V011-C08-DISCUSSION-017. How should a team decide whether its repeated bursts are sufficiently similar for its particular spectral reconstruction?

- 01. Moderator, opening proposition: Introduce the exact dispute, “How should a team decide whether its repeated bursts are sufficiently similar for its particular spectral reconstruction?” Put this particular dispute to the panel: How should a team decide whether its repeated bursts are sufficiently similar for its particular spectral reconstruction. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

- 02. Student A, terminology and scope: Agree the operational meanings of repeated, bursts, sufficiently and similar, particular, reconstruction in “How should a team decide whether its repeated bursts are sufficiently similar for its particular spectral reconstruction”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §8.8 Validate transient and gated measurements with the intended waveform (p. 4446)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of how should a team decide whether its repeated bursts are sufficiently similar for its particular spectral reconstruction; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §8.17 Distinguishing a spectral estimator from a persuasive-looking display (p. 4466)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “8. Distinguishing a spectral estimator from a persuasive-looking display”. A nominal period match is insufficient Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §8.17 Distinguishing a spectral estimator from a persuasive-looking display (p. 4466)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original

V011-C08-DISCUSSION-020. The team wants one default sweep time for every mode because Equation 15 is easy to automate. What safeguards would a technically sound implementation need?

- 01. Moderator, opening proposition: Introduce the exact dispute, “The team wants one default sweep time for every mode because Equation 15 is easy to automate. What safeguards would a technically sound implementation need?” Put this particular dispute to the panel: The team wants one default sweep time for every mode because Equation 15 is easy to automate. What safeguards would a technically sound implementation need. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

- 02. Student A, terminology and scope: Agree the operational meanings of sweep, easy, technically and sound, implementation, need in “The team wants one default sweep time for every mode because Equation 15 is easy to automate. What safeguards would a technically sound implementation need”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a

specific example from the stated receiver scenario. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of The team wants one default sweep time for every mode because Equation 15 is easy to automate; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Interpret a swept trace through its frequency-time trajectory”. Test representative signals and retain actual usable timing Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

Copyright 2026, James M. Atkinson

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of The team wants one default sweep time for every mode because Equation 15 is easy to automate; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §8.10 Sweep Method Acceptance (p. 4449)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Interpret a swept trace through its frequency-time trajectory”. Test representative signals and retain actual usable timing Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Limit the scaling to validated regimes, include instrument/filter factors and acceptance criteria, and detect settings such as segmentation or gating outside that scope Put two specific questions to Student D about the stated

competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

- 08. Student D, answer to Student E: Design a discriminating experiment involving The team wants one default sweep time for every mode because Equation 15 is easy to automate: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of The team wants one default sweep time for every mode because Equation 15 is easy to automate; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §8.10 Sweep Method Acceptance (p. 4449)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving The team wants one default sweep time for every mode because Equation 15 is easy to automate: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §8.5 Sweep Time, Triggering, and Transient Signals (p. 4441)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving The team wants one default sweep time for every mode because Equation 15 is easy to automate, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §8.6 Interpret a swept trace through its frequency-time trajectory (p. 4442)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving

Chapter 8 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C08-ESSAY-001 — Identify the event's time-frequency trajectory and the receiver's valid frequency-time intervals; exclude tuning and settling; test the actual duration, startup, repetition, and prior gain state; reproduce survey span, RBW, VBW, detector, sweep time, trigger, trace, and gain. Compare event-resolved reference captures with the aggregate. Select a capture architecture with sufficient instantaneous bandwidth if the method misses or distorts the target. State the event class and remaining gaps rather than claiming universal coverage.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-ESSAY-002 — Define each statistic with the same reference power. Apply concavity of ln to show the average logarithm is no greater than the logarithm of the arithmetic mean. State that equality requires equal positive powers. Explain that the inequality applies record by record but supplies no fixed correction, Gaussian model, or confidence statement.

Review: Chapter 8 — A stated statistical model.

V011-C08-ESSAY-003 — Begin with independent zero-mean equal-variance Gaussian quadratures and calibrated exponential power. Normalize by its mean, use the integral of exp(-u) ln(u) to obtain minus Euler's constant, and convert to decibels. Distinguish identical marginal distributions needed for expectation from independence needed for simple scatter reduction. Exclude tones, clipping, and changing mixtures; state that corrected decibel expectation does not imply watt unbiasedness.

Review: Chapter 8 — A stated statistical model.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-004 — Define both operation orders. For the log average, retain the minus 2.5068 dB expectation. For the logged four-power mean, use H_3 minus gamma minus ln(4) to obtain approximately minus 0.56535 dB. Explain why adding 2.5068 dB to the latter overcorrects by about 1.94147 dB in expectation. Preserve the original statistic and already-applied corrections.

Review: Chapter 8 — Power averaging before the logarithm.

V011-C08-ESSAY-005 — Hold source and receiver state fixed, characterize both equivalent noise bandwidths, retain linear-power data, and use compatible detector and averaging order. Predict 10 log10 of the bandwidth ratio for unchanged white density. Separate source/environment challenges from bandwidth changes. Investigate nonwhite input, receiver noise, filter weighting, and correction history when the comparison fails; do not infer a unique cause from the mismatch.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-ESSAY-006 — Use the independent inverse-square-root scatter relation and the stipulated common-correlation variance. Perfect copies have rho = 1 and retain the original relative standard deviation; independent samples can reduce it. Explain why file or record count does not establish independence and why the gamma correction cannot automatically use the duplicate count. Preserve the acquisition relationship rather than presenting storage volume as evidence strength.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-007 — Compute the weighted linear mean of 1 and 100 mW as 10.9 mW and its level as about 10.3743 dBm. Compute the corrected weighted log levels as 2 dBm. Attribute the remaining difference to operation order across changing means, not an arithmetic error in the single-state offset. Retain state durations and state-resolved estimates and avoid describing the mixture as one exponential distribution.

Review: Chapter 8 — Ten worked applications.

V011-C08-ESSAY-008 — Explain how successive frequency visits and repeated max hold can combine different time fragments. Distinguish observed activity from simultaneous carriers. Use event-resolved capture to support the trajectory interpretation, identify the capture's bandwidth and timing limits, and retain both records and configurations. Report the comb as a portrayal artifact in this tested case without declaring every comb an artifact.

Review: Chapter 8 — Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-ESSAY-009 — Specify the measurand, integration interval, spectral weighting, appropriate power statistic, calibration plane, and source state. Explain that a narrow filter samples only part of the occupied energy and a broad filter can include neighbors. Account for filter settling and compatible processing. Validate with a representative modulated reference and avoid treating a minimum noise display as proof of total-power accuracy.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-010 — Separate the paths and failure modes each challenge probes. Internal alignment may omit cables, antennas, filters, and environmental overload; termination exposes residual responses under that condition; external references at several frequencies and levels probe the installed chain. Explain why agreement among these tests strengthens a bounded result but does not establish all transient behavior or universal source absence.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

V011-C08-ESSAY-011 — Map trigger and gate to the valid response interval. Require enough settling within the selected portion, and examine changes in startup, amplitude, phase, and modulation across events. Explain why aligning an edge or matching repetition period is insufficient. Compare event-resolved records with the proposed aggregate and describe the result as a collection when reconstruction assumptions are unproven.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-ESSAY-012 — Use proportionality to span divided by RBW squared to obtain an eightfold scale within one validated regime. Identify the omitted filter/architecture factor and acceptance criterion. Explain that automatic or qualitative timing does not validate unusual signals, segmentation, or gating; use the instrument's validated model and a representative reference for an absolute setting.

Review: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-013 — State the validated event class, tested level and waveform criterion, observed bands, usable durations, gain and acquisition settings, and excluded intervals. Distinguish no observed qualifying event from universal absence. Retain unsuccessful captures and automatic state changes. Identify a next timing or acquisition strategy directed at the unresolved classes or gaps.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-ESSAY-014 — Distinguish nominal width, equivalent noise bandwidth, passband/skirt weighting, and impulse or settling response. Use flat-density integration for noise and actual weighting for a varying spectrum. Explain nearby-tone leakage and the time needed for burst response. Reject a universal conversion factor inferred only from the label and specify characterization evidence required for comparison.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-ESSAY-015 — Include native data and setup, mode, segment boundaries and timestamps, usable intervals, span, bandwidth definitions, detector order, gain state, averaging counts, max-hold repetitions, masked bands, and trigger settings. Relate these to the event's trajectory and duration. Explain what remains unknowable if only a final image survives and why a later correction cannot restore unobserved data.

Review: Chapter 8 — Sweep Method Acceptance.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-016 — Require compatible mean-power estimators at the same plane and bandwidth and justify the independent zero-mean Gaussian model. Convert to linear units, subtract there, and interpret a small residual with the errors of both estimates. Explain ill-conditioning, avoid treating the dB difference as residual power, and identify coherent or correlated cases outside the example.

Review: Chapter 8 — Ten worked applications.

V011-C08-ESSAY-017 — Trace each operation in its actual sequence, state its input/output statistic and weighting, and preserve software/mode settings. Resolve ambiguous RMS or average labels using the relevant implementation record. Determine whether the log or finite-power correction applies and whether it has already been applied. Explain why a screenshot and a dBm axis cannot supply this audit retrospectively.

Review: Chapter 8 — Measurement consequence.

V011-C08-ESSAY-018 — Separate visual scatter, mean bias, and uncertainty. Use independent averaging to explain legitimate repeatability improvement, then show how correlation and log bias survive a smooth display. Require sample provenance, distribution, stationarity, and correction history. Do not promote smoothness to an accuracy guarantee or turn a local propagated standard deviation into an exact interval.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-019 — Reproduce the preceding state, recovery interval, burst turn-on, duration, modulation, and repetition. Test with the actual gain, bandwidth, detector, trigger, and gate settings. Compare the usable response with a steady-tone check and explain why steady agreement is incomplete. Define the validated initial-state/event combinations and retain failures instead of averaging them away.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-ESSAY-020 — Show that equal positive powers give $L_N = A_N$, independent of N. Applying the exponential-noise offset then overstates the tone by about 2.5068 dB. Connect the error to an unsupported distributional assumption rather than a failure of calibration units. Require evidence for the actual statistic and signal class before applying any correction.

Review: Chapter 8 — Ten worked applications.

V011-C08-ESSAY-021 — State the expected corrected input-referred behavior and retain attenuation, preamplifier, mixer level, reference level, and source conditions. Repeat controlled settings, compare terminated-input and external-reference observations, and consider compression or internal products. Explain that the challenge reveals a departure needing localization rather than proving a unique origin from one change.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-022 — Describe successive frequency-time visits versus the instantaneous bandwidth and record of the capture. Identify which signal evolution each preserves or loses, including repeated-event assumptions for reconstruction. Match bandwidth, detector, and calibration before quantitative comparisons. Keep the limits of both methods explicit and choose according to the target measurand.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

V011-C08-ESSAY-023 — Identify the marker's pre-log statistic, bandwidth normalization, and correction history. Distinguish the single-log offset, finite-power-log bias, and noise-bandwidth correction. Show why applying an already included correction twice shifts the reported value. Require retained raw/native values and an explicit correction ledger so the original indication and derived result can both be audited.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-ESSAY-024 — Distinguish arithmetic consistency from demonstrated model applicability. Identify required evidence for calibrated power plane, input distribution, stationarity, independence, bandwidth, and processing sequence. Use examples as checks of interpretation, not as measured specifications or universal detector constants. State which additional representative references and configuration records are needed for acceptance.

Review: Chapter 8 — Ten worked applications.

Copyright 2026, James M. Atkinson

V011-C08-ESSAY-025 — Describe both successful and failed tests, the configuration and waveform differences, and the specific capability not established. Avoid allowing the continuous test to overrule transient failure. Propose a suitable alternate timing or capture architecture, repeat acceptance in the survey settings, and constrain any interim findings to the event classes and usable coverage actually demonstrated.

Review: Chapter 8 — Sweep Method Acceptance.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-C08-DISCUSSION-001 — Require acquisition mode, timing, native records, and evidence that all displayed components coexisted. Discuss whether repeatable-event reconstruction is supportable or a simultaneous capture is needed. A defensible outcome may retain the trace as observations while revising the instantaneous-spectrum claim; visual smoothness alone is insufficient.

Review: Chapter 8 — Interpret a swept trace through its frequency-time trajectory.

V011-C08-DISCUSSION-002 — Begin with the intended quantity and signal width. Compare separation, integrated noise, neighbor inclusion, and transient response. Require a defined power integration and representative validation. Accept different settings for different measurands rather than treating one front-panel choice as universally superior.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-DISCUSSION-003 — Ask for pre-log statistic, distribution, correction history, and bandwidth definitions for each record. Separate the specified single-exponential log model from tones, power-averaged outputs, mixtures, and already corrected markers. Discuss which records can be recovered and which retain irreducible uncertainty; do not invent missing metadata.

Review: Chapter 8 — Measurement consequence.

Copyright 2026, James M. Atkinson

V011-C08-DISCUSSION-004 — Assess what each record permits a reviewer to reconstruct: timing, detector sequence, corrections, segments, and excluded intervals. Native data and settings generally retain more measurement meaning than repeated images. Consider practical volume and necessary images, but avoid counting stored files as independent observations or as proof of coverage.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-DISCUSSION-005 — State the tested event class, usable observation intervals, bands, and sensitivity/timing criteria. Explain possible gaps for weak, short, hopping, or out-of-band events. Preserve the bounded negative finding and propose a targeted next observation where the present method cannot resolve the concern.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-DISCUSSION-006 — Discuss which waveform features must be repeatable for the intended aggregate. Request event-resolved records and compare phase, amplitude, startup, and modulation where relevant. An aggregate can document activity without representing one event; choose its label and subsequent capture method accordingly.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-DISCUSSION-007 — Separate the empirical scatter of the actual estimator from the independent-sample formulas. Examine overlap, filter correlation, and sample provenance; use the stipulated covariance example only as an illustration. Do not infer a gamma correction from count alone, and state limitations if dependence has not been characterized.

