the nonnegative linear magnitude ratio from its logarithmic representation. Ratios below one have negative decibel values under twenty times the base-ten logarithm. Changing the sign would define another reported quantity and reverse the stated convention. Show one disclosed conversion and check whether the reviewer actually expects a reciprocal measure such as a differently defined quality ratio. Agree on the metric name and convention before changing labels. Also distinguish zero linear EVM from a finite display floor, and avoid treating a minus sign as evidence of a physically negative error energy. Review: Equation 13C.

Review: Chapter 7 — Equation 13C. Percent and decibel reporting.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-003 — Relate the fit to the intended measurand. Removing a constant gain and phase offset may be appropriate for residual modulation quality after alignment; it can conceal a discrepancy when absolute amplitude or phase calibration is the question. Keep the fitted coefficient visible and specify its training set, allowed complexity and evaluation use. Discuss whether a fixed reference, a fitted reference or both should normalize the reported result. A fit is justified by the declared purpose and validation, not by its ability to improve the display. Review: Equations 13D–13F; Applications 7A.1–7A.2.

Review: Chapter 7 — Equation 13D. Optional complex-gain fit on a training set; Chapter 7 — Equation 13E. Least-squares completion of the square; Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Application 7A.1: Show which error a fitted gain removes; Chapter 7 — Application 7A.2: Quantify a fixed phase error.

V011-C07-DISCUSSION-004 — State exactly what has been excluded from fitting and parameter selection. Holding out symbol pairs avoids direct fitting on those pairs for the declared estimator, but shared clock metadata, reference construction, signal conditions and later tuning can preserve dependence. If results from the held-out interval guide another parameter choice, its role has changed and another evaluation strategy may be needed. The discussion should distinguish a procedural holdout from statistical independence and independent physical validation. Record the actual sequence of choices rather than use the word independent as a blanket guarantee. Review: Equation 13F; Metric Validation and Held-Out Data.

Review: Chapter 7 — Equation 13F. Held-out evaluation with a nonzero fitted reference; Chapter 7 — Metric Validation and Held-Out Data.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-005 — Inspect the residual vector and its association with symbol identity and time. A common offset can appear in the residual mean; a conjugate term can vary with the conjugated reference; a frequency ramp can produce ordered phase progression. Those patterns guide hypotheses but do not alone prove their physical origin. Check permitted fits, population balance and whether preprocessing removed the feature. Propose known-reference or bypass challenges that test different mechanisms. Equal scalar energy is compatible with several structures, so the report should avoid assigning a unique cause from the shared EVM. Review: Equations 13H–13J; Applications 7A.3–7A.4 and 7A.8.

Review: Chapter 7 — Equation 13H. Fixed gain and phase impairments; Chapter 7 — Equation 13I. Balanced-reference offset and conjugate terms; Chapter 7 — Equation 13J. Residual sums for a disclosed selection; Chapter 7 — Application 7A.3: Preserve a DC impairment when fitting only complex gain; Chapter 7 — Application 7A.4: Expose a conjugate-image impairment; Chapter 7 — Application 7A.8: Keep a residual frequency rotation in a finite symbol record.

V011-C07-DISCUSSION-006 — Consider whether the decision concerns settled payload quality, burst capture success or the complete event. Exclusion can define a useful steady-state result, but acquisition duration, errors and failures remain relevant to the broader task. Specify the selection criterion before judging the result and retain enough information to reconstruct complete-record and conditional metrics where needed. Discuss how a burst that ends before usable lock should enter the record. The choice should answer a stated question, with no implication that omitted intervals were successfully characterized. Review: Application 7A.6; acquisition and tracking record.

Review: Chapter 7 — Application 7A.6: Make selection and weighting visible.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-007 — Audit reference construction, selected symbol locations, allowed corrections, weighting, timing, normalization and implementation scope. The same format label can coexist with different summary and trace conventions or special handling for a particular mode. Determine whether exported paired symbols permit a common recalculation; if not, describe the unresolved comparison limit. A declared conversion is useful only when its denominator assumptions actually apply to the selected records. The group should decide what evidence is sufficient for a threshold comparison, rather than infer equivalence from the label and percent sign. Review: Equation 13G; cited implementation help.

Review: Chapter 7 — Equation 13G. Average-reference and maximum-reference normalization; Chapter 7 — Model 7A: a finite, declared EVM comparison.

V011-C07-DISCUSSION-008 — Ask whether isolated errors matter to the decision and define the peak's population and normalization if it is reported. A largest residual can expose a feature that a long RMS aggregate dilutes, but it does not replace the energy measure or identify the fault mechanism. Retain the time location and surrounding data so a transient can be examined against acquisition, filtering and continuity records. Discuss susceptibility to record length and selection. Avoid an undocumented combined score; each supplementary statistic should have a clear purpose and reproducible definition. Review: Application 7A.10; residual selection.

Review: Chapter 7 — Application 7A.10: Audit a complete finite residual vector.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-009 — Separate arithmetic agreement from validation of shared premises. Tools can reproduce the same finite sum correctly while using the same wrong reference, clock metadata, mapping or synchronization estimate. Identify a known-input challenge that would fail under the suspected common error, and retain its actual outcome. Compare intermediate residuals and energy sums to localize arithmetic differences when they exist. Agreement is useful evidence within its scope; the group should state which dependencies remain common before calling the overall result independently verified. Review: Reproducible acceptance record; Metric Validation and Held-Out Data.

Review: Chapter 7 — Metric Validation and Held-Out Data; Chapter 7 — Turn a quality metric into a reproducible acceptance record.

V011-C07-DISCUSSION-010 — Define the intended compensation and inspect performance on data excluded from selecting and fitting the model. Retain coefficient count, regularization, training duration, convergence and adaptation policy, along with pre-compensation results when the original path matters. A stable improvement under appropriate challenges can support the chosen processing, but visual tightness alone cannot establish transfer or locate distortion. Discuss whether the additional parameters answer the engineering question and whether their effect remains reproducible. Avoid selecting flexibility solely because it produces the lowest training residual. Review: Matched Filtering, Pulse Shaping, and Channel Effects.

Review: Chapter 7 — Matched Filtering, Pulse Shaping, and Channel Effects.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-011 — Compare the event duration with the acquisition history and the actual symbols included in the metric. A later settled result may describe a different interval and cannot retroactively establish valid synchronization during the transient. Preserve lock indicators, timing estimates, excluded samples and any independent waveform evidence from the early interval. Discuss whether a known repeated event or a separately validated acquisition method can answer the original question. Report what was measured successfully while leaving the uncharacterized interval explicit. Review: Carrier and Timing Synchronization; acquisition record.

Review: Chapter 7 — Carrier and Timing Synchronization.

V011-C07-DISCUSSION-012 — Compare actual coefficients, span, delay, sample-rate convention, scaling and initialization before attributing the difference to the signal. Boundary handling can differ when prior or future samples are unavailable, even with the same filter-family name. Use a known sequence with disclosed history to test the implementations, and define any excluded edge interval before evaluating quality. The discussion should distinguish an implementation mismatch from a legitimate difference in the declared finite-record experiment. Preserve the choice in the acceptance record rather than trimming until the values agree. Review: Definition of the symbol experiment; filter-history treatment.

Review: Chapter 7 — Define the symbol experiment before fitting the constellation.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-013 — It demonstrates a false-output mechanism for the tested processing and control conditions. It does not prove that every candidate from the original capture was false or that the band contained no communication signal. Preserve trial counts, format searches, checks and failed outputs so apparent rarity is not overstated. Discuss further known-reference and independent validation challenges appropriate to the authorized task. A useful conclusion can reject an unvalidated identification while retaining valid waveform observations and unresolved alternatives. Review: Hypothetical Case Adjudication.

Review: Chapter 7 — Hypothetical Case Adjudication: Digital Modulation Reception, Synchronization, EVM, and Error Metrics.

V011-C07-DISCUSSION-014 — Separate the decoded consistency relation from authentication and localization. A pass can strengthen confidence in a particular decoded structure under the tested assumptions, while identity or physical-origin claims need different evidence. Discuss replay, relaying, spoofed fields and common-format reuse as possibilities only where relevant, without claiming that they occurred. State which checks actually ran and whether cryptographic or physical validation was performed. Keep the permitted level of metadata recovery and retention tied to the engagement authority. Review: Defensive Interpretation of Digital Signals.

Review: Chapter 7 — Defensive Interpretation of Digital Signals.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-015 — Technical capability and task authority answer different questions. Review the agreed acquisition, processing, retention and reporting scope before expanding from waveform classification to content. A valid EVM or plausible decoder output does not supply missing authorization. The discussion should identify a useful result that can be reported within the current scope and what additional authority would be required for any proposed expansion. Avoid introducing speculative legal conclusions; apply the actual engagement boundary and retain only the information needed for the approved technical purpose. Review: Defensive Interpretation of Digital Signals.

Review: Chapter 7 — Defensive Interpretation of Digital Signals.

V011-C07-DISCUSSION-016 — Each count supports a different reduction and denominator. A pilot consumes a slot, coding adds label-bit redundancy, headers consume information-bit capacity and repeated payload can add instances without adding unique content. Reconstruct the count chain for a concrete complete interval and check that every ratio uses its own population. Discuss how a combined efficiency can be valid when its components are explicit, and how applying a component again creates double counting. The separation also exposes zero-denominator cases and prevents an observed constellation from supplying unknown code or framing assumptions. Review: Equation 14A; Applications 7B.1–7B.3.

Review: Chapter 7 — Equation 14A. Count the distinct bit and slot populations; Chapter 7 — Application 7B.1. Reconcile coded bits, information bits and modulation symbols; Chapter 7 — Application 7B.2. Separate two overhead populations without counting either twice; Chapter 7 — Application 7B.3. Count disjoint pilot and nonpayload slots explicitly.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-017 — Both can be useful when clearly named. The active clock describes symbol spacing during transmission; the wall-interval payload rate includes the declared guards, idle periods or other elapsed time. Define the numerator, interval and any nominal opportunity grid, then calculate the relationship from common counts. Discuss which quantity answers the user's performance question and why one cannot be substituted for the other. A continued accounting grid through a guard does not assert that physical symbols were transmitted there. Review: Application 7B.4.

Review: Chapter 7 — Application 7B.4. Distinguish active-burst rate from rate over the full interval.

V011-C07-DISCUSSION-018 — Check how the two factors vary together and how long each realized mode persists. The aggregate payload rate follows total counts divided by total elapsed time; separate averages can destroy the joint relationship and give the wrong result. A distribution or schedule may summarize the modes only when it is actually known and its weighting is stated. Discuss transitions, overhead and incomplete blocks if they belong to the interval. Do not invent intermediate formats or probabilities from an unqualified mean. Review: Equation 14C; Application 7B.5.

Review: Chapter 7 — Equation 14C. Combine counts before dividing by time; Chapter 7 — Application 7B.5. Weight changing modes by their actual durations.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-019 — Use the actual frame rules to count whole frames, headers and final padding. A request that does not fill the final frame can use the same symbol clock and coding correctly while delivering fewer original request bits per elapsed time than a repeating full-frame stream. Preserve both the capacity denominator and the actual request numerator. Discuss whether gaps, retransmissions or failed frames were supplied as evidence before including them. A count difference explained by finite-frame structure does not establish that every implementation detail is correct, but it prevents misclassifying predictable padding as a fault. Review: Equation 14D; Application 7B.7.

Review: Chapter 7 — Equation 14D. Retain the integer frame boundary; Chapter 7 — Application 7B.7. Retain integer frames and last-frame padding.

V011-C07-DISCUSSION-020 — Require compatible elapsed intervals and acceptance definitions, then determine whether the payload identities are disjoint. Equal binary values are not sufficient to establish duplicates, and differing waveforms are not sufficient to establish unique content. If overlap is known, remove repeated identified positions for a unique-count claim; if it is unknown, state bounds or retain the instance-rate label. Discuss internal duplicates separately from cross-stream overlap. The arithmetic aggregation should not imply emitter identity or completion of an intended request that was never checked. Review: Equation 14C; Application 7B.6.

Review: Chapter 7 — Equation 14C. Combine counts before dividing by time; Chapter 7 — Application 7B.6. Remove duplicate payload before reporting unique throughput.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-021 — Identify what the supplied interval means. Exact count divided by a positive duration enclosure yields endpoint bounds, but no coverage probability follows without a justified uncertainty or statistical construction. Compare exact reciprocal bounds with a linear approximation and label the latter's approximation status. Discuss which additional count, boundary or format uncertainties are actually present, rather than adding hypothetical instrument specifications. A transparent enclosure can be useful without claiming a confidence level that the evidence does not support. Review: Equation 14E; Application 7B.9.

Review: Chapter 7 — Equation 14E. Bound a rate with an exact count and uncertain positive duration; Chapter 7 — Application 7B.9. Propagate a positive timing enclosure through an exact count.

V011-C07-DISCUSSION-022 — The broad enclosure preserves the extremes but can include rates that no supplied configuration produces. Retain the union when admissibility or feasibility depends on those gaps, and state any independence or joint constraints among the factors. An actual time-sharing schedule could produce another aggregate rate, but it is new evidence that must be accounted for through counts and durations. Discuss whether the decision only needs a conservative bound or needs the exact feasible set. Do not interpret the empty gap as low probability when no probability model was supplied. Review: Application 7B.10.

Review: Chapter 7 — Application 7B.10. Preserve discrete coding alternatives rather than inventing a single payload rate.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-023 — Unknown and zero represent different premises. A known zero fraction implies no represented payload in the specified population and prevents a finite positive-target inverse through that configuration. An unknown fraction may require an admissible range, additional evidence or an explicitly conditional result. Discuss whether a lower bound alone answers the engineering question and whether an upper feasibility bound remains available from other factors. The report should not convert missing information into a measured absence or use an invented nominal value without labeling the assumption. Review: Model 7B domain; Application 7B.8.

Review: Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload; Chapter 7 — Application 7B.8. Test a positive target against the declared rate limit.

V011-C07-DISCUSSION-024 — The matching digest supports file identity and provenance. It does not establish which inputs were processed, which settings were active, whether execution succeeded or whether the model premises held. Bind the run to its actual data, version, arguments, selected intervals, intermediate counts and residual sums. Then validate the timing, reference, corrections and population boundaries relevant to the result. Discuss an execution record and known-input challenge that would reveal a wrong setup despite a correct file hash. Keep result traceability distinct from the provenance of one software artifact. Review: Reproducible acceptance record; Chapter 1 measurement-chain evidence.

Review: Chapter 7 — Turn a quality metric into a reproducible acceptance record; Chapter 1 — Keep the evidence chain reversible to its declared inputs.

Copyright 2026, James M. Atkinson

V011-C07-DISCUSSION-025 — Report the verified finite comparison and count relationship with their declared scope, including normalization, processing, population and elapsed interval. State that source attribution and unobserved or unsuccessful acquisition intervals remain unresolved, rather than weakening the valid arithmetic or expanding it into a broader claim. Identify the specific additional evidence needed for those questions, such as authorized device-state correlation, a known timing reference or a complete acquisition log. The discussion should produce a usable bounded finding whose wording matches the checks actually completed and preserves the remaining uncertainties. Review: Models 7A–7B; acceptance record and inference limits.

Review: Chapter 7 — Model 7A: a finite, declared EVM comparison; Chapter 7 — Model 7B: finite rate accounting for symbols, coding and payload.

Chapter Glossary

ACQUISITION-CONDITIONED METRIC: A result calculated only on intervals for which the receiver met its declared acquisition or lock criterion. It describes that selected population and must be accompanied by attempted acquisitions, failures and exclusions when the complete event matters. It does not establish uninterrupted reception during omitted intervals.

ACTIVE SYMBOL RATE: The rate of transmitted symbol instances during a declared active interval, determined from their spacing or count under the stated clock convention. It can differ from the average number of transmitted data symbols per second over an interval that also includes guards or idle time. A nominal accounting grid must be identified separately.

ADMISSIBLE RATE SET: The collection of rates permitted by all supplied count, duration and format premises. Discrete alternatives combined with bounded continuous factors can produce a union of separated intervals. Its overall minimum-to-maximum enclosure can include values that no stipulated configuration realizes; neither representation assigns probabilities without additional evidence.

ALIGNMENT TRAINING SET: The disclosed samples or symbols used to estimate the corrections applied before an error-vector evaluation.

CARRIER PHASE AMBIGUITY: An unresolved choice among carrier-phase alignments that can preserve the apparent constellation point set while changing the association between points and intended labels. A tight fitted constellation does not resolve the ambiguity. Known reference structure or another justified check must establish the required mapping.

Copyright 2026, James M. Atkinson

CARRIER SYNCHRONIZATION: The estimation and tracking of the frequency and phase relationship needed to compare an observed modulated signal with its declared carrier reference. Its acquisition range, loop behavior, fitted parameters and slips affect the symbol experiment. Successful numerical alignment does not by itself establish source identity or correct symbol labels.

CEILING FRAME COUNT: The smallest integer number of complete frames whose stated payload capacities can contain a positive request. With fixed positive capacity, it is the request size divided by capacity rounded upward. This rule preserves the complete-frame boundary; multiplying that count by full capacity can include final padding that is not original request payload.

CODED LABEL BIT: A bit position in the specified binary label mapped to a data symbol. A known power-of-two constellation with its declared labeling determines how many such positions belong to each symbol. This count does not by itself specify input-information bits, entropy, delivered unique payload or stored ADC data.

CODE RATE: For the complete-block count convention in Model 7B, the number of input-information bits divided by the corresponding coded label bits. The model scopes this ratio to redundancy-adding coding without compression. It is distinct from framing efficiency and cannot be estimated as a zero-over-zero empirical ratio from an empty record; a configured rate may be known separately.

Copyright 2026, James M. Atkinson

COMPLETE CODE BLOCK: An included input-and-output population whose coding relationship is fully represented for the declared count ratio. Counting only a partial segment can require explicit treatment of boundaries, termination and other coding structure. The chapter's fixed code-rate products assume complete stipulated populations rather than inferring them from a constellation display.

COMPLETE-FRAME PAYLOAD CAPACITY: The number of useful payload positions available in one fully specified frame after the separately declared coding and header conventions. Repeating full frames can achieve a capacity rate different from the actual rate for a finite request whose last frame contains padding. Capacity is not evidence that every position was filled with requested data or delivered successfully.

CONSTANT COMPLEX-GAIN FIT: A weighted least-squares estimate of one complex coefficient that scales and rotates a disclosed ideal-reference sequence. Positive training reference energy makes the minimizer unique. The fit minimizes training residual energy, not every normalized EVM or held-out error, and its coefficient remains part of the result when the correction is permitted.

CONSTELLATION MAPPING: The declared correspondence between symbol labels and complex reference values. A geometric point set alone does not establish this correspondence. Rotation or relabeling can preserve a constellation's appearance while changing the represented labels, so mapping validation is separate from a visually tight or numerically well-aligned display.

Copyright 2026, James M. Atkinson

DATA-SLOT FRACTION: The number of data-symbol slots divided by all nominal opportunities on the explicitly declared finite grid. It accounts for pilot or other nondata opportunities in that grid and differs from a payload-bit fraction. Its denominator must be positive, and any combined efficiency that already includes this reduction must not apply it again.

DECISION INSTANT: The declared time at which an observed, processed waveform sample is paired with a reference symbol for detection or quality assessment. Filtering, delay, symbol-clock configuration and timing recovery determine that pairing. Samples between decision instants are not silently included in a metric whose stated population consists only of symbol points.

DURATION-WEIGHTED AGGREGATION: A rate calculation that adds each interval's represented count and divides the total by the sum of compatible elapsed durations. It preserves the joint modulation, coding and efficiency factors realized within each interval. Separately averaging factors, or assigning equal weight to unequal-duration modes, generally gives a different result.

EQUALIZER: Adaptive or fixed filter used to compensate channel distortion and intersymbol interference.

ERROR VECTOR: The complex difference between an observed symbol value and its paired reference under the declared amplitude, timing and mapping conventions. Its real and imaginary components retain directional information. Squared magnitude contributes to residual energy, while the scalar EVM aggregate discards information about direction, symbol dependence and temporal ordering.

Copyright 2026, James M. Atkinson

ERROR VECTOR MAGNITUDE: Normalized distance between measured and reference modulation symbols after stated processing.

FALSE LOCK: Apparent synchronization to noise or an incorrect structure.

FITTED-REFERENCE EVM: The normalized residual magnitude when the permitted fitted complex gain multiplies the ideal symbols in both the comparison reference and its energy denominator. The fitted coefficient must be nonzero and evaluation reference energy positive. Reducing the residual numerator does not guarantee a smaller ratio if the fitted denominator also falls.

FIXED-REFERENCE EVM: The normalized residual magnitude relative to a declared reference that is not adjusted by fitting the evaluated observation record. It can retain an amplitude or phase discrepancy that an allowed fit would remove. The reference, population, weights and compatible amplitude convention must still be specified; fixed does not mean independently validated.

FRAME PADDING: Unused positions filled under the declared complete-frame rule when a finite request does not occupy all available payload capacity. These positions consume transmitted frame resources but do not add original request bits. Padding must be distinguished from headers, coding redundancy and retransmitted payload to avoid double counting their effects.

HELD-OUT SYMBOL EVALUATION: Error-vector assessment on symbols excluded from fitting the stated alignment parameters.

Copyright 2026, James M. Atkinson

INFORMATION-BIT COUNT: The number of input bits belonging to the complete coding populations included in Model 7B. This count can include payload, headers and padding under the stated framing convention. It is therefore different from both coded label-bit count and useful request-payload count; its interpretation must accompany any code-rate or payload-fraction calculation.

MATCHED FILTER: Filter designed to maximize output signal-to-noise ratio for a known waveform under specified noise assumptions.

MAXIMUM-REFERENCE NORMALIZATION: Normalization of residual mean square by a declared maximum ideal-symbol energy rather than the record's average reference energy.

NOMINAL SLOT GRID: An explicitly defined sequence of equal-duration opportunities used for finite rate accounting. It can be continued through a guard interval when that convention is stated, without asserting that physical symbols were transmitted in every opportunity. Its count divided by the common elapsed duration defines the slot rate used by the model.

OVERLAP-CORRECTED THROUGHPUT: A rate based on unique identified accepted payload positions after repeated instances across compatible streams have been removed. For two sets, add their counts and subtract the known intersection before dividing by their common duration. Equal bit values do not establish duplicate identity, and unknown overlap supports bounds rather than an invented exact unique rate.

Copyright 2026, James M. Atkinson

PAYLOAD-BIT FRACTION: The useful represented payload-instance count divided by the corresponding input-information count under the declared framing convention. It excludes separately identified nonpayload information positions such as headers or padding. It acts on bits rather than slots, differs from code rate, and requires a positive information-count denominator.

PAYLOAD INSTANCE: One counted occurrence of a payload bit in the specified transmission or accepted-stream population. Retransmissions or parallel streams can contain additional occurrences of the same identified payload position. An instance count is valid for its stated purpose but does not automatically equal the number of unique useful positions delivered.

REFERENCE-RMS NORMALIZATION: Normalization by the root mean square magnitude of the actual selected reference symbols under the declared weights. In a multilevel constellation, that realized energy depends on the included symbol population and need not equal a uniformly used alphabet's mean energy. It is distinct from normalization by a fixed constellation maximum.

RESIDUAL-ENERGY SUM: The sum of the declared nonnegative weights times squared complex error-vector magnitudes over the selected population. It retains squared-amplitude units before division by reference energy. The same sum can arise from different residual directions and time histories, so it does not uniquely identify an impairment or its physical origin.

Copyright 2026, James M. Atkinson

RESIDUAL FREQUENCY OFFSET: The remaining frequency difference between the signal's declared carrier reference and the local conversion or recovery reference. Under the chapter's convention it is carrier minus LO frequency and adds a linear baseband phase trend. Estimating that trend from modulated data can absorb part of the modulation unless the estimation model and interval are justified.

SYMBOL-RATE MISMATCH: A difference between the actual symbol timing rate and the rate assumed by the reconstruction or demodulator. It can make relative decision timing drift away from a chosen alignment point across a finite record. A constant timing adjustment does not generally remove that accumulating discrepancy; clock and processing premises require separate checks.

SYMBOL TIMING: Estimate of the sampling instant associated with each transmitted symbol.

UNIQUE PAYLOAD POSITION: A payload identity counted once in a declared accepted set, even when several transmission instances refer to it. Identity requires more than the binary value zero or one. Unique-position counting must specify the request or sequence boundary, acceptance rule and time interval before it can support a delivered-throughput claim.

WALL-INTERVAL PAYLOAD RATE: The represented payload-instance count divided by a stated elapsed interval that includes all specified active, guard and idle portions. Its numerator and time boundary must match. It differs from active-burst rate and becomes a unique-delivery rate only when the acceptance and duplicate-removal evidence supports that additional interpretation.

Copyright 2026, James M. Atkinson

WEIGHTED COMPLEX CORRELATION: In the chapter's gain fit, the sum of each training observation multiplied by the conjugate of its paired ideal reference and its fixed nonnegative weight. Dividing this complex quantity by positive training reference energy gives the fitted coefficient. The conjugation direction matters because it determines the estimated phase.

WEIGHTED REFERENCE ENERGY: The positive sum of declared nonnegative weights times squared reference-symbol magnitudes used in an EVM normalization.

Copyright 2026, James M. Atkinson

8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method

Copyright 2026, James M. Atkinson

8.1.1 Learning outcomes, measurement purpose, and the nature of a spectrum

A spectrum analyser is a frequency-domain measurement instrument. It normally represents frequency on the horizontal axis and measured amplitude, power, or power density on the vertical axis. It is not merely a colourful radio display. Its interpretation depends upon the reference plane, the acquisition architecture, the frequency selectivity, the amplitude estimator, and the period during which signals were actually observed. The novice's first obligation is to write a measurement question before adjusting a knob: is the object to find a carrier, measure its power, distinguish two nearby components, characterise broadband noise, observe an intermittent burst, or compare two operating states? These objectives do not necessarily require the same instrument settings.

In a classical swept-tuned analyser, a receiver tunes successive frequencies through a resolution filter; the completed trace combines observations made at different instants. An FFT-based instrument analyses a captured time record, perhaps over a bounded instantaneous bandwidth, and may still scan or stitch additional bands. A real-time mode can maintain gap-free capture only within its qualified bandwidth, memory, trigger and processing limits. Consequently, a trace is a measurement product, not proof that every point in a wide frequency range was simultaneously monitored. The following introductory method supplies the operating vocabulary required for the advanced treatment in Sections 8.2–8.27.

Upon completing this section, a learner should be able to identify the RF input and its safe limits; configure frequency and amplitude axes; choose

Copyright 2026, James M. Atkinson

reasonable RBW, VBW, sweep and detector settings; obtain and interpret marker readings; perform reference-plane corrections and elementary uncertainty calculations; and design a repeatable laboratory record that can distinguish actual RF activity from instrument artefacts. The reader must also explain what a negative search does not establish when the receiver was not continuously observing the entire stated span.

Operational interpretation. In measurement purpose and the nature of a spectrum, the central rule is that the trace should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about frequency occupancy, discrete carriers, and wideband noise. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is treating a colourful display as if it were self-executing proof. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to time coverage, reference plane, and selectivity. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary,

Copyright 2026, James M. Atkinson

or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

Figure 31. Spectrum-analyser measurement question and interpretation chain.

Laboratory method. The working rule for this topic is to state the measurement question before touching the instrument. That instruction sounds simple, but it creates a measurable increase in repeatability because it forces the student to pause and connect the physical setup, the displayed trace, and the final conclusion. In class, an instructor should require the student to record at least the instrument identity, reference plane, active settings, and the reason those settings were selected. If repeated measurements are made under apparently identical conditions, any remaining variation then becomes analytically useful rather than mysterious. The student can compare runs, compute deltas, and decide

Copyright 2026, James M. Atkinson

whether the difference arises from the source, the path, the detector model, or the observer's own procedural change.

Measurement consequences. This topic should also be tied explicitly to frequency occupancy, discrete carriers, and wideband noise. In practice, these details govern whether a reported value is simply a useful indication or a defensible measurement statement. A good educational method is to ask the learner what would happen if one of the controlling assumptions were changed: What if the signal became intermittent? What if the span were widened? What if the reference level were moved without changing attenuation? What if external loss were omitted from the correction? Such counterfactual checks train the learner to view the trace as conditional. The analyser is excellent at displaying behaviour, but the analyst remains responsible for stating the conditions under which the displayed behaviour was obtained.

Instructional emphasis. Instructors should revisit measurement purpose and the nature of a spectrum during practical exercises so that students hear the same doctrine in conducted work, chamber work, and authorised range work. The educational aim is not rote control-pushing; it is the formation of judgement. When a student can explain, in complete sentences, how time coverage, reference plane, and selectivity shaped the displayed result and why an alternative setup would have produced a different answer, that student has moved beyond superficial instrument familiarity. This deeper understanding is what allows later chapters on selectivity, detector statistics, and uncertainty to remain connected to laboratory reality rather than floating free as abstract formulas.

Copyright 2026, James M. Atkinson

8.1.2 Front-panel controls, connections, and the signal path

Locate the RF input connector, its nominal impedance and coupling mode, the applicable maximum continuous and peak input ratings, the permitted DC level, the protective attenuator or limiter, and the instrument's reference-frequency connector before applying an external signal. Typical controls include frequency, span, amplitude, bandwidth, sweep, trigger, detector, trace, marker, measurement, system or calibration, preset, and save or recall. Modern analysers may implement them as soft keys, touch menus or remote-control commands; the measurement meaning, rather than the shape of a physical button, governs the record. A display's status region should be copied into the acquisition log because auto-coupled settings can change when the operator changes only one apparent control.

The simplified conducted path is: calibrated source or antenna terminal; any external protection and known cable; RF input attenuator; preselector and gain stages; conversion or digitisation; resolution-selective or transform processing; detection and averaging; marker or measurement calculation; and displayed or exported result. Each component can contribute loss, gain, mismatch, nonlinear distortion, time delay or uncertainty. The true input power at an antenna connector is not automatically the number indicated at the analyser display. When an external preamplifier is present, record its power supply, gain calibration, overload limit and noise behaviour as part of the path, not as an optional accessory.

On first use, obtain the instrument manual and calibration-status record, check connectors for damage, choose a harmless test level at the input, select a recognised frequency standard if required, and record the

Copyright 2026, James M. Atkinson

instrument configuration before connecting any unknown source. Never assume that a displayed reference level constitutes an input-power safety rating. Use conducted, terminated laboratory sources initially; do not connect an unidentified aerial, power circuit, radiating transmitter or active line directly to a sensitive input.

Operational interpretation. In front-panel controls and the signal path, the central rule is that the instrument control state should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about input protection, gain distribution, and detector selection. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is changing settings without recording coupled parameters. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to safe connection practice, power limits, and calibration status. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later

Copyright 2026, James M. Atkinson

reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

Figure 32. Front-panel groups and internal signal path.

Laboratory method. The working rule for this topic is to copy the status line and all active control states. That instruction sounds simple, but it creates a measurable increase in repeatability because it forces the student to pause and connect the physical setup, the displayed trace, and the final conclusion. In class, an instructor should require the student to record at least the instrument identity, reference plane, active settings, and the reason those settings were selected. If repeated measurements are made under apparently identical conditions, any remaining variation then becomes analytically useful rather than mysterious. The student can compare runs, compute deltas, and decide whether the difference arises from the source, the path, the detector model, or the observer's own procedural change.

Copyright 2026, James M. Atkinson

Measurement consequences. This topic should also be tied explicitly to input protection, gain distribution, and detector selection. In practice, these details govern whether a reported value is simply a useful indication or a defensible measurement statement. A good educational method is to ask the learner what would happen if one of the controlling assumptions were changed: What if the signal became intermittent? What if the span were widened? What if the reference level were moved without changing attenuation? What if external loss were omitted from the correction? Such counterfactual checks train the learner to view the trace as conditional. The analyser is excellent at displaying behaviour, but the analyst remains responsible for stating the conditions under which the displayed behaviour was obtained.

Instructional emphasis. Instructors should revisit front-panel controls and the signal path during practical exercises so that students hear the same doctrine in conducted work, chamber work, and authorised range work. The educational aim is not rote control-pushing; it is the formation of judgement. When a student can explain, in complete sentences, how safe connection practice, power limits, and calibration status shaped the displayed result and why an alternative setup would have produced a different answer, that student has moved beyond superficial instrument familiarity. This deeper understanding is what allows later chapters on selectivity, detector statistics, and uncertainty to remain connected to laboratory reality rather than floating free as abstract formulas.

8.1.3 Frequency coordinates, span, and horizontal resolution

The centre frequency f_c is the midpoint of the requested frequency interval. For start frequency f_s and stop frequency f_e, $f_c = (f_s + f_e)/2$ and span $S = f_e - f_s$. Conversely, $f_s = f_c - S/2$ and $f_e = f_c + S/2$. All variables must use consistent frequency units. If the display has D equal horizontal divisions, the nominal frequency-per-division is S/D, although a discrete trace has finite frequency-bin or point spacing that must be considered separately. Zero span is a time-domain observation at a selected tuning frequency or filter, not a promise of infinitely fine spectral resolution.

A broad search span is valuable for discovery but may hide two nearby carriers within one display point or resolution-filter response. Narrow the span around a candidate, then verify that the actual resolution bandwidth and detector still support the claim. A centre-frequency marker identifies a displayed or fitted feature according to the instrument's algorithm; it does not automatically yield the absolute frequency accuracy of an independent counter. Frequency-reference error, local-oscillator stability, bin interpolation and the signal's own modulation can all affect an apparent peak position.

Operational interpretation. In frequency coordinates and span control, the central rule is that the horizontal axis should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about centre frequency, start/stop limits, and point spacing. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any

Copyright 2026, James M. Atkinson

reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is assuming that a broad span gives fine resolution. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to frequency accuracy, interpolation, and display spacing. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

Copyright 2026, James M. Atkinson

Figure 33. Centre, span, start, and stop relationships.

Laboratory method. The working rule for this topic is to shrink the span as the question becomes more specific. That instruction sounds simple, but it creates a measurable increase in repeatability because it forces the student to pause and connect the physical setup, the displayed trace, and the final conclusion. In class, an instructor should require the student to record at least the instrument identity, reference plane, active settings, and the reason those settings were selected. If repeated measurements are made under apparently identical conditions, any remaining variation then becomes analytically useful rather than mysterious. The student can compare runs, compute deltas, and decide whether the difference arises from the source, the path, the detector model, or the observer's own procedural change.

Copyright 2026, James M. Atkinson

Measurement consequences. This topic should also be tied explicitly to centre frequency, start/stop limits, and point spacing. In practice, these details govern whether a reported value is simply a useful indication or a defensible measurement statement. A good educational method is to ask the learner what would happen if one of the controlling assumptions were changed: What if the signal became intermittent? What if the span were widened? What if the reference level were moved without changing attenuation? What if external loss were omitted from the correction? Such counterfactual checks train the learner to view the trace as conditional. The analyser is excellent at displaying behaviour, but the analyst remains responsible for stating the conditions under which the displayed behaviour was obtained.

Instructional emphasis. Instructors should revisit frequency coordinates and span control during practical exercises so that students hear the same doctrine in conducted work, chamber work, and authorised range work. The educational aim is not rote control-pushing; it is the formation of judgement. When a student can explain, in complete sentences, how frequency accuracy, interpolation, and display spacing shaped the displayed result and why an alternative setup would have produced a different answer, that student has moved beyond superficial instrument familiarity. This deeper understanding is what allows later chapters on selectivity, detector statistics, and uncertainty to remain connected to laboratory reality rather than floating free as abstract formulas.

Copyright 2026, James M. Atkinson

8.1.4 Amplitude scale, reference level, input attenuation, and overload

A logarithmic display usually expresses power as dBm, with 0 dBm representing 1 milliwatt in the stated measurement convention. For power P in milliwatts, P_dBm = 10 log10(P/1 mW); P_mW = 10^(P_dBm/10). The reference level normally locates a designated amplitude near the top of the graticule; the scale may be 5 dB or 10 dB per vertical division. The reference level affects display placement and often interacts with automatic gain or attenuation, but it must not be mistaken for a hardware input rating. A linear-voltage display uses different interpretation and calibration rules.

Input attenuation reduces the signal presented to subsequent nonlinear stages and increases the apparent room for high-power blockers; it generally raises the effective input-referred noise floor when downstream noise dominates. Reducing attenuation may expose a weak carrier but can also provoke mixer compression or intermodulation. A preamplifier may improve sensitivity while sacrificing blocker tolerance. Select attenuation first according to the highest plausible aggregate signal, not merely the desired weak component. Examine overload annunciators, unexpected harmonics, gain-state logs and the response to a controlled attenuation change; a peak that changes by 20 dB when an external signal changes by 10 dB is not behaving as a simple linear external tone.

The protection plan must account for the maximum possible RF power and DC bias at the connector, plus transients, electrostatic discharge, mismatches and unknown energy outside the visible span. Apply rated external protection or an isolation network where warranted and obtain

Copyright 2026, James M. Atkinson

confirmation of its frequency response and power handling. The analyser's internal attenuator may not protect every coupling mode or every vulnerable component. Disconnect before changing uncertain paths.

Operational interpretation. In amplitude scaling and overload control, the central rule is that the amplitude scale should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about reference level, attenuation, and headroom. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is confusing display placement with safe power handling. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to compression, intermodulation, and protection margins. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

Figure 34. Reference level, attenuation, and overload margin.

Laboratory method. The working rule for this topic is to set attenuation for the strongest plausible signal first. That instruction sounds simple, but it creates a measurable increase in repeatability because it forces the student to pause and connect the physical setup, the displayed trace, and the final conclusion. In class, an instructor should require the student to record at least the instrument identity, reference plane, active settings, and the reason those settings were selected. If repeated measurements are made under apparently identical conditions, any remaining variation then becomes analytically useful rather than mysterious. The student can compare runs, compute deltas, and decide whether the difference arises from the source, the path, the detector model, or the observer's own procedural change.

Copyright 2026, James M. Atkinson

Measurement consequences. This topic should also be tied explicitly to reference level, attenuation, and headroom. In practice, these details govern whether a reported value is simply a useful indication or a defensible measurement statement. A good educational method is to ask the learner what would happen if one of the controlling assumptions were changed: What if the signal became intermittent? What if the span were widened? What if the reference level were moved without changing attenuation? What if external loss were omitted from the correction? Such counterfactual checks train the learner to view the trace as conditional. The analyser is excellent at displaying behaviour, but the analyst remains responsible for stating the conditions under which the displayed behaviour was obtained.

Instructional emphasis. Instructors should revisit amplitude scaling and overload control during practical exercises so that students hear the same doctrine in conducted work, chamber work, and authorised range work. The educational aim is not rote control-pushing; it is the formation of judgement. When a student can explain, in complete sentences, how compression, intermodulation, and protection margins shaped the displayed result and why an alternative setup would have produced a different answer, that student has moved beyond superficial instrument familiarity. This deeper understanding is what allows later chapters on selectivity, detector statistics, and uncertainty to remain connected to laboratory reality rather than floating free as abstract formulas.

8.1.5 Resolution bandwidth, selectivity, and noise measurement

Resolution bandwidth (RBW) describes the effective frequency selectivity of the measurement filter or equivalent digital estimator. A smaller RBW may separate close signals and admits less approximately white noise; it may also require longer settling or observation. Different filter shapes and FFT windows possess different 3 dB bandwidths, equivalent noise bandwidths and sidelobes. Thus, a nominal RBW value alone does not define two-tone resolvability or amplitude accuracy. Distinguish a narrow continuous wave, whose integrated tone power can remain roughly constant after proper detector and calibration corrections, from noise power, which scales with equivalent noise bandwidth.

For thermal noise near 290 K, a commonly used reference density is approximately -174 dBm/Hz at a matched measurement plane. With equivalent noise bandwidth B_e in hertz and receiver noise figure NF in decibels, the simplified input-referred estimate is $N_{dBm} \approx -174 + 10 \log10(B_e/1\ Hz) + NF$. The approximation assumes stationary white noise over the selected interval, a defined impedance, valid calibration, and no dominating external noise or spur. When RBW and equivalent noise bandwidth differ, use the latter in the power equation. A smaller RBW lowers the noise measured in that filter; it does not physically remove noise from the incoming signal.

Operational interpretation. In resolution bandwidth and selectivity, the central rule is that the RBW choice should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a

Copyright 2026, James M. Atkinson

machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about two-tone separation, equivalent noise bandwidth, and settling time. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is using nominal RBW alone to justify a resolution claim. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to tone power, noise power, and filter shape. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

8.1.6 Video bandwidth, smoothing, and averaging

Video bandwidth (VBW) is ordinarily a post-detection smoothing or filtering parameter, although its exact implementation depends on the analyser. Lowering VBW can make a noisy trace appear quieter without creating additional frequency resolution or reducing the noise already admitted through the RBW filter. Excessively narrow VBW may distort pulse amplitudes, smear changing signals or require more sweep time. Similarly, trace averaging is meaningful only after one identifies what is averaged: linear power, envelope voltage, logarithmic amplitude, complex FFT bins or another quantity. Arithmetic averaging in watts followed by conversion to dBm need not equal averaging the dBm readings. The two operations are mathematically different.

Record RBW, VBW, averaging count and mathematical domain. The variance reduction ordinarily attributed to averaging presumes an effective number of independent observations. Consecutive heavily overlapped FFT frames or repeated readings of the same slowly varying filter output are correlated; they must not be counted as independent evidence. For transient discovery, compare a relatively unsmoothed acquisition with a deliberately smoothed display and preserve both configurations.

Operational interpretation. In video bandwidth and smoothing, the central rule is that the display treatment should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about trace readability, post-detection filtering, and variance reduction. For that reason, the student should learn to read each

Copyright 2026, James M. Atkinson

displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is mistaking a smoother display for better resolution. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to display cosmetics, pulse fidelity, and response lag. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

8.1.7 Sweep time, dwell, triggering, and temporal coverage

Sweep time is the interval associated with a frequency traversal or a stated acquisition, not a guarantee that every frequency was observed throughout that interval. In a swept analyser, the resolution-filter response must settle sufficiently at successive tuned frequencies. Narrow RBW and VBW settings can lengthen the sweep, although automatic controls and digital architectures complicate any simple sweep-time law. Detector bucket dwell, inter-sweep dead time, retrace, triggering, preselection switching and hidden averaging each alter the likelihood of intercepting a brief emission. Record the actual sweep or capture time, trace points, trigger condition, holdoff and observed occupancy.

A triggered trace may begin after an event, depending upon detection latency and pre-trigger storage. Zero-span recording measures amplitude versus time only within the chosen IF or digital analysis bandwidth. For a suspected short burst, select a time-resolved or real-time mode whose specified instantaneous bandwidth and probability-of-intercept limits are appropriate, rather than mistaking a static max-hold peak for complete temporal evidence. In any negative-result report, state the observation interval and the instrument's unobserved intervals explicitly.

Operational interpretation. In sweep time, dwell, and temporal coverage, the central rule is that the time coverage should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about revisit interval, dwell, and trigger state. For that reason, the student should learn to read each displayed trace as the

Copyright 2026, James M. Atkinson

consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is claiming absence when the instrument was elsewhere in frequency. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to intermittent bursts, revisit probability, and acceptance criteria. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

8.1.8 Detector modes, trace functions, and truthful displays

Peak, negative-peak, sample, RMS or power-average, quasi-peak and other detector modes answer different questions. Peak detection emphasises the largest selected amplitude within a bucket, often helping discover intermittent activity; negative peak emphasises the smallest. A sample detector retains a selected sample and may miss an isolated event. RMS or power-based methods estimate average energy under the instrument's documented sample and bandwidth model. Quasi-peak is a weighted response specified by particular measurement conventions, not an interchangeable synonym for peak. The label on the display must be interpreted with the actual detector implementation and any correction factors.

Max hold retains the largest displayed value over multiple traces and is useful for discovering intermittent spectral components, but the resulting composite is not a spectrum acquired at one instant. Min hold and averaging have similarly distinct interpretations. Document the starting time, reset action, number of contributing sweeps, detector mode, and any missing acquisition interval. An investigator must not claim that a max-hold line represents simultaneous emissions unless independent time-aligned records support that conclusion.

Operational interpretation. In detector modes and trace functions, the central rule is that the detector model should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about peak, sample, average, RMS, and trace

Copyright 2026, James M. Atkinson

persistence. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is mixing detector results as if they were directly comparable. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to regulatory compatibility, repeatability, and statistical meaning. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

8.1.9 Markers, delta measurements, and amplitude corrections

A marker usually returns the frequency coordinate and displayed amplitude of one trace point or a fitted estimate. A delta marker returns a difference relative to a reference marker, potentially in frequency and dB. Peak-search, next-peak, noise-marker, occupied-bandwidth and channel-power functions are not equivalent. In particular, an amplitude marker on a noise trace is not automatically the integrated power of a whole channel. For calibrated channel-power measurements, specify integration limits, instrument resolution, detector or estimator law, corrections and uncertainty.

Inspect the marker's trace source and correction table. A cable-loss table, antenna factor, external attenuation or gain compensation can shift the displayed level or change its physical unit. A correction may be expressed at a specified reference plane only. For comparative measurements, apply identical detection, resolution and reference settings or document a validated correction. Preserve the original raw trace or complex samples when possible, together with the transformed result and its settings.

Operational interpretation. In markers and delta measurements, the central rule is that the marker report should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about frequency offset, amplitude difference, and applied correction. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in

Copyright 2026, James M. Atkinson

plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is copying the readout without stating its correction basis. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to cable loss, gain offsets, and frequency-reference limits. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

8.1.10 Calibration, traceability, reference planes, and daily verification

Calibration establishes specified relations between a measurement indication and quantities realised through a traceable measurement chain, with associated uncertainty; an instrument's internal alignment routine is not a universal substitute for external calibration. Confirm the calibration date and stated interval, warm-up requirements, amplitude and frequency accuracy, reference clock selection, connector condition, firmware configuration, and the applicable operating temperature. Where power is transferred through a cable or attenuator, define a connector reference plane and distinguish scalar insertion loss from mismatch uncertainty. For precision frequency work, verify the internal reference or lock to a documented external standard and record the lock state.

A daily verification should use a known, appropriately low-level reference signal at a frequency inside the planned working range, with a check at another frequency or amplitude when relevant. Compare the indicated reading with an acceptance interval formed from the reference specification and the analyser's published uncertainty, and document any failure before measuring unknown signals. Conduct a repeatability test, an input-attenuation challenge, a noise-floor check and a connector inspection as the scope warrants. An apparent correction that merely makes a trace pleasing to the eye is not calibration.

Operational interpretation. In calibration, traceability, and reference planes, the central rule is that the calibration chain should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a

Copyright 2026, James M. Atkinson

machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about known sources, correction tables, and uncertainty terms. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is reporting corrected amplitudes without naming a reference plane. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to traceability, uncertainty budgets, and daily confidence checks. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

8.1.11 Ten worked examples: elementary calculations and their limitations

Worked example 1. Frequency centre and span. A student specifies f_s = 145.000 MHz and f_e = 149.000 MHz across D = 8 horizontal divisions. The frequency centre is 147.000 MHz and span is 4.000 MHz; each division represents 0.500 MHz. A marker at 148.250 MHz lies 1.250 MHz to the right of the centre, corresponding to 2.5 divisions. These are display coordinates, not a proof of absolute marker-frequency accuracy.

> $f_c = (145 + 149)/2 = 147$ MHz; $S = 149 - 145 = 4$ MHz; $S/D = 4/8 = 0.5$ MHz/div.

Worked example 2. Converting dBm to watts and voltage. Assume a matched 50-ohm system and a steady sinusoidal signal measured at -30 dBm. The corresponding power is $10^{(-3)}$ mW = 0.001 mW = 1.0 microwatt. The associated RMS voltage across an actual 50-ohm load is sqrt(P R) = 7.071 millivolts. The voltage calculation must not be transferred unchanged to an unmatched connector or an unknown impedance.

> $P = 10^{(-30/10)}$ mW = 0.001 mW = 10^{-6} W; $V_{rms} = \sqrt{(10^{-6}\ W)(50\ ohm)} = 7.071$ mV.

Worked example 3. Correcting a known conducted-path loss. A generator produces -20.0 dBm at its specified output reference plane. A calibrated external attenuator and cable have a combined insertion loss of 10.0 dB at the measurement frequency. The ideal analyser input is -30.0 dBm. If the analyser reads -30.0 dBm with its internal correction disabled, then the inferred generator-plane power is -20.0 dBm after adding the

Copyright 2026, James M. Atkinson

external loss. The analysis must separately account for mismatch and calibration uncertainty.

> P_{input} = -20.0 dBm - 10.0 dB = -30.0 dBm; P_{source} = -30.0 dBm + 10.0 dB = -20.0 dBm.

Worked example 4. Noise power and RBW. Assume a 290 K input, equivalent noise bandwidth B_e = 10,000 Hz, and an effective system noise figure NF = 12 dB. The estimated input-referred noise is -122 dBm. Reducing B_e to 1,000 Hz, with all else unchanged, reduces noise in the filter by 10 dB to -132 dBm. The assumption of unchanged NF may fail if the gain or attenuation state changes between the two measurements.

> N_{10k} = -174 + 10 log10(10000) + 12 = -122 dBm; N_{1k} = -174 + 10 log10(1000) + 12 = -132 dBm.

Worked example 5. Two-tone spacing and RBW choice. Two steady carriers are at 100.000 MHz and 100.004 MHz, giving a 4 kHz separation. An RBW of 10 kHz is generally inadequate to distinguish them as separate narrow responses, while 1 kHz is a more defensible starting choice. Final resolvability still depends on filter shape, relative carrier amplitudes, dynamic range and window sidelobes. The spacing itself is 4 kHz, regardless of the display span.

> Delta f = 100.004 MHz - 100.000 MHz = 0.004 MHz = 4 kHz; choose RBW << Delta f, then verify experimentally.

Worked example 6. Averaging and the independence assumption. Suppose one independent power observation has a standard deviation equal to its own mean under a specified exponential-noise model. The relative standard deviation of the mean of N independent observations is

Copyright 2026, James M. Atkinson

1/sqrt(N). Twenty-five independent observations give 20%; 100 give 10%; 400 give 5%. This is an averaging calculation, not a universal prediction from selecting a particular VBW; correlated records reduce the effective sample count.

> Relative sigma_mean = 1/sqrt(N); N = 25: 20%; N = 100: 10%; N = 400: 5%.

Worked example 7. Dwell and minimum frame duration. An illustrative sweep has 200 independent frequency positions, each requiring at least 2 ms of observation and settling. Its dwell-only lower bound is 400 ms, excluding retrace, calibration actions and processing. A 1 ms burst is shorter than an individual 2 ms dwell, and may fail to coincide with the tuned frequency. It is therefore wrong to infer complete time coverage from the nominal 400 ms sweep time.

> T_dwell,min = N_positions x t_position = 200 x 0.002 s = 0.400 s; T_actual >= 0.400 s.

Worked example 8. Peak indication versus mean power. Consider three equal-duration, independently sampled power readings of -40, -35 and -50 dBm in a stated RBW. Their linear powers are 100.00 nW, approximately 316.23 nW and 10.00 nW. The largest is -35 dBm; the arithmetic mean of the linear powers is approximately 142.08 nW, equivalent to -38.47 dBm. Simply averaging the three dBm labels would give -41.67 dBm, a different statistical operation.

> P_mean = (100 + 316.23 + 10)/3 = 142.08 nW; 10 log10(142.08 nW/1 mW) = -38.47 dBm.

Copyright 2026, James M. Atkinson

Worked example 9. Delta-marker frequency and amplitude. A reference marker identifies a component at 2450.000 MHz and -42.0 dBm. A second marker identifies another component at 2450.025 MHz and -48.0 dBm. Their frequency separation is 25 kHz, while the second component is 6.0 dB lower. For comparable corrected powers the power ratio is approximately 0.251. Neither delta alone proves whether the components are harmonically related or originate outside the analyser.