Review: Chapter 8 — Power averaging before the logarithm.

Copyright 2026, James M. Atkinson

V011-C08-DISCUSSION-008 — Identify what the internal path actually tests and what remains external or environment-dependent. Discuss cable, antenna, filter, gain state, blockers, and transient behavior. Use external references, attenuation challenges, and termination as complementary evidence rather than treating alignment as either worthless or conclusive.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

V011-C08-DISCUSSION-009 — Hold state fixed, verify equivalent bandwidth and processing, inspect noise color and receiver contribution, then challenge source/environment separately. Discuss how each observation narrows possible causes. The initial discrepancy tests a compound assumption and cannot alone choose between the proposed diagnoses.

Review: Chapter 8 — Choose bandwidth from the quantity being estimated.

V011-C08-DISCUSSION-010 — Identify the missed event class and conditions, retain unsuccessful tests, and restrict findings to demonstrated capability and actual coverage. Discuss a different architecture or timing strategy and its validation. Do not turn schedule pressure into an unsupported universal negative statement.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-DISCUSSION-011 — List the unresolved stages and the interpretations they would support. Preserve native outputs, settings, and version information; avoid assuming the RMS label determines the final mean-power statistic. Request or test the actual operation order, then apply only justified corrections and retain the original values.

Review: Chapter 8 — Measurement consequence.

Copyright 2026, James M. Atkinson

V011-C08-DISCUSSION-012 — Discuss the trade between scatter reduction and mixing different quantities. Use state-resolved means and durations where changes matter, and distinguish repeated independent estimates from correlated or duplicated data. Choose the averaging interval based on stationarity and the question being answered, not the largest available count.

Review: Chapter 8 — Ten worked applications.

V011-C08-DISCUSSION-013 — Preserve both configurations and explain their different frequency-time constructions. Establish that the simultaneous capture had suitable bandwidth and timing for the event. Treat the contradiction as evidence for the tested portrayal mechanism, while avoiding claims that every comb or every swept measurement is unreliable.

Review: Chapter 8 — Hypothetical Case Adjudication: Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-DISCUSSION-014 — Require original statistic, power plane, bandwidth, detector/averaging order, sample dependence assumptions, corrections and their order, and excluded intervals. Discuss a readable final result with accessible provenance. A simplified interface should not make double correction or unsupported reinterpretation impossible to detect.

Review: Chapter 8 — Measurement consequence.

V011-C08-DISCUSSION-015 — Read the visible settings as evidence, but identify missing equivalent bandwidth, processing sequence, timing, gain, native data, and correction history. Avoid automatic log correction or reconstruction of unobserved events. Distinguish a descriptive record of the image from a validated power or absence claim.

Review: Chapter 8 — Measurement consequence.

Copyright 2026, James M. Atkinson

V011-C08-DISCUSSION-016 — Examine filter settling, burst duration, frequency trajectory, signal energy excluded, and detector time response. Test the intended waveform in the actual configuration. The best choice follows demonstrated detection or measurement capability for the target class, not noise-floor appearance alone.

Review: Chapter 8 — Resolution Bandwidth and Selectivity.

V011-C08-DISCUSSION-017 — Define which features the reconstruction relies on, then inspect event-resolved amplitude, phase, modulation, startup, timing, and prior receiver state as appropriate. A nominal period match is insufficient. Record the acceptance criterion and describe any unresolved variation rather than demanding or assuming irrelevant universal identity.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

V011-C08-DISCUSSION-018 — Explain that the dB difference is a ratio, verify compatible mean estimators at the same plane and bandwidth, and subtract in linear units only under the stated model. Examine near-cancellation uncertainty and coherent/correlated exceptions. Preserve original readings and the revised derivation rather than silently replacing them.

Review: Chapter 8 — Ten worked applications.

V011-C08-DISCUSSION-019 — Discuss cancellation of common offsets within each compatible comparison and the remaining differences in estimator, bandwidth, gain, and correction. Agreement can support a conditional bandwidth trend while absolute calibration or statistics remain unresolved. Request the information needed to compare the mean-power quantities themselves.

Review: Chapter 8 — Ten worked applications.

Copyright 2026, James M. Atkinson

V011-C08-DISCUSSION-020 — Limit the scaling to validated regimes, include instrument/filter factors and acceptance criteria, and detect settings such as segmentation or gating outside that scope. Test representative signals and retain actual usable timing. The software should not manufacture an absolute timing law from a proportionality.

Review: Chapter 8 — Quantitative Model for Swept-Tuned Spectrum Analyzers, RBW, VBW, Detectors, and Sweep Validity.

V011-C08-DISCUSSION-021 — Retain both states and their expected corrected relationships. Examine compression, internal products, mixer level, and external source changes through controlled challenges. Accept only a configuration-bound interpretation supported by the evidence; disagreement is a diagnostic observation, not a reason to delete data.

Review: Chapter 8 — Amplitude Accuracy and Analyzer Self-Tests.

V011-C08-DISCUSSION-022 — Distinguish clock duration from valid observation, record the state transitions and excluded bands/times, and explain their effect on event coverage. Discuss whether additional observation is needed. Avoid representing the entire run as one uninterrupted uniform-capability exposure.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-DISCUSSION-023 — Explain that those formulas concern specific filter/noise estimators and do not supply a universal interception model. Require a defined event class, timing/coverage model, and validated acquisition behavior for any probabilistic claim. Offer bounded observed findings and unresolved classes rather than assigning an unsupported number.

Review: Chapter 8 — Validate transient and gated measurements with the intended waveform.

Copyright 2026, James M. Atkinson

V011-C08-DISCUSSION-024 — Compare the actual measurand, stationarity, required frequency range, validated sensitivity, timing, and evidence needs. A swept method may be adequate for a demonstrated stationary or repeatable class. Availability of another architecture does not itself invalidate it, but relevant failed challenges require a capable alternative.

Review: Chapter 8 — Sweep Method Acceptance.

V011-C08-DISCUSSION-025 — The reviewer should reconstruct mode and settings, source/reference class, calibration plane, processing and corrections, frequency-time coverage, failures, exclusions, and the scope of each finding. Discuss native data and timestamps as supporting evidence. Identify remaining assumptions explicitly so that independent review does not depend on undocumented operator memory.

Review: Chapter 8 — Sweep Method Acceptance.

Chapter Glossary

AVERAGE OF LOGARITHMIC POWERS: The arithmetic mean of calibrated power levels after each sample has been converted to logarithmic units. It estimates a different statistic from the logarithm of an arithmetic power mean. Under the chapter's single exponential noise-power model, its decibel expectation has a fixed offset that additional independent averaging does not remove.

CHANNEL-POWER INTEGRATION: An estimate formed by combining calibrated spectral contributions over a declared channel interval using the appropriate frequency weighting and detector convention. A single narrow marker is generally insufficient when a modulated signal spans several filters. The integration limits, normalization and calibration must distinguish wanted energy from neighboring admitted components.

DISPLAY BUCKET: The group of processed observations assigned to one displayed trace location before the selected detector reduces them to an ordinate. Bucket formation and detector operation are implementation details that affect the statistic. A display pixel count cannot be treated automatically as a count of independent calibrated power samples.

EFFECTIVE SAMPLE INDEPENDENCE: Degree to which samples supply distinct information after filtering, overlap and processing, rather than their nominal count.

Copyright 2026, James M. Atkinson

EQUIVALENT NOISE BANDWIDTH: The bandwidth of an ideal rectangular power weighting that admits the same integrated white-noise power as the actual filter under the stated gain normalization. It can differ from a nominal resolution-bandwidth label. Nonuniform spectra require the actual weighting or a justified approximation rather than automatic multiplication by this one number.

EVENT REPEATABILITY: Consistency of the particular waveform properties that a repeated-event measurement needs to combine. Similar nominal repetition periods alone do not establish stable amplitude, phase, modulation or startup behavior. A spectrum assembled from repeated bursts requires evidence for the relevant consistency; otherwise it remains an aggregate of different observations.

EXPONENTIAL POWER DISTRIBUTION: The positive power distribution generated by the squared magnitude of the chapter's zero-mean circular complex Gaussian sample at a calibrated plane. Its mean fixes its scale, and its variance is the square of that mean. A tone, clipping or a mixture of changing noise levels does not automatically have this distribution.

FILTER SETTLING: The development of a filter response toward the state required by the measurement criterion after tuning, switching or a change in input. A short commanded dwell may include an unusable settling portion. The necessary interval depends on filter shape, architecture and accepted error, so bandwidth alone does not supply a universal wait time.

Copyright 2026, James M. Atkinson

FINITE-RECORD LOGARITHMIC BIAS: The difference between the expected logarithm of a finite arithmetic power average and the logarithm of its underlying mean power. For the chapter's independent exponential samples this depends on sample count and approaches zero as that count increases. It differs from the fixed offset of averaging the individual logarithms.

FREQUENCY SPAN: The frequency interval covered by a stated analyzer acquisition or display. In a swept mode, covering that span takes time and does not establish simultaneous observation of all included frequencies. Span must be interpreted with the actual sweep trajectory, selected filters, segment boundaries and usable observation intervals.

FREQUENCY-TIME TRAJECTORY: The sequence of frequency regions observed as a swept or stepped instrument progresses through its acquisition.

GAMMA POWER-SUM MODEL: The probability model for the normalized sum of the chapter's independent, identically distributed exponential power samples. It supplies the logarithmic moment used to derive the finite-record correction. Repeated copies, overlapping observations or other dependence do not acquire this model merely because the file contains the same nominal number of samples.

GATED SWEEP: Measurement restricted to a selected time interval relative to a trigger.

Copyright 2026, James M. Atkinson

GATE WIDTH: The duration of the selected time interval admitted by a gated measurement. It determines which part of the event contributes, together with trigger delay, timing uncertainty and receiver response. A narrow gate does not by itself establish settled operation or capture of all the signal energy required by the intended measurand.

LINEARITY CHALLENGE: A controlled change of input attenuation or another justified operating condition whose predicted response is tested while reference-plane corrections are retained. Departure from the prediction can expose overload or internally generated structure. It does not alone identify the cause, so the comparison must preserve or explicitly model other changed states.

LINEAR-POWER SUBTRACTION: Removal of an identified additive power contribution after converting compatible estimates to linear power units at the same reference plane and bandwidth. It requires justified power additivity. Subtracting decibel levels gives a ratio, and near-cancellation of total and background can make the recovered difference highly sensitive to measurement errors.

LOGARITHM CONCAVITY: The mathematical property that makes the average of positive-power logarithms no greater than the logarithm of their arithmetic average. Equality holds when all included powers are equal. This establishes the direction of the difference for each record; it does not prescribe a universal numerical correction or prove a Gaussian noise model.

Copyright 2026, James M. Atkinson

LOGARITHM OF AVERAGED POWER: A level obtained by first averaging calibrated powers in linear units and then taking the logarithm of that average relative to the reference power. The linear average is unbiased under the stated stationary model, while its logarithmic conversion can retain a finite-record bias. The number and dependence of the contributing samples matter.

LOG-AVERAGE BIAS: Difference between the expectation of an averaged logarithmic noise statistic and the logarithm of mean power under a specified probability model.

MAX HOLD: Trace process retaining the highest detected value at each display point over repeated acquisitions.

NEGATIVE-PEAK DETECTOR: A detector that retains the lowest indication within its specified observation or display bucket. Its meaning depends on the quantity entering the detector and the instrument's bucket convention. It does not estimate the same statistic as a positive-peak, sample or power detector simply because all results share a decibel display axis.

NOISE-MARKER CORRECTION: A declared processing adjustment used by an instrument or analysis method to convert its measured noise statistic into a specified reported convention. Detector-statistic and noise-bandwidth adjustments have different causes. Establish which adjustments are already present before applying additional corrections, and do not infer the sequence from a marker name alone.

Copyright 2026, James M. Atkinson

NOISE POWER SPECTRAL DENSITY: Mean noise power per unit frequency at a declared reference plane, with the side convention and units stated. A flat density gives integrated mean power proportional to equivalent noise bandwidth. A logarithmic noise display also depends on detector and averaging conventions, so its ordinate is not automatically the density times a front-panel bandwidth label.

PAIRWISE POWER CORRELATION: A stated covariance relationship between two power samples after normalization by their standard deviations. In the chapter's equal-variance illustration, positive common correlation slows the reduction in the arithmetic mean's variance. A nominal sample count therefore cannot replace evidence about filtering, overlap or duplication when estimating repeatability.

POSITIVE-PEAK DETECTOR: A detector that retains the largest indication within its specified observation or display bucket. It can aid discovery of brief activity, but its population and timing differ from an average-power estimate. Changing to this detector changes the measurement statistic and must be disclosed when traces are compared.

POWER-AVERAGE ESTIMATOR: Arithmetic mean of calibrated instantaneous powers; subsequent logarithmic conversion has distinct finite-record statistical properties.

POWER-ESTIMATION PLANE: The declared point in a calibrated measurement model at which samples represent a specified power quantity. Resistance, gain calibration, admitted bandwidth and processing connect that quantity to the original signal path. Raw converter counts are not power samples until that relationship is established; comparisons must use compatible planes.

Copyright 2026, James M. Atkinson

RESOLUTION BANDWIDTH: Analyzer filter bandwidth determining frequency discrimination and admitted noise.

RMS DETECTOR: A detector whose intended power-related statistic derives from mean square signal magnitude before square-root or level reporting. Its actual bucket operation, weighting, normalization and subsequent video or trace processing must be established from the instrument implementation. The name alone does not determine every operation that produced the displayed number.