> Delta f = 0.025 MHz = 25 kHz; Delta P = -48 - (-42) = -6 dB; P_2/P_1 = 10^(-6/10) = 0.251.

Worked example 10. Reference-plane correction and combined uncertainty. An analyser displays -60.0 dBm at its RF input. The cable loss to the declared source plane is 1.7 dB, so the inferred source-plane power is -58.3 dBm. Assume independent standard uncertainties of 0.6 dB for the amplitude indication and 0.3 dB for the cable correction. Their root-sum-square combination is 0.671 dB; an illustrative expanded uncertainty with coverage factor k = 2 is about 1.34 dB. If the two uncertainties are correlated, the covariance term must be included rather than omitted.

> P_source = -60.0 + 1.7 = -58.3 dBm; u_c = sqrt(0.6^2 + 0.3^2) = 0.671 dB; U(k=2) = 1.34 dB.

These examples are controlled instructional models. An actual instrument may add filter-shape corrections, nonlinear responses, averaging bias, mismatch, time-varying gain, trace quantisation and specification limits. Each student should document assumptions and compare the analytic estimate with an independently checked physical measurement.

Copyright 2026, James M. Atkinson

Operational interpretation. In worked calculations and interpretive discipline, the central rule is that the calculation should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about unit conversion, dBm arithmetic, and sanity checking. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is trusting automation without an order-of-magnitude estimate. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to rounding, assumptions, and configuration-specific limits. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

Copyright 2026, James M. Atkinson

Figure 41. Worked example map: unit conversions and display reasoning.

Laboratory method. The working rule for this topic is to solve the simple version by hand before accepting the display. That instruction sounds simple, but it creates a measurable increase in repeatability because it forces the student to pause and connect the physical setup, the displayed trace, and the final conclusion. In class, an instructor should require the student to record at least the instrument identity, reference plane, active settings, and the reason those settings were selected. If repeated measurements are made under apparently identical conditions, any remaining variation then becomes analytically useful rather than mysterious. The student can compare runs, compute deltas, and decide whether the difference arises from the source, the path, the detector model, or the observer's own procedural change.

Copyright 2026, James M. Atkinson

Measurement consequences. This topic should also be tied explicitly to unit conversion, dBm arithmetic, and sanity checking. In practice, these details govern whether a reported value is simply a useful indication or a defensible measurement statement. A good educational method is to ask the learner what would happen if one of the controlling assumptions were changed: What if the signal became intermittent? What if the span were widened? What if the reference level were moved without changing attenuation? What if external loss were omitted from the correction? Such counterfactual checks train the learner to view the trace as conditional. The analyser is excellent at displaying behaviour, but the analyst remains responsible for stating the conditions under which the displayed behaviour was obtained.

Instructional emphasis. Instructors should revisit worked calculations and interpretive discipline during practical exercises so that students hear the same doctrine in conducted work, chamber work, and authorised range work. The educational aim is not rote control-pushing; it is the formation of judgement. When a student can explain, in complete sentences, how rounding, assumptions, and configuration-specific limits shaped the displayed result and why an alternative setup would have produced a different answer, that student has moved beyond superficial instrument familiarity. This deeper understanding is what allows later chapters on selectivity, detector statistics, and uncertainty to remain connected to laboratory reality rather than floating free as abstract formulas.

8.1.12 Supervised laboratory exercises and acceptance criteria

Practical A. Front-panel identification and safe conducted connection. Objective: identify the principal control groups and the chain from source to analyser input. Apparatus: a serviceable analyser, its current instruction manual, a 50-ohm termination, a calibrated low-power source, a rated attenuator, and suitable coaxial leads. With the generator output disabled, record the analyser model, RF input ratings, connector condition, coupling mode, reference source, attenuation state and calibration status. Connect the terminated path, enable a harmless known source at least the margin specified by the laboratory safety procedure below the RF input rating, then save a complete instrument-state record. Acceptance: the student can reconstruct the connection and explain why reference level is not a safety limit.

Practical B. Frequency, span, power scales, and markers. Objective: measure the frequency and amplitude of a stable continuous-wave signal. Configure a broad span to find a calibrated generator tone, narrow the span, and report centre, start, stop, span, division spacing, marker frequency, marker amplitude, RBW, detector mode and connector reference plane. Repeat after shifting the source frequency by a known interval. Acceptance: the reported marker difference agrees with the source shift within the combined instrument and source accuracy; an unexplained disagreement is investigated rather than erased.

Practical C. RBW, selectivity and noise-floor contrast. Objective: distinguish the displayed continuous-wave response from the stationary

Copyright 2026, James M. Atkinson

noise background. Select a safe fixed-power tone, then measure at two RBW values differing by a factor of ten. Preserve the same reference plane, attenuation and other states, and record whether the tone power is consistent while the noise in a resolution filter changes. Use two low-level tones of known separation to explore filter selectivity if suitable equipment is available. Acceptance: the report states the RBW filter shape or ENBW convention and explains why a wider filter may conceal a weak adjacent tone.

Practical D. VBW, detectors and trace statistics. Objective: separate display smoothing from measurement bandwidth. With a stable source and noise background, hold RBW constant while changing VBW and averaging configuration. Capture unsmoothed and smoothed traces, then compare sample, peak and power-average modes where the instrument offers them. Acceptance: the student identifies which changes affect apparent ripple, which change spectral resolution, and why an average of dBm values differs from a dBm conversion of mean linear power. Do not infer independent samples merely from a trace count.

Practical E. Intermittent-signal visibility and sweep-time bias. Objective: demonstrate that swept traces do not provide gap-free time observation across the entire span. Use a laboratory-approved low-power burst generator through a conducted and shielded path; select two sweep times and two detector/trace combinations, recording every trigger and reset state. Compare detections with an independent time-stamped observation at the source. Acceptance: state the measured detection fraction for the tested stimulus, the acquisition conditions, and a bounded negative

Copyright 2026, James M. Atkinson

conclusion; do not generalise that fraction to signals with unknown timing. The exercise must not radiate outside authorised test facilities.

Practical F. Calibration check, overload challenge and uncertainty budget. Objective: verify a traceable input level while demonstrating protection of the receiver. Start with a suitably weak known tone and an adequate rated attenuation path. Record raw amplitude, cable correction, gain or attenuation state, reference accuracy, and the resultant standard and expanded uncertainties. Reduce source level or add external attenuation in controlled increments and check for expected linear change; do not deliberately exceed instrument ratings or induce damage. Acceptance: provide a configuration-specific measurement statement, a dated calibration and uncertainty record, an identified reference plane, a saved native trace, and a rule for suspending work if overload or calibration failure occurs.

Laboratory logistics and authorisation. A two-semester instructor-led course should begin with conducted connections into terminated loads, then progress to an RF-isolated chamber under a documented site procedure, followed by supervised indoor and outdoor test ranges when the instructor can establish lawful operation, emission control, personnel exclusion zones and frequency coordination. An anechoic chamber is not automatically a perfectly isolated chamber, and a shielded enclosure does not make excessive RF exposure or poor electrical practice acceptable. Never use a live service, a third-party transmission, a mains connection, or personal communications content as an unapproved test source. Record spectrum occupancy and non-content technical observables only within the authority granted for the exercise.

Copyright 2026, James M. Atkinson

Common laboratory reporting template. Every exercise report must identify the measurement question, test date and place, instrument identity and calibration status, source characteristics, permitted operating authority, reference planes, impedance, external losses and gains, attenuation, RBW, VBW, detector, sweep time, trigger, frequency reference, correction tables, saved native observations, uncertainty, operator notes and final bounded conclusion. Distinguish an observed spectral feature from an assertion concerning its source, purpose or lawfulness. Export the settings and the raw record before producing annotated figures for an assessment submission.

Competency and progression. A student should not advance to blind-survey or transient-evidence exercises merely because a frequency peak can be located. Progress requires a repeatable setup, adequate overload margin, correct conversion between linear power and dBm, an explanation of the noise and selectivity tradeoffs, a defensible time-coverage statement, and correct use of marker and reference-plane uncertainty. Advanced treatments of RBW, detector statistics, sweep validity, transient probability and amplitude uncertainty follow in the remaining sections of this chapter.

Operational interpretation. In supervised laboratory exercises, the central rule is that the laboratory record should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about conducted setups, chamber work, and range progression. For that reason, the student should learn to read each displayed trace as the consequence of a method. Before copying any reading into a notebook or report, the operator should state the problem in

Copyright 2026, James M. Atkinson

plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is jumping to radiated work before mastering conducted control. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to safety, legal authority, and reproducibility. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

8.1.13 Swept Architecture and Frequency-Time Mapping

A swept-tuned spectrum analyzer translates successive input frequencies through a narrow resolution filter while its local oscillator moves across the selected span. The horizontal axis is therefore generated over time, not acquired simultaneously. A signal that changes during the sweep can appear at the wrong amplitude, be split, be missed, or be drawn as a misleading shape. Sweep time, span, resolution bandwidth, detector, and trigger determine whether the display represents the event.[5]

The analyzer may contain multiple conversions, tracking preselection, step attenuators, logarithmic IF paths, digital IF filters, and display processing. Modern instruments can combine swept and FFT techniques, so the selected mode should be identified rather than inferred. The practitioner records whether the trace was continuously swept, stepped, FFT-based, max-held over many passes, or assembled from segments.

Operational interpretation. In swept architecture and frequency-time mapping, the central rule is that the architecture statement should answer the measurement question actually posed by the analyst. A spectrum analyser is not simply a machine that paints peaks on a screen; it is a bounded measurement system whose display reflects choices about local-oscillator motion, filter settling, and trace assembly. For that reason, the student should learn to read each displayed trace as the consequence of a

method. Before copying any reading into a notebook or report, the operator should state the problem in plain language and then explain why the chosen settings are suited to that problem. This habit prevents the common error of letting the instrument's convenience determine the observation, rather than letting the observation requirement determine the settings.

Common interpretive failure. A persistent error in beginner work is forgetting that a swept trace is a time-sequenced product. The operator may obtain a trace that appears neat and plausible, yet still answers the wrong question or answers it only weakly. The corrective discipline is to write a short statement of intent in the record, then justify the chosen configuration with reference to visit order, missed events, and interpretive bounds. If the intent changes, the setup should change as well, and the change should be written down. This practice is particularly important in forensic, evidentiary, or acceptance-testing environments where a later reviewer was not present when the measurement was made and must reconstruct the logic of the setup from the record alone.

Copyright 2026, James M. Atkinson

Figure 44. Swept architecture and frequency-time mapping overview.

Laboratory method. The working rule for this topic is to describe how the displayed line was acquired. That instruction sounds simple, but it creates a measurable increase in repeatability because it forces the student to pause and connect the physical setup, the displayed trace, and the final conclusion. In class, an instructor should require the student to record at least the instrument identity, reference plane, active settings, and the reason those settings were selected. If repeated measurements are made under apparently identical conditions, any remaining variation then becomes analytically useful rather than mysterious. The student can compare runs, compute deltas, and decide whether the difference arises from the source, the path, the detector model, or the observer's own procedural change.

Measurement consequences. This topic should also be tied explicitly to local-oscillator motion, filter settling, and trace assembly. In practice, these details

Copyright 2026, James M. Atkinson

govern whether a reported value is simply a useful indication or a defensible measurement statement. A good educational method is to ask the learner what would happen if one of the controlling assumptions were changed: What if the signal became intermittent? What if the span were widened? What if the reference level were moved without changing attenuation? What if external loss were omitted from the correction? Such counterfactual checks train the learner to view the trace as conditional. The analyser is excellent at displaying behaviour, but the analyst remains responsible for stating the conditions under which the displayed behaviour was obtained.

Instructional emphasis. Instructors should revisit swept architecture and frequency-time mapping during practical exercises so that students hear the same doctrine in conducted work, chamber work, and authorised range work. The educational aim is not rote control-pushing; it is the formation of judgement. When a student can explain, in complete sentences, how visit order, missed events, and interpretive bounds shaped the displayed result and why an alternative setup would have produced a different answer, that student has moved beyond superficial instrument familiarity. This deeper understanding is what allows later chapters on selectivity, detector statistics, and uncertainty to remain connected to laboratory reality rather than floating free as abstract formulas.

Field-minded caution. Spectrum analysers are frequently used by intelligent operators who are nevertheless tempted to move too quickly from observation to attribution. An observed emission line may be real while its origin remains uncertain. A clean display may still conceal missed events, detector bias, or an incorrect correction sign. A beautifully smoothed trace may tell less truth than a rough one if the smoothing process masks the

Copyright 2026, James M. Atkinson

temporal behaviour that matters to the question. For that reason, the fundamental doctrine of this introductory section is restraint joined to precision: connect safely, declare the question, choose settings that suit the question, record them faithfully, check the result against a simple hand estimate, and state the conclusion in bounded terms. Once that discipline has become habitual, the student is ready to approach resolution filters, detector statistics, swept acceptance criteria, and FFT methods as tools of professional measurement rather than as isolated menu selections on a screen.

Synthesis for advanced work. Before leaving the introductory material, the learner should be able to narrate a full measurement sequence from start to finish. A good oral check is to ask the student to explain what happens when a weak carrier is sought in the presence of stronger neighbours. The student should mention the reference plane, safe connection practice, input attenuation, reference level, preamplifier use, span choice, RBW, VBW, detector model, marker method, and the uncertainty of the corrected amplitude. The student should then explain what evidence would show overload or misleading smoothing, what record would be saved for later review, and what negative conclusion would remain impermissible if the time coverage were incomplete. This integrated explanation is often more revealing than a single numerical answer because it shows whether the learner understands the relationship between settings, architecture, and interpretation. It also prepares the learner to read the more exact sections that follow in this chapter, where selectivity, detector mathematics, and sweep validity are treated with greater depth and where the language of the

Copyright 2026, James M. Atkinson

manufacturer's specification must be reconciled with classroom demonstrations.

Course transition. The reader should therefore enter the remainder of Chapter 8 with a disciplined checklist already internalised: define the question, protect the input, set a justifiable span, choose attenuation and reference level together, relate RBW and VBW to the signal model, state the detector and trace mode, document marker corrections, verify calibration lineage, and describe what time interval and probability of observation the trace actually represents. When this checklist is used consistently, later discussions of selectivity curves, sweep acceptance, amplitude uncertainty, and missed-event probability become easier to understand because each advanced concept already has a practical home in the operator's routine.

Copyright 2026, James M. Atkinson

8.2 Resolution Bandwidth and Selectivity

Resolution bandwidth controls the analyzer's ability to separate nearby components and the noise admitted to the detector. Narrowing RBW lowers displayed noise and improves frequency discrimination, but increases filter settling and sweep time. The filter's noise bandwidth, shape factor, and response to pulsed or frequency-agile signals matter. An RBW label does not fully describe the filter.

Copyright 2026, James M. Atkinson

Figure 45. Resolution versus video bandwidth.

Measurements such as channel power, occupied bandwidth, phase noise, adjacent-channel power, and discrete spur amplitude have different RBW requirements. If the RBW is wider than the signal, the analyzer integrates most of the signal but also more noise. If it is narrower, a modulated signal

Copyright 2026, James M. Atkinson

is measured in pieces as the filter sweeps. The method should follow the desired measurand rather than a habit of selecting the narrowest available bandwidth.

Copyright 2026, James M. Atkinson

Figure 46. Swept spectrum-analyser control chain.

Copyright 2026, James M. Atkinson

8.3 Video Bandwidth, Averaging, and Detector Choice

Copyright 2026, James M. Atkinson

Figure 47. Detector modes and intermittent RF bursts.

Video bandwidth or post-detection filtering smooths the trace and reduces visible noise variation at the cost of response time. Trace averaging can improve repeatability for stationary random processes, while max hold captures intermittent peaks across repeated sweeps. Neither creates simultaneous observation. A short burst may be caught on one sweep and

Copyright 2026, James M. Atkinson

missed on the next, producing a partial spectral outline. The detector-dependent burst example is illustrated in Figure 33.

Peak, sample, negative peak, average, RMS, and quasi-peak detectors produce different results. Regulatory measurements may prescribe a detector and time behavior. A survey search may use positive peak and max hold for discovery, then RMS or averaging for power estimates. The detector setting is part of the measurement definition and should not be changed between traces that are compared quantitatively.

Copyright 2026, James M. Atkinson

8.4 Noise averages, detector statistics, and the meaning of a decibel trace

The word average does not identify a noise-power estimator. A receiver may average instantaneous powers, voltage magnitudes or logarithmic readings, then apply another detector or marker correction. A logarithmic display of an already averaged power is not equivalent to an average of logarithmic power samples. Two traces can therefore differ systematically even when their analog input, bandwidth and gain are unchanged. Equation 16 remains useful only after these estimator conventions have been reconciled.

The distinction appears explicitly in manufacturer help. The Keysight E505xA spectrum-analyzer application describes separate voltage, power and logarithmic video-averaging operations, applied after the DFT and before image rejection; its detector selection is another operation on display buckets. Those details describe that implementation, not every analyzer.[6] The N9000B CXA specification guide, edition 6 of May 2024, states at printed page 56, note d, that its cited DANL uses logarithmic averaging and therefore lies 2.51 dB below the corresponding noise density before a separate bandwidth correction. This is a specification convention, not

6 International Electrotechnical Commission, CISPR 16-1-1:2019, Specification for Radio Disturbance and Immunity Measuring Apparatus and Methods, Part 1-1: Radio Disturbance and Immunity Measuring Apparatus: Measuring Apparatus, 5th ed. 8.4.1 A stated statistical model

Take a fixed frequency, a linear receiver, and stationary zero-mean circular complex Gaussian noise at a calibrated power-estimation plane. Let X and Y be independent real Gaussian quadrature components with mean zero and variance one. Define an instantaneous power sample $P = \frac{\mu (X^2 + Y^2)}{2}$, where $\mu > 0$ is mean noise power in watts. This normalization incorporates reference resistance and gain calibration; P is not an uncalibrated ADC count. The dimensionless variable $U = \frac{P}{\mu}$ has exponential density $\exp(-u)$ for $u \geq 0$, with mean and variance both one. Consequently $\mathrm{E}[P] = \mu$ and $\mathrm{Var}(P) = \mu^2$. A deterministic tone, clipped envelope or mixture of changing noise levels generally lacks this distribution.

For N equally weighted positive samples, with $P_{ref} = 1\ \mathrm{mW}$, define

Equation 16A. Log averages and the logarithm of average power

$$L_N = \frac{10}{N \ln 10} \sum_{i=1}^{N} \ln\left(\frac{P_i}{P_{ref}}\right)$$

$$A_N = \frac{10}{\ln 10} \ln\left(\frac{\sum_{i=1}^{N} P_i}{N P_{ref}}\right)$$

Both statistics are in dBm, but L_N averages logarithms while A_N logs an arithmetic power mean. Concavity of logarithm gives $L_N \leq A_N$ for every realized record, with equality only when all sampled powers are equal. This inequality establishes direction, not a numerical correction or Gaussian statistics.

Copyright 2026, James M. Atkinson

Let γ be Euler's constant, approximately 0.5772156649. Substitution $P = \mu U$ and the integral $\int_0^\infty \exp(-u) \ln(u)\, du = -\gamma$ over the positive real axis give

Equation 16B. Expected logarithmic noise level

$$E[L_N] = 10 \log_{10}\left(\frac{\mu}{P_{ref}}\right) - \frac{10\gamma}{\ln 10}$$

$$E[L_N] \approx 10 \log_{10}\left(\frac{\mu}{P_{ref}}\right) - 2.506815781\, dB$$

NIST DLMF equation 5.9.18 supplies the integral.[8] Identically distributed samples suffice for this expectation; independence is not required. More independent log samples reduce fluctuation but do not remove the mean offset. Adding the modeled offset, approximately 2.5068 dB, is an unbiased correction in decibel expectation for this specified statistic and single exponential distribution. It is not distribution-free and does not make the exponentiated estimate unbiased in watts.

The 2024 edition of Keysight's Spectrum and Signal Analyzer Measurements and Noise distinguishes log-envelope under-response from equivalent-noise-bandwidth correction.[9] The statistical derivation here states the

8.4.2 Power averaging before the logarithm

For N independent exponential power samples, $S=\frac{\sum_{i=1}^{N} P_i}{\mu}$ has density $\frac{s^{N-1}\exp\backslash(-s\backslash)}{\backslash(N-1\backslash)!}$ on $s\geq 0$, by repeated convolution. Differentiating the gamma integral yields $\mathrm{E}[\ln S]=\psi\backslash(N\backslash)=H_{N-1}-\gamma$, where H_n is the sum $1+\frac{1}{2}+\cdots+\frac{1}{n}$ and $H_0=0$. DLMF equations 5.9.16 and 5.9.19 give the corresponding harmonic and logarithmic-moment identities. Therefore

Equation 16C. Finite-record logarithmic bias after power averaging

$$E[A_N]=10\log_{10}(\frac{\mu}{P_{ref}})+b_N$$

$$b_N=\frac{10}{\ln 10}[H_{N-1}-\gamma-\ln N]$$

The arithmetic power mean is unbiased in watts. Its conversion to decibels has finite-record bias b_N. At $N=1$ the two formulas agree. At $N=4$, $b_N\approx-0.565350\ \mathrm{dB}$; at $N=100$, $b_N\approx-0.021751\ \mathrm{dB}$. It tends to zero from below. Adding 2.5068 dB to a well-averaged power estimate would introduce error. The relevant N counts independent exponential samples entering this estimator, not automatically sweeps, FFT samples or display pixels.

For independent samples the arithmetic mean has relative standard deviation $\frac{1}{\sqrt{N}}$. The exponential density's second logarithmic moment gives variance $\backslash(\frac{10}{\ln\backslash(10\backslash)}\backslash)^2\frac{\pi^2}{6}$ for one log sample, and thus standard deviation $\frac{10\pi}{\ln\backslash(10\backslash)\times\sqrt{6N}}$ for L_N. Dependence changes these variance results. For power samples with common variance μ^2 and common pairwise correlation

Copyright 2026, James M. Atkinson

ρ, direct expansion of the variance of their sum gives relative standard deviation $\sqrt{\frac{1+\backslash(N-1\backslash)\rho}{N}}$. This is a stipulated covariance illustration, not a substitute for investigating overlap or filter correlation. The gamma formula in Equation 16C generally does not survive that dependence.

8.4.3 Ten worked applications

All cases are hypothetical model calculations, not measured performance of a named receiver.

1. Order of operations. Two power samples are 0.1 and 1.9 mW. Their arithmetic mean is 1 mW, so $A_2 = 0\ \text{dBm}$. Their log average is $\frac{10\log_{10}\backslash(0.1\backslash) + 10\log_{10}\backslash(1.9\backslash)}{2}\ \text{dBm} \approx -3.606232\ \text{dBm}$. This particular record satisfies the inequality, but its observed difference need not equal an ensemble-mean correction.

2. The specified log statistic. A long log average of single-sample Gaussian-noise powers is -102.00 dBm. Equation 16B associates it with approximately $\backslash(-102.00 + 2.506816\backslash)\ \text{dBm} = -99.493184\ \text{dBm}$ mean-power level, before other calibration and bandwidth corrections. Keep the original statistic and correction in the record. This corrected value is not an upper confidence bound.

3. Constant-envelope counterexample. Suppose every calibrated sample represents an ideal tone at -102.00 dBm. Both Equation 16A statistics equal -102.00 dBm for any N. Adding the Gaussian correction gives -99.493184 dBm, overstating the tone by 2.506816 dB. A dBm axis does not establish applicability of a noise correction.

4. Noise-bandwidth change. A flat mean power spectral density of -150 dBm/Hz in 100 kHz equivalent noise bandwidth gives mean power -100 dBm and expected $L_N \approx -102.506816\ \text{dBm}$. At 1 kHz the corresponding levels are -120 and -122.506816 dBm. The change is -20 dB in both conventions because the identical bias cancels. The bandwidth ratio therefore identifies a

Copyright 2026, James M. Atkinson

change in integrated noise even when the absolute log level differs from mean power.

5. RBW label versus integration bandwidth. Stipulate a filter labeled 1 kHz whose independently established noise bandwidth is 1128 Hz; no universal filter factor is assumed. At -150 dBm/Hz the integrated mean is -119.476909 dBm and expected uncorrected log average is -121.983725 dBm. Recovery gives

$$[-121.983725+2.506816-10\log_{10}\left(\frac{1128\ \text{Hz}}{1\ \text{Hz}}\right)]\ \text{dBm/Hz}\approx-150.000000\ \text{dBm/Hz}.$$

Subtracting just 30 dB for the label instead gives -149.476909 dBm/Hz, 0.523091 dB high.

6. Four powers averaged first. For $N=4$, Equation 16C gives $\frac{10}{\ln(10)}\left(1+\frac{1}{2}+\frac{1}{3}-\gamma-\ln(4)\right)\ \text{dB}\approx-0.565350\ \text{dB}$. A statistic with expectation -100.565350 dBm corresponds to a -100 dBm mean-power level. Adding 2.506816 dB produces -98.058534 dBm, 1.941466 dB too high in expectation. With 100 independent powers the finite-log correction is just 0.021751 dB. An algorithm already correcting its statistic must not receive another correction.

7. Repeatability versus bias. At $N=100$ the arithmetic power mean has relative standard deviation 0.1. The log mean has standard deviation $\frac{10\pi}{\ln(10)\times\sqrt{600}}\ \text{dB}\approx0.557004\ \text{dB}$, yet its expectation remains 2.506816 dB low. For a sufficiently concentrated arithmetic power mean, first-order propagation gives approximate decibel standard deviation $\frac{10}{10\times\ln(10)}\ \text{dB}\approx0.434294\ \text{dB}$. That local approximation is not an exact

Copyright 2026, James M. Atkinson

confidence interval. A steadier trace need not estimate the intended quantity accurately.

8. Correlated records. For $N = 100$ and stipulated $\rho = 0.2$, relative standard deviation is $\sqrt{\frac{1 + 99 \times 0.2}{100}} \approx 0.456070$, not 0.1. If one sample is copied 100 times, $\rho = 1$ and relative standard deviation remains one. Storage count creates no independent information. Substituting the duplicate count into the gamma correction is unjustified.

9. Removing a Gaussian background. Two independent zero-mean Gaussian contributions each have mean power -100 dBm in the same bandwidth and at the same plane. Their total mean is 2×10^{-10} mW, or -96.989700 dBm. Converting normalized mean-power estimates to linear units and subtracting the background leaves 10^{-10} mW, or -100 dBm. The 3.010300 dB level difference is a ratio, not the desired power. Subtraction becomes ill-conditioned as the estimated total and background approach each other. This case excludes correlated background and coherent tones.

10. A changing noise level. Suppose 90% of records have Gaussian mean power 1 mW and 10% have Gaussian mean power 100 mW. Overall arithmetic mean is 10.9 mW, or 10.374265 dBm. Conditional use of Equation 16B gives an approximate expected log average \(0.9 \times 0 + 0.1 \times 20 - 2.506816 \) $\text{dBm} = -0.506816\ \text{dBm}$. Adding 2.506816 gives 2.000000 dBm, still 8.374265 dB below the overall mean-power level. The mixture is not one exponential distribution with one μ. Retain state-resolved results and durations instead of hiding the change under a constant correction.

Copyright 2026, James M. Atkinson

8.4.4 Measurement consequence

Specify input plane, effective bandwidth, pre-log statistic, detector order, averaging weights, independence assumptions, corrections already applied and excluded intervals. A power or RMS label may describe a bucket detector, video operation or final output; the applicable documentation must resolve the sequence. A screenshot without processing history cannot be repaired automatically by adding 2.51 dB. Chapter 9 owns FFT-window normalization and overlapping estimates; Chapter 14 owns calibration and the complete uncertainty budget.

Where the instrument suppresses values below a detection or display threshold, the unreported power is a censored observation, not a measured zero and not necessarily an observation at the threshold. Replacing it with an arbitrary positive number merely to permit a logarithm changes both the arithmetic mean power and the mean of logarithmic power readings. Retain the native power or I/Q record when available, together with the censoring indication, detector and gain state, frequency-time opportunity, calibration plane and threshold-setting history. Where an inference requires the distribution of unobserved values, state and test the statistical model rather than treating substituted data as measurements. The applicable statistical distinction is established in the censored-sample work of Rukhin and Samarov (2011) and the bias investigation by George and colleagues (2021); neither source, without receiver-specific validation, establishes the sensitivity or source attribution of a particular RF instrument.

Copyright 2026, James M. Atkinson

8.5 Sweep Time, Triggering, and Transient Signals

Sweep time must allow the resolution and video filters to settle as the analyzer moves. Instruments often calculate a minimum value, but automatic settings can fail for unusual signals, segmented sweeps, gated measurements, or external triggering. Too-fast sweeps broaden or lower narrow components and distort noise. Too-slow sweeps can miss state changes or make the result vulnerable to drift.

Triggering can align a sweep with a repetitive burst, pulse, or controlled state. Gated sweep or time-selective analysis restricts measurement to a portion of the event. Trigger delay, gate width, jitter, and repetition stability then become part of the uncertainty. If the event is not repeatable, a real-time or digitized capture may be more appropriate than forcing a swept instrument to portray it.

Copyright 2026, James M. Atkinson

8.6 Interpret a swept trace through its frequency-time trajectory

A swept trace should be read as a sequence of observations along a frequency-time trajectory. A stationary source can produce a stable spectral outline because the signal remains comparable while the analyzer visits successive frequencies. A changing source may instead contribute different states at different trace locations. Repeated sweeps and max hold retain more observations, but the assembled result still need not describe any one simultaneous waveform. The distinction follows directly from swept architecture and is also explicit in the Tektronix discussion of successive-frequency analysis.[10]

Map the intended event onto the actual sweep before choosing settings. Identify the interval during which the channel response and detector are valid at each frequency. For a stepped implementation, exclude tuning and settling intervals rather than counting every commanded dwell as fully usable. For a continuously swept implementation, use the validated relationship among sweep rate, filter response, and amplitude error. Equation 15 expresses a common qualitative dependence; it is not a universal numerical timing law because filter shape, processing architecture, and acceptance criterion determine the missing proportionality.

These are identified examples of preselection, gain placement, and protection, not a universal front-end architecture or an instrument-independent limit.

Copyright 2026, James M. Atkinson

Model 15A can describe conditional coverage at one frequency when the usable observation windows and required event overlap are established. It does not turn a swept instrument into a simultaneous wideband recorder. If an event changes frequency during the sweep, its trajectory and the analyzer trajectory must be compared, or the event must be captured in a mode whose instantaneous bandwidth contains it. A trace assembled from several bursts can reveal that activity exists while leaving its instantaneous spectral shape unresolved.

Copyright 2026, James M. Atkinson

8.7 Choose bandwidth from the quantity being estimated

Resolution bandwidth has several consequences that should be separated. It controls the frequency weighting applied before detection, influences the time needed for the response to develop, and changes the integrated noise admitted to the estimator. The nominal width, equivalent noise bandwidth, passband shape, and transient response are distinct properties. Model 2B uses noise bandwidth for a flat input-referred density; Model 11B uses the actual weighting when phase noise varies across the admitted band. The same front-panel label cannot replace both calculations without supporting characterization.

When a modulated signal extends across several resolution filters, one marker reading is generally not its total power. A channel-power calculation must identify the integration interval, spectral weighting, detector statistic, and calibration. Conversely, a broad filter can admit a neighboring component into a marker intended for one tone. The choice should follow the measurand and the signal environment. Narrower settings may reduce a noise display while slowing response or excluding signal energy needed by the measurement.

The statistical treatment earlier in this chapter explains why averaging in logarithmic units and logging an average power differ. Keep that distinction when changing bandwidth. Equation 16 compares integrated white-noise powers through compatible equivalent bandwidths and processing. A change in detector, averaging order, state distribution, or noise color can create an additional difference. A noise marker that already applies a correction should not receive the same correction again in postprocessing.

Copyright 2026, James M. Atkinson

Use a controlled comparison to separate the possible causes. Preserve the input and receiver state while changing one bandwidth parameter, and retain linear-power data when the instrument provides them. Compare the result with the declared filter response and estimator. Then challenge the source or environment separately. A mismatch with the simple bandwidth ratio is evidence that one of its assumptions needs examination; it does not by itself identify an external interferer or prove an instrument fault.

Copyright 2026, James M. Atkinson

8.8 Validate transient and gated measurements with the intended waveform

A continuous calibration tone verifies only part of a burst measurement. A gated or triggered method must also reproduce the relevant turn-on behavior, duration, repetition, frequency trajectory, and prior receiver state. Model 5A shows how a bounded AGC response can depend on the time available to settle. Model 6B separates instantaneous frequency from an interval average. Chapter 15 distinguishes trigger location from the data path. These mechanisms can all change a transient indication while leaving a long continuous-tone check apparently correct.

If repeated events are used to build a spectrum, establish the aspect of repeatability needed by that construction. Matching nominal repetition periods is insufficient when phase, amplitude, modulation, or startup varies from event to event. A trigger can align a chosen edge without aligning the internal waveform. Retain event-resolved records where practical and compare the proposed aggregate with them. When repeatability is not established, describe the aggregate as a collection of observations rather than one reconstructed event.

For a negative result, report the validated event class and coverage. State which bands were observed, how long each usable observation lasted, what transient criterion the method could meet, and which gaps or automatic state changes occurred. A max-hold trace with no peak can support a bounded statement about that procedure. It cannot establish that every short, weak, hopping, or out-of-band event was absent. The next observation should target the remaining uncertainty, using a different

Copyright 2026, James M. Atkinson

timing strategy or acquisition architecture when the existing method cannot resolve it.

Copyright 2026, James M. Atkinson

8.9 Amplitude Accuracy and Analyzer Self-Tests

Amplitude accuracy depends on input attenuation, preamplifier state, mixer level, IF gain, detector, reference level, frequency response, impedance, and calibration. The analyzer should be tested for compression and spurious response in the actual environment. Changing input attenuation while correcting the indicated level is a fundamental linearity check. A component that does not follow the expected relationship may be internally generated.

Self-alignment and internal calibration improve confidence but do not test the external cable, antenna, filter, or overload caused by the site. Known external references at several frequencies and levels verify the complete chain. The practitioner also checks frequency accuracy, residual responses with a terminated input, and responses to strong out-of-band signals. The final trace is accepted only after these challenges are recorded.

Copyright 2026, James M. Atkinson

8.10 Sweep Method Acceptance

A swept method is accepted only after its ability to represent the target signal has been demonstrated with a known continuous, modulated, pulsed, or frequency-agile reference. The test uses the same span, RBW, VBW, detector, sweep time, trigger, trace mode, and gain state as the survey. Where the method cannot reproduce the reference without distortion or missed events, a different architecture is selected.

The trace archive retains setup files and native data rather than only images. Segment boundaries, masked bands, averaging counts, sweep repetitions, and time stamps are documented. This permits a later reviewer to determine which frequencies were observed at each moment and whether a transient could have escaped the sweep.

Copyright 2026, James M. Atkinson

8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity

Equation 3. FFT-independent sweep-time scaling

$$T_{\text{sweep}} \propto \frac{\text{Span}}{\text{RBW}^2}$$

For many swept analyzers, minimum sweep time scales approximately with frequency span divided by the square of resolution bandwidth, with a proportionality determined by filter and instrument design. The relation is qualitative unless the manufacturer's validated model is used.

Equation 4. Noise normalization between bandwidths

$$P_{\text{n,2,dB}} = P_{\text{n,1,dB}} + 10\log_{10}\left(\frac{B_2}{B_1}\right)$$

For stationary white noise measured with compatible detectors and equivalent noise bandwidths, integrated noise changes by ten times the logarithm of the bandwidth ratio. Nonwhite interference, different filters, and trace processing invalidate the simple correction.

Equation 15 describes the familiar conditional trend for a swept filter implementation; its proportionality factor is not specified here and must not be invented for an unknown analyzer. Equation 16 follows by integrating an unchanged white power density over two positive equivalent noise bandwidths. Model 2B, the averaging treatment in this chapter, and the finite-window normalization in Chapter 9 identify the separate assumptions behind those statements.

8.12 Hypothetical Applied Calculation: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity

A white-noise trace reads -102 dBm in a 100 kHz noise bandwidth. Reducing the equivalent noise bandwidth to 1 kHz should lower integrated noise by about 20 dB, to -122 dBm, if the detector and processing are compatible. A smaller change suggests nonwhite interference, instrument noise, or inconsistent normalization.

Copyright 2026, James M. Atkinson

8.13 Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity

A max-hold sweep shows a comb of narrow peaks around a pulsed device. Real-time capture reveals that the peaks are fragments of a chirped burst observed at different moments during repeated sweeps. The comb is a sweep-time portrayal artifact, not a set of simultaneous carriers.

Copyright 2026, James M. Atkinson

8.14 Sweep-time adequacy as a dynamic measurement rather than a display preference

A swept-tuned analyser samples different frequencies at different times. Its plotted spectral line is therefore a synthesis of observations made at successive tuning states, not a simultaneous picture of an instantaneous wideband field. Let the instrument traverse span F_{span} over sweep duration T_s, and write the nominal local tuning velocity $v = F_{span}/T_s$ in hertz per second. A feature occupying effective filter bandwidth B is available for approximately B/v seconds during a uniform sweep, excluding additional settling and detector-memory constraints. A brief pulse may fall entirely outside that interval even while the frequency coordinate is present on the eventual trace. A later viewer can easily mistake a blank trace for a negative observation of a whole span; in reality it may document only a sequence of narrow temporal opportunities.

A synthetic example illustrates the scale: a 100 MHz uniform span traversed in 1 s has velocity 100 MHz per second. A 100 kHz instantaneous analysis bandwidth corresponds to approximately 1 ms of nominal frequency-specific observation. A single 100 microsecond pulse, arriving at a time unrelated to the sweep, need not overlap that millisecond. A detector configured for persistence or maximum hold can accumulate successive detections and produce a stable-looking line, yet this display does not establish continuous monitoring of the line's frequency. The duty factor of the observed opportunity and the pulse arrival distribution are needed to estimate capture probability. The calculation is deliberately idealised; real

Copyright 2026, James M. Atkinson

instruments have varying filter and sweep response, dwell overhead and detector settling.

Some measurements require a dwell sufficient for the selected IF and postdetection weighting to respond. A nominal short RBW may narrow the noise bandwidth and improve separation of carriers while increasing settling time; reducing sweep time without establishing adequate response can bias level and broaden or shift a short component. The trace's video-bandwidth setting changes displayed variability and temporal memory, not necessarily the original analogue channel's admitted noise. Where an applicable EMI receiver method specifies detector weighting and measurement time, the programme should retain the actual detector law and validity conditions rather than substitute generic speed settings. The official apparatus scope of CISPR 16-1-1:2019 covers specified radio-disturbance measuring equipment, not universal proof of TSCM emitter identity.

A defensible challenge uses a calibrated synthesised burst at prearranged frequencies, varied relative to sweep start, with actual instrument time markers and independent event timing. Repeat at different sweep speeds, resolution and video bandwidths, detector modes and preselection states. Keep source amplitude constant and test both in-span and near-boundary pulses. Record missed-event counts separately from underestimated amplitudes or invalid detector states. A negative swept trace should be reported with its actual frequency-time coverage and the tested event class. If the engagement demands continuous coverage of a rare short burst, a real-time digitising path or parallel receiver may be required, and its own bandwidth and overload limitations must then be verified independently.

Copyright 2026, James M. Atkinson

8.15 Swept-spectrum observation as a sampling-design and probability problem

The displayed span of a swept-tuned analyser is not equivalent to continuous simultaneous observation of every frequency in that span. A swept architecture selects successive frequency positions through an RF or IF passband and integrates a detector response over time. An intermittent emission may begin, end or change frequency between relevant dwells. A trace that includes a beautifully resolved noise floor therefore supplies no direct evidence about an event that occurred outside the time-frequency observation window. To make the inference reviewable, define the tune trajectory $f_c(t)$, effective filter response $H(f-f_c(t))$, settling exclusions, detector response and valid acquisition intervals. Only then can a specific class of burst be assigned a demonstrated opportunity for observation.

Copyright 2026, James M. Atkinson

Figure 49. Sweep trajectory versus intermittent emissions.

Suppose an idealised scan repeats once every T seconds and a particular narrow channel is monitored for dwell duration d seconds in each cycle, with the receiver settled throughout and zero sensitivity outside the dwell. Assume a burst of duration b shorter than T occurs with start time uniformly

Copyright 2026, James M. Atkinson

distributed over one scan period. The burst overlaps the monitored interval if its start falls within the dwell enlarged by b in the circular time domain. Provided d+b is no greater than T, the overlap probability is (d+b)/T. With T = 5 s, d = 25 ms and b = 10 ms, the ideal overlap probability is 0.035/5 = 0.007, or 0.7 per cent. This is not the probability of detecting the burst, because overlap may occur for too little time or with too little signal-to-noise ratio for the chosen detector. It is not valid if event start time is synchronised to the scan, if scan intervals vary, or if the channel's effective coverage extends beyond the idealised dwell.

A stronger capture criterion requires the receiver to observe at least q seconds of the burst after settling, where q is defined by the detector and signal amplitude. For one valid dwell of length d and event duration b, the interval of start times that yields an overlap of at least q has length max(0,d+b-2q) when 0 less than q less than or equal to min(d,b), subject to the periodic-boundary conditions. With the previous d and b and q = 5 ms, the admissible length is 25 ms, giving 0.5 per cent under the ideal uniform-start model. A duty-cycle figure alone cannot distinguish the 0.7 per cent any-overlap opportunity from the 0.5 per cent five-millisecond opportunity. The probability of a valid decision must also incorporate signal retention, calibrated noise and detector statistics. This example illustrates a mathematical distinction, not an actual instrument's probability of intercept.

The minimum sweep time implied by an RBW setting is also a conditional engineering relation. A high-selectivity resolution filter requires a finite time to respond to frequencies that move through its passband. If frequency changes rapidly compared with the filter's response, the displayed amplitude of a continuous tone can be biased and its apparent frequency

Copyright 2026, James M. Atkinson

distorted. Sweep time depends on filter shape and response, centre-frequency trajectory, detector averaging, available preselection, and the acceptable error criterion. A familiar proportional rule in span divided by RBW squared may be a useful instrument-specific approximation, but it is not a universal law for all filter topologies, FFT-assisted sweep modes or detector implementations. The proper acceptance test compares swept readings against a verified reference while varying sweep rate and measuring convergence under the actual observation mode.

It is particularly important to separate the first crossing of a pulse from later detector persistence. Video filtering can smear a genuine burst across time samples, while peak hold can preserve a former event in the displayed trace long after the source has ceased. A max-hold trace conveys the highest retained statistic across a specified set of visits; it does not provide a continuously observed event history. Conversely, zero detections in a sparse set of dwells do not establish continuous absence between visits. Retain the number, duration and placement of valid observations as part of the forensic record. A line on a waterfall cannot replace the original trace acquisition timestamps and instrument-state transitions.

A practical experiment uses a shielded controlled source with independently recorded randomised burst times. Prepare narrow continuous signals, short and long pulses, frequency-agile bursts and signals near a resolution-filter skirt. Repeat the challenge at several RBW, VBW, detector and sweep-time settings. Measure actual event coverage from hardware timing or native acquisition logs rather than assuming ideal scan scheduling. Report the fraction of source events overlapping a valid dwell, the fraction meeting the required retained-response criterion, the false-alarm behaviour in source-off

Copyright 2026, James M. Atkinson

trials, and the uncertainty in each fraction. Sources and receiver must remain within a valid linear range, and the burst programme should be held out from any settings used to tune the detection threshold. The chapter can then distinguish waveform capture, peak-level fidelity and broad discovery screening, which are different engineering objectives even when all three are displayed in a spectrum-analyser interface.

Copyright 2026, James M. Atkinson

8.16 Additional study: swept observation as a space-time sampling experiment

A swept spectrum analyser does not observe every frequency throughout the duration of a scan. Its tuned passband occupies a moving neighbourhood of the frequency axis, and its response at one nominal display bin depends on the frequency trajectory, filter memory, detector integration interval and trace-processing rule. The familiar image of a stationary spectrum can consequently conceal a complex sequence of observations separated in both frequency and time. To interpret a brief or intermittent emission, define the acquisition as a time-varying observation operator rather than a completed rectangular measurement of the frequency-time plane. This formulation is essential for distinguishing a genuine absent signal from an unobserved event and a receiver-generated product that appears only during a particular sweep state.

Let the nominal tuned frequency be $f_c(t)$, measured in hertz as a known function of time in seconds. Let $H(f; f_c(t))$ describe the selected IF resolution filter translated to that centre frequency under the bounded approximation that its response follows tuning without an additional unmodelled transition. An input component at frequency $f_s(t)$ contributes significantly only while its instantaneous spectral support overlaps the admitted response. For a stationary narrow tone, a first approximation to its time in an effective passband of width B_{eff} during a linear sweep at rate $v = |df_c/dt|$ is $T_{cross} \approx B_{eff}/v$. This is a geometric overlap, not automatically a usable independent measurement. If the resolution filter requires settling time comparable to or longer than T_{cross}, the displayed amplitude may be

Copyright 2026, James M. Atkinson

systematically biased. The trajectory also needs guards for preselector switching and gain-state transitions.

The same relation gives a transparent planning inequality. Suppose a linear sweep covers span S in total active sweep time T_s, so $v=S/T_s$. To provide at least a stated overlap duration T_{req} for a stationary tone under the boxcar approximation, require $B_{eff} T_s/S \geq T_{req}$, or $T_s \geq S\, T_{req}/B_{eff}$. All quantities must use compatible hertz and seconds. For a filter whose effective response and settling differ materially from a boxcar, replace the approximation by the actual time-domain convolution of the swept response and stipulated input waveform. A sweep-time setting derived from filter bandwidth alone does not certify the observed amplitude unless the detector and control state have also been considered.

A short burst presents a second sampling problem. Let an emission occupy frequency f_0 for event duration T_b, and let an analyser admit that frequency during actual valid time intervals I_j. If event start time t_0 is unknown and the detection rule requires overlap of at least δ seconds, a start is eligible for detection only when the shifted event interval $[t_0, t_0+T_b]$ overlaps at least one I_j by δ. The union of eligible starts can be computed from the real intervals, including gaps due to switching or loss of valid IF response. It may be very small even when the total scan duration is large. A probability of capture additionally requires a stated distribution of event start times. Without that distribution, the mathematically defensible statement is a coverage set, not a numerical probability.

The difference becomes especially serious for frequency-agile signals. If the emitter's frequency evolves as $f_s(t)$, the instrument acquires a substantial fraction of its energy only when the separation $|f_s(t)-f_c(t)|$ lies within the

Copyright 2026, James M. Atkinson

actual filter response and the acquisition state is valid. Two trajectories can cross at one instant but have very different dwell within the passband. A waveform that follows the analyser sweep rate may remain visible much longer than a stationary burst of the same duration, while one moving in the opposite direction can traverse the passband very quickly. A display that assigns the peak to a single stationary frequency can misrepresent its physical history. The raw sweep timing and any reconstruction of frequency-time motion should therefore be preserved separately.

Detection also depends on the detector's selection law. A peak detector may register an event whose instantaneous IF power is high enough during one brief overlap, while an average or RMS detector can dilute its contribution across an interval that includes a larger amount of noise-only data. A video filter may reduce trace variance while broadening the temporal response and increasing persistence. These are measurements of different statistics. To compare them, the test must stipulate the same physical event, input level, analysis band, source state and observation opportunities, then identify the statistic each mode reports. A cleaner-looking average spectrum is not proof of improved sensitivity to rare bursts.

Preselector behaviour adds hidden discontinuities to the sweep geometry. An instrument may switch front-end filters as its nominal centre frequency passes a boundary. The selected preselector has its own insertion loss, image rejection, switching transient and thermal behaviour, and a transition can exclude some observation intervals. An older static contents table may imply continuous coverage across the boundary even where the installed receiver was blind or in a different gain state. Forensic capture coverage should be computed from the actual interval record, not solely from the

Copyright 2026, James M. Atkinson

requested centre-frequency list or the final rendered trace. If the instrument does not expose exact switching intervals, a calibrated challenge source spanning the boundary can bound the blind period, but that result is valid only for the tested operating states.

One synthetic sweep illustration uses a span of 200 MHz traversed in 100 ms with an effective resolution-filter width of 20 kHz. The sweep rate is 2 GHz/s, so geometric overlap with a stationary tone is 20,000/2,000,000,000 seconds, or 10 μs. If the filter and detector need at least 100 μs of usable response to provide the declared amplitude criterion, this sweep does not meet that criterion. The requested sweep time would have to rise at least to one second under the elementary boxcar calculation, before adding settling and switching guards. A manufacturer-recommended sweep-time model may require a different factor because a resolution filter is not a perfect brick-wall gate. The example is a planning counterexample, not an instrument-specific specification.

A second illustration examines a rare ten-millisecond burst in a channel revisited every two seconds, with a valid observation window of five milliseconds per cycle. Assume the event start phase is uniform relative to the cycle, and detection requires at least one millisecond of overlap. The eligible start interval around each five-millisecond valid window has length $T_b + 5\ \text{ms} - 2\delta = 13\ \text{ms}$, assuming no wrap-around interactions among windows. The idealised capture probability is 13 ms/2 s = 0.0065, or 0.65 percent, for one randomly phased event. This value is conditional on the assumed start-phase distribution, waveform retention, detector validity and one-millisecond criterion. A deterministic transmitter synchronised to the

Copyright 2026, James M. Atkinson

scan could repeatedly miss the windows, even after many scans; the uniform-phase model would then be inappropriate.

A third synthetic example considers a centre-frequency trajectory moving upward at 100 MHz/s and a chirp sweeping upward at 90 MHz/s. Their relative sweep rate is 10 MHz/s, so an effective 10 kHz passband gives a nominal encounter of one millisecond. If the chirp instead moves downward at 90 MHz/s while the analyser moves upward, relative rate becomes 190 MHz/s, giving approximately 52.63 μs. The two events may therefore produce substantially different IF amplitudes even if the instantaneous input spectral density is equal. A strong conclusion about RF event duration or intensity would require accounting for the relative time-frequency trajectory and filter impulse response.

Copyright 2026, James M. Atkinson

8.17 Distinguishing a spectral estimator from a persuasive-looking display

A sweep trace is a collection of filtered, detected and often logarithmically transformed observations. Its bin values may not share a common acquisition time, and the detector may have visited different physical states along the axis. The operation that averages traces across several sweeps adds another time model: it combines observations of a possibly changing environment, not repeated samples of one unchanged random variable by definition. For stationary signals and validated conditions such averaging may reduce variability; for intermittent emissions it can conceal the event frequency, time or peak level. A final interpretation must therefore specify whether the reported quantity is peak observed level, mean occupancy, a percentile, a fitted amplitude or a threshold-crossing count.

When deriving uncertainty, separate amplitude calibration from sampling uncertainty. A calibrated reference tone can establish the scale of a valid filtered measurement without establishing that a rare event would have been observed. The probability of observing an event is not a conventional dB correction. Similarly, a sweep trajectory can visit the correct nominal frequency but fail to deliver enough integration time for the required detector statistic. These two limitations should be reported in different parts of the result: amplitude uncertainty for valid observations and conditional coverage for unobserved opportunities. Combining them into one unexplained uncertainty number would obscure the reason a negative survey might fail.

Copyright 2026, James M. Atkinson

A defensible experiment must contain known positive trials, negative controls and held-out combinations. Generate short CW bursts, chirps, frequency hops and modulated transients under lawful shielded conditions, with independent waveform truth and independently verified source amplitudes. Randomise event starts relative to the analyser sweep, vary duration and frequency slope, and document all receiver configuration transitions. Freeze the event-detection rule before examining held-out trials. For each trial record whether the receiver actually observed the relevant channel, whether its IF path was settled, whether the detector crossed the criterion, and whether source or analyser artefacts could mimic the result. A false negative caused by no observation opportunity must not be pooled indiscriminately with one caused by insufficient instantaneous sensitivity.