SAMPLE DETECTOR: A detector that selects a sample according to a defined rule for each display bucket instead of retaining the bucket's extremum or a power average. Its sampling rule and relation to the input processing must be documented. A short event between selected samples may not appear in the resulting trace.

SAMPLE INDEPENDENCE: The joint statistical condition in which the samples' probability law factors into their individual laws. It is an additional premise for the chapter's gamma sum and simple variance reductions. Distinct timestamps or storage positions do not establish independence when filters, overlapping records or repeated data create shared information.

SEGMENTED SWEEP: A sweep assembled from separately specified frequency or acquisition segments. Each segment's limits, settings and time position belong in the record so the combined trace can be reconstructed. Segmenting can change which events are observed and when; it does not make the full assembled frequency range simultaneous.

Copyright 2026, James M. Atkinson

STATE MIXTURE: An observation population containing contributions from distinct receiver or source states with different stated distributions or mean powers. Averaging their logarithmic levels and then applying a single-state correction generally does not recover the overall arithmetic mean power. Preserve state-resolved measurements and their weights when those differences matter.

STATIONARITY: The assumed stability of the statistical properties needed by a specified estimator over its included observations. The chapter's noise-power calculations hold one distribution and mean fixed unless a case explicitly varies them. A stable-looking averaged trace does not prove this premise, because averaging can conceal changes in the underlying state.

STEPPED SWEEP: An acquisition that visits selected frequency settings through successive tuning and dwell intervals. The usable part of each dwell excludes whatever settling or invalid state the validated method requires. Commanded dwell duration is therefore not automatically valid observation time, and the resulting trace still combines observations made at different times.

SWEEP TIME: Time required for the analyzer to traverse the selected frequency span or measurement points.

TRANSIENT VALIDATION: A controlled check that the selected receiver method represents the event duration, modulation, timing and prior state required by the intended measurement.

Copyright 2026, James M. Atkinson

TRIGGER DELAY: The specified interval between the trigger reference and the acquisition or gate position used for the measurement. Its sign and time reference must follow the instrument convention. Delay, jitter and the event's own repeatability determine which portion of a burst is observed; matching a trigger edge does not align every internal waveform feature.

USABLE OBSERVATION WINDOW: The portion of an acquisition during which its channel response, detector and receiver state meet the declared measurement requirements. Tuning and recovery intervals may need exclusion. In a sweep, the windows at different frequencies occur at different times, which limits what can be concluded about a changing or intermittent event.

VIDEO BANDWIDTH: Post-detection filtering bandwidth controlling trace smoothing and response time.

Chapter 9. FFT Analyzers, Windowing, Averaging, and Spectral Estimation

Cross-volume technical interface. S001-V008(RF Theory Propagation and Spectrum Behaviour) treats time-varying channels and their physical coherence assumptions, whileS001-V022(Computational Electromagnetics Modelling Simulation and Diagnostic Mathematics) supplies a wider modelling context.S001-V024(Series Conventions Standards Units and Citation Practice) governs the terminology and units shared across the series. The present derivation must nevertheless state the sampled-data convention, window sum, coherent gain, equivalent noise bandwidth, sidedness, spectral units, estimator averaging rule and covariance assumptions here. FFT zero-padding changes frequency-grid display density, not the physical information or equivalent noise bandwidth in the original record.

Copyright 2026, James M. Atkinson

9.1 Discrete Records and Spectral Estimates

An FFT analyzer begins with a finite sampled record. The transform returns coefficients associated with discrete frequency bins, but the underlying signal is not necessarily periodic within that record or centered on a bin. Record length determines nominal bin spacing, while sample rate determines the represented Nyquist interval. The displayed spectrum is an estimate conditioned by acquisition length, window, overlap, averaging, scaling, and any preprocessing.[1]

A single transform does not distinguish a stable tone from a short transient, a drifting carrier, or a windowed fragment. Time-domain inspection and repeated records are essential. The practitioner preserves the original samples, trigger, time stamps, overflow flags, and acquisition parameters rather than only exporting an image of the spectrum. This permits later checks of clipping, nonstationarity, and processing choices.

Harris's 1978 review organized window selection around finite observations: a weak tone near a strong one, nearby tones of comparable strength, moving tones, and biased parameter estimates. That historical framing remains useful because the measurement question determines the acceptable tradeoff. Model 9W makes the finite record, weight sums, and amplitude or noise normalization explicit. Its calculations let the reader test a proposed window against the quantity being estimated. Model 9C adds a

These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

Copyright 2026, James M. Atkinson

separate paired-record question: how much of one measured series is represented by the declared reference series under the stated estimator. Neither a window choice nor a high coherence value supplies a physical source attribution. Those conclusions require the acquisition controls and competing-path checks developed through this chapter.[2]

2 Joint Committee for Guides in Metrology, International vocabulary of metrology: Basic and general concepts and associated terms, VIM3 online edition, entries 2.48, 2.49 and 2.53, https://jcgm.bipm.org/vim/en/2.48.html, https://jcgm.bipm.org/vim/en/2.49.html and https://jcgm.bipm.org/vim/en/2.53.html, read November 2, 2026. These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

9.2 Spectral Leakage and Window Selection

A finite record implicitly multiplies the signal by a time window. A rectangular window offers narrow main-lobe width for bin-centered coherent tones but high sidelobes for off-bin components. Tapered windows reduce sidelobes at the cost of wider main lobes and different amplitude and noise corrections. No window is universally best; selection follows the need to resolve close tones, measure amplitude, estimate noise, or observe transients.

Window coherent gain, equivalent noise bandwidth, scalloping loss, and sidelobe behavior should be included when quantitative results are reported. Software may normalize some effects automatically, but the normalization convention must be known. Applying two different windows to the same samples is a useful interpretive challenge because a genuine component and leakage from a stronger component change differently.

9.3 Windowed DFT normalization: line amplitude, noise density, and finite-record energy

Copyright 2026, James M. Atkinson

9.3.1 Define the record before interpreting the display

A spectrum requires a normalization as well as a frequency axis. Let x_n be N samples of voltage, measured in volts, at sampling frequency f_s in hertz, and let w_n be a specified dimensionless real window for $n=0,\ldots,N-1$. The data can be real or complex, but that choice changes how a one-sided display is constructed. Here no mean subtraction or other detrending is applied. If preprocessing is used, x_n denotes its output and the reported result must identify that preprocessing. Define

Copyright 2026, James M. Atkinson

Hann reduces far sidelobes but broadens the main lobe.
Equivalent noise bandwidth: 1.0 bin (rectangular), ~1.5 bins (Hann).

Figure 50. Rectangular and Hann spectral windows.

Equation 9W1.

$$X_w[k] = \sum_{n=0}^{N-1} w_n x_n \exp\left(-j\frac{2\pi k n}{N}\right)$$

Copyright 2026, James M. Atkinson

$$S_1 = \sum_{n=0}^{N-1} w_n, S_2 = \sum_{n=0}^{N-1} w_n^2, CG = \frac{S_1}{N}$$

The transform X_w has units of volts because the sum is dimensionless apart from x_n. Require $S_2 > 0$; require $S_1 \neq 0$ whenever coherent-gain normalization is used. For the coherent complex tone $x_n = a \exp\backslash(j 2\pi k_0 \frac{n}{N} \backslash)$, substitution gives $X_w[k_0] = a S_1$. Thus $\frac{X_w[k_0]}{S_1}$ recovers the complex amplitude a under these assumptions. Harris distinguishes the coherent sum of the weights from their squared sum when discussing coherent signal gain and noise gain.[3] These are different operations, even though a rectangular window makes their associated bandwidths particularly simple.

For a real sinusoid $A \cos\backslash(2\pi k_0 \frac{n}{N} + \varphi \backslash)$, the negative-frequency image must also be retained in the derivation. Write $W[r] = \sum_n w_n \exp\backslash(- j 2\pi \frac{r n}{N} \backslash)$. At the positive-frequency bin,

$$X_w[k_0] = \frac{A}{2}\left(e^{j\varphi} S_1 + e^{-j\varphi} W[2k_0]\right).$$

Consequently, $\frac{2 \mid X_w[k_0] \mid}{\mid S_1 \mid}$ equals A only when the image term vanishes, or is negligible to a justified accuracy. A coherent frequency alone is insufficient for an arbitrary window and bin. DC and the Nyquist bin are special cases, not ordinary positive-frequency sinusoids. Off-grid tones

introduce a further window-response error. The examples below separate these conditions instead of treating coherent gain as a universal amplitude correction.

9.3.2 Noise density uses a different denominator

Suppose initially that the samples have zero mean and covariance $\mathrm{E}[x_n x_m^*]=\sigma^2\delta_{nm}$, where σ^2 has units V². Expanding the squared transform gives $\mathrm{E}\,|\,X_w[k]\,|^2=\sigma^2\sum_n w_n^2=\sigma^2 S_2$: the cross terms vanish by the covariance assumption. Gaussianity is unnecessary for this expectation. Define the two-sided density estimate D_2 and the tone-normalized squared spectrum Q_2 by

Equation 9W2.

$$D_2[k]=\frac{|X_w[k]|^2}{f_s S_2},\ Q_2[k]=\frac{|X_w[k]|^2}{|S_1|^2}$$

$$B_e=\frac{f_s S_2}{|S_1|^2},\ Q_2[k]=B_e D_2[k]$$

D_2 has units V²/Hz, Q_2 has units V², and the equivalent noise bandwidth B_e has units Hz. Under the white covariance assumption, $\mathrm{E}\,D_2=\frac{\sigma^2}{f_s}$. The last identity in 9W2, however, is an algebraic equality for every record with the stated nonzero denominators; it does not require whiteness. A line-calibrated spectrum and a density estimate can therefore be consistent while showing different numerical ordinates. The report by Heinzel, Rüdiger and Schilling derives the two weight sums and the resulting conversion between squared spectrum and density.[4]

Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. These sources distinguish receiver noise from source and path contributions; the scalar assumptions and synthetic cases are stated in Model 2B.

Copyright 2026, James M. Atkinson

For real data, combine the equal contributions at positive and negative frequencies. Double interior positive-frequency values of D_2 and Q_2, but do not double DC or, when N is even, the Nyquist value. For odd N there is no Nyquist sample and the highest retained positive bin is doubled. Complex records do not generally have this conjugate symmetry and normally retain a two-sided density. The Heinzel report explicitly sets aside the DC and Nyquist corrections in its presentation; the endpoint convention used here instead preserves the exact finite-record sum. This distinction must survive implementation. The current SciPy periodogram documentation supplies the same spectrum-to-density ratio and describes one-sided folding, but its default detrending removes a constant: reproducing the present model requires that option to be disabled.[5] Agreement with a software convention does not establish that a receiver uses it.

9.3.3 Energy closure and its limits

Discrete Fourier orthogonality gives $\sum_k | X_w[k] |^2 = N \sum_n w_n^2 | x_n |^2$ for this unnormalized transform. Multiplying D_2 by the frequency spacing $\frac{f_s}{N}$ therefore yields

Equation 9W3.

$$\sum_{k=0}^{N-1} D_2[k] \frac{f_s}{N} = \frac{\sum_{n=0}^{N-1} w_n^2 |x_n|^2}{S_2}$$

The correctly folded one-sided sum has the same value for real records. The right side is a window-weighted mean square. It is not necessarily the unweighted sample mean square $\frac{\sum_n | x_n |^2}{N}$. For stationary white samples their expectations agree, but an individual transient can be suppressed or emphasized by its position within the window. This is a material limitation when a sweep is intended to detect an intermittent signal. Energy closure checks arithmetic and normalization; it does not validate stationarity, sampling adequacy, sensor calibration, source attribution, or the absence of overload.

For the periodic Hann window $w_n = \frac{1 - \cos \backslash(\frac{2\pi n}{N} \backslash)}{2}$ and $N > 2$, finite trigonometric sums give $S_1 = \frac{N}{2}$ and $S_2 = \frac{3N}{8}$. Hence $\mathrm{CG} = \frac{1}{2}$ and $B_e = \frac{3 f_s}{2N}$, equal to 1.5 unpadded bin intervals. The endpoint-symmetric Hann window instead uses $N-1$ in the cosine denominator. For $N > 3$ it has $S_1 = \frac{N-1}{2}$,

Copyright 2026, James M. Atkinson

$S_2 = \frac{3(N-1)}{8}$, and $B_e = \frac{3 f_s}{2(N-1)}$. These statements are derived from the actual coefficient vectors, not adopted from a window table. The official Hann documentation distinguishes the symmetric filter-design form from the periodic spectral-analysis form.[6] Their difference is appreciable for short records.

Multiplying all weights by one nonzero real constant changes X_w, S_1 and S_2 together and leaves Q_2, D_2 and B_e unchanged. It does not excuse mixing sums calculated from different vectors. Cauchy–Schwarz gives $|S_1|^2 \le N S_2$ and therefore $B_e \ge \frac{f_s}{N}$ whenever S_1 is nonzero. A zero-sum window still permits density normalization if $S_2 > 0$, but neither Q_2 nor B_e as defined here exists. That domain restriction matters more than assigning an arbitrarily large display correction.

Zero-padding evaluates the same finite-record transform at additional frequencies. If the windowed record is padded to $M \ge N$ samples, use spacing $\frac{f_s}{M}$ on the left of 9W3 while retaining the original S_1 and S_2 in 9W2. No new observations have been acquired and B_e has not narrowed. Rust and Donnelly discuss zero-padding in the context of finite-record spectral estimates; their original paper also emphasizes that infinitely many

9.3.4 Ten worked applications of the normalization model

Copyright 2026, James M. Atkinson

9.3.4.1 Application 1: A coherent tone with a stated image condition

Take $N = 1024$, $f_s = 48{,}000\ \text{Hz}$ and the periodic Hann window. For a real 0.100 V peak sinusoid at $k_0 = 64$, $W[128] = 0$. The sums are $S_1 = 512$ and $S_2 = 384$. Thus $|X_w[64]| = \frac{0.100 \times 512}{2}\ \text{V} = 25.6\ \text{V}$, and the recovered peak is $\frac{2 \times 25.6}{512}\ \text{V} = 0.100\ \text{V}$. The one-sided Q value is $\frac{2\backslash(25.6\backslash)^2}{512^2}\ \text{V}^2 = 0.005\ \text{V}^2$. Across a stipulated purely resistive 50 Ω load this is 0.000100 W, or −10.000 dBm. This is a hypothetical voltage-to-power conversion, not an instrument calibration or antenna-power claim.

Copyright 2026, James M. Atkinson

9.3.4.2 Application 2: White-noise density and noise bandwidth

Keep the same record and window, but stipulate white real noise with variance $\sigma^2 = 10^{-6}\ \mathrm{V}^2$. The interior one-sided density expectation is $\frac{2\sigma^2}{f_s} \approx 4.166666667 \times 10^{-11}\ \mathrm{V}^2/\mathrm{Hz}$. Its square root is 6.454972244 μV/√Hz. Here $B_e = 70.3125\ \mathrm{Hz}$, so the expected interior Q value is $B_e \mathrm{E}[D_1] = 2.9296875 \times 10^{-9}\ \mathrm{V}^2$, corresponding to 54.12658774 μV rms. Dividing this expected mean square by 50 Ω and converting to dBm gives −72.32148706 dBm. This is the logarithm of expected power; it is not the expectation of a logarithmic display, whose averaging bias is treated in Chapter 8.

Copyright 2026, James M. Atkinson

9.3.4.3 Application 3: Do not sum line-calibrated ordinates as independent powers

In Application 1, the positive-frequency central Q value is 0.005 V^2 and each adjacent Hann bin has 0.00125 V^2. Their sum is 0.0075 V^2, apparently 50 percent above the sinusoid's mean square. This is not additional physical power. Q is calibrated for a coherent line at a selected frequency. To integrate the spectrum, convert to density and multiply by the 46.875 Hz spacing: $\frac{0.0075 \times 46.875}{70.3125}\ \mathrm{V}^2 = 0.005\ \mathrm{V}^2$. The finite Hann side bins are part of the same window response, not three independently generated signals.

Copyright 2026, James M. Atkinson

9.3.4.4 Application 4: Padding does not replace N in the bandwidth

Pad the 1024-sample record to $M = 8192$. The displayed spacing becomes $\frac{48,000\ \text{Hz}}{8192} = 5.859375\ \text{Hz}$, while B_e remains 70.3125 Hz, now twelve displayed intervals. Incorrectly using $\frac{1.5 f_s}{M}$ would give 8.7890625 Hz. Dividing the unchanged Q ordinate by that erroneous bandwidth would overstate its density by a factor of eight, or $10 \log_{10} \backslash(8 \backslash)\ \text{dB} \approx 9.03089987\ \text{dB}$. At every eighth padded bin the transform equals its original unpadded value; the correctly weighted density integral is unchanged.

Copyright 2026, James M. Atkinson

9.3.4.5 Application 5: Short symmetric and periodic windows differ

Set $N=16$ and $f_s=1600\ \text{Hz}$. The symmetric Hann vector gives $S_1=7.5$, $S_2=5.625$ and $B_e=160\ \text{Hz}$; the periodic vector gives $S_1=8$, $S_2=6$ and $B_e=150\ \text{Hz}$. For a coherent complex tone processed with the symmetric vector, erroneously dividing its transform by 8 produces $\frac{7.5}{8}=0.9375$ times the true amplitude, an error of −0.56057447 dB. Converting the symmetric Q value to density with 150 rather than 160 Hz overstates density by 0.28028724 dB. A real-tone measurement additionally needs the image-term condition; it is not silently substituted for this complex-tone calculation.

Copyright 2026, James M. Atkinson

9.3.4.6 Application 6: Coherent gain does not remove scalloping

For a complex tone halfway between bins of an $N = 1024$ record, compare the nearest-bin magnitude with $|aS_1|$. The rectangular-window ratio is $\frac{1}{N \sin[\frac{\pi}{\backslash(2N\backslash)}]} \approx 0.6366200220$, or −3.92239413 dB. Evaluating the periodic Hann coefficient sum gives 0.8488263632, or −1.42362281 dB. The latter reduces this particular error but does not make it zero. Padding to $2N$ places a sample at this stipulated half-bin tone frequency and can recover the response peak for the isolated complex tone. It does not narrow the underlying window response or establish separation from another nearby component.

Copyright 2026, James M. Atkinson

9.3.4.7 Application 7: DC and Nyquist are not doubled

Use $N = 16$, a rectangular window and the constant record $x_n = 0.002\ \mathrm{V}$. Then $X[0] = 0.032\ \mathrm{V}$ and $Q[0] = \backslash(\frac{0.032}{16}\backslash)^2\ \mathrm{V}^2 = 4 \times 10^{-6}\ \mathrm{V}^2$. The alternating record $x_n = 0.002(-1)^n\ \mathrm{V}$ gives the same mean square entirely at the Nyquist bin. Both bins retain their two-sided values in the one-sided sum. Doubling either would introduce a factor-of-two error, 3.01029996 dB. Removing the mean first would eliminate the DC example: that changes the processed measurand rather than correcting its normalization.

Copyright 2026, James M. Atkinson

9.3.4.8 Application 8: Window position changes transient energy

For $N=16$ with periodic Hann weights, $S_2=6$. A single 1 V sample among fifteen zero samples has unweighted mean square $\frac{1}{16}\ \mathrm{V}^2=0.0625\ \mathrm{V}^2$ regardless of location. At $n=0$, the Hann weight is zero, so its windowed density integrates to zero. At $n=8$, the weight is one, so the integral is $\frac{1}{6}\ \mathrm{V}^2\approx 0.16666667\ \mathrm{V}^2$. Both outcomes satisfy 9W3. Neither is a contradiction of Parseval's identity. A single window can therefore miss an edge impulse completely; an acquisition strategy must address temporal coverage separately from spectral normalization.

Copyright 2026, James M. Atkinson

9.3.4.9 Application 9: Colored covariance changes an ordinate, not energy closure

Take $N=8$, $f_s=800\ \mathrm{Hz}$ and rectangular weights. Specify stationary covariance $R_{nm}=\left(\frac{3}{5}\right)^{|n-m|}\ \mathrm{V}^2$, realizable by a stationary first-order process with coefficient $\frac{3}{5}$ and innovation variance $\frac{16}{25}\ \mathrm{V}^2$. At DC,

$\mathrm{E}\,|\,X[0]\,|^2=[8+2\sum_{h=1}^{7}\backslash(8-h\backslash)\left(\frac{3}{5}\right)^h]\ \mathrm{V}^2=\frac{1923904}{78125}\ \mathrm{V}^2$. Hence

$\mathrm{E}\,D_2[0]=0.003847808\ \mathrm{V}^2/\mathrm{Hz}$. The white assumption with the same variance would give $\frac{1}{800}\ \mathrm{V}^2/\mathrm{Hz}=0.00125\ \mathrm{V}^2/\mathrm{Hz}$, lower by a factor of 3.0782464. Summing the expected density across all eight bins with 100 Hz spacing still gives 1 V^2. A correct integrated level alone cannot establish a white spectrum.

Copyright 2026, James M. Atkinson

9.3.4.10 Application 10: A valid density can coexist with undefined coherent normalization

Choose four weights (1,−1,1,−1) at $f_s = 400\ \mathrm{Hz}$. They have $S_1 = 0$ and $S_2 = 4$. For unit-variance white samples, $\mathrm{E}\,|\,X_w[k]\,|^2 = 4\ \mathrm{V}^2$ and $\mathrm{E}\,D_2[k] = \frac{4}{400 \times 4}\ \mathrm{V}^2/\mathrm{Hz} = 0.0025\ \mathrm{V}^2/\mathrm{Hz}$. Density normalization remains well-defined, while Q_2 and B_e in 9W2 involve division by zero. A constant complex tone at its coherent bin has zero response. It is therefore invalid to interpret this operation as an ordinary line-amplitude window using a numerical coherent-gain correction.

Copyright 2026, James M. Atkinson

9.3.5 Measurement consequence

A reproducible spectral result states the coefficient vector or its unambiguous generation convention, sample count, sample rate, transform length, preprocessing, side convention, ordinate units and power-conversion impedance. The worked examples use stipulated sequences and covariance models. They do not identify the origin of a field signal, validate a specific analyzer, or supply uncertainty bounds for an acquisition chain. Chapter 8's averaging treatment remains necessary when repeated noisy records are combined, and the existing coherence discussion addresses a different cross-channel question. Window normalization supplies neither of those conclusions by itself.

For a transient, the window-weighted spectrum describes the samples admitted to that estimator. It does not establish that the acquisition offered a usable observation of the event. Model 15A treats that separate opportunity through validated record windows and the required contiguous overlap. Model 10E determines which processed samples retain valid source dependencies across recording boundaries; Model 5A identifies a control-recovery exclusion when its local response assumptions apply. Establish those continuity and receiver-state conditions before interpreting a transient spectrum, and retain the actual spectral weighting rather than replacing it with the timing-window geometry.

Copyright 2026, James M. Atkinson

The original samples, analysis parameters, and channel calibration remain linked to every derived spectrum.

Figure 52. FFT spectral estimation and multichannel checks.

Copyright 2026, James M. Atkinson

9.4 Averaging and Statistical Stability

Linear power averaging reduces random variation for a stationary process, while vector averaging preserves coherent phase and can suppress uncorrelated components. Exponential averaging weights recent records more heavily. Peak hold and percentile displays answer different questions. The number of averages alone does not state effective independence when records overlap or the process is correlated.

Averaging can conceal intermittency and state changes. A weak burst repeated once in a hundred records may disappear in a simple average yet dominate a high percentile or max-hold result. Conversely, a coherent internal spur can become increasingly prominent under vector averaging. The analysis plan uses multiple summaries and retains the distribution of per-record measurements when probability of occurrence matters.

Copyright 2026, James M. Atkinson

9.5 Cross-Spectra, Coherence, and Multichannel Analysis

Cross-spectral methods compare two synchronized channels. A component common to both can be enhanced while independent receiver noise is reduced. Magnitude-squared coherence quantifies the fraction of output spectral power linearly related to an input under the measurement conditions. High coherence supports a relationship but does not prove causality, direction, or a unique physical path.

Phase and delay estimates require calibrated channel skew, common clock behavior, sample alignment, and stable geometry. Leakage, common power, shared references, and direct cable coupling can create coherence without an environmental field. Channel swapping, independent terminations, physical separation, and known injected references challenge those alternatives. Multichannel conclusions are reported with the synchronization and calibration residuals.

Copyright 2026, James M. Atkinson

Figure 53. Coherence and the limits of source attribution.

Copyright 2026, James M. Atkinson

9.5.1 Define the ensemble before normalizing

Equation 18 concerns a relationship between channels, whereas the preceding window-normalization model concerns the scaling of one channel. At a fixed frequency bin, let X_r and Y_r be corresponding complex windowed Fourier coefficients from paired records $r=1,\ldots,K$. The samples must represent the same acquisition times after declared alignment and preprocessing. Suppose x is voltage in volts and y is current in amperes. Define nonnegative weights a_r summing to one and a common positive density normalization $d=\frac{1}{f_s S_2}$, where f_s is sample rate in hertz and S_2 is the window squared sum from 9W2. For an interior positive-frequency bin of real records, use $d=\frac{2}{f_s S_2}$ consistently in all three spectra. All numerical applications below are hypothetical. Define the paired spectral estimates by

$$P_{xx}=d\sum_{r=1}^{K} a_r \left|X_r\right|^2$$

$$P_{yy}=d\sum_{r=1}^{K} a_r \left|Y_r\right|^2$$

$$P_{xy}=d\sum_{r=1}^{K} a_r X_r^{*} Y_r$$

$$C=\frac{\left|P_{xy}\right|^2}{P_{xx}P_{yy}} \quad (9C1)$$

The autospectra have units V^2/Hz and A^2/Hz, and the cross-spectrum has units V A/Hz. C is dimensionless. If both channels measure voltage, replace amperes with volts throughout. Require positive P_{xx} and P_{yy}; a zero denominator makes C undefined, not zero. The asterisk means complex conjugation. Our P_{xy} convention conjugates X, matching SciPy's

Copyright 2026, James M. Atkinson

documented cross-spectral estimator. Nelson, Hati and Howe instead describe $X Y^*$. Conjugating the whole cross-spectrum reverses its phase but leaves C unchanged. A delay claim must state which convention was used.[8]

Apply Cauchy–Schwarz to vectors $\sqrt{a_r} X_r$ and $\sqrt{a_r} Y_r$. Their squared inner-product magnitude cannot exceed the product of their squared lengths; multiplication by d^2 gives $|P_{xy}|^2 \le P_{xx} P_{yy}$. Hence $0 \le C \le 1$ for these paired, consistently weighted estimates. Equality holds when $Y_r = H X_r$ for one complex scalar H on every positive-weight record, provided neither vector vanishes. Independence between records is not needed for this algebraic bound. Independence, stationarity, overlap and record selection do matter for statistical uncertainty. A large record count is not a substitute for establishing effective independent information.

The order of operations is essential. Average complex products first, then square their magnitude. Do not average the per-record normalized magnitudes: each nonzero single-record ratio is identically one. Nor may one estimate the three spectra from different retained records and assume that the bound survives. The displayed coherence is an estimator conditioned by these processing choices; it is not an intrinsic probability that a transmitter caused a receiver output.