For quantitative reporting, a coverage map may list the valid time intervals at every tested frequency and the event classes for which detection has been demonstrated. If a probability is desired, specify the event-start distribution and show how its density is integrated over the union of eligible start intervals. The same framework accommodates a regular scan, a deliberately jittered sweep and an adaptive monitoring schedule. An adaptive schedule requires special caution: future measurement decisions can depend on earlier observations, so the schedule may be correlated with the event process. An assumption of independently random timing would then need evidence rather than assertion. This is particularly consequential when a receiver changes bandwidth or sweep speed in response to a possible anomaly.

A fourth hypothetical example demonstrates an adaptive bias. Suppose the instrument sweeps a particular band quickly after three quiet passes and

Copyright 2026, James M. Atkinson

slowly immediately after a threshold crossing. If a later analyst averages only the slow passes, the selected traces will disproportionately represent periods following apparent activity. An apparent high occupancy fraction may be caused partly by the selection rule rather than the underlying emitter duty cycle. The correct estimator needs the complete observation schedule and an explicit description of the selection mechanism. A software file containing only the positive traces cannot establish the required denominator for an occupancy estimate.

A fifth example considers video filtering of a finite pulse. Let a detector produce a unit rectangular output for 0.5 ms, and let a subsequent one-pole video filter have time constant 2 ms. Under a simple linear filter assumption, the maximum rise before the pulse ends is $1-\exp(-0.5/2) = 0.2212$ of the unit step. A threshold set to 0.3 would not be crossed even though the unfiltered pulse reached unit amplitude. Increasing display averaging would not repair the miss. Conversely, the post-event decay can produce a trace response after the physical event has ended. To assert event timing, the report must refer to the detector and video-filter temporal response rather than treating the displayed peak position as the incident emission time.

The proposed qualification standard is therefore two-dimensional at minimum: sensitivity to a specified event when the channel is validly observed, and the opportunities for observation under the actual sweep schedule. More elaborate receiver plans may need further dimensions for blockers, environmental noise, gain, preselector state and frequency-dependent detector response. The resulting acceptance surface can support useful, carefully bounded negative statements. It cannot prove that every

Copyright 2026, James M. Atkinson

conceivable transmission was absent from an unobserved or invalid region of the frequency-time plane.

Copyright 2026, James M. Atkinson

8.18 Advanced technical expansion. Swept observation as a sampling problem in time and frequency

A swept spectrum analyser does not observe every frequency continuously. Its local oscillator follows a trajectory through a span while a resolution filter, envelope detector and display estimator each retain memory of earlier inputs. A screen containing many frequency points is therefore a map of measurements made at different times. An intermittent emitter can be active at a frequency when the analyser is elsewhere, and a short burst can begin while the filter has not settled sufficiently to produce a valid displayed peak. A rigorous survey must record sweep direction, sweep period, active frequency trajectory, preselector selection, resolution-bandwidth filter, video bandwidth and detector type. The difference between physical opportunity to observe and amplitude sensitivity during that opportunity should remain visible in the result.

An illustrative filter-limited lower bound on swept time has the form T_sweep proportional to span divided by B squared, with the coefficient depending on filter response and tolerated amplitude error. This relation is documented in Rohde & Schwarz application literature for classical swept analysis; it is an engineering approximation rather than a universally valid timing law for FFT-based or hybrid analysers. If a chosen span is 10 MHz and the relevant bandwidth B is 10 kHz, the ratio span/B squared has units of 0.1 second; a dimensionless filter factor of 2.5 yields 0.25 second under the stated simple model. Reducing B to 1 kHz increases the same term by a factor of 100. This is the physical reason a narrow displayed noise floor may cost observation speed and event-capture opportunity. The exact

Copyright 2026, James M. Atkinson

instrument behaviour must be verified rather than assumed from the illustrative coefficient.

There are two distinct forms of error during a fast sweep. First, a continuous tone may fail to drive the filter to its steady amplitude before the LO moves on, biasing level and sometimes frequency. Second, an intermittent emission may not occur during the analyser's valid observation opportunity at that frequency. Slowing a sweep may repair the first deficiency while increasing the interval between revisits, worsening the second for some event distributions. A single sweep-time setting cannot optimise all objectives simultaneously. The proper experimental design states the event family, required amplitude accuracy, detector response and tolerated revisit interval, then characterises the instrument against a pulsed reference with a known onset schedule independent of the sweep clock.

A probability-of-observation model begins with a binary coverage function $c_f(t)$ that equals one when a particular frequency is being observed under valid conditions and zero otherwise. For a burst with start time t_0 and duration d, successful capture depends on the intersection of $[t_0, t_0+d]$ with intervals where $c_f(t)=1$, together with a required overlap or signal-detection criterion. If start time is assumed uniform on a stated period, the eligible fraction can be calculated from the geometry of these intervals. No probability follows without an event-time model; periodic transmitters synchronised to the sweep may repeatedly fall in the same blind window. The correct report can state measured or derived opportunity and the model assumptions rather than translating a coverage fraction into universal confidence.

Copyright 2026, James M. Atkinson

Resolution and video filters also alter the display statistic. A peak detector operating on unsmoothed eligible samples can show rare excursions differently from a sample or average detector; video smoothing reduces visible fluctuations but may conceal brief peaks. A logarithmic video average is not the same as an arithmetic mean of linear power. A quasi-peak detector applies a specified temporal weighting and cannot be equated with a generic maximum-hold trace. A defensible report names the detector and processing conventions and retains the native trace where possible. Comparing two spectra without matching those conventions can produce apparently contradictory results that are entirely explained by instrumentation.

Acceptance testing should include a continuous reference for level accuracy, an independently triggered burst source for observation probability, and controlled blockers for overload behaviour. Vary burst duration, repetition, phase relative to sweep and frequency position, especially near preselector transitions. Preserve every trial including misses, record the actual analyser trace and state, and compare with an independently monitored source schedule. A single successful capture does not establish universal sensitivity; a single missed event may establish either a coverage gap or a deficient detector, depending on the independently verified opportunity. The distinction is central when using swept measurements to defend a negative technical-security finding.

Copyright 2026, James M. Atkinson

8.19 Swept analysis as a moving, state-dependent measurement aperture

A conventional swept-tuned spectrum analyser does not observe a displayed span simultaneously. It moves a frequency-selective response through the spectrum, integrating, detecting and displaying each part at a different time. A trace is therefore a constructed function of frequency and observation time, not an instantaneous photograph of the electromagnetic environment. The distinction becomes decisive when an intermittent transmitter changes carrier, pulse duration or modulation while the analyser is tuned elsewhere. A clean final trace may be entirely consistent with an external signal that occurred during an unobserved frequency-time interval. Conversely, a displayed peak may derive from a response that persisted within the analyser after the external event ended. The scientific task is to connect every plotted point with the physical interval, admitted frequency response and detector law that produced it.

For an ideal linear sweep across span S hertz in time T_s seconds, the nominal tuned centre is $f_s(t)=f_{start}+(S/T_s)t$ for $0 \le t \le T_s$. The sweep rate $v=S/T_s$ has units hertz per second. A stationary tone at f_0 spends approximately $t_{pass}=B_R/v$ seconds within a nominal resolution-filter width B_R hertz if the sweep law and passband shape can be approximated as locally constant. This is a kinematic estimate, not a calibrated response model. A real filter has an impulse response, a centre-frequency-dependent tuning transfer and a finite time to settle after excitation; a tone passing briefly through it may be reported with a diminished amplitude, broadened

Copyright 2026, James M. Atkinson

profile or shifted apparent frequency. The governing condition must involve the filter's actual transient response, not merely its nominal 3 dB bandwidth.

For a family of similarly shaped filters one may use an approximate settling time $t_{set}=k/B_R$, with dimensionless constant k fixed by the required amplitude and timing accuracy. Requiring $t_{pass}\geq t_{set}$ gives $T_s\geq kS/B_R^2$. The square-law dependence is a powerful engineering scaling, but k is not a universal number. A Gaussian-like analogue RBW filter, a digitally synthesised filter and a steep multi-section IF filter can have different ringing and measurement criteria. If the output detector requires additional dwell or the analyser has discrete tuning steps, the actual minimum may be longer. The relevant data are the specified filter family, its centre and shape, detector mode, input signal type and required measurement accuracy.

Copyright 2026, James M. Atkinson

8.20 Resolution, equivalent noise bandwidth and distortion of transient waveforms

The indicated resolution bandwidth is not automatically the equivalent noise bandwidth of the same filter, nor is either one the instantaneous spectrum of the input signal. The resolution specification commonly describes selectivity or a response-width convention, while equivalent noise bandwidth B_{eq} is defined from the power response $H(f)$: $B_{eq}=[\text{integral } |H(f)|^2 df]/|H(f_c)|^2$ for a reference frequency f_c and a normalised gain convention. For white input noise with applicable spectral density N_0, admitted mean noise is $N_0 B_{eq}$. A narrow filter can improve separation of two stable tones and lower admitted white noise, yet attenuate or temporally smear short pulses. Noise-floor improvement and preservation of a transient are independent measurements, not two names for the same bandwidth trade.

A finite-resolution filter also has asymmetry, group delay and memory. If a swept tone changes frequency while passing the filter, its response is not necessarily the response that would have been measured by dwelling at the final frequency. A narrowband filter can remain excited after the instantaneous LO tuning has moved, generating a trace feature displaced from the actual tone. An analyser whose sweep-time coupling is overridden may therefore produce consistent but wrong results on repeated sweeps. A useful calibration includes a known continuous tone, a stepped tone near passband boundaries, a controlled pulse and a frequency-agile source, each with independent confirmation of the actual waveform. Separating centre-

Copyright 2026, James M. Atkinson

frequency error from settling error prevents correction of one with an unrelated scalar offset.

Copyright 2026, James M. Atkinson

8.21 Detector laws, video filtering and the asymmetry of logarithmic statistics

A swept analyser can use peak, negative-peak, sample, RMS, quasi-peak or average detectors, depending on its architecture and intended standard. A peak detector retains a maximum in the samples assigned to a pixel or bin; RMS detection estimates a mean-square quantity; a sample detector reports one selected observation. These operations may agree for a stable continuous tone but diverge greatly for a noise-like signal or rare pulse. Their numerical outputs must not be treated as interchangeable merely because the vertical unit is dBm. The precise quantity measured depends on the placement of the detector relative to the resolution filter, video filter and logarithmic conversion. An instruction to use average trace is incomplete unless it states whether linear power, voltage, logarithmic level or selected detector outputs are averaged.

Video bandwidth typically acts after part of the amplitude detection process. It controls the display or measured envelope's time response and can suppress visible fluctuations, but it does not automatically reduce the thermal noise admitted by the front-end resolution filter. A low VBW can conceal narrow peaks or make a brief event appear as a delayed broad hump. For an ideal first-order low-pass video filter with 3 dB bandwidth B_V, $\tau=1/(2\pi B_V)$. Its step response reaches about 95 percent after approximately three τ, under the specific first-order model. Real detector and instrument filters need separate calibration. One cannot safely use a bandwidth value alone to infer a universal recovery delay, particularly when

Copyright 2026, James M. Atkinson

a swept trace contains automatic detector transitions or quasi-peak weighting.

For an ideal complex Gaussian noise sample, instantaneous detected power is exponentially distributed with mean P_bar. The expected logarithm of one sample lies below the logarithm of that mean: $E[10\log10(P/P_bar)]= -10\gamma/\ln10\approx-2.5068$ dB, where γ is Euler's constant. This is a mathematical consequence of taking the logarithm before averaging, not a calibration loss in the receiver. If K independent exponential power samples are averaged in linear units before taking the logarithm, the bias is $(10/\ln10)[\psi(K)-\ln K]$, where ψ is the digamma function; it becomes smaller in magnitude as K increases. Correlated samples, non-Gaussian interference and a different detector invalidate the particular distributions. Consequently a visually smoother or lower average trace does not automatically demonstrate a physically lower noise temperature.

Copyright 2026, James M. Atkinson

8.22 Periodic sweeps and the probability of observing a rare event

For a fixed frequency f_0, let $c_f(t)$ equal one during intervals where the analyser can validly observe a specified event and zero during retune, filter-settling, blanking, overload or off-frequency periods. For a known event $e(t)$, the observation can be analysed deterministically from the overlap of its occurrence and $c_f(t)$. A probability requires an additional stochastic model of event start times, durations, frequencies and the detector's response conditional on overlap. Uniform start phase is sometimes a useful hypothetical assumption, but must not be silently adopted for intentional, phase-locked or environmentally correlated transmitters. Repeated sweeps create periodic holes; an emitter whose start time is synchronised to those holes may be missed indefinitely despite a large number of apparently complete traces.

Consider a single valid observation window of duration W in each period T, a fixed-frequency burst of duration d, and a requirement for at least q seconds of temporal overlap to achieve a specified detection statistic. Under uniformly distributed burst start phase on the periodic interval, and assuming one simple window and $q \leq \min(W,d)$, the eligible start-phase measure is $W+d-2q$, clipped to the periodic domain when necessary. Thus $P_{overlap}=\min[1,(W+d-2q)/T]$ for nonnegative eligible width in this idealised geometry. This is not automatically a calibrated probability of RF detection; it ignores receiver sensitivity, burst spectral energy, nonlinear response and threshold variability. The overlap rule also requires modification when multiple observation windows interact or the event can overlap a window

Copyright 2026, James M. Atkinson

across the periodic boundary. A full implementation should calculate the eligible set explicitly rather than extrapolate this simple case.

The operator may try to improve capture by reducing span, enlarging RBW, increasing dwell, triggering a narrow watch channel, or using a wideband real-time parallel acquisition. Each changes different properties of the observation. Reducing span increases revisit opportunity at frequencies inside the new span but removes all coverage outside it. Enlarging RBW can shorten filter settling while admitting more noise and potentially stronger blockers. A continuous narrow watch channel gives uninterrupted time coverage in its passband but cannot see frequency-agile components outside that region. A real-time analyser can reduce sweep-specific temporal gaps within its actual instantaneous bandwidth while retaining front-end, converter, memory and trigger limits. Claims of universal 100 percent probability of intercept must state the tested event class, duration, power, bandwidth and internal instrument state.

Copyright 2026, James M. Atkinson

8.23 False alarms, maximum hold and selected displays

Maximum hold is useful for detecting rare excursions but is a selection operation. Even in noise-only data, the maximum tends to rise as the number of independent opportunities grows. If a fixed threshold has a stipulated false-alarm probability p per independent trial, the probability of at least one false alarm in K trials is 1-(1-p)^K. Actual spectral bins and successive traces may be correlated because of filter bandwidth, overlap and shared disturbances; replacing K with the visible number of pixels is not a justified independence argument. Threshold studies should include noise-only survey-length records and a declaration of how many frequencies, sweeps and detector outputs were searched. An apparent peak discovered after extensive parameter tuning is vulnerable to selection bias unless confirmed on a distinct, predeclared acquisition.

Peak response is also affected by limited sampling of the detector output. A very short pulse may occur between sample points, while a peak detector with suitable internal sub-sampling may retain it. The instrument's detector definition and trace resolution matter. A post-event display showing one isolated peak can be authentic yet lack enough temporal data to establish its physical duration, source waveform or exact event time. A screen capture should therefore be a presentation artifact linked to the native trace and settings. It is not a substitute for state records, actual sweep timing or an independently captured transient waveform.

Copyright 2026, James M. Atkinson

8.24 Ten worked calculations and controlled counterexamples

Application 8C.1. For span S=1 MHz, RBW B_R=10 kHz and stipulated filter factor k=2, the scaling estimate $T_s \geq kS/B_R^2$ is 2×10^6/10^8=0.020 s. Reducing RBW to 1 kHz makes the estimate 2×10^6/10^6=2.0 s, a hundredfold increase for a tenfold narrower filter. These are hypothetical filter-family estimates; an instrument's permitted minimum sweep time and amplitude-error criterion must be checked independently.

Application 8C.2. A sweep spans 40 MHz in T_s=1 s. Its nominal rate is 40 MHz/s. For a 20 kHz effective pass window, the ideal time a stationary tone remains within the window is 20,000/(40×10^6)=0.00050 s, or 0.50 ms. A 2 ms burst may overlap that window or miss it altogether, depending on start phase. Its actual detected amplitude still depends on filter settling and detector processing.

Application 8C.3. An ideal one-pole VBW filter has B_V=100 Hz. Its time constant is 1/(2π×100)=1.592 ms and its ideal 95-percent step-response time is approximately 3τ=4.775 ms. A 0.5 ms burst cannot be inferred to have reached full steady-state video amplitude. This does not imply that a peak detector positioned before that filter would necessarily miss the event; the actual signal path must be established.

Application 8C.4. A white-noise input has flat density -150 dBm/Hz under a stipulated reference convention, and the receiver's equivalent noise bandwidth changes from 100 kHz to 10 kHz with unchanged gain and noise law. Integrated mean noise changes from -100 dBm to -110 dBm, a 10 dB

Copyright 2026, James M. Atkinson

difference. The underlying spectral density has not changed, and a desired burst may lose energy in the narrower response.

Application 8C.5. A single exponentially distributed power sample is converted to decibels before averaging over repeated independent noise realisations. Its expected reported level lies 2.5068 dB below the logarithm of its physical mean. If four independent power samples are averaged before logarithmic conversion, the digamma formula gives approximately -0.565 dB instead. The values are model-dependent mathematical biases, not universal spectrum-analyser calibration corrections.

Application 8C.6. One eligible observation window of W=1 ms occurs every T=100 ms, while a fixed-frequency event has d=2 ms duration and a successful observation requires q=0.2 ms overlap. Under the stated uniform random start phase and adequate amplitude, P_overlap=(1+2-0.4)/100=0.026, or 2.6 percent. Repeating the sweep does not guarantee independent event phases if the source repetition is synchronised to the same cycle.

Application 8C.7. An instrument scans a 100 MHz span with a 10 kHz approximate pass window and nominal 1 s sweep. Under the linear mapping, the local time in the window is (10,000×1)/100,000,000=0.0001 s, or 0.1 ms. If the relevant filter needs 0.3 ms of response under a specified amplitude criterion, the chosen sweep cannot satisfy that criterion. Lengthening the sweep to at least 3 s would provide the nominal 0.3 ms window, subject to the filter's true transient response and other detector constraints.

Copyright 2026, James M. Atkinson

Application 8C.8. A noise-only detector has a stipulated threshold-crossing probability p=0.01 in each of 100 independent sweeps. Maximum-hold selection produces at least one crossing with probability 1-(0.99)^100≈0.634, or 63.4 percent. This does not imply any external transmitter. Actual correlated noise requires a different calculation or an empirical full-survey false-alarm validation.

Application 8C.9. The analyser's nominal sweep covers 10 seconds, but 2 seconds are lost to settling and 1 second to an independently recorded overload episode. If these intervals are disjoint, the demonstrated valid time fraction is 7/10=70 percent. If overload lies entirely within settling, the valid fraction is 8/10=80 percent. Neither fraction gives a probability of intercept without a model of event time, frequency and amplitude response.

Application 8C.10. A fixed calibrated tone gives -80 dBm in a sufficiently slow sweep and -83 dBm after a faster sweep with unchanged frequency, input path, gain and detector mode. The 3 dB discrepancy is compatible with a transient-response bias but does not uniquely prove it. A controlled step of sweep time, with source verification, fixed RBW/VBW and recorded internal state, tests whether the level approaches the slow-sweep value as the available filter dwell increases. An amplitude correction of +3 dB should not be applied universally to unknown pulses without this separate validation.

Copyright 2026, James M. Atkinson

8.25 A robust acceptance test for transient and stationary measurements

A credible instrument acceptance programme compares four classes: a stable continuous tone to establish level and frequency calibration, two closely spaced tones to test resolution and sweep transient effects, a controlled burst population to measure actual observation probability, and strong blockers to test overload and spurious response. Each class must be tested at more than one centre frequency, detector mode and relevant gain state. The source path must be independently checked to prevent generator products from being assigned to the analyser. Preserve the actual tuning schedule, filters, detectors, video processing, trigger state and native traces. When the result depends on a subtle frequency-time interaction, supplement the swept measurement with a suitable independent coherent capture rather than converting a plausible-looking display into unsupported source chronology.

The final report should distinguish stationary-spectrum accuracy, transient-event observation, probability of capture and validity under blockers as four separate acceptance claims. It must state how unobserved frequency-time regions were handled, whether calibration was applied at the correct reference plane and whether measurements from different sweep settings were made commensurate. A defensible negative statement is that no event meeting the specified criterion was detected during the demonstrated eligible coverage, not that an entire wideband environment remained silent. That language preserves scientific utility without allowing the convenient

Copyright 2026, James M. Atkinson

vertical scale or quiet screen to exceed the evidential meaning of the acquisition.

Copyright 2026, James M. Atkinson

8.26 Why a swept analyser cannot certify continuous capture of an unknown wideband pulse

Swept analysis is a controlled experiment in which the receiver's frequency-time acceptance changes while the external environment continues to evolve. Let $f_s(t)$ denote the instantaneous tuning trajectory, $H(f,t)$ the state-dependent RF and resolution-filter transfer, and $v(t)$ the video or detector output. The recorded trace is a set of summaries of different parts of the environment observed at different times. It is generally not the spectrum of one common RF instant. A slowly swept display may provide excellent frequency discrimination and amplitude measurement for a stationary calibrated carrier; it need not offer comprehensive evidence about nanosecond or microsecond bursts, coincident signals in distant bands, or a transmitter that changes state between dwell intervals. The distinction becomes acute when the user requests a 40 GHz monitored range and 30 Hz narrowband resolution simultaneously.

For a simple uniform sweep covering span S hertz over time T_s seconds, the nominal sweep rate is $R=S/T_s$ hertz per second. If a resolution filter has an effective passband B_r hertz, the nominal tuning trajectory spends approximately B_r/R seconds near one frequency, before allowing for the filter's impulse response, detector integration, retuning pauses and preselector switching. When $S=40\times10^9$ Hz, $B_r=30$ Hz and $T_s=1$ second, this nominal opportunity is 7.5×10^{-10} seconds. That figure is not an actual achievable dwell for a 30 Hz filter. Rather, it demonstrates the internal contradiction of treating an extremely fast 40 GHz swept trace as though every narrow filter had time to settle. Increasing sweep time alone cannot

Copyright 2026, James M. Atkinson

restore simultaneous observation of frequencies that were scanned at different times.

A 30 Hz rectangular-window DFT bin spacing corresponds to approximately 33.33 milliseconds of phase-continuous sample data; a Hann-window measurement with a 30 Hz equivalent noise bandwidth requires a longer interval because its ENBW is 1.5 times its bin spacing. Even this duration says nothing by itself about the ability to see an event lasting much less than the window. A real-time channel can compute narrowband spectral products from a continuous I/Q buffer while a parallel short-window energy detector examines the same samples, but a conventional tuned sweep observes a given RF region only when its analogue path actually accepts that region. Where a trigger occurs during an unobserved interval, no later mathematical increase in display resolution restores the lost waveform.

A credible wideband receiver acceptance test must therefore publish a coverage matrix. For each candidate frequency and time interval, the matrix records whether the analogue path accepted the energy, whether the converter was linear, whether native data were retained, whether a detector examined the event class, and whether a valid calibration was in force. A spectral heat map is not an equivalent of this matrix. Averaging and maximum hold create representations with different selection laws. A maximum-hold point is the maximum of a succession of detector outputs acquired at different times; it cannot establish that all maxima existed simultaneously. A blank region may mean lower signal amplitude, insufficient dwell, detector response, data loss, input filtering, or simply that the environment was never observed at that moment.

Copyright 2026, James M. Atkinson

Where a swept and a channelised wideband receiver are compared, the valid experiment retains the same calibration planes and comparable admitted environments. The narrow swept system is often better suited to sensitive slow measurements in a constrained band; the wideband channelised system is suited to simultaneous transient observation in the bandwidth it actually digitises. Neither dominates by definition. A wideband system must contend with more total admitted noise, blockers, ADC headroom and data rate. A swept system must contend with dwell coverage, settling and tuning-state dependence. A defensive technical report should present these complementary roles rather than advertise that a single sweep setting is both narrowest in resolution and greatest in transient probability of intercept.

Copyright 2026, James M. Atkinson

8.27 Quantitative worked contrasts: sweep coverage, channelised capture and resolution claims

Application W8.1. A 40 GHz nominal sweep in one second with a 30 Hz frequency acceptance has a geometric dwell of 0.75 nanoseconds at a fixed frequency. This is far shorter than a 33 millisecond measurement window, confirming that the proposed combination cannot be interpreted as settled 30 Hz measurement at every tuned location.

Application W8.2. A 100 MHz simultaneous complex channel contains 100,000,000/30≈3.33 million nominal 30 Hz DFT bins if rectangular bin spacing is taken as the resolution measure. The transform needs roughly 33.33 milliseconds of data and must be repeated or overlapped as required by the event-monitoring strategy.

Application W8.3. With a Hann window whose equivalent noise bandwidth is 1.5 bins, 30 Hz ENBW calls for 20 Hz bin spacing and a 50 millisecond observation, assuming the conventional periodic Hann approximation. Labelling a 30 Hz bin width as a 30 Hz noise bandwidth without identifying the window would understate admitted noise by about 1.76 dB.

Application W8.4. A 500 microsecond burst repeats every 100 milliseconds and begins with uniformly random phase relative to an isolated 1 millisecond valid dwell. In the absence of filter memory, capture opportunity for some overlap is approximately min[1,(0.001+0.0005)/0.1]=1.5 percent under an idealised periodic observation model. The event duration and criterion must be defined before this overlap probability becomes a detection probability.

Copyright 2026, James M. Atkinson

Application W8.5. Two 10 GHz halves of a monitoring range are observed in alternation, one for 250 milliseconds and the other for 250 milliseconds. Even with perfect equipment, a pulse seen in the first half cannot be assumed simultaneous with an apparent pulse in the second half. Time alignment in a concatenated display does not recreate simultaneous acquisition.

Application W8.6. A swept detector reports 100 maximum-hold results from 100 distinct dwells. If each independent noise-only dwell has a 1 percent probability of crossing a selected threshold, the probability of at least one crossing is $1-0.99^{100}\approx 63.4$ percent. In a correlated sequence the actual figure differs. A conspicuous maximum is not a stand-alone signal-identification result.

Chapter Summary

A swept spectrum is a frequency-time construction. RBW, VBW, detector, sweep, triggering, and linearity controls determine whether the trace represents a stationary spectrum, a partial transient, or an analyzer artifact.

Bandwidth selection follows the intended quantity. Nominal resolution width, equivalent noise bandwidth and transient response have different roles. A narrow setting can improve separation while excluding useful signal energy or leaving insufficient settling time. Gated and repeated-event methods require waveform-specific validation, with usable observation intervals distinguished from commanded sweep time.

Noise estimates also depend on operation order. Averaging individual logarithmic powers differs from logging their arithmetic average. The chapter derives separate corrections for its stated Gaussian-noise model and shows how finite sample count, correlation, changing states and already-applied processing affect the interpretation. A smoother trace does not establish an unbiased or compatible power estimate.

Acceptance connects the displayed trace to native data, configuration, frequency-time mapping and controlled references. Attenuation challenges, terminated-input observations and representative transient tests probe different limitations. Preserve excluded intervals and unsuccessful captures. A negative trace supports a finding only for the validated event class and actual coverage; it cannot establish universal absence.

Chapter 8 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C08-MCQ-001. A conventional swept analyzer constructs its horizontal frequency axis by which process?

A. Visiting successive input frequencies over time

B. Averaging all input frequencies into one detector value

C. Storing only one fixed-frequency time record

D. Observing the full displayed span at one instant

Answer: A. Successive tuning makes the trace a frequency-time construction; a displayed span is not necessarily instantaneous coverage. Source: §8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method (p. 4360)

Why the selected alternative fits: Visiting successive input frequencies over time.

Distinguishing consideration: compare this with option B, “Averaging all input frequencies into one detector value”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

Review: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

V011-C08-MCQ-002. An instrument offers swept, FFT-assisted, and segmented modes. What establishes the acquisition model for an archived trace?

A. The selected mode and its documented acquisition sequence

B. The analyzer product-family name without the selected acquisition mode

C. The displayed span compared with the nominal RBW alone

D. The use of a logarithmic amplitude scale rather than a linear scale

Answer: A. Hybrid instruments can implement different architectures. The selected mode must be recorded rather than inferred from the enclosure or display. Source: §8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method (p. 4360)

Why the selected alternative fits: The selected mode and its documented acquisition sequence.

Distinguishing consideration: compare this with option B, “The analyzer product-family name without the selected acquisition mode”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

Review: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

V011-C08-MCQ-003. A trace is assembled from several frequency segments. Which additional record is most useful when interpreting an intermittent source?

A. The total averaging count without segment boundaries

B. The common final RBW without segment timing

C. The acquisition times and boundaries of the segments

D. The maximum amplitude within each segment without acquisition times

Answer: C. Segment timing reveals which frequencies were observed during each source state; one image can conceal those gaps. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why the selected alternative fits: The acquisition times and boundaries of the segments.

Distinguishing consideration: compare this with option A, “The total averaging count without segment boundaries”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-004. Why can narrowing RBW make a brief emission harder to characterize despite a lower displayed noise floor?

A. The narrower filter takes longer to develop a valid response

B. The whole span becomes simultaneous when RBW is narrow

C. The detector becomes immune to startup behavior

D. Narrower RBW always increases the emission's duration

Answer: A. Improved separation and lower admitted noise are accompanied by slower settling; a short event may end before a representative response forms.

Source: §8.2 Resolution Bandwidth and Selectivity (p. 4422)

Why the selected alternative fits: The narrower filter takes longer to develop a valid response.

Distinguishing consideration: compare this with option B, “The whole span becomes simultaneous when RBW is narrow”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Resolution Bandwidth and Selectivity.

Review: Chapter 8 — Resolution Bandwidth and Selectivity.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-005. Two filters have the same nominal RBW but different skirts. Which property helps explain their different rejection of a nearby strong component?

A. The nominal RBW label by itself

B. The total frequency span

C. The averaging count after detection

D. Filter shape factor

Answer: D. The nominal width does not describe the complete frequency weighting. Skirt shape affects nearby-signal rejection. Source: §8.2 Resolution Bandwidth and Selectivity (p. 4422)

Why the selected alternative fits: Filter shape factor.

Distinguishing consideration: compare this with option A, “The nominal RBW label by itself”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Resolution Bandwidth and Selectivity.

Review: Chapter 8 — Resolution Bandwidth and Selectivity.

V011-C08-MCQ-006. A wide resolution filter contains a wanted tone and a neighboring tone. What is the principal risk in treating its marker as wanted-tone power?

A. The marker resolves the two components whenever it is RMS detected

B. The marker may include energy from the neighboring component

C. The marker must be the arithmetic mean of the two tone powers

D. The marker necessarily reports only the stronger tone

Answer: B. A broad filter can admit more than the intended component; its reading is then not uniquely attributable to the wanted tone. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: The marker may include energy from the neighboring component.

Distinguishing consideration: compare this with option A, “The marker resolves the two components whenever it is RMS detected”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-007. A modulated signal occupies several resolution filters. What is generally required to estimate its total channel power?

A. The narrowest available RBW regardless of signal width

B. The highest single marker without further information

C. The lowest negative-peak reading across the band

D. A declared integration interval, weighting, detector statistic, and calibration

Answer: D. A single narrowband reading measures only part of the occupied signal; a defined integration is required for total power. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: A declared integration interval, weighting, detector statistic, and calibration.

Distinguishing consideration: compare this with option A, “The narrowest available RBW regardless of signal width”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-MCQ-008. What tradeoff accompanies stronger video filtering?

A. Less visible trace variation with slower response

B. Improved separation of adjacent frequencies with no timing cost

C. Reduced sweep duration because less video noise is visible

D. Lower integrated pre-detection noise with unchanged transient response

Answer: A. VBW acts after detection and smooths fluctuations, but its time response can obscure short changes. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why the selected alternative fits: Less visible trace variation with slower response.

Distinguishing consideration: compare this with option B, “Improved separation of adjacent frequencies with no timing cost”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-009. Trace averaging is most readily interpreted as improved repeatability when what condition holds?

A. All records have equal length even when their source distributions differ

B. The detector is changed to follow the largest reading on each sweep

C. Each sweep is separately normalized despite changing source states

D. The random process is stationary over the averaging interval

Answer: D. Stationarity supports combining repeated estimates of the same quantity; state changes can make the average represent a mixture. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why the selected alternative fits: The random process is stationary over the averaging interval.

Distinguishing consideration: compare this with option A, “All records have equal length even when their source distributions differ”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-010. A max-hold comb disappears into a chirped burst on simultaneous capture. What explains the original comb?

A. Different burst fragments populated different frequencies on repeated sweeps

B. The chirp proves a separate continuous carrier at every tooth

C. The swept analyzer had measured all teeth simultaneously

D. Max hold converted frequency into absolute phase

Answer: A. The chapter's case shows that repeated swept observations can assemble a comb that no single waveform contained at one instant. Source: §8.13 Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4453)

Why the selected alternative fits: Different burst fragments populated different frequencies on repeated sweeps.

Distinguishing consideration: compare this with option B, “The chirp proves a separate continuous carrier at every tooth”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Review: Chapter 8 — Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-MCQ-011. Two traces are compared quantitatively after one changes from sample to peak detection. What should happen before interpreting their difference?

A. Match RBW alone and treat the detector change as irrelevant

B. Interpret the difference as a change of mean input power without checking statistics

C. Apply the same bandwidth correction and assume the detectors then agree

D. Reconcile the detector statistics or repeat with compatible settings

Answer: D. Different detectors estimate different quantities. A change in indication need not reflect an input-power change. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why the selected alternative fits: Reconcile the detector statistics or repeat with compatible settings.

Distinguishing consideration: compare this with option A, “Match RBW alone and treat the detector change as irrelevant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-012. Which pairing matches the chapter's example of discovery followed by power estimation?

A. Positive peak with max hold, then an appropriate RMS or averaging method

B. Positive peak for both discovery and mean power without a detector model

C. Negative peak with averaging, then positive-peak max hold as mean power

D. Max hold for discovery, then the uncorrected largest marker as channel power

Answer: A. Discovery and power estimation have different aims. The final method must still identify the statistic and suit the signal. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why the selected alternative fits: Positive peak with max hold, then an appropriate RMS or averaging method.

Distinguishing consideration: compare this with option B, “Positive peak for both discovery and mean power without a detector model”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

V011-C08-MCQ-013. A prescribed measurement requires a particular detector and time behavior. What is the sound response?

A. Replace it with RMS whenever average power is desired

B. Match the nominal RBW while substituting a faster detector

C. Use positive peak and regard it as conservative for every specified quantity

D. Use that prescribed behavior and document it

Answer: D. A detector and its timing can be part of the measurement definition; an attractive display is not a valid substitute. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why the selected alternative fits: Use that prescribed behavior and document it.

Distinguishing consideration: compare this with option A, “Replace it with RMS whenever average power is desired”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-014. A menu contains both an RMS bucket detector and logarithmic video averaging. Which conclusion is justified?

A. The two settings necessarily describe the same operation

B. The full processing sequence must be established before interpreting the final statistic

C. The log averaging automatically cancels the detector's time response

D. The RMS label guarantees an unbiased final mean in watts

Answer: B. Detector selection and averaging can occur at different stages; a label alone does not specify their composition. Source: §8.4.4 Measurement consequence (p. 4440)

Why the selected alternative fits: The full processing sequence must be established before interpreting the final statistic.

Distinguishing consideration: compare this with option A, “The two settings necessarily describe the same operation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Measurement consequence.

Review: Chapter 8 — Measurement consequence.

V011-C08-MCQ-015. Only a noise-trace screenshot survives. Why is adding 2.51 dB automatically unjustified?

A. Every noise marker requires both the log offset and the nominal-RBW correction

B. A displayed average always means the arithmetic power mean

C. The dBm label proves logarithms were averaged rather than powers

D. The pre-log statistic, correction history, and distribution may be unknown

Answer: D. The modeled offset applies to a specified statistic and distribution, not to every image with a dBm axis. Source: §8.4.4 Measurement consequence (p. 4440)

Why the selected alternative fits: The pre-log statistic, correction history, and distribution may be unknown.

Distinguishing consideration: compare this with option A, “Every noise marker requires both the log offset and the nominal-RBW correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Measurement consequence.

Review: Chapter 8 — Measurement consequence.

V011-C08-MCQ-016. What defines the logarithmic average L_N?

A. Take the logarithm after averaging the powers

B. Choose the greatest power and convert it to decibels

C. Average the logarithms of the individual positive powers

D. Average the complex voltage phasors and square once

Answer: C. L_N applies the logarithm before averaging. Reversing those operations produces A_N, a different estimator. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: Average the logarithms of the individual positive powers.

Distinguishing consideration: compare this with option A, "Take the logarithm after averaging the powers"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-017. Which operation defines A_N in Equation 16A?

A. Average the individual dBm readings

B. Convert the arithmetic mean of the powers to decibels

C. Convert the sum to decibels without dividing by sample count

D. Take the median of the log powers

Answer: B. A_N logs the mean power; the division by N is part of the mean and must not be omitted. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: Convert the arithmetic mean of the powers to decibels.

Distinguishing consideration: compare this with option A, “Average the individual dBm readings”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-018. For any realized record of positive powers, what does logarithm concavity establish?

A. L_N is no less than A_N

B. Their ensemble expectations must be equal whenever samples are independent

C. L_N is no greater than A_N

D. L_N is always exactly 2.5068 dB below A_N

Answer: C. The inequality is deterministic. A particular offset requires distributional assumptions and is not implied by concavity alone. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: is no greater than.

Distinguishing consideration: compare this with option A, “is no less than”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-019. When are L_N and A_N equal for a positive finite record?

A. Whenever the detector is calibrated in dBm

B. When all sampled powers are equal

C. Whenever N exceeds 100

D. Whenever samples are independent

Answer: B. Strict concavity makes equality occur for equal powers; sample count and independence do not force it. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: When all sampled powers are equal.

Distinguishing consideration: compare this with option A, "Whenever the detector is calibrated in dBm"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-020. What does the inequality between L_N and A_N fail to establish by itself?

A. A numerical noise correction

B. The direction of their difference

C. A consequence of operation order

D. Equality for a constant-power record

Answer: A. Concavity gives direction for positive records, but neither Gaussian statistics nor a fixed bias follows from it. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: A numerical noise correction.

Distinguishing consideration: compare this with option B, “The direction of their difference”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

V011-C08-MCQ-021. Which quadrature model underlies the chapter's exponential instantaneous-power distribution?

A. Independent zero-mean Gaussian components with equal normalized variance

B. Clipped quadratures with unknown distribution

C. An arbitrary changing mixture of quadrature means

D. Two fixed quadrature constants

Answer: A. Circular complex Gaussian noise with the stated normalization yields exponential power; other models require separate analysis. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: Independent zero-mean Gaussian components with equal normalized variance.

Distinguishing consideration: compare this with option B, “Clipped quadratures with unknown distribution”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-022. Why does the definition of instantaneous power incorporate reference resistance and gain calibration?

A. To establish independence between successive power estimates

B. To express power at a calibrated estimation plane rather than raw ADC counts

C. To make the exponential model valid regardless of clipping

D. To make the measured noise bandwidth equal to the nominal RBW

Answer: B. The statistical power variable is calibrated. Applying its units and correction to uncalibrated counts would omit the measurement mapping. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: To express power at a calibrated estimation plane rather than raw ADC counts.

Distinguishing consideration: compare this with option A, “To establish independence between successive power estimates”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-023. For the model's U = P divided by mean power, what are its mean and variance?

A. Zero and one

B. One and one

C. One and zero

D. Two and four

Answer: B. The stipulated normalized exponential density has unit mean and unit variance, which gives the stated moments of P. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: One and one.

Distinguishing consideration: compare this with option A, “Zero and one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-024. If the modeled mean power is mu, what is the instantaneous-power variance?

A. Zero because the receiver is linear

B. mu divided by N for every single sample

C. The logarithm of mu

D. mu squared

Answer: D. The single exponential power sample has variance equal to the square of its mean. Averaging changes this only under additional assumptions. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: mu squared.

Distinguishing consideration: compare this with option A, “Zero because the receiver is linear”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-025. Which observation directly challenges use of the single exponential-power model?

A. A documented calibrated power plane

B. Independent zero-mean Gaussian quadratures

C. A clipped envelope caused by overload

D. A positive equivalent noise bandwidth

Answer: C. Clipping changes the distribution; the model's exponential moments and resulting correction then need not apply. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: A clipped envelope caused by overload.

Distinguishing consideration: compare this with option A, “A documented calibrated power plane”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-026. For the expected value of L_N, which condition suffices without requiring independence?

A. Every sample is copied from a deterministic tone

B. Each sample has the same stipulated exponential distribution

C. Every record contains a different unrecorded mean power

D. Only the first sample has known statistics

Answer: B. Linearity of expectation gives the mean log offset from the marginal distribution. Independence is needed for the simple variance reduction, not this expectation. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: Each sample has the same stipulated exponential distribution.

Distinguishing consideration: compare this with option A, “Every sample is copied from a deterministic tone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-027. One thousand independent single-sample log powers are averaged. What happens to the modeled mean offset?

A. It falls in inverse proportion to the number of logarithmic samples

B. It is replaced by the much smaller bias of a logged thousand-power arithmetic mean

C. It remains about 2.5068 dB while random fluctuation decreases

D. It vanishes once the standard deviation is smaller than the offset

Answer: C. Averaging more logarithms reduces variance under independence but does not change their common expectation. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: It remains about 2.5068 dB while random fluctuation decreases.

Distinguishing consideration: compare this with option A, “It falls in inverse proportion to the number of logarithmic samples”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-028. Adding the modeled log correction is unbiased in which stated sense?

A. Expectation in watts after arbitrary exponentiation

B. A guaranteed upper confidence bound for every record

C. An exact recovery of every individual noise sample

D. Expectation in decibel units for the specified statistic and model

Answer: D. An unbiased decibel expectation does not imply an unbiased exponentiated estimator or a confidence limit. Source: §8.4.1 A stated statistical model (p. 4431)

Why the selected alternative fits: Expectation in decibel units for the specified statistic and model.

Distinguishing consideration: compare this with option A, “Expectation in watts after arbitrary exponentiation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

V011-C08-MCQ-030. How are the log-envelope correction and equivalent-noise-bandwidth correction related?

A. One automatically determines the other from the RBW label

B. They are two names for exactly the same factor

C. They address different causes and must be tracked separately

D. Both are universally equal to 2.5068 dB

Answer: C. One concerns estimator statistics; the other concerns integrated bandwidth. Neither substitutes for the other's characterization. Source: §8.4 Noise averages, detector statistics, and the meaning of a decibel trace (p. 4429)

Why the selected alternative fits: They address different causes and must be tracked separately.

Distinguishing consideration: compare this with option A, “One automatically determines the other from the RBW label”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

Review: Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

V011-C08-MCQ-032. What should N count in Equation 16C?

A. Every display bucket after the detector

B. Every FFT record entering an overlapping average without a dependence check

C. Independent exponential samples actually entering the power mean

D. Every repeated sweep regardless of the statistic entering the mean

Answer: C. The formula's sample count belongs to its statistical model and estimator, not automatically to a storage or display count. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why the selected alternative fits: Independent exponential samples actually entering the power mean.

Distinguishing consideration: compare this with option A, “Every display bucket after the detector”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

V011-C08-MCQ-033. Four independent, identically distributed exponential power samples with the same positive mean are averaged before logging. Which correction addresses the stated expected bias?

A. Minus 10 log10 of 4 dB

B. Exactly zero for any four-sample mean

C. About plus 2.50682 dB

D. About plus 0.56535 dB

Answer: D. The finite-log bias at N = 4 is about minus 0.56535 dB; the single-sample log correction would overcorrect this statistic. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why the selected alternative fits: About plus 0.56535 dB.

Distinguishing consideration: compare this with option A, “Minus 10 log10 of 4 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-034. At N = 100 independent, identically distributed exponential powers with the same positive mean, what is the approximate bias magnitude after averaging powers and then logging?

A. Exactly 0.56535 dB

B. Exactly 20 dB

C. About 2.5068 dB

D. About 0.02175 dB

Answer: D. Equation 16C approaches zero from below as N grows; its N = 100 magnitude is much smaller than the log-sample offset. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why the selected alternative fits: About 0.02175 dB.

Distinguishing consideration: compare this with option A, “Exactly 0.56535 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

V011-C08-MCQ-035. An instrument's noise marker already corrects the reported statistic. What should postprocessing do?

A. Replace the applied correction by the nominal RBW in decibels

B. Add the log correction again because offline processing is a new measurement

C. Identify and retain the applied correction without applying it a second time

D. Apply the finite-sample correction solely from the number of displayed points

Answer: C. Duplicating a valid correction introduces error. The record must show which stage already applied it. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: Identify and retain the applied correction without applying it a second time.

Distinguishing consideration: compare this with option A, “Replace the applied correction by the nominal RBW in decibels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-MCQ-036. For 100 independent, identically distributed exponential powers with the same positive mean, what is the relative standard deviation of their arithmetic mean?

A. 10

B. 0.01

C. 0.1

D. 1

Answer: C. The independent mean has relative standard deviation 1 divided by the square root of N, giving 0.1 at N = 100. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why the selected alternative fits: 0.1.

Distinguishing consideration: compare this with option A, “10”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-037. For 100 independent log-power samples under the stated model, what is approximately the standard deviation of L_N?

A. 20 dB

B. 0.02175 dB

C. 2.507 dB

D. 0.557 dB

Answer: D. The chapter's log-sample variance gives about 0.557 dB. The mean offset and finite-log bias are different quantities. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: 0.557 dB.

Distinguishing consideration: compare this with option A, “20 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-038. A very steady log-averaged trace remains systematically below the mean-power level. What does this illustrate?

A. Improved repeatability does not establish absence of estimator bias

B. The reduced trace scatter proves that the mean-power estimate is now unbiased

C. A smaller sample standard deviation automatically supplies the missing mean correction

D. Averaging logarithms and logging average power become equivalent once the trace is smooth

Answer: A. Random scatter and mean bias are separate properties. More independent log samples can reduce scatter while retaining the offset. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: Improved repeatability does not establish absence of estimator bias.

Distinguishing consideration: compare this with option B, “The reduced trace scatter proves that the mean-power estimate is now unbiased”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-039. For 100 equal-mean exponential power samples, the common correlation between every distinct pair of power samples is 0.2. What is the approximate relative standard deviation of their arithmetic mean?

A. 0.020

B. 0.456

C. 0.010

D. 0.100

Answer: B. The stipulated covariance model gives sqrt[(1 + 99 times 0.2)/100] = sqrt(0.208), approximately 0.456. This is a variance calculation, not a claim that the dependent sum retains a gamma distribution. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: 0.456.

Distinguishing consideration: compare this with option A, “0.020”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-040. A single random power sample is copied 100 times. What happens to the relative standard deviation of their average in the stipulated model?

A. It becomes one hundredth

B. It remains one

C. It vanishes exactly

D. It becomes one tenth

Answer: B. Perfectly correlated copies add no independent information; averaging them reproduces the original random sample. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: It remains one.

Distinguishing consideration: compare this with option A, "It becomes one hundredth"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-041. A noise record mixes two distinct operating levels. Why can the single-level log correction fail for its overall mean power?

A. A mixture of means is not the single exponential distribution assumed

B. The logarithm becomes undefined for every positive sample

C. The two states necessarily have identical arithmetic means

D. Averaging always removes the higher state

Answer: A. Correcting each conditional log expectation does not make the average of state log levels equal the log of the overall linear mean. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: A mixture of means is not the single exponential distribution assumed.

Distinguishing consideration: compare this with option B, “The logarithm becomes undefined for every positive sample”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-042. Ninety percent of records have mean 1 mW and ten percent have mean 100 mW. What is their overall arithmetic mean power?

A. 50.5 mW

B. 10.9 mW

C. 2 mW

D. 100 mW

Answer: B. The time or record weights apply in linear power: 0.9 times 1 plus 0.1 times 100 equals 10.9 mW. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: 10.9 mW.

Distinguishing consideration: compare this with option A, “50.5 mW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-043. Under the chapter's independent Gaussian-contribution model, compatible total and background mean-power estimates at the same plane and bandwidth are minus 60 and minus 70 dBm. What is the background-subtracted mean-power level?

A. Minus 10 dBm

B. Approximately minus 59.59 dBm

C. Approximately minus 60.46 dBm

D. Minus 130 dBm

Answer: C. The estimates are 1 nW and 0.1 nW. Their linear difference is 0.9 nW, or approximately minus 60.46 dBm. Direct dBm subtraction gives a ratio; adding the linear powers gives the wrong sign of correction. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: Approximately minus 60.46 dBm.

Distinguishing consideration: compare this with option A, “Minus 10 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-044. Why is background subtraction fragile when estimated total and background nearly coincide?

A. A small level difference directly gives a precise residual power

B. Subtracting in logarithmic units eliminates the near-cancellation problem

C. The residual uncertainty equals the smaller of the two input uncertainties

D. A small difference is sensitive to errors in either estimate

Answer: D. Subtracting similar numbers can make the residual poorly determined relative to its size; the uncertainty cannot be ignored. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: A small difference is sensitive to errors in either estimate.

Distinguishing consideration: compare this with option A, “A small level difference directly gives a precise residual power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-049. Why can a measured minus 20 dB bandwidth change be correct even when both absolute log levels are biased?

A. The identical estimator bias cancels under unchanged valid noise and processing assumptions

B. Decibel subtraction always converts a mixture to white noise

C. Every relative measurement cancels every error

D. A bandwidth change proves the source is a tone

Answer: A. A common offset cancels in the difference if the same model and statistic remain applicable; that does not validate the absolute levels. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: The identical estimator bias cancels under unchanged valid noise and processing assumptions.

Distinguishing consideration: compare this with option B, “Decibel subtraction always converts a mixture to white noise”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-051. Why cannot Equation 15 alone supply an absolute sweep time for an unknown analyzer?

A. Its proportionality depends on the filter, architecture, and acceptance criterion

B. Its qualitative trend automatically includes every gated-mode timing requirement

C. Its factor is always one when frequencies are entered in hertz

D. Its proportionality is fixed by the selected span alone

Answer: A. The qualitative scaling omits the instrument-specific factor; using it as an absolute timing law invents missing information. Source: §8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4450)

Why the selected alternative fits: Its proportionality depends on the filter, architecture, and acceptance criterion.

Distinguishing consideration: compare this with option B, “Its qualitative trend automatically includes every gated-mode timing requirement”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-MCQ-052. Within one validated regime, doubling span with unchanged RBW has what conditional effect on the Equation 15 scaling?

A. It doubles the predicted sweep-time scale

B. It halves the predicted sweep-time scale

C. It leaves the scale unchanged

D. It increases the scale fourfold

Answer: A. The stated proportionality is linear in span when the implementation and all other applicable conditions remain fixed. Source: §8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4450)

Why the selected alternative fits: It doubles the predicted sweep-time scale.

Distinguishing consideration: compare this with option B, “It halves the predicted sweep-time scale”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Review: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-MCQ-053. Within one validated regime, halving RBW at fixed span changes the Equation 15 sweep-time scale by what factor?

A. One half

B. One quarter

C. Four

D. Two

Answer: C. The denominator contains RBW squared. Halving RBW gives a fourfold scale, subject to the same validated timing regime. Source: §8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4450)

Why the selected alternative fits: Four.

Distinguishing consideration: compare this with option A, “One half”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Review: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-054. Why should automatic sweep-time selection be challenged for unusual gated or segmented signals?

A. The trigger edge guarantees a settled response throughout every gate

B. The automatic minimum also validates every event reconstruction assumption

C. A segmented sweep has no settling interval if all segments share RBW

D. The automatic rule may not cover the actual waveform and acquisition timing

Answer: D. A nominal automatic minimum need not validate a specialized acquisition; representative signal tests remain necessary. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

Why the selected alternative fits: The automatic rule may not cover the actual waveform and acquisition timing.

Distinguishing consideration: compare this with option A, “The trigger edge guarantees a settled response throughout every gate”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Time, Triggering, and Transient Signals.

Review: Chapter 8 — Sweep Time, Triggering, and Transient Signals.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-055. What can an excessively fast sweep do to a narrow component?