---

8 Keysight Technologies, Keysight X-Series Signal Analyzers: N9069C Noise Figure Measurement Guide, part N9069-90001, edition 1 (March 2016), 10–11, 73–81, especially “Using Loss Compensation” and “Setting Temperature of Loss,” https://www.keysight.com/us/en/assets/9018-04256/user-manuals/9018-04256.pdf. This identified edition supports the stated measurement controls, not a claim about every current analyzer.

Copyright 2026, James M. Atkinson

This bound applies to a common nonnegative weighted mean, not automatically to separately chosen robust summaries. For example, take three paired voltage coefficients $X = \(1, 10, 0\)\ \mathrm{V}$ and $Y = \(10, 1, 0\)\ \mathrm{V}$ with $d = 1\ \mathrm{Hz}^{-1}$. The three X autospectral products are \(1, 100, 0\), the Y products are \(100, 1, 0\), and the cross-products are \(10, 10, 0\), all in V^2/Hz. Separate medians give autospectra 1 and 1 but cross-spectrum 10, so their substituted ratio is 100. Common mean estimates instead give autospectra $\frac{101}{3}$ and cross-spectrum $\frac{20}{3}$, hence $C = \frac{400}{10201} \approx 0.03921184$. A common positive bias correction cancels from either ratio. The failure is loss of a single paired Gram-matrix construction, not negative input weights or floating-point error. SciPy documents a median option for csd; selecting that option separately for the three spectra does not inherit the weighted-mean proof. This qualification does not claim that the coherence routine itself uses that median construction.

Copyright 2026, James M. Atkinson

9.5.2 The projection interpretation and its boundary

For a trial complex gain H, form the weighted residual density $J(H) = d\sum_{r=1}^{K} a_r \left|Y_r - H X_r\right|^2$. Expanding and completing the square gives

$$\hat{H} = \frac{P_{xy}}{P_{xx}}$$

$$J(H) = P_{yy} - \frac{\left|P_{xy}\right|^2}{P_{xx}} + P_{xx} \mid H - \hat{H} \mid^2 (9C2)$$

Thus $J_{\min} = P_{yy}(1 - C)$. $\hat{H}$ has units A/V for the example channels. This proves precisely the fraction interpretation: C is the fraction of the output spectral sum of squares explained by the best single complex gain at that bin under the stated weights. For ensemble spectra of a stationary linear system it has a corresponding second-order interpretation. For finite records it is a fitted relationship, and a perfect fit can occur for trivial reasons. It does not prove a causal direction, a unique physical path, statistical independence of the residual, or a valid extrapolation to other states.

If $Y = H X + N$ and the input and output disturbance have zero cross-spectrum, ensemble spectra give $P_{xy} = H P_{xx}$ and $P_{yy} = \left|H\right|^2 P_{xx} + P_{nn}$. Therefore $C = \frac{\left|H\right|^2 P_{xx}}{\left|H\right|^2 P_{xx} + P_{nn}}$. The associated output signal-to-noise ratio is $\frac{C}{1-C}$ only under this model. Noise in the measured input violates its premise. In particular, $X = S + U$ and $Y = H S + N$ with mutually uncorrelated components gives $C = \frac{\left|H\right|^2 P_{ss}^2}{(P_{ss} + P_{uu})(\left|H\right|^2 P_{ss} + P_{nn})}$. Several different noise allocations can produce the same C. No universal input-noise correction follows from coherence alone.

Copyright 2026, James M. Atkinson

Cross-channel cancellation is another limitation. If independent components S and D enter $X = S + D$ and $Y = S - D$, then $P_{xy} = P_{ss} - P_{dd}$ while both autospectra equal $P_{ss} + P_{dd}$. Equal component spectra give $C = 0$ although both physical components occur in both channels. This is the mechanism discussed by Nelson, Hati and Howe in their original cross-spectrum analysis. The manuscript example below is independently stipulated arithmetic, not a replication of their measurements.[9]

9 James P. Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. Its historical radiometer thresholds are not adopted as acceptance limits for the present constructed receiver.

Copyright 2026, James M. Atkinson

9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization

Copyright 2026, James M. Atkinson

9.5.3.1 Application 1 One record cannot establish a relationship

At a selected bin let $X = \backslash(1 + j\backslash)\ \mathrm{V}$ and $Y = \backslash(2 - j\backslash)\ \mathrm{V}$, with any common $d > 0$. Then $|X|^2 = 2\ \mathrm{V}^2$, $|Y|^2 = 5\ \mathrm{V}^2$, and $X^* Y = \backslash(1 - 3j\backslash)\ \mathrm{V}^2$. Consequently $C = \frac{d^2 \backslash(1^2 + 3^2 \backslash)}{2d \times 5d} = 1$. The fitted gain is $\frac{1 - 3j}{2}$. Any nonzero pair permits such a fit. Reporting unity from this single pair supplies no evidence of repeatable coupling.

Copyright 2026, James M. Atkinson

9.5.3.2 Application 2 Average complex products before taking the magnitude

Use two equal-weight pairs $X = \backslash(1,1\backslash)\ \mathrm{V}$ and $Y = \backslash(1,-1\backslash)\ \mathrm{V}$. Set $d = 1\ \mathrm{Hz}^{-1}$ for these normalized coefficients. The autospectra are both 1 V^2/Hz; $P_{xy} = \frac{1-1}{2}\ \mathrm{V}^2/\mathrm{Hz} = 0\ \mathrm{V}^2/\mathrm{Hz}$ and $C = 0$. Each individual normalized ratio is one, whose average would also be one. The discrepancy is entirely the order of operations, not a numerical rounding issue.

Copyright 2026, James M. Atkinson

9.5.3.3 Application 3 Conjugation changes a delay sign

At $f = 1000\ \mathrm{Hz}$, stipulate $Y = \exp\backslash(-j2\pi f\tau\backslash)X$ with $\tau = 125\ \mu\mathrm{s}$ and repeatable nonzero input. Then $H = \exp\backslash(\frac{-j\pi}{4}\backslash)$, $\frac{P_{xy}}{P_{xx}} = H$ and $C = 1$. Under $X^* Y$ the phase is −45 degrees, yielding $\tau = -\frac{\arg\backslash(H\backslash)}{2\pi f} = 125\ \mu\mathrm{s}$ on the chosen phase branch. Under $X Y^*$ it is +45 degrees. A single-bin phase also allows integer-cycle delay ambiguities; the calculation alone does not determine an absolute propagation delay.

9.5.3.4 Application 4 Fixed channel gains cancel from coherence

Take two voltage-channel spectra $P_{xx}=2\ \mathrm{V}^2/\mathrm{Hz}$, $P_{yy}=8\ \mathrm{V}^2/\mathrm{Hz}$ and $P_{xy}=2\ \mathrm{V}^2/\mathrm{Hz}$, so $C=\frac{4}{16}=0.25$. Rescale X by 3 and Y by $2j$. The new autospectra are 18 and 32 V^2/Hz and the new cross-spectrum is $12j\ \mathrm{V}^2/\mathrm{Hz}$. Thus $C=\frac{144}{18\times 32}=0.25$. The fitted gain and phase have changed. Coherence invariance does not make amplitude or phase calibration unnecessary, and a zero channel gain would destroy the denominator.

Copyright 2026, James M. Atkinson

9.5.3.5 Application 5 Calculate the least-squares residual

Let $P_{xx} = 4\ \mathrm{V}^2/\mathrm{Hz}$, $P_{yy} = 5\ \mathrm{A}^2/\mathrm{Hz}$ and $P_{xy} = \backslash(3 + j\backslash)\ \mathrm{V}\ \mathrm{A}/\mathrm{Hz}$. Then $C = \frac{10}{20} = 0.5$, $\widehat{H} = \backslash(0.75 + 0.25j\backslash)\ \mathrm{A}/\mathrm{V}$, and $J_{\min} = \backslash(5 - \frac{10}{4}\backslash)\ \mathrm{A}^2/\mathrm{Hz} = 2.5\ \mathrm{A}^2/\mathrm{Hz}$. Using the trial gain $H = 1\ \mathrm{A}/\mathrm{V}$ gives $J = [5 + 4 - 2\mathrm{Re}\backslash(3 + j\backslash)]\ \mathrm{A}^2/\mathrm{Hz} = 3\ \mathrm{A}^2/\mathrm{Hz}$. The excess 0.5 equals $4\left|1 - (0.75 + 0.25j)\right|^2$, checking the completed-square result. Half the spectral sum of squares is explained by this fit; half remains residual.

Copyright 2026, James M. Atkinson

9.5.3.6 Application 6 An SNR interpretation needs a noise model

Stipulate exact input observation, unit transfer gain, input spectrum 9 V^2/Hz and uncorrelated output disturbance 1 V^2/Hz. Then $P_{xx} = 9\ \mathrm{V}^2/\mathrm{Hz}$, $P_{xy} = 9\ \mathrm{V}^2/\mathrm{Hz}$ and $P_{yy} = 10\ \mathrm{V}^2/\mathrm{Hz}$, giving $C = \frac{81}{90} = 0.9$. The model's output SNR is 9, or 9.542425 dB, also $\frac{C}{1-C}$. A measured value of 0.9 without the exact-input and uncorrelated-output assumptions does not establish that SNR.

Copyright 2026, James M. Atkinson

9.5.3.7 Application 7 The same coherence does not locate the noise

Let $H=1$ and $P_{ss}=1\ \mathrm{V}^2/\mathrm{Hz}$. If $P_{uu}=P_{nn}=1\ \mathrm{V}^2/\mathrm{Hz}$, then $P_{xx}=P_{yy}=2\ \mathrm{V}^2/\mathrm{Hz}$, $P_{xy}=1\ \mathrm{V}^2/\mathrm{Hz}$ and $C=0.25$; the output SNR is 1. Instead let $P_{uu}=0\ \mathrm{V}^2/\mathrm{Hz}$ and $P_{nn}=3\ \mathrm{V}^2/\mathrm{Hz}$. Then $P_{xx}=1\ \mathrm{V}^2/\mathrm{Hz}$, $P_{yy}=4\ \mathrm{V}^2/\mathrm{Hz}$, $P_{xy}=1\ \mathrm{V}^2/\mathrm{Hz}$ and C remains 0.25, but output SNR is $\frac{1}{3}$. Applying $\frac{C}{1-C}$ to the first case would incorrectly infer $\frac{1}{3}$. Equal coherence has not identified where the disturbance entered.

Copyright 2026, James M. Atkinson

9.5.3.8 Application 8 Common source and direct path are observationally ambiguous

With independent unit spectra for S, U and N, take $X = S + U$ and $Y = 2S + N$. The spectra are $P_{xx} = 2\ \mathrm{V}^2/\mathrm{Hz}$, $P_{yy} = 5\ \mathrm{V}^2/\mathrm{Hz}$ and $P_{xy} = 2\ \mathrm{V}^2/\mathrm{Hz}$, so $C = \frac{4}{10} = 0.4$. These same second-order spectra arise from $Y = X + R$ with an uncorrelated residual spectrum $P_{rr} = 3\ \mathrm{V}^2/\mathrm{Hz}$. The first construction has a common latent source; the second is an alternative linear representation. No choice between those physical narratives follows from this spectral matrix alone.

Copyright 2026, James M. Atkinson

9.5.3.9 Application 9 Two shared sources can cancel

Use $X = S + D$ and $Y = S - D$ with uncorrelated component spectra $P_{ss} = P_{dd} = 1\ \mathrm{V}^2/\mathrm{Hz}$. Both autospectra are 2 V²/Hz, but $P_{xy} = 0\ \mathrm{V}^2/\mathrm{Hz}$ and $C = 0$. If P_{dd} instead equals 0.8 V²/Hz, both autospectra become 1.8, P_{xy} becomes 0.2, and $C = \frac{0.04}{3.24} = \frac{1}{81} \approx 0.01234568$. Low coherence therefore does not exclude components shared by the channels. Complex cross-spectrum inspection and changes to the coupling configuration address a different question from increasing the number of averages.

Copyright 2026, James M. Atkinson

9.5.3.10 Application 10 State mixing can erase perfect within-state coherence

Use four equal-weight records $X = \backslash(1,1,1,1\backslash)\ \mathrm{V}$ and $Y = \backslash(1,1,-1,-1\backslash)\ \mathrm{V}$. In either pair of same-sign states, $C = 1$, with fitted gain +1 or −1. Pooling all four gives $P_{xx} = P_{yy} = d\backslash(1\ \mathrm{V}^2\backslash)$, $P_{xy} = 0\ \mathrm{V}^2/\mathrm{Hz}$ and $C = 0$. If the positive-gain state receives total weight $\frac{3}{4}$ and the negative-gain state $\frac{1}{4}$, $P_{xy} = \frac{d}{2}\backslash(1\ \mathrm{V}^2\backslash)$ and $C = \frac{1}{4}$. The result depends on state weighting. State-conditioned reporting requires a defensible state rule specified independently of the desired result.

The paired-spectrum complex-gain projection and Model 7A share a least-squares structure, but their reference sets, weights, and normalization denominators serve different questions. Model 7A uses declared finite symbol references; the spectral treatment here uses the paired spectral quantities defined above. Do not substitute one error percentage for the other without preserving those definitions. Model 12A addresses deterministic timing and phase conventions, while Model 12B develops covariance-dependent coherent power under its stated assumptions. Its jointly Gaussian phase-vector requirement belongs to that particular coherent-power expression and is not an additional assumption for Equation 18.

Copyright 2026, James M. Atkinson

9.6 Time-Frequency and Nonstationary Methods

Short-time Fourier transforms divide a record into overlapping windows to show spectral evolution. Wavelets, filter banks, reassigned spectra, and cyclostationary methods can reveal transients, chirps, periodic statistics, and symbol timing. Their time and frequency resolution are linked, and postprocessing parameters can create apparent structure. A compelling image is not a substitute for a quantified detection rule.