A. Resolve closer tones because less time is spent in the filter

B. Lower or broaden its displayed response

C. Guarantee the response of a short burst once the center frequency is correct

D. Preserve exact amplitude while changing only displayed noise variance

Answer: B. Insufficient settling while tuning can distort both amplitude and shape; a visually narrow input is not necessarily faithfully portrayed. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

Why the selected alternative fits: Lower or broaden its displayed response.

Distinguishing consideration: compare this with option A, “Resolve closer tones because less time is spent in the filter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Time, Triggering, and Transient Signals.

Review: Chapter 8 — Sweep Time, Triggering, and Transient Signals.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-056. What risk can arise from making a sweep unnecessarily slow?

A. Longer sweep time always increases the usable overlap with every short event

B. A longer sweep guarantees a simultaneous representation of a changing source

C. State changes and drift can affect different trace locations

D. A slower sweep eliminates all need to examine source stationarity

Answer: C. A longer construction interval exposes the trace to changes between frequency visits; slow is not an unconditional improvement. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

Why the selected alternative fits: State changes and drift can affect different trace locations.

Distinguishing consideration: compare this with option A, “Longer sweep time always increases the usable overlap with every short event”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Time, Triggering, and Transient Signals.

Review: Chapter 8 — Sweep Time, Triggering, and Transient Signals.

V011-C08-MCQ-063. Repeated bursts share a nominal period but vary in startup modulation. What prevents straightforward reconstruction of one spectrum?

A. A stable trigger period makes any within-burst modulation difference irrelevant

B. Matching the average repetition period also establishes identical startup modulation

C. The same RBW guarantees the same waveform segment is represented each time

D. The waveform features needed by the reconstruction are not repeatable

Answer: D. Matching repetition periods alone does not ensure equal amplitude, phase, modulation, or startup at corresponding measurement times. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: The waveform features needed by the reconstruction are not repeatable.

Distinguishing consideration: compare this with option A, “A stable trigger period makes any within-burst modulation difference irrelevant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-064. Why does repeatable trigger-edge alignment alone fail to establish repeatability of the waveform inside a burst?

A. Startup modulation, amplitude, or phase can vary relative to the aligned edge

B. Matching the burst period is sufficient even when modulation changes

C. A stable trigger edge forces every internal waveform feature to repeat

D. The same gate width guarantees identical samples regardless of waveform evolution

Answer: A. The trigger constrains a selected edge, not every internal feature. The relevant waveform and its relationship to the gate require event-resolved validation.

Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: Startup modulation, amplitude, or phase can vary relative to the aligned edge.

Distinguishing consideration: compare this with option B, “Matching the burst period is sufficient even when modulation changes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-065. Why should a burst validation reproduce the prior receiver state?

A. A trigger reset guarantees the same AGC state in every instrument

B. A continuous-tone calibration makes recovery history irrelevant

C. AGC and other transient responses can depend on that state

D. Only the final steady-state gain can affect a short burst

Answer: C. The response available during a burst can depend on preceding gain or recovery conditions; a continuous-tone check can miss this behavior. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: AGC and other transient responses can depend on that state.

Distinguishing consideration: compare this with option A, “A trigger reset guarantees the same AGC state in every instrument”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-MCQ-066. A long continuous calibration tone measures correctly. What remains unvalidated for a short burst?

A. Turn-on, duration, repetition, and transient acquisition behavior

B. The ability to display the tested continuous tone at its measured level

C. The use of the same amplitude reference unit for both signals

D. The steady-state gain at the tested tone and configuration

Answer: A. A steady tone checks only part of the method. Burst-specific timing and waveform behavior require representative tests. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: Turn-on, duration, repetition, and transient acquisition behavior.

Distinguishing consideration: compare this with option B, “The ability to display the tested continuous tone at its measured level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-MCQ-067. How can event-resolved records support assessment of a repeated-event spectral aggregate?

A. They remove the need to establish the trigger-to-waveform relationship

B. They make a repeated-sweep aggregate simultaneous without waveform comparison

C. They permit comparison of the aggregate with the individual events

D. They ensure phase-coherent reconstruction solely because timestamps exist

Answer: C. Keeping individual events allows the claimed repeatability and aggregate construction to be examined. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: They permit comparison of the aggregate with the individual events.

Distinguishing consideration: compare this with option A, “They remove the need to establish the trigger-to-waveform relationship”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-068. A no-peak max-hold result is reported. What scope is defensible?

A. Any event weaker than the validated reference regardless of duration

B. Every possible emission at the site

C. The validated event class under the actual observed bands and usable intervals

D. All out-of-band signals for the full survey day

Answer: C. A negative result is bounded by tested sensitivity, waveform class, timing, and coverage; unobserved possibilities remain unresolved. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: The validated event class under the actual observed bands and usable intervals.

Distinguishing consideration: compare this with option A, “Any event weaker than the validated reference regardless of duration”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-MCQ-069. Which event is plainly outside a negative result restricted to a documented frequency band?

A. A captured calibration tone in the band

B. The validated reference within the band

C. A stored in-band control signal

D. An emission entirely outside that band

Answer: D. Frequency coverage is one of the explicit boundaries of the finding. Lack of an in-band peak says nothing directly about an out-of-band event. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: An emission entirely outside that band.

Distinguishing consideration: compare this with option A, “A captured calibration tone in the band”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-MCQ-070. After a swept procedure repeatedly misses the target reference, what should guide the next observation?

A. Accept only the sweeps that happened to capture the reference

B. Increase the repetition count while leaving the demonstrated timing gap unchanged

C. The specific remaining uncertainty and a method capable of resolving it

D. Apply the white-noise bandwidth ratio to compensate for missed reference bursts

Answer: C. A failed representative challenge identifies a capability gap; a different timing strategy or architecture may be necessary. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: The specific remaining uncertainty and a method capable of resolving it.

Distinguishing consideration: compare this with option A, “Accept only the sweeps that happened to capture the reference”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-MCQ-071. Which configuration belongs in the amplitude-accuracy record?

A. Center frequency and nominal RBW alone

B. Input attenuation, preamplifier state, mixer level, and reference level

C. Internal alignment date and displayed amplitude alone

D. Detector label and total averaging count alone

Answer: B. Amplitude response depends on the actual gain and detector configuration as well as calibration and frequency. Source: §8.9 Amplitude Accuracy and Analyzer Self-Tests (p. 4448)

Why the selected alternative fits: Input attenuation, preamplifier state, mixer level, and reference level.

Distinguishing consideration: compare this with option A, “Center frequency and nominal RBW alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-072. What is the purpose of changing input attenuation and correcting the indicated level for that change?

A. Guarantee that every unchanged peak is external

B. Challenge linearity and possible internally generated responses

C. Convert the trace from swept to simultaneous acquisition

D. Measure trigger jitter directly

Answer: B. The expected input-referred relationship is a controlled challenge; departures can indicate nonlinear or internal behavior and require interpretation.

Source: §8.9 Amplitude Accuracy and Analyzer Self-Tests (p. 4448)

Why the selected alternative fits: Challenge linearity and possible internally generated responses.

Distinguishing consideration: compare this with option A, “Guarantee that every unchanged peak is external”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-073. Why is a successful internal alignment insufficient to verify the complete survey chain?

A. It does not test the external cable, antenna, filter, or site overload

B. Internal alignment proves that external losses remain at their calibration values

C. Internal alignment establishes the antenna response at the site automatically

D. Internal alignment validates every strong out-of-band input condition

Answer: A. Internal routines cover their own paths. Installed external components and environmental stresses require external checks. Source: §8.9 Amplitude Accuracy and Analyzer Self-Tests (p. 4448)

Why the selected alternative fits: It does not test the external cable, antenna, filter, or site overload.

Distinguishing consideration: compare this with option B, “Internal alignment proves that external losses remain at their calibration values”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-074. What does a terminated-input observation help characterize?

A. The original antenna-path field strength without retaining the antenna connection

B. Complete rejection of every external out-of-band blocker

C. Residual analyzer responses under that test condition

D. The transient interception capability of the full installed chain

Answer: C. Termination removes the ordinary antenna input path for a challenge, making residual responses informative without proving universal absence. Source: §8.9 Amplitude Accuracy and Analyzer Self-Tests (p. 4448)

Why the selected alternative fits: Residual analyzer responses under that test condition.

Distinguishing consideration: compare this with option A, “The original antenna-path field strength without retaining the antenna connection”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-075. Why include strong out-of-band signals in an analyzer challenge?

A. An internally aligned analyzer is insensitive to out-of-band mixer loading

B. They can reveal overload or spurious behavior not visible in an isolated weak-tone check

C. A low displayed noise floor proves that all earlier stages remain linear

D. Only signals inside final RBW can affect receiver linearity

Answer: B. The actual environment can stress stages before final selectivity; the method must be tested against relevant blockers. Source: §8.9 Amplitude Accuracy and Analyzer Self-Tests (p. 4448)

Why the selected alternative fits: They can reveal overload or spurious behavior not visible in an isolated weak-tone check.

Distinguishing consideration: compare this with option A, “An internally aligned analyzer is insensitive to out-of-band mixer loading”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-076. Which reference set best challenges complete-chain amplitude performance?

A. A terminated-input residual trace used alone as an amplitude-gain calibration

B. Known external references at several frequencies and levels

C. Repeated internal alignment at one frequency without the external path

D. One external reference level at one frequency used to certify the full range

Answer: B. Multiple external frequencies and levels probe response and linearity across the installed chain instead of relying solely on an internal routine. Source: §8.9 Amplitude Accuracy and Analyzer Self-Tests (p. 4448)

Why the selected alternative fits: Known external references at several frequencies and levels.

Distinguishing consideration: compare this with option A, “A terminated-input residual trace used alone as an amplitude-gain calibration”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

V011-C08-MCQ-077. Which settings should a representative sweep-method acceptance test reproduce?

A. Trigger period and reference level without reproducing trace mode or sweep time

B. RBW and VBW while substituting a continuous untriggered acquisition

C. Center frequency and span while allowing detector and gain to vary

D. Span, RBW, VBW, detector, sweep time, trigger, trace mode, and gain state

Answer: D. The validity of the test is configuration-bound. Changing acquisition or gain settings can change the method's performance. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why the selected alternative fits: Span, RBW, VBW, detector, sweep time, trigger, trace mode, and gain state.

Distinguishing consideration: compare this with option A, “Trigger period and reference level without reproducing trace mode or sweep time”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-MCQ-078. The reference is repeatedly distorted in the survey configuration. What is the chapter's acceptance consequence?

A. Accept because a separate continuous tone measured correctly

B. Accept after averaging until the distorted reference trace becomes smooth

C. Remove unsuccessful reference captures and assess only detections

D. Use a different suitable architecture when the method cannot reproduce it

Answer: D. A method that cannot represent its target reference has not demonstrated the needed capability; failures belong in the record. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why the selected alternative fits: Use a different suitable architecture when the method cannot reproduce it.

Distinguishing consideration: compare this with option A, “Accept because a separate continuous tone measured correctly”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-MCQ-079. Why retain setup files and native trace data alongside images?

A. They reconstruct emissions that were outside all usable acquisition intervals

B. They allow later examination of acquisition and processing details

C. They remove the need to identify detector and correction history

D. They establish independence of all stored records automatically

Answer: B. Native data and configuration support reconstruction and audit; a picture alone omits essential state and processing information. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why the selected alternative fits: They allow later examination of acquisition and processing details.

Distinguishing consideration: compare this with option A, “They reconstruct emissions that were outside all usable acquisition intervals”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-MCQ-080. Which archive entry is especially important when some bands were intentionally omitted?

A. Only the final minimum and maximum displayed frequencies

B. Only a total sweep duration that includes masked intervals

C. Only the number of successful sweeps in the unmasked regions

D. Masked-band boundaries and their timing

Answer: D. Excluded bands and intervals bound the claim of coverage and must remain visible in the record. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why the selected alternative fits: Masked-band boundaries and their timing.

Distinguishing consideration: compare this with option A, “Only the final minimum and maximum displayed frequencies”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-MCQ-081. An unknown source is challenged while RBW and gain are also changed. What is the main interpretation problem?

A. Several causes can explain the changed indication

B. The source and RBW changes cancel automatically if their level effects oppose

C. A gain change can be ignored whenever the display remains in dBm

D. The comparison isolates bandwidth because the source challenge is deliberate

Answer: A. A controlled comparison preserves input and receiver state while changing one bandwidth parameter, then challenges the source separately. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: Several causes can explain the changed indication.

Distinguishing consideration: compare this with option B, “The source and RBW changes cancel automatically if their level effects oppose”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-082. Why retain linear-power data during a bandwidth comparison when available?

A. They preserve the estimator domain needed to examine integration and normalization

B. They establish independence between overlapping records

C. They permit arbitrary mixtures to use the single-exponential correction

D. They remove the need to characterize equivalent noise bandwidth

Answer: A. Linear data help distinguish power integration from later logarithmic processing; they do not cure invalid acquisition assumptions. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: They preserve the estimator domain needed to examine integration and normalization.

Distinguishing consideration: compare this with option B, “They establish independence between overlapping records”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-MCQ-083. Which combination can invalidate a simple white-noise bandwidth correction even when nominal RBWs are known?

A. Positive equivalent bandwidths at a fixed plane

B. Identical valid processing and a flat density

C. A stable source with the same calibration

D. Changed detector order and a nonwhite input spectrum

Answer: D. Equation 16 requires compatible processing and unchanged white density; known labels alone do not supply those assumptions. Source: §8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4450)

Why the selected alternative fits: Changed detector order and a nonwhite input spectrum.

Distinguishing consideration: compare this with option A, “Positive equivalent bandwidths at a fixed plane”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Review: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-MCQ-084. Under the stated model, what happens to the finite-record bias of A_N as independent N grows?

A. It approaches zero from below

B. It remains exactly minus 2.5068 dB for every N

C. It increases without bound

D. It becomes positive after N = 4

Answer: A. Power averaging concentrates the mean; its subsequent logarithm still has a finite-record negative bias that decreases with N. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why the selected alternative fits: It approaches zero from below.

Distinguishing consideration: compare this with option B, “It remains exactly minus 2.5068 dB for every N”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

V011-C08-MCQ-085. What is the status of the approximate 0.434 dB fluctuation obtained by first-order propagation at N = 100?

A. The fixed log-average mean bias

B. A local approximation, not an exact confidence interval

C. A correction valid for every changing mixture

D. An exact universal 95 percent bound

Answer: B. First-order propagation describes a concentrated arithmetic mean locally; it must not be presented as an exact probabilistic bound. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: A local approximation, not an exact confidence interval.

Distinguishing consideration: compare this with option A, “The fixed log-average mean bias”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-086. If power samples share covariance, which claim needs particular caution?

A. The definition of a positive arithmetic mean

B. The identity of the reference power unit

C. The independent gamma formula for the logged power mean

D. Linearity of expectation for identical log marginals

Answer: C. Dependence changes the sum distribution and variance; the chapter explicitly warns against retaining the gamma bias formula automatically. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why the selected alternative fits: The independent gamma formula for the logged power mean.

Distinguishing consideration: compare this with option A, “The definition of a positive arithmetic mean”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-MCQ-087. Why is counting overlapping FFT records as independent N unsafe?

A. The nominal FFT length alone determines independent sample count

B. Overlap necessarily makes every power sample an exact duplicate

C. Every FFT estimate has the same independence properties regardless of window

D. Overlap can create dependence that violates the estimator's assumed sample model

Answer: D. The actual dependence must be established; a record count does not by itself justify independent-exponential formulas. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why the selected alternative fits: Overlap can create dependence that violates the estimator's assumed sample model.

Distinguishing consideration: compare this with option A, “The nominal FFT length alone determines independent sample count”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

V011-C08-MCQ-089. Why must nominal RBW and equivalent noise bandwidth remain distinct in analysis?

A. Equivalent noise bandwidth also determines every transient settling response

B. The two widths are interchangeable once both are expressed in hertz

C. They describe different filter properties and answer different measurement questions

D. Nominal RBW always specifies the same integrated noise for every filter shape

Answer: C. Noise integration uses equivalent bandwidth, whereas detailed response and transient questions can require the actual weighting and time behavior. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: They describe different filter properties and answer different measurement questions.

Distinguishing consideration: compare this with option A, “Equivalent noise bandwidth also determines every transient settling response”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-MCQ-090. Which claim about max hold is defensible without additional waveform evidence?

A. Every event in the displayed span was detected

B. All retained peaks were present simultaneously

C. Its level is the mean channel power

D. It retains observed maxima across the repeated acquisitions

Answer: D. Max hold is an aggregation of observed extrema. Coexistence, complete interception, and mean-power interpretation require separate evidence. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

Why the selected alternative fits: It retains observed maxima across the repeated acquisitions.

Distinguishing consideration: compare this with option A, “Every event in the displayed span was detected”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

V011-C08-MCQ-092. A bandwidth comparison keeps the filter ratio but changes the source between two operating states. What essential condition has been lost?

A. An unchanged input density or state for the comparison

B. The ability to compare two positive equivalent bandwidths mathematically

C. The identity of the filter label even when the source density changes

D. The same pre-log statistic for every possible state automatically

Answer: A. The predicted ratio concerns the same stationary density. State changes introduce another cause for a level difference. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: An unchanged input density or state for the comparison.

Distinguishing consideration: compare this with option B, “The ability to compare two positive equivalent bandwidths mathematically”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-MCQ-095. Why should excluded intervals be retained in the archive?

A. They bound usable coverage and show where conclusions cannot be drawn

B. They establish that the source was inactive whenever the analyzer was settling

C. They increase the demonstrated transient sensitivity of the observed intervals

D. They can be counted as valid exposure if the total run time is documented

Answer: A. Omitted or invalid acquisition intervals are part of the evidence for a bounded finding, not empty time to conceal. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why the selected alternative fits: They bound usable coverage and show where conclusions cannot be drawn.

Distinguishing consideration: compare this with option B, “They establish that the source was inactive whenever the analyzer was settling”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-MCQ-096. Repeated bursts have matching power envelopes and trigger times but varying carrier phase. What is justified before coherent waveform reconstruction?

A. Matching power envelopes proves identical carrier phase

B. A repeatable trigger edge supplies the missing carrier-phase relationship automatically

C. Validate the phase repeatability required by that reconstruction separately from power-envelope repeatability

D. Equal mean power permits coherent combination without retaining phase information

Answer: C. Repeatability is specific to the construction. Matching timing and power does not establish the phase relationship needed to combine waveforms coherently. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: Validate the phase repeatability required by that reconstruction separately from power-envelope repeatability.

Distinguishing consideration: compare this with option A, “Matching power envelopes proves identical carrier phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-MCQ-097. A lower noise display follows a narrower filter. Why might that be unhelpful for the desired measurand?

A. The narrower filter removes all uncertainty

B. The filter may exclude signal energy needed for that measurement

C. Lower displayed noise guarantees total-power accuracy

D. The source's entire bandwidth necessarily shrinks with RBW

Answer: B. Bandwidth selection serves the quantity being estimated; reducing the display floor alone can sacrifice relevant signal content or response time. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why the selected alternative fits: The filter may exclude signal energy needed for that measurement.

Distinguishing consideration: compare this with option A, “The narrower filter removes all uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Choose bandwidth from the quantity being estimated.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-MCQ-098. What makes a negative trace's conclusion reproducible?

A. A stated event criterion, actual usable coverage, configuration, and retained failed or excluded observations

B. A continuous-tone test applied without limits to every burst duration

C. A large number of repeated files without the usable observation intervals

D. One no-peak image with the maximum advertised span

Answer: A. A reviewer needs the tested capability and actual coverage to assess what absence claim is supported. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why the selected alternative fits: A stated event criterion, actual usable coverage, configuration, and retained failed or excluded observations.

Distinguishing consideration: compare this with option B, “A continuous-tone test applied without limits to every burst duration”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-MCQ-099. Which statement correctly treats the chapter's numerical noise examples?

A. They replace calibration of the installed chain

B. They are hypothetical model calculations, not measured specifications of a named receiver

C. They prove every real noise process is Gaussian

D. They certify every analyzer with the same detector label

Answer: B. The examples illustrate declared assumptions and arithmetic; transferring them to equipment requires evidence that those assumptions and settings apply. Source: §8.4.3 Ten worked applications (p. 4437)

Why the selected alternative fits: They are hypothetical model calculations, not measured specifications of a named receiver.

Distinguishing consideration: compare this with option A, “They replace calibration of the installed chain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-MCQ-100. What is the central acceptance question for a swept measurement?

A. Does the averaged trace have sufficiently small visible variation?

B. Do maximum span and minimum RBW alone meet the target requirement?

C. Does a successful internal alignment cover all external-chain behavior?

D. Can this configured method represent the intended signal class with demonstrated limits?

Answer: D. Acceptance links the trace to a validated measurement capability, configuration, and event class, rather than an attractive appearance or large archive. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why the selected alternative fits: Can this configured method represent the intended signal class with demonstrated limits?.

Distinguishing consideration: compare this with option A, “Does the averaged trace have sufficiently small visible variation?”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

Fill-in-the-Blank Questions

V011-C08-FIB-001. In the conventional swept architecture, successive input frequencies pass through a narrow _____ filter.

Answer: resolution. The moving local oscillator presents successive frequencies to the resolution filter; the display is built sequentially. Source: §8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method (p. 4360)

Why this term is required: “resolution” completes the stated technical proposition.

Question context: In the conventional swept architecture, successive input frequencies pass through a narrow _____ filter

Basis and qualification: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

Review: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

Copyright 2026, James M. Atkinson

V011-C08-FIB-002. A continuously swept frequency axis has an associated _____ axis even when it is not shown on the display.

Answer: time. Each trace location is observed at a different time, which matters for changing signals. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

Why this term is required: “time” completes the stated technical proposition.

Question context: A continuously swept frequency axis has an associated _____ axis even when it is not shown on the display

Basis and qualification: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

Copyright 2026, James M. Atkinson

V011-C08-FIB-003. To distinguish a stepped trace from a swept or FFT-assisted trace, retain the selected acquisition _____.

Answer: mode. Modern instruments can support several architectures whose limitations differ. Source: §8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method (p. 4360)

Why this term is required: “mode” completes the stated technical proposition.

Question context: To distinguish a stepped trace from a swept or FFT-assisted trace, retain the selected acquisition _____

Basis and qualification: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

Review: Chapter 8 — Swept Architecture and Frequency-Time Mapping.

Copyright 2026, James M. Atkinson

V011-C08-FIB-004. The nominal width alone does not specify a filter's skirts; the chapter also requires attention to its _____ factor.

Answer: shape. The shape factor describes selectivity beyond one nominal bandwidth value. Source: §8.2 Resolution Bandwidth and Selectivity (p. 4422)

Why this term is required: “shape” completes the stated technical proposition.

Question context: The nominal width alone does not specify a filter's skirts; the chapter also requires attention to its _____ factor

Basis and qualification: Chapter 8 — Resolution Bandwidth and Selectivity.

Review: Chapter 8 — Resolution Bandwidth and Selectivity.

Copyright 2026, James M. Atkinson

V011-C08-FIB-005. For noise integration, the relevant filter width is its equivalent _____ bandwidth.

Answer: noise. Integrated flat-density noise depends on this bandwidth, which need not equal the nominal RBW label. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Why this term is required: “noise” completes the stated technical proposition.

Question context: For noise integration, the relevant filter width is its equivalent _____ bandwidth

Basis and qualification: Chapter 8 — Choose bandwidth from the quantity being estimated.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

Copyright 2026, James M. Atkinson

V011-C08-FIB-006. After narrowing RBW, the time needed for a valid filter response is its _____ time.

Answer: settling. A narrow filter can improve frequency discrimination while taking longer to respond. Source: §8.2 Resolution Bandwidth and Selectivity (p. 4422)

Why this term is required: “settling” completes the stated technical proposition.

Question context: After narrowing RBW, the time needed for a valid filter response is its _____ time

Basis and qualification: Chapter 8 — Resolution Bandwidth and Selectivity.

Review: Chapter 8 — Resolution Bandwidth and Selectivity.

V011-C08-FIB-007. The post-detection bandwidth commonly used to smooth a displayed trace is called _____ bandwidth.

Answer: video. Video bandwidth affects visible variation and response after detection; it does not create simultaneous coverage. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why this term is required: “video” completes the stated technical proposition.

Question context: The post-detection bandwidth commonly used to smooth a displayed trace is called _____ bandwidth

Basis and qualification: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-FIB-008. The trace process that retains the largest observed value in each bucket across repeated acquisitions is _____ hold.

Answer: max. Max hold preserves observed extrema, which can come from different events and times. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why this term is required: “max” completes the stated technical proposition.

Question context: The trace process that retains the largest observed value in each bucket across repeated acquisitions is _____ hold

Basis and qualification: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-FIB-009. A statistic intended to represent average power should not be inferred solely from the word _____ in a menu.

Answer: average. Averaging voltage magnitudes, powers, and logarithms are different operations. Source: §8.4 Noise averages, detector statistics, and the meaning of a decibel trace (p. 4429)

Why this term is required: “average” completes the stated technical proposition.

Question context: A statistic intended to represent average power should not be inferred solely from the word _____ in a menu

Basis and qualification: Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

Review: Chapter 8 — Noise averages, detector statistics, and the meaning of a decibel trace.

Copyright 2026, James M. Atkinson

V011-C08-FIB-010. For repeat estimates of one unchanged random process, the chapter identifies _____ as the condition supporting ordinary trace averaging.

Answer: stationarity. A mixture of operating states can change the meaning of an aggregate even when many traces are included. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why this term is required: “stationarity” completes the stated technical proposition.

Question context: For repeat estimates of one unchanged random process, the chapter identifies _____ as the condition supporting ordinary trace averaging

Basis and qualification: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-FIB-011. An RMS bucket detector can precede a different averaging operation, so the record must state the processing _____.

Answer: order. The sequence determines the final statistic; an isolated RMS label is insufficient. Source: §8.4.4 Measurement consequence (p. 4440)

Why this term is required: “order” completes the stated technical proposition.

Question context: An RMS bucket detector can precede a different averaging operation, so the record must state the processing _____

Basis and qualification: Chapter 8 — Measurement consequence.

Review: Chapter 8 — Measurement consequence.

Copyright 2026, James M. Atkinson

V011-C08-FIB-012. For regulatory or other prescribed methods, the required detector's time _____ is part of the measurement.

Answer: behavior. The specified detector and temporal response should be reproduced rather than replaced by a convenient display mode. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Why this term is required: “behavior” completes the stated technical proposition.

Question context: For regulatory or other prescribed methods, the required detector's time _____ is part of the measurement

Basis and qualification: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Review: Chapter 8 — Video Bandwidth, Averaging, and Detector Choice.

Copyright 2026, James M. Atkinson

V011-C08-FIB-013. In Equation 16A, L_N applies the logarithm _____ averaging.

Answer: before. It averages individual log powers, unlike A_N, which logs an arithmetic power mean. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “before” completes the stated technical proposition.

Question context: In Equation 16A, applies the logarithm _____ averaging

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-014. In Equation 16A, A_N applies the logarithm _____ averaging.

Answer: after. The order preserves a linear power average before conversion to decibels. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “after” completes the stated technical proposition.

Question context: In Equation 16A, applies the logarithm _____ averaging

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-015. For positive powers, the deterministic relation L_N no greater than A_N follows from logarithm _____.

Answer: concavity. This mathematical property establishes the direction of the difference without specifying a noise distribution. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “concavity” completes the stated technical proposition.

Question context: For positive powers, the deterministic relation no greater than follows from logarithm _____

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-016. For the inequality L_N no greater than A_N for positive powers, equality holds only when all sampled powers are _____.

Answer: equal. Strict concavity makes equality depend on equal powers, not independence or sample count. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: "equal" completes the stated technical proposition.

Question context: For the inequality no greater than for positive powers, equality holds only when all sampled powers are _____

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-017. The reference power used for dBm in Equation 16A is one _____.

Answer: milliwatt. The logarithm is applied to a dimensionless ratio to this reference power. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “milliwatt” completes the stated technical proposition.

Question context: The reference power used for dBm in Equation 16A is one _____

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-018. The quadrature components in the stated circular Gaussian model have _____ mean.

Answer: zero. The specified model is zero-mean noise; a deterministic component changes the power distribution. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “zero” completes the stated technical proposition.

Question context: The quadrature components in the stated circular Gaussian model have _____ mean

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-019. The two normalized Gaussian quadratures are assumed _____ of one another.

Answer: independent. Their independence, equal variance, and zero means yield the stated exponential power model. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “independent” completes the stated technical proposition.

Question context: The two normalized Gaussian quadratures are assumed _____ of one another

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-020. The power variable is defined at a calibrated estimation _____, rather than as an uncalibrated count.

Answer: plane. Reference resistance and gain calibration connect the random variable to physical power. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “plane” completes the stated technical proposition.

Question context: The power variable is defined at a calibrated estimation _____, rather than as an uncalibrated count

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-021. The normalized instantaneous power U has an _____ distribution under the chapter's Gaussian model.

Answer: exponential. Its density on nonnegative u is exp(-u), with unit mean and variance. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “exponential” completes the stated technical proposition.

Question context: The normalized instantaneous power U has an _____ distribution under the chapter's Gaussian model

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-022. If mean power is mu, the modeled single-sample standard deviation in watts is _____.

Answer: mu. The exponential power variance is mu squared, so its standard deviation equals its mean. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “mu” completes the stated technical proposition.

Question context: If mean power is mu, the modeled single-sample standard deviation in watts is _____

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-023. The expectation of the logarithmic average contains Euler's constant, conventionally denoted _____.

Answer: gamma. The integral of exp(-u) times ln(u) is minus gamma, producing the expected log offset. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “gamma” completes the stated technical proposition.

Question context: The expectation of the logarithmic average contains Euler's constant, conventionally denoted _____

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-024. To four decimal places, the specified mean log-power under-response is _____ dB.

Answer: 2.5068. The value is 10 times Euler's constant divided by ln(10); it is tied to the stipulated exponential model. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “2.5068” completes the stated technical proposition.

Question context: To four decimal places, the specified mean log-power under-response is _____ dB

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-025. Identical marginal distributions suffice for the expectation of L_N; _____ is not required for that expectation.

Answer: independence. Expectation is linear even when samples are dependent, although the simple variance reductions change. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “independence” completes the stated technical proposition.

Question context: Identical marginal distributions suffice for the expectation of _____ is not required for that expectation

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-026. An unbiased estimate in decibel expectation need not remain unbiased after conversion back to _____.

Answer: watts. Exponentiation is nonlinear, so unbiasedness does not automatically survive the transformation. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “watts” completes the stated technical proposition.

Question context: An unbiased estimate in decibel expectation need not remain unbiased after conversion back to _____

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-027. The corrected expected log level is not, merely by being corrected, an upper confidence _____.

Answer: bound. A bias correction and a confidence statement answer different statistical questions. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “bound” completes the stated technical proposition.

Question context: The corrected expected log level is not, merely by being corrected, an upper confidence _____

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-028. A _____ envelope caused by receiver overload is one example that invalidates the stipulated exponential-noise distribution.

Answer: clipped. Clipping changes the sample distribution and the resulting logarithmic moments. Source: §8.4.1 A stated statistical model (p. 4431)

Why this term is required: “clipped” completes the stated technical proposition.

Question context: A _____ envelope caused by receiver overload is one example that invalidates the stipulated exponential-noise distribution

Basis and qualification: Chapter 8 — A stated statistical model.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-029. The sum of N independent, identically distributed exponential powers with a common positive mean has a _____ distribution.

Answer: gamma. The common scale and independence are needed for the finite-record gamma-sum derivation. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “gamma” completes the stated technical proposition.

Question context: The sum of N independent, identically distributed exponential powers with a common positive mean has a _____ distribution

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-030. In Equation 16C, the harmonic sum stops at index _____.

Answer: N minus 1. The expectation uses H_{N-1} minus gamma and ln(N), with H_0 defined as zero. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: "N minus 1" completes the stated technical proposition.

Question context: In Equation 16C, the harmonic sum stops at index _____

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-031. For N = 1, the finite-record formula and the single-sample logarithmic formula _____.

Answer: agree. A one-sample power mean and its individual log reading are the same statistic. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “agree” completes the stated technical proposition.

Question context: For N = 1, the finite-record formula and the single-sample logarithmic formula _____

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-032. The arithmetic power mean is unbiased in watts, but its logarithm has finite-record _____.

Answer: bias. Nonlinear conversion creates a negative expected offset for the stated finite independent sample model. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “bias” completes the stated technical proposition.

Question context: The arithmetic power mean is unbiased in watts, but its logarithm has finite-record _____

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-033. For four independent, identically distributed exponential powers with a common positive mean, logging their arithmetic mean gives an expected level about _____ dB below the true mean-power level.

Answer: 0.56535. Equation 16C applies to the stated common-scale gamma sum; it differs from averaging individual logarithms. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “0.56535” completes the stated technical proposition.

Question context: For four independent, identically distributed exponential powers with a common positive mean, logging their arithmetic mean gives an expected level about _____ dB below the true mean-power level

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-034. For 100 independent, identically distributed exponential powers with a common positive mean averaged before logging, the finite-log correction is about _____ dB upward.

Answer: 0.021751. The gamma-mean bias is negative and small at this independent sample count. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “0.021751” completes the stated technical proposition.

Question context: For 100 independent, identically distributed exponential powers with a common positive mean averaged before logging, the finite-log correction is about _____ dB upward

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-035. For independent, identically distributed exponential powers with a common positive mean, the relative standard deviation of their arithmetic mean scales as the inverse _____ root of N.

Answer: square. Variance of the independent sum yields relative standard deviation $\frac{1}{\sqrt{N}}$. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “square” completes the stated technical proposition.

Question context: For independent, identically distributed exponential powers with a common positive mean, the relative standard deviation of their arithmetic mean scales as the inverse _____ root of N

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-036. For 25 independent, identically distributed exponential powers with a common positive mean, the relative standard deviation of their arithmetic mean is _____.

Answer: 0.2. Under these marginals and independence, $\frac{1}{\sqrt{25}}$ = 0.2. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “0.2” completes the stated technical proposition.

Question context: For 25 independent, identically distributed exponential powers with a common positive mean, the relative standard deviation of their arithmetic mean is _____

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-FIB-037. For the same independent, identically distributed exponential-power model, halving the relative standard deviation of the mean requires _____ times as many independent samples.

Answer: four. The inverse-square-root relation makes a factor-of-two scatter reduction require a factor of four in N. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

Why this term is required: “four” completes the stated technical proposition.

Question context: For the same independent, identically distributed exponential-power model, halving the relative standard deviation of the mean requires _____ times as many independent samples

Basis and qualification: Chapter 8 — Power averaging before the logarithm.

Review: Chapter 8 — Power averaging before the logarithm.

V011-C08-FIB-046. Changing equivalent bandwidth from 10 kHz to 1 kHz produces a modeled noise change of _____ dB with compatible processing.

Answer: minus 10. The ratio is 0.1, whose ten-times logarithm is minus 10 dB.

Source: §8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4450)

Why this term is required: “minus 10” completes the stated technical proposition.

Question context: Changing equivalent bandwidth from 10 kHz to 1 kHz produces a modeled noise change of _____ dB with compatible processing

Basis and qualification: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Review: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Copyright 2026, James M. Atkinson

V011-C08-FIB-047. Changing equivalent bandwidth from 1 kHz to 2 kHz produces a modeled increase of approximately _____ dB.

Answer: 3.0103. The bandwidth doubles; 10 log10(2) is approximately 3.0103 dB.

Source: §8.11 Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4450)

Why this term is required: "3.0103" completes the stated technical proposition.

Question context: Changing equivalent bandwidth from 1 kHz to 2 kHz produces a modeled increase of approximately _____ dB

Basis and qualification: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Review: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-FIB-052. If independent Gaussian contributions each have mean power 0.1 nW, their total mean power is _____ nW.

Answer: 0.2. Under the stated independent zero-mean model, the mean powers add at the same plane and bandwidth. Source: §8.4.3 Ten worked applications (p. 4437)

Why this term is required: “0.2” completes the stated technical proposition.

Question context: If independent Gaussian contributions each have mean power 0.1 nW, their total mean power is _____ nW

Basis and qualification: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

Copyright 2026, James M. Atkinson

V011-C08-FIB-053. Subtracting nearly equal total and background estimates is described as ill-_____.

Answer: conditioned. Small errors in either input can be large relative to the small residual. Source: §8.4.3 Ten worked applications (p. 4437)

Why this term is required: “conditioned” completes the stated technical proposition.

Question context: Subtracting nearly equal total and background estimates is described as ill-_____

Basis and qualification: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

Copyright 2026, James M. Atkinson

V011-C08-FIB-054. The simple background example excludes _____ tones because phase-dependent cross terms can matter.

Answer: coherent. The stated independent Gaussian-power subtraction is not a general coherent-voltage subtraction rule. Source: §8.4.3 Ten worked applications (p. 4437)

Why this term is required: “coherent” completes the stated technical proposition.

Question context: The simple background example excludes _____ tones because phase-dependent cross terms can matter

Basis and qualification: Chapter 8 — Ten worked applications.

Review: Chapter 8 — Ten worked applications.

V011-C08-FIB-092. If the chosen method cannot reproduce the reference, the chapter calls for a different acquisition _____.

Answer: architecture. A capability failure cannot be repaired merely by relabeling or smoothing the same invalid trace. Source: §8.10 Sweep Method Acceptance (p. 4449)
Why this term is required: “architecture” completes the stated technical proposition.
Question context: If the chosen method cannot reproduce the reference, the chapter calls for a different acquisition _____
Basis and qualification: Chapter 8 — Sweep Method Acceptance.
Review: Chapter 8 — Sweep Method Acceptance.

Copyright 2026, James M. Atkinson

V011-C08-FIB-093. The archive should retain setup files and _____ data as well as images.

Answer: native. Native records preserve acquisition and processing information for later review. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why this term is required: “native” completes the stated technical proposition.

Question context: The archive should retain setup files and _____ data as well as images

Basis and qualification: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

Copyright 2026, James M. Atkinson

V011-C08-FIB-094. Segment boundaries, averaging counts, sweep repetitions, and time _____ support reconstruction of coverage.

Answer: stamps. These records connect each frequency observation to when and how it was acquired. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why this term is required: “stamps” completes the stated technical proposition.

Question context: Segment boundaries, averaging counts, sweep repetitions, and time _____ support reconstruction of coverage

Basis and qualification: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

Copyright 2026, James M. Atkinson

V011-C08-FIB-095. In the chirped-burst example, the apparent comb is a sweep-time portrayal _____.

Answer: artifact. It arose from fragments at different moments rather than simultaneous carriers. Source: §8.13 Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity (p. 4453)

Why this term is required: "artifact" completes the stated technical proposition.

Question context: In the chirped-burst example, the apparent comb is a sweep-time portrayal _____

Basis and qualification: Chapter 8 — Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Review: Chapter 8 — Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-FIB-096. Max hold estimates observed per-bucket _____ across acquisitions, not a mean-power spectrum.

Answer: maxima. These extrema can originate at different times; they do not establish simultaneous coexistence. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

Why this term is required: “maxima” completes the stated technical proposition.

Question context: Max hold estimates observed per-bucket _____ across acquisitions, not a mean-power spectrum

Basis and qualification: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

Copyright 2026, James M. Atkinson

V011-C08-FIB-097. Before repeated bursts are used to reconstruct one event, the relevant waveform and trigger relationship require demonstrated _____.

Answer: repeatability. Period and edge alignment alone do not establish the amplitude, phase, modulation, and startup properties needed by the construction.

Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Why this term is required: “repeatability” completes the stated technical proposition.

Question context: Before repeated bursts are used to reconstruct one event, the relevant waveform and trigger relationship require demonstrated _____

Basis and qualification: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-FIB-099. Before transferring a hypothetical exponential-noise calculation to an actual trace, establish the trace statistic and the applicable power-sample _____.

Answer: distribution. The model does not automatically cover tones, clipping, or mixtures of changing means. Source: §8.4.1 A stated statistical model (p. 4431)
Why this term is required: “distribution” completes the stated technical proposition.
Question context: Before transferring a hypothetical exponential-noise calculation to an actual trace, establish the trace statistic and the applicable power-sample _____
Basis and qualification: Chapter 8 — A stated statistical model.
Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-FIB-100. The chapter's acceptance record links the displayed trace to controlled references, configuration, native data, and frequency-time _____.

Answer: mapping. Those elements support a reproducible interpretation of what the swept procedure actually observed. Source: §8.10 Sweep Method Acceptance (p. 4449)

Why this term is required: “mapping” completes the stated technical proposition.

Question context: The chapter's acceptance record links the displayed trace to controlled references, configuration, native data, and frequency-time _____

Basis and qualification: Chapter 8 — Sweep Method Acceptance.

Review: Chapter 8 — Sweep Method Acceptance.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C08-ESSAY-001. Develop a validation plan for a swept analyzer intended to characterize a short frequency-agile burst. Explain how you would decide whether the swept mode remains suitable.

- Opening: Present a thesis that answers this precise question: Develop a validation plan for a swept analyzer intended to characterize a short frequency-agile burst. Explain how you would decide whether the swept mode remains suitable. Identify which evidence would falsify the proposed conclusion Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)
- Core terminology and scope: Define validation, swept, analyzer in the question's particular technical setting; explain how intended, characterize, mode differ if that distinction would change the analysis of "Develop a validation plan for a swept analyzer intended to characterize a short frequency-agile burst. Explain how you would decide whether the swept mode remains suitable" Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Identify the event's time-frequency trajectory and the receiver's valid frequency-time intervals Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a validation plan for a swept analyzer intended to characterize a short frequency-agile burst to the claimed result, following "Validate transient and gated measurements with the intended waveform"; name the

intermediate states and measurable outputs Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a validation plan for a swept analyzer intended to characterize a short frequency-agile burst. Compare event-resolved reference captures with the aggregate Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Swept Architecture and Frequency-Time Mapping” that resolves the question about a validation plan for a swept analyzer intended to characterize a short frequency-agile burst; derive the relevant result with units and stated validity conditions Source: §8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method (p. 4360)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a validation plan for a swept analyzer intended to characterize a short frequency-agile burst. Select a capture architecture with sufficient instantaneous bandwidth if the method misses or distorts the target Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)
- Worked application or illustrative case: Build a worked example of “a validation plan for a swept analyzer intended to characterize a short frequency-agile burst”, addressing this associated condition: Explain how you would decide whether the swept mode remains suitable. Identify the event's time-frequency trajectory and the receiver's valid

frequency-time intervals Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- Alternative explanations and failure modes: Construct two plausible technical explanations for “a validation plan for a swept analyzer intended to characterize a short frequency-agile burst”. Using “Swept Architecture and Frequency-Time Mapping”, specify a discriminator and the result expected under each explanation Source: §8.1 Fundamentals of Spectrum Analyser Operation and Laboratory Method (p. 4360)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to a validation plan for a swept analyzer intended to characterize a short frequency-agile burst, including the effect of missing measurements and inconsistent operating conditions Source: §8.10 Sweep Method Acceptance (p. 4449)
- Scholarly synthesis and implications: Explain what the result about a validation plan for a swept analyzer intended to characterize a short frequency-agile burst authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)
- Closing: Conclude by answering “Develop a validation plan for a swept analyzer intended to characterize a short frequency-agile burst. Explain how you would decide whether the swept mode remains suitable” using only the demonstrated evidence; state the remaining decisive verification step Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

V011-C08-ESSAY-002. Derive the deterministic relation between L_N and A_N and explain what it says about a record containing unequal powers.

- Opening: Define L_N as the arithmetic mean of logarithmic power readings and A_N as the logarithm of mean linear power; give a falsifiable thesis for the inequality L_N <= A_N when all P_i are strictly positive and share a reference P_ref. Distinguish this deterministic inequality from any distribution-dependent numerical offset. Source: §8.4.3 Ten worked applications (p. 4437)
- Core terminology and scope: State N (sample count), P_i (positive linear power in milliwatts at the declared reference plane), P_ref (one milliwatt), L_N (mean logarithmic power in dBm) and A_N (logarithm of arithmetic mean power in dBm). Distinguish an average of decibel readings, an RMS-power detector, a voltage-envelope mean and a video-bandwidth-smoothed display. Source: §8.4.3 Ten worked applications (p. 4437)
- Problem statement and purpose: Formulate the measurement as the comparison of two estimators derived from the same N calibrated linear-power observations. Establish which detector, trace statistic, bandwidth, time interval, input attenuation and reference plane generated P_i. Explain why a nominally identical dBm label does not establish identical estimands. Source: §8.4.3 Ten worked applications (p. 4437)
- Physical and computational context: Follow the chain from analogue input and IF filtering through sampled I/Q, power formation, calibration and averaging. For L_N apply 10 log10(P_i/P_ref) before taking the mean; for A_N average P_i first and then apply 10 log10.

Copyright 2026, James M. Atkinson

Identify where window energy, equivalent noise bandwidth, detector choice and any trace-level clipping enter. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

- Assumptions, conditions and reference planes: Require finite strictly positive P_i, a common P_{ref} and comparable acquisition states. Apply strict concavity of ln to derive $L_N <= A_N$ for every realised record, with equality if and only if the sample powers are identical. State why this direction-of-inequality proof does not assume Gaussian noise, stationarity or statistical independence. Source: §8.4.2 Power averaging before the logarithm (p. 4434)
- Analytical framework: Starting from Equation 16A derive $A_N - L_N = 10 \log10[(\text{arithmetic mean of } P_i)/(\text{geometric mean of } P_i)] >= 0$ dB. Verify that the argument of the logarithm is dimensionless, and separate this exact finite-record identity from the asymptotic approximately 2.5068 dB ensemble correction for independent exponential power samples. Source: §8.24 Ten worked calculations and controlled counterexamples (p. 4482)
- Evidence and method: Preserve timestamped linear-power samples or calibrated complex I/Q, receiver gain and attenuation states, detector settings, RBW and equivalent noise bandwidth, window coefficients, averaging order, rejected samples and any logarithmic floor. State a reproducible calculation that independently reconstructs both L_N and A_N and tests their source-record consistency. Source: §8.4.3 Ten worked applications (p. 4437)
- Worked application or illustrative case: For two equal-duration samples $P_1 = 1$ mW and $P_2 = 4$ mW with $P_{ref} = 1$ mW, calculate

Copyright 2026, James M. Atkinson

L_2 = 3.010300 dBm and A_2 = 3.979400 dBm; explain the 0.969100 dB disparity using the arithmetic/geometric mean ratio. Repeat under a uniform calibration gain to show which quantities shift and which contrast remains invariant. Source: §8.4.2 Power averaging before the logarithm (p. 4434)

- Alternative explanations and failure modes: Distinguish estimator-order bias from a changing mixture of receiver states, signal intermittency, saturated or censored samples, noise-floor subtraction and vendor-specific detector algorithms. Specify controlled interventions, including a constant reference level and a recorded state change, that would discriminate two plausible explanations of an observed trace discrepancy. Source: §8.24 Ten worked calculations and controlled counterexamples (p. 4482)
- Uncertainty and evidential limits: Propagate uncertainty in the calibrated powers using sensitivity coefficients and covariance rather than treating all samples or calibration channels as independent. Distinguish aleatory noise fluctuations, shared systematic error, finite-sample uncertainty, dependence induced by overlapping FFT windows and selection bias due to threshold censoring. Explain when the logarithm is undefined for nonpositive reconstructed powers. Source: §8.4 Noise averages, detector statistics, and the meaning of a decibel trace (p. 4429)
- Scholarly synthesis and implications: Establish what the deterministic L_N <= A_N relation proves about the recorded numbers, then state separately the evidence required to attribute any gap to Gaussian-noise statistics or instrument architecture.

Treat the often-cited 2.5 dB offset as a qualified response for specified conditions, never a universal correction for a tone, impulsive signal or arbitrary mixture. Source: §8.4.3 Ten worked applications (p. 4437)

- Closing: Present both labelled statistics L_N and A_N, their observed difference in dB, the common reference power, the detector/averaging chain and uncertainty limitations. Conclude whether the measurements support the narrower arithmetic claim; identify the decisive independent calibration or replay experiment still needed before any stronger forensic or engineering inference. Source: §8.4.3 Ten worked applications (p. 4437)

V011-C08-DISCUSSION-001. A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. What evidence should the review group request before accepting that description?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. What evidence should the review group request before accepting that description?” Put this particular dispute to the panel: A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. What evidence should the review group request before accepting that description. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 02. Student A, terminology and scope: Agree the operational meanings of smooth, instantaneous, review and group, request, description in “A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. What evidence should the review group request before accepting that description”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the

Copyright 2026, James M. Atkinson

outcome and request a specific example from the stated receiver scenario. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Video Bandwidth, Averaging, and Detector Choice”. Discuss whether repeatable-event reconstruction is supportable or a simultaneous capture is needed Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

Copyright 2026, James M. Atkinson

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Video Bandwidth, Averaging, and Detector Choice”. Discuss whether repeatable-event reconstruction is supportable or a simultaneous capture is needed Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Require acquisition mode, timing, native records, and evidence that all displayed components coexisted Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask

Copyright 2026, James M. Atkinson

which setting or observation would discriminate between them without changing the measurand. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving

Copyright 2026, James M. Atkinson

A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. A defensible outcome may retain the trace as observations while revising the instantaneous-spectrum claim; visual smoothness alone is insufficient Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request

Copyright 2026, James M. Atkinson

an explicit statement of what evidence would reverse the conclusion. Source: §8.3 Video Bandwidth, Averaging, and Detector Choice (p. 4426)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. A defensible outcome may retain the trace as observations while revising the instantaneous-spectrum claim; visual smoothness alone is insufficient Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device and What evidence should the review group request before accepting that description; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §8.14 Sweep-time adequacy as a dynamic measurement rather than a display preference (p. 4454)

Copyright 2026, James M. Atkinson

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device”, addressing “What evidence should the review group request before accepting that description”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. What evidence should the review group request before accepting that description”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “A colleague wants to publish a smooth max-hold trace as the instantaneous spectrum of a device. What evidence should the review group request before accepting that description”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted

trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Two teams disagree because one always uses minimum RBW and the other follows a channel-power procedure; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §8.20 Resolution, equivalent noise bandwidth and distortion of transient waveforms (p. 4475)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Resolution Bandwidth and Selectivity”. Compare separation, integrated noise, neighbor inclusion, and transient response Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §8.2 Resolution Bandwidth and Selectivity (p. 4422)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Begin with the intended quantity and signal width Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving Two teams disagree because one always uses minimum RBW and the other follows a channel-power procedure: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Two teams disagree because one always uses minimum RBW and the other follows a channel-power procedure; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §8.20 Resolution, equivalent noise bandwidth and distortion of transient waveforms (p. 4475)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving Two teams disagree because one always uses minimum RBW and the other follows a channel-power procedure: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §8.7 Choose bandwidth from the quantity being estimated (p. 4444)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving Two teams disagree because one always uses minimum RBW and the other follows a channel-power procedure, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §8.2 Resolution Bandwidth and Selectivity (p. 4422)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving

V011-C08-DISCUSSION-003. A technician proposes a universal plus 2.51 dB adjustment to every archived noise image. What would make the proposal defensible or require rejecting it?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A technician proposes a universal plus 2.51 dB adjustment to every archived noise image. What would make the proposal defensible or require rejecting it?” Put this particular dispute to the panel: A technician proposes a universal plus 2.51 dB adjustment to every archived noise image. What would make the proposal defensible or require rejecting it. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §8.4.4 Measurement consequence (p. 4440)

- 02. Student A, terminology and scope: Agree the operational meanings of universal, plus, adjustment and proposal, defensible, rejecting in “A technician proposes a universal plus 2.51 dB adjustment to every archived noise image. What would make the proposal defensible or require rejecting it”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §8.4.4 Measurement consequence (p. 4440)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A technician proposes a universal plus 2.51 dB adjustment to every archived noise image; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §8.4.3 Ten worked applications (p. 4437)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Ten worked applications”. Separate the specified single-exponential log model from tones, power-averaged outputs, mixtures, and already corrected markers Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §8.4.3 Ten worked applications (p. 4437)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to