Time-frequency products should be traceable to the original samples and analysis script. Color scales, thresholds, interpolation, and normalization affect what appears visible. The practitioner verifies important features in the raw record, with alternate window or segment lengths, and on held-out data. Results are described as processing-dependent estimates rather than direct photographs of the spectrum.

Copyright 2026, James M. Atkinson

9.7 Estimator Validation and Reporting

Spectral estimators are validated with known tones, noise, bursts, chirps, and multichannel references selected to exercise the method's intended use. The validation includes amplitude bias, frequency bias, leakage, noise statistics, time localization, overlap, and confidence under the actual record length. Processing parameters are frozen before evaluation on held-out data.

The report states whether results are single-record, averaged, cross-spectral, coherence-based, or time-frequency estimates. It identifies window corrections, excluded intervals, threshold selection, and the relationship between plotted color or amplitude and the physical quantity. Derived images remain linked to source samples and executable analysis.

Copyright 2026, James M. Atkinson

9.8 Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation

Equation 1. DFT bin spacing

$$\Delta f = \frac{f_s}{N}$$

Nominal frequency-bin spacing Δf equals sample rate f_s divided by record length N samples. Actual resolution also depends on window main-lobe width, signal-to-noise ratio, estimator, and observation duration.

Equation 2. Magnitude-squared coherence

$$\gamma_{xy}^2(f) = \frac{\left|S_{xy}(f)\right|^2}{S_{xx}(f)S_{yy}(f)}$$

Magnitude-squared coherence compares cross-spectrum S_{xy} with autospectra S_{xx} and S_{yy}. Values lie between zero and one for valid estimates. Bias, averaging, leakage, common references, and nonstationarity must be considered.

Equation 17 uses the record length when the transform length equals that length; zero padding changes the displayed grid without creating observation time. The finite-window treatment and its ten applications establish the amplitude and power normalizations. Equation 18 belongs to the paired spectral-estimate treatment and its ten applications; positive autospectra and the same paired records are required for its stated normalization.

9.9 Hypothetical Applied Calculation: FFT Analyzers, Windowing, Averaging, and Spectral Estimation

A 2.0 MS/s acquisition uses 131,072 samples, giving nominal bin spacing of about 15.26 Hz. Applying a tapered window with a main-lobe width spanning several bins means two components 20 Hz apart may not be resolved despite the bin spacing. Increasing record length improves nominal spacing but also lengthens the period over which stationarity is assumed.

Copyright 2026, James M. Atkinson

9.10 Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation

Hypothetical case. A line at 19.2 MHz appears in a room probe and a power-line current probe with coherence above 0.9. Swapping the probes between two isolated digitizers destroys the coherence, and an injected reference reveals a shared-clock leakage path in the original recorder. The original recorder therefore has a mechanism that can contaminate the paired measurement, so its high coherence does not establish coupling through the room. Any remaining room-coupling claim requires a comparison that preserves the declared measurement sensitivity and state while testing that path.

Copyright 2026, James M. Atkinson

9.11 Multitaper spectra, estimator covariance and uncertainty under intermittent observation

Copyright 2026, James M. Atkinson

Figure 54. Multitaper spectra and estimator dependence.

A spectrum is an estimate conditioned upon a time record and an analysis operator, not a natural image of the electromagnetic field. If N complex samples x[n] are acquired at a valid uniform rate f_s, then a windowed transform X_w[k] = sum over n of x[n] w[n] exp(-j2 pi kn/N) reports the coefficients of the observed product x[n]w[n]. Its frequency-bin spacing is

Copyright 2026, James M. Atkinson

f_s/N, but the ability to resolve or quantify closely spaced components additionally depends on window response, effective observation duration, leakage and signal coherence. Zero padding can interpolate the sampled transform; it does not introduce new independent information about the underlying waveform. Treating an interpolated peak's many output digits as evidence of corresponding frequency accuracy confuses numerical representation with instrument uncertainty. The shared-record covariance example is illustrated in Figure 40.

Multitaper estimation addresses a particular weakness of using one taper by averaging spectra obtained from several orthogonal concentration windows over the same observation. The method can reduce estimator variability and leakage under appropriate stationarity and bandwidth assumptions, but each taper is a different mathematical weighting of the same acquired record. The resulting spectra are not independent field acquisitions, and confidence calculations must account for the taper design and statistical dependence. A rapidly changing intermittent burst can violate a stationary-spectrum model even when each taper is calculated correctly. The investigator should record the tapers, time-bandwidth product, number retained, normalization, overlap, sample gaps and any selection of favourable segments. It is particularly dangerous to discard windows in which an unusual emission does not fit a presumed spectral model, then claim sensitivity established from the survivors.

A quantitative example shows the independent-information trap. Imagine eight nominally equal-power spectral estimates, each with variance one squared power unit and equal pairwise correlation 0.3. The average's variance is [8 + 8(7)(0.3)]/64 = 0.3875 squared units, whereas independence

Copyright 2026, James M. Atkinson

would predict 0.125. Its standard deviation is approximately 0.6225 rather than 0.3536. This equicorrelation model is an educational illustration, not the covariance structure of any specific multitaper implementation. Its lesson is to estimate or justify the actual dependence. Adjacent overlapped windows, shared phase-noise processes and a common strong interferer can prevent nominal segment counts from translating into independent evidence.

The correct analysis should preserve the time-frequency support of the observation. When acquisition contains gaps or receiver retuning, do not compute one continuous FFT by concatenating the surviving samples and pretending that missing physical time never occurred. Instead retain separate valid segments or a justified missing-data model. A robust spectral estimator can be cross-checked against a deliberately different taper and a second receiver path, but agreement is persuasive only when likely shared errors are challenged. The report should distinguish a statistic of the retained samples from the possibility of an unobserved transient in a discarded interval. This preserves the useful precision of spectral methods without allowing the algorithm to replace the evidence it was supposed to interpret.

Copyright 2026, James M. Atkinson

9.12 Spectral confidence intervals and why averaging is not the same as independence

An FFT produces coefficients determined by a finite sequence of samples, a window, a sampling rate and a normalisation. The numerical output is not a direct census of continuously existing electromagnetic amplitudes at labelled frequencies. A finite observation convolves the input spectrum with a spectral window, producing leakage and estimator bias. For a continuous sinusoid not located at the centre of an FFT bin, the apparent peak depends on its fractional-bin offset and the selected window. For a stochastic input, the periodogram is itself a random statistic whose variance may remain substantial even when the record length increases. The laboratory must therefore distinguish frequency resolution, amplitude accuracy and statistical precision; increasing the number of plotted bins by zero-padding changes interpolation but not the physical observation duration.

For a zero-mean stationary Gaussian process and an appropriate independent-segment idealisation, each properly normalised raw periodogram ordinate behaves as an exponential-like power statistic with variance equal to the square of its mean. Averaging K independent identically distributed such ordinates reduces that ideal variance by a factor K. Yet practical Welch processing often overlaps windows, and the resulting segment estimates are correlated. If their common variance is sigma squared and their cross-covariances are C_ij, the variance of the average is K^-2 times the sum of all K squared covariance entries. This identity should be the default reasoning tool for claimed noise-floor precision. The

Copyright 2026, James M. Atkinson

independent K^-1 simplification is earned by an actual covariance argument, not by the existence of K saved spectra.

Multitaper estimation uses several orthogonal concentration sequences designed to control leakage and variance for a specified frequency bandwidth and sample interval. Orthogonality of the tapers as vectors does not guarantee independent spectral estimates for every coloured or deterministic interference environment. The analyst must check the estimator assumptions, taper bandwidth, adaptive weights if used, and confidence interpretation. Strong isolated tones can contaminate neighbouring spectral bands, while nonstationary bursts violate the single stationary-spectrum premise over the full observation. A reported confidence interval around a smoothed estimate may quantify estimator variability under a model while excluding model bias, receiver overload and missing time coverage entirely.

A controlled comparison can make the distinction concrete. Consider K = 12 equal-quality segment power estimates, each with variance 9 squared arbitrary units, and assume equal pairwise correlation rho = 0.2. Their average variance is 9[1 + 11(0.2)]/12 = 2.4 squared units. Under independence it would be 9/12 = 0.75. Thus the standard-deviation ratio is sqrt(2.4/0.75), approximately 1.789. The example's equicorrelation assumption is artificial and must not be transferred to any particular implementation; its purpose is to show that overlapping or shared-noise observations can substantially weaken the improvement inferred from file count alone. An honest measurement report documents the basis of its covariance or effective-degrees-of-freedom estimate.

Copyright 2026, James M. Atkinson

Cross-spectral techniques add another nuance. Coherence between two channels may reveal a shared deterministic or stochastic component, but a shared acquisition clock, power-supply disturbance or digital reference can produce coherence without an external RF emitter. The instrument should record cross-spectra and phase conventions at declared reference planes, then compare paths in which suspected common-mode errors change. Averaging spectra in power units is appropriate for specified average-power targets; averaging complex amplitudes can destroy a phase-incoherent signal or enhance a phase-locked one. Neither operation is inherently superior without a defined measurand. A narrow candidate appearing in several derived transforms from the same raw samples is not independent corroboration.

Missing samples create a separate class of error. Concatenating valid pieces of a record without representing the missing physical time changes the sampling law and can produce incorrect spectral interpretation. Zero-filling gaps creates yet another window with its own leakage, and can falsely suggest that the input was zero during unobserved intervals. Preserve a binary validity mask or an equivalent segment register. Compute spectra on justified valid intervals, or employ an explicit missing-data model whose assumptions are tested with known signals. The released result should identify what the retained data support and which unobserved events no spectral estimator can reconstruct without additional assumptions.

Copyright 2026, James M. Atkinson

9.13 Advanced technical expansion. Spectral-estimator confidence beyond a clean FFT display

A discrete Fourier transform provides a representation of retained samples, not a unique description of the original electromagnetic field. The physical measurement requires an acquisition record, an analogue anti-aliasing response, an effective sample clock, a window, a normalisation convention and an estimator whose statistical properties are understood. For N samples x[n] and a deterministic window w[n], a windowed transform X[k] = sum from n=0 to N-1 of x[n] w[n] exp(-j2 pi kn/N) preserves a clear mathematical relation between the stored sequence and the reported bins. It does not establish that a sinusoid necessarily falls at a bin centre or that an observed bin is attributable to an external emitter. The digital frequency axis also assumes the actual sampling interval. If the converter clock was different from the nominal setting, a spectrally sharp display can have a wrong physical-frequency calibration while retaining entirely correct FFT arithmetic.

Amplitude estimation and noise-density estimation need different window normalisations. A coherent tone at a bin centre experiences the window's coherent gain, proportional to the sum of its coefficients, whereas white noise passes according to the sum of squared coefficients. The equivalent noise bandwidth of the window, expressed in bin widths, is N times sum(w[n]^2) divided by [sum(w[n])]^2, provided the coefficient sum is nonzero. A rectangular window has an equivalent width of one bin under that convention, but other windows generally trade a wider equivalent noise bandwidth for reduced sidelobe leakage. A report that applies the coherent-gain correction to random noise without the corresponding power

Copyright 2026, James M. Atkinson

normalisation can be wrong even when its displayed trace looks plausible. Both correction factors must accompany the reported quantity.

For a simple numerical experiment, consider a 4,096-point transform at a true sample rate of 4.096 MHz, giving bin spacing exactly 1 kHz. A 100.0-kHz continuous tone corresponds to the hundredth bin; a 100.3-kHz tone falls between bins and distributes energy according to the chosen finite window. The presence of power in several bins does not by itself establish several transmitted components. Conversely, a strong tone's sidelobes can conceal a weak neighbour. The measured peak of the windowed transform therefore cannot be interpreted as absolute power without accounting for leakage, coherent gain, overlap with other components and the actual amplitude reference plane. The values in this example are stipulated for explanation; they are not recordings from a receiver.

Averaging periodograms reduces the variability of a suitable spectral estimate when successive data segments carry sufficiently independent information. Overlapping segments do not automatically create independent averages. If the jth segment estimator has covariance with its neighbours, the variance of the mean includes all cross-covariances divided by the square of the number of segments. Merely doubling the number of overlapped FFT frames may produce a smoother plot without halving variance or creating twice the observational evidence. Welch processing is useful when its window, overlap and estimator are declared; multitaper processing can reduce leakage sensitivity through several orthogonal concentration windows, but its statistical interpretation depends on the taper eigenvalues and signal class. Neither technique is an unrestricted cure for nonstationary bursts or receiver artefacts.

Copyright 2026, James M. Atkinson

Cross-spectral analysis can help distinguish common signals from channel-specific noise, but coherence also has failure modes. Two receivers sharing a local oscillator or digital processing artefact may exhibit strong cross-spectral coherence even when the source is internal to the measurement system. A common antenna feed may make the sensor outputs more dependent, not more independently corroborative. Magnitude-squared coherence is calculated from averaged cross- and auto-spectral estimates, and its bias and confidence depend on effective degrees of freedom. A high number cannot be interpreted sensibly without the signal and noise covariance and the measurement architecture that produced it. A controlled test with an independently injected reference, alternative clock or changed signal path can supply more information about physical origin than a raw coherence threshold.

The final measurement protocol should preserve raw samples, realised sample rate and clock source, FFT length, window coefficients, overlap rule, transform sign, normalisation, detector statistic, accepted records and every automatic rejection decision. Validate on synthetic records with known tones, adjacent blockers, impulses and gaps, then use physically measured references to challenge assumptions about analogue bandwidth and digitiser linearity. When a receiver cannot retain the raw samples, the report must identify which subsequent analyses are impossible and which estimates remain meaningful. Spectral-estimator elegance is not a substitute for a valid acquisition record and a falsifiable explanation of observed spectral structure.

Copyright 2026, James M. Atkinson

9.14 Thirty-hertz spectral resolution is a measurement design, not a guarantee of pulse detection

The manuscript must distinguish DFT bin separation from noise equivalent bandwidth, waveform resolving power and frequency-estimator precision. For N complex samples collected at rate F_s, a conventional N-point DFT has nominal bin spacing $\Delta f=F_s/N=1/T$, where $T=N/F_s$ is the uninterrupted observation duration. That identity fixes a time scale but not the point-spread function or sensitivity. Spectral leakage follows the selected window, coherent tones may fall between bins, and uncertain frequency drift smears energy during a long transform. A frequency estimator fitting a stable sinusoid may achieve standard uncertainty much smaller than one bin under sufficiently strong and appropriately modelled observations, whereas two uncalibrated pulse events separated by one bin cannot automatically be resolved as distinct emitters.

For white input noise from an approximately matched 290 K source, the conventional available noise spectral density is $10 \log10(kT/0.001\ W)$, approximately −173.98 dBm per hertz. A 30 Hz ideal rectangular noise bandwidth admits $-173.98+10 \log10(30)=-159.21$ dBm, before front-end loss, receiver-added noise and detector correction. A reported −170 dBm noise value needs a specified bandwidth and representation. A figure of −170 dBm/Hz can represent an input-referred spectral density for a low-noise receiver whose noise factor raises the −174 dBm/Hz thermal limit by roughly 4 dB. A display line at −170 dBm can also describe a signal estimate after coherent processing against a larger integrated noise background, but it cannot simultaneously be described as an uncorrected total thermal input-

Copyright 2026, James M. Atkinson

noise power at 290 K in a 30 Hz bandwidth. The distinction is an engineering requirement, not a semantic preference.

Thermal noise in a frequency channel is not the only limiting interference. At 40 GHz RF frequency, oscillator phase noise, nearby broadband interferers, image bands, converter spurs, ADC aperture jitter and lossy preselection may dominate. A 30 Hz analysis band may suppress broadband thermal noise yet remain vulnerable to a phase-noise skirt from a strong adjacent carrier. The appropriate model integrates a measured noise power spectral density through the actual filter and includes any deterministic or correlated terms separately. A laboratory terminated-input result is useful for the configured hardware, but a survey connected to an antenna sees a different source temperature, impedance and set of environmental emissions. A single global noise-floor label for a continuously distributed 0–40 GHz architecture is therefore inadequate.

Narrowband averaging must be assessed by its estimator. For independent, zero-mean measurement noise, a coherent integration of a known, stable complex waveform can increase detectability with observation time; a noncoherent power average reduces the variance of the noise-power estimate without necessarily reducing its physical mean. Averaging independent receiver output noise by cross-correlation can suppress uncorrelated internal components, but it does not eliminate common source noise, a coherent interferer or common clock-related error. Two channels driven by the same 290 K input termination can agree because they receive the same thermal realization; that agreement must not be misreported as discovery of a weak external emitter.

Copyright 2026, James M. Atkinson

Wideband detection must preserve a fast observation branch. An energy detector with submicrosecond time resolution should be evaluated with bandwidth and false-alarm rates appropriate to the pulse. A secondary slow branch can compute fine spectral summaries for stable lines and persistent emissions. Candidate triggers are linked to sample indices in a rolling raw I/Q buffer. The long-window spectrum can then support frequency refinement, while the time-resolved record supports pulse duration, repetition and intra-pulse modulation. Both branch results require validation in the presence of blockers and data gaps; neither can replace the missing input samples if they were not recorded.

Copyright 2026, James M. Atkinson

9.15 Numerical reality checks for resolution, noise density and detection

Application F9.1. At 290 K and 30 Hz ideal noise bandwidth, P=kTB=1.201×10^-19 watts and the level is about −159.2 dBm. A 3 dB receiver noise figure raises the equivalent input noise by about 3 dB under the matched reference convention, yielding −156.2 dBm in that 30 Hz band before other site contributions.

Application F9.2. −170 dBm denotes 10^-20 watt. Dividing by k times 30 Hz yields an equivalent input noise temperature of approximately 24.14 K. This is below room temperature and therefore cannot arise as uncorrected total noise from a conventional matched 290 K termination under the declared assumptions.

Application F9.3. A nominal −170 dBm/Hz density integrated over 30 Hz corresponds to −155.23 dBm, not −170 dBm. Confusion between per-hertz density and a thirty-hertz total changes the result by 14.77 dB.

Application F9.4. A 1,000 Hz white-noise measurement referenced to −174 dBm/Hz contains approximately −144 dBm of thermal noise. Narrowing the effective bandwidth to 30 Hz reduces the integrated power by 10 log10(1000/30)=15.23 dB under identical source conditions. It does not recover waveform components rejected by the narrower filter.

Application F9.5. A one-second complex recording with 100 million samples per second contains 100 million samples and 1 Hz nominal DFT spacing. A 30 Hz display can average or rebin that representation, but the extra duration does not imply a broader instantaneous RF input band.

Copyright 2026, James M. Atkinson

9.16 Long-duration multiresolution spectrum retention and the limits of thirty-hertz FFT bins

A multi-day spectral archive should be designed as a hierarchy of time-frequency observations, not as a single full-bandwidth waterfall file. For the stipulated forty gigahertz of simultaneous useful coverage, the nominal thirty-hertz frequency grid contains roughly 1.333 billion bins. Storing every bin in a sixteen-bit scalar format consumes about 2.667 decimal gigabytes for one complete frequency snapshot before any clock, calibration, validity or event metadata. One complete snapshot per second would therefore yield approximately 38.4 terabytes over four hours and 691.2 terabytes over seventy-two hours. A snapshot every ten seconds would reduce volume by a factor of ten but would also eliminate recoverable short-time ordering in the intervals between summaries. Neither policy is equivalent to archiving raw complex samples, and both require an explicit statement of how continuous observation, detector behaviour and loss are recorded.

A hierarchical solution can retain coarse time-frequency summaries for the whole fifteen-minute to seventy-two-hour run, fine-resolution spectra around occupied or suspicious areas, and short raw-I/Q segments where an event meets an authorised technical criterion. The layers should carry different decision purposes: low-rate summary for navigation through days of data, stable noise and calibration profiles for metrological interpretation, event-centred fine spectra for classification, and original complex samples for reprocessing or adversarial challenge. Selecting a period from the list of fifteen, sixty, two hundred and forty, four hundred and eighty, seven hundred and twenty, fourteen hundred and forty, eighteen hundred and

Copyright 2026, James M. Atkinson

four thousand three hundred and twenty minutes does not confer the same ability to reconstruct an unsaved pulse. The record must distinguish long-duration monitoring from long-duration raw waveform retention.

Sparse spectral recording presents a selection-bias problem. If bins are committed to long-term storage only when a trigger exceeds a threshold, an investigator examining the archive later will find a distribution enriched for large excursions. Treating that selected distribution as representative of the underlying noise law can create false occupancy estimates, distorted amplitude histograms or spuriously precise claims about emitter duty cycle. Preserve the detector threshold, background estimation history, hysteresis, event-coalescing behaviour, overload exclusions, and negative-test opportunities, and retain periodic or randomised control records independent of the event trigger. A non-triggered interval may be validly labelled no detector event meeting criterion C, but not no RF event of any physical kind.

The FFT response to a pulse depends upon its time of arrival and the analysis window. A thirty-hertz bin grid cannot supply thirty-hertz-independent assurance about a microsecond event; the event may excite a broad set of spectral bins and its energy may be diluted by the window length. A separate fast multiresolution path, including short-window transforms, pulse-energy statistics or suitable matched filters, must be available for event families the surveillance objective names. A GPU cannot reconstruct pulse phase and precise onset from averaged magnitude-only bins. If an event is identified later from a spectral summary, raw waveform preservation depends upon whether the rolling buffer still contains the source samples when the retrospective trigger fires.

Copyright 2026, James M. Atkinson

A useful long-duration archive index is ordered by acquisition sample counter, UTC time mapping and local oscillator/clock epoch, then by absolute RF frequency and receiver slice. This permits exact association of a coarse spectral anomaly with the original complex samples, subject to demonstrated buffer retention. The frequency-time map must include missing acquisitions, ADC overload, calibration transitions, failed FFT buffers and detected source packets that arrived too late for preservation. Signal extraction then proceeds by searching a small number of candidate intervals and verifying their original sampling context. That approach limits petabyte ingestion without mistaking selective storage for universal capture or treating a pretty waterfall as a complete forensic record.

9.17 The spectral measurand: differentiating a line, a density, a band power, and a probability of observation

The central intellectual difficulty of advanced spectrum analysis is not the Fourier transform itself. It is the choice of the quantity which the Fourier transform is being asked to estimate. A laboratory operator may use the same graphical axis to display the amplitude of a narrow coherent carrier, the mean power in a resolution filter, a one-sided power spectral density, the integrated energy of a brief emission, a channel-occupancy statistic, or a maximum value accumulated across many acquisition intervals. Those quantities are not interchangeable. Their units, estimators, uncertainties, and validity conditions differ. When an instrument reports a single ordinate in dBm, the reader must ask whether it refers to power in a nominal filter, total power from a calibrated tone, or an integrated result corrected for equivalent noise bandwidth. The answer depends on the physical measurement architecture and on the detector selected. A source can be weak in band-integrated power yet conspicuous in a narrow-resolution display; conversely, a signal that is strong in peak amplitude can have little average power when its duty factor is small. The first responsibility of an expert is therefore to define the measurand in words, mathematical notation, reference plane, and time interval before invoking a spectral estimator. [C9-01; C9-02; C9-18]

Let x[n] denote N complex baseband samples acquired at sample frequency f_s samples per second, and let w[n] be a finite window. Define X_w[k] as the sum, for n from zero to N minus one, of x[n]w[n]exp(-j2πkn/N). A discrete spectral ordinate is a complex projection of the observed record; it is not by

Copyright 2026, James M. Atkinson

itself a physical power density. For a resistance-referenced voltage recording, an appropriate normalization must incorporate the voltage calibration, the load or reference resistance, sample frequency, and window energy. If the digitised values are already power-wave quantities, the normalization changes accordingly. A narrowband sinusoid and a stationary random process require different denominators: line amplitude involves coherent gain $G_c = \mathrm{sum}(w[n])/N$, whereas white-noise density depends on $\mathrm{sum}(w[n]^2)$ and f_s. To quote a line-calibrated amplitude spectrum as though it were a density spectrum is to confuse coherent accumulation with incoherent energy. To sum line-calibrated bins and call the result total noise power is equally hazardous, particularly after overlapping windows or averaging. A manuscript that teaches spectral analysis at postgraduate level must make this distinction unavoidable. [C9-03; C9-20; C9-23]

For a one-sided power spectral density, the factor of two applied to positive-frequency interior bins requires special care. DC and, when N is even, the Nyquist-frequency bin are not duplicated. Complex analytic or complex baseband data ordinarily retain a two-sided spectral convention unless a specific one-sided transformation is defined. The effective noise bandwidth $B_e = f_s\, \mathrm{sum}(w[n]^2)/(\mathrm{sum}(w[n]))^2$, expressed in hertz, describes the relationship between a window's coherent response and the white noise admitted to its spectral estimator. These expressions presume that the window sum is nonzero and that the quantities being transformed have been calibrated in compatible units. A coherent-gain correction may become ill-conditioned for some specially constructed filters or differenced records; it is not a licence to divide by a near-zero number. In a forensic report, every figure should therefore state whether it presents amplitude, power, or

Copyright 2026, James M. Atkinson

density, what one-sided convention was used, and whether the display has been corrected for gain and effective bandwidth. [C9-18; C9-20; C9-23]

A further complication arises when the signal is intermittent. An FFT applied to a ten-millisecond window containing a half-millisecond burst does not estimate the same physical quantity as a window drawn entirely from inside that burst. The former may describe energy accumulated across a longer observation, while the latter may describe the spectral character of the active state. Neither is inherently superior, but their conclusions must be framed differently. The investigator should preserve the start sample, stop sample, trigger event, discontinuity mask, and relationship between the local record clock and the stated time origin. If those fields are missing, no amount of elegant frequency-domain processing can retrospectively reconstruct precisely when the emission was present. The estimate remains scientifically interesting yet evidentially limited. [C9-02; C9-10; C9-26]

Consider three observations of the same nominal 146 MHz source. The first is a narrow line measured at -72 dBm with a detector appropriate for stable tones; the second is a channel-power result of -58 dBm over a declared 200 kHz integration; the third is a peak-hold value of -49 dBm accumulated during fifteen minutes of surveillance. The numbers do not disagree merely because they are different. They represent different estimands. A proper comparison begins by asking whether the signal was active during all three measurements, whether the integration bandwidth included modulation sidebands, whether the maximum detector selected rare bursts, and whether every result refers to the same antenna-terminal plane. Only then may one construct a common scale. The same principle applies to historical analog analysers and modern FFT instruments. The newer instrument is not

Copyright 2026, James M. Atkinson

automatically more truthful; it is capable of more elaborate operations whose meaning must be stated with greater precision. [C9-06; C9-07; C9-11]

An adequate scholarly report consequently records at least six contracts: the physical source and measurement boundary; the acquisition interval and its clock; the frequency-band and one-sided or two-sided convention; the selected window and normalization; the detector or averaging operation; and the uncertainty model under which a value is offered as evidence. When comparison is sought, a seventh contract is necessary: a mapping that makes the two reported measurands genuinely commensurable. Instrument screens are convenient interfaces, not substitutes for those contracts. [C9-18; C9-24]

9.18 Window families as measurement decisions rather than decorative software choices

Windowing is frequently introduced as a remedy for leakage, but that formulation conceals the important fact that leakage suppression is bought with changes in coherent gain, equivalent noise bandwidth, main-lobe width, sidelobe pattern, and transient weighting. A finite record can be understood as an infinite record multiplied by a time-limiting window. In the frequency domain, the desired spectrum is convolved with the window transform; energy from one component is therefore distributed across spectral frequencies according to that transform. The analyst never observes a pure underlying spectrum without a measurement kernel. The rectangular window gives a relatively narrow central lobe for a coherent sinusoid but substantial sidelobes. A Hann window reduces distant sidelobes at the cost of a wider main lobe and a greater white-noise bandwidth. A flat-top window improves amplitude stability under frequency-bin mismatch but sacrifices resolution and typically admits more noise. These are not mere software preferences. They determine which signals are distinguishable and which amplitude claims are defensible. [C9-03; C9-20; C9-23]

To see the practical implications, imagine a weak spectral line a few kilohertz away from a strong carrier. The problem is not simply whether the weak line lies on a different nominal FFT bin. The strong carrier's window sidelobes may dominate the very part of the spectrum where the weak line would otherwise be visible. A window with more sidelobe suppression could uncover the weak line, while a narrower window might distinguish two

Copyright 2026, James M. Atkinson

comparable carriers whose separation is barely larger than a bin. Choosing one window to optimize both tasks may be impossible. A mature procedure states which error is more costly: failing to resolve adjacent equal-power signals, losing a weak signal beside a strong interferer, or estimating the amplitude of a sinusoid whose exact frequency is unknown. Each goal implies a different weighting of main-lobe and sidelobe behaviour. [C9-20; C9-22; C9-23]

The coherent-gain correction is $G_c = (1/N)\mathrm{sum}(w[n])$, whereas the equivalent noise bandwidth is $B_e = f_s\, \mathrm{sum}(w[n]^2)/(\mathrm{sum}(w[n]))^2$. These measures should be computed from the actual sampled window coefficients, not copied uncritically from a convenient reference table. A symmetric N-point Hann window and its periodic counterpart differ at the endpoints, which produces measurable differences at small N. A library that silently changes its convention can invalidate an exact reproduction of a historical data product. Recording the formula, number of points, coefficient precision, and relevant software version is therefore part of the measurement. A laboratory should retain a short test vector of a coherent tone, an off-bin tone, and stationary synthetic noise, together with expected results. If a software change alters the numerical answer, the operator has an immediate basis for investigating its cause. [C9-18; C9-23]

Scalloping loss describes the change in a line's indicated amplitude as its frequency moves relative to the DFT grid. For an uncorrected rectangular window the worst half-bin offset produces a familiar attenuation approaching 3.92 dB in the long-record idealisation. That figure is not a general statement about every detector, every interpolation scheme, or every subsequent amplitude correction. A peak-interpolated estimate can

Copyright 2026, James M. Atkinson

perform differently; a flat-top window is designed to be much less sensitive to bin-centre placement. In the presence of noise, however, interpolation also changes estimator variance and selection bias. One cannot simultaneously promise unbiased peak selection, arbitrarily fine frequency resolution, and zero statistical cost merely by adding more displayed FFT points. Zero padding samples the same continuous windowed transform at more frequency coordinates; it does not lengthen the underlying acquisition record. [C9-03; C9-04; C9-20]

A second window issue is often neglected: weighting changes the temporal importance assigned to events. A burst near the centre of a Hann-weighted record contributes much more to the result than the same burst near an endpoint. This is sensible when the intention is to reduce leakage for an approximately stationary process. It is potentially misleading when the task is to compare short emissions at unknown times. Moving the frame by a small amount may change the indicated peak dramatically, even if the physical emission is perfectly repeatable. A robust transient procedure archives the unwindowed samples, repeats analysis at several time positions, and reports the selected window explicitly. If a feature is found only after trying dozens of frame positions, the selection procedure must also enter the statistical interpretation. [C9-10; C9-18]

The original contributions of Harris and the subsequent practical work by Heinzel, Rüdiger and Schilling help establish a disciplined sequence. Identify the signal model; evaluate leakage hazards; determine amplitude or density calibration; compute coherent gain and equivalent bandwidth; estimate loss and bias; and test the implemented code against known signals. The result should be a stated measurement rule, not an incantation to use a favourite

Copyright 2026, James M. Atkinson

window because it looks tidy. In a safety-critical or evidential context, the choice must remain reconstructable after the original operator has left the laboratory. [C9-20; C9-23]

Copyright 2026, James M. Atkinson

9.19 FFT frequency resolution, physical time, and the illusion of finer displays

The relation $\Delta f = f_s/N = 1/T$, where $T = N/f_s$, is basic but persistently misunderstood. It specifies the spacing of DFT samples for a record of duration T, not an unconditional guarantee that two arbitrary sinusoids separated by Δf can be resolved. The shape and width of the window response, signal-to-noise ratio, phase relationship, coherent frequency offset, and detector design all matter. When the record length is doubled while the sample rate is held constant, the nominal FFT spacing is halved and the measurement integrates over twice as much time. When only the zero-padded transform length is doubled, the displayed grid becomes finer without changing the temporal aperture or the underlying information. A responsible figure caption distinguishes these operations. [C9-04; C9-06; C9-18]

A claim of 30 Hz spectral resolution therefore begins with a measurement design. An FFT of 33.333 ms of contiguous data yields nominal bin spacing near 30 Hz. The selected window usually broadens the main lobe beyond that spacing; filter-equivalent and density conventions must also be declared. To detect a brief event lasting 100 microseconds while preserving that 30 Hz spacing, the investigator confronts a conflict between the long observation necessary for narrow spectral bins and the short temporal support of the event. The event may occupy a tiny fraction of the window and become diluted when the output is normalised as a stationary amplitude. Triggered short-window analysis provides better temporal localisation, but it cannot preserve the same narrow-frequency information

Copyright 2026, James M. Atkinson

from that short event alone. The correct response is multiresolution analysis and bounded reporting, not an assertion that one FFT has magically achieved both aims. [C9-03; C9-10; C9-11]

This distinction is especially important when comparing a swept analyzer with an FFT processor. The swept instrument's nominal resolution bandwidth reflects its filter shape and settling; the FFT display's apparent spacing reflects the finite record, window, sampling and possibly zero padding. These can be made approximately comparable for a specified stable signal, but they are not automatically equivalent. A fair comparison should use a common source, input reference plane, detector objective, integration or dwell time, and amplitude correction. The operator may need to adjust the FFT window's equivalent noise bandwidth or the swept instrument's resolution filter to produce matched white-noise readings. The instruments can then be evaluated against the same physical question rather than against each other's marketing description. [C9-01; C9-02; C9-11]

Consider a record sampled at 4 MS/s. With N = 200,000 samples, the acquisition lasts 50 ms and the nominal spacing is 20 Hz. Increasing the transform length to 400,000 by appending zeros gives a displayed increment of 10 Hz; it does not improve the ability to separate physical lines by the factor implied by that display. Instead, acquiring 400,000 genuine consecutive samples at the same sample rate yields 100 ms of observation and a genuine 10 Hz native bin spacing. Those two processing histories must not be conflated. A laboratory that stores only the final plot, without N, f_s and the actual number of observed samples, may be unable to distinguish them later. [C9-04; C9-18]

Copyright 2026, James M. Atkinson

Another distinction concerns chirps and nonstationary oscillators. A 50 ms window can yield narrow bins for a stationary tone, yet a source whose carrier sweeps several kilohertz during that interval spreads energy across numerous bins. Treating the widened spectrum as an increase in transmitter noise may be mistaken. The signal might instead have coherent frequency motion. Time-frequency representations, phase unwrapping and instantaneous-frequency analysis can help, but each relies on its own bandwidth and noise assumptions. Narrower frequency bins do not preserve a source's instantaneous frequency trajectory unless the measurement method retains the relevant temporal information. [C9-10; C9-24]

The pedagogical rule is straightforward. Whenever a spectrum is described as high resolution, print the number of observed samples, the sample frequency, record duration, window family, equivalent bandwidth, transform length and whether padding was applied. Explain which physical discrimination task was tested. If those details are absent, the phrase high resolution is a visual description, not a metrological certification. [C9-20; C9-23]

Copyright 2026, James M. Atkinson

9.20 Welch averaging, overlapping records, and statistical dependence

Averaging individual periodograms is a powerful way to reduce the notorious variability of finite-record power spectral estimates. Welch's 1967 construction divides a record into shorter pieces, typically overlapping them, multiplies each by a specified window, calculates modified periodograms and averages the resulting powers. It exchanges some frequency resolution for more stable estimates. The method is ubiquitous because it is computationally straightforward and interpretable, but an important qualification is often omitted: overlapping records are not statistically independent merely because the program displays a separate FFT for each one. Their samples are shared, and their windowed estimates can be correlated. A confidence interval that assumes independent averages without testing that condition may be too narrow. [C9-19; C9-22; C9-24]

Let T_r denote the total available duration, L the segment length in samples, O the number of overlapping samples, and $H = L - O$ the hop size. The number of complete segments is $K = 1 + \mathrm{floor}((N_{total} - L)/H)$, provided N_{total} is at least L. This count is an accounting identity; it is not the number of independent statistical observations. Two adjacent Hann-weighted segments with fifty per cent overlap may share half their raw samples, although the covariance between their spectral estimates depends on window weights and the underlying process. For white Gaussian noise, the covariance can be studied analytically or with controlled Monte Carlo experiments; for coloured noise or bursty interference it may be markedly different. The effective degrees of freedom ν_{eff} should therefore be

Copyright 2026, James M. Atkinson

derived or validated for the actual averaging scheme before a chi-square interval is invoked. [C9-18; C9-19; C9-22]

A common mistake is to average decibels instead of linear powers. If P_i denotes a positive power estimate, $10 \log10((1/K)\text{sum}(P_i))$ is generally not equal to $(1/K)\text{sum}(10 \log10(P_i))$. Jensen's inequality explains the direction of the difference under the usual conditions. The logarithm of the arithmetic mean is at least the arithmetic mean of the logarithms. When a noise estimator averages logarithmic display values, the resulting number can carry a systematic offset from a mean-power estimate. An instrument may include correction functions, but the operator must identify them rather than assume the display's word average is unambiguous. Report averaging domain, detector, number of transforms, overlap fraction, and any bias correction. [C9-01; C9-02; C9-06]

For a worked numerical illustration, suppose twelve segments yield estimates fluctuating around a common noise density. The arithmetical average can suppress variation, but if adjacent segments share substantial samples, it would be misleading to report twelve independent spectral observations. If a conservative covariance analysis determines that the equivalent number is eight, the relative standard deviation of a simple mean based on exponentially distributed single-bin powers is closer to $1/\text{sqrt}(8)$ than $1/\text{sqrt}(12)$. The difference is not cosmetic when the resulting confidence interval governs a threshold decision. For a two-sided interval based on a chi-square approximation, the analyst must state the degrees of freedom, tail probabilities, and whether the assumptions of a stationary Gaussian process have been assessed. If interference bursts contaminate

Copyright 2026, James M. Atkinson

only two segments, the mean and interval may reflect a mixture of process states rather than one stationary population. [C9-18; C9-19]

One suitable laboratory exercise uses a reproducible synthetic complex Gaussian sequence with a fixed seed and known variance. Students estimate its power spectral density using nonoverlapping records, fifty per cent overlap, and seventy-five per cent overlap while holding the total observation time fixed. They compare empirical variance over many independent trials and the achieved frequency resolution. A further experiment inserts short bursts at controlled times and tests how much the estimate and confidence interval are altered. The experiment should be repeated for rectangular and Hann windows, because window weights change the covariance structure. The conclusion should include a table of effective rather than merely nominal averaging counts, together with the consequences for false-alarm decisions. [C9-18; C9-19; C9-23]

The forensic lesson is that displaying a smoother spectrum cannot by itself justify a stronger claim. Smoothing may reduce random fluctuations, conceal intermittent behaviour, and make dependent records look deceptively numerous. A defensible statement names the population, period of observation, method of averaging, independence assumptions and quantitative uncertainty. Whenever those conditions cannot be established, the result should be called a descriptive average rather than a statistically certified estimate. [C9-24; C9-26]

Copyright 2026, James M. Atkinson

9.21 Multitaper spectra, bias, variance, and the meaning of several views of one record

The multitaper method addresses the instability and leakage of spectral estimates through a carefully chosen family of orthogonal data tapers, commonly the discrete prolate spheroidal sequences. Thomson's construction exploits the concentration properties of these sequences so that several differently weighted estimates can be formed from the same finite record. An appropriately weighted combination can reduce variance while controlling spectral leakage, particularly when the underlying process is sufficiently stationary for the model to make sense. The point is not that the tapers manufacture independent physical measurements. Rather, they offer multiple nearly orthogonal projections of the same observation and a means of balancing bandwidth, bias and variance. Their apparent independence is limited by the actual process covariance and finite-sample conditions. [C9-21; C9-22; C9-18]

The time-bandwidth product NW governs the trade between spectral concentration and the number of useful tapers. It should be presented as a dimensionless design parameter, with N equal to the number of samples and W equal to a specified half-bandwidth in cycles per sample. A familiar practical choice uses approximately 2NW - 1 well-concentrated tapers, but this is a heuristic, not a universal rule for deciding how many independent claims can be made from the data. The eigenvalues of the discrete prolate spheroidal concentration problem describe the proportion of taper energy retained within the design band. At higher taper indices that concentration can deteriorate, allowing more leakage. Adaptive weighting may help, but it

Copyright 2026, James M. Atkinson

introduces further model assumptions that should be disclosed. [C9-21; C9-22]

A key virtue of the method becomes apparent beside a strong spectral line. A single rectangular or short Hann window can spread line energy across adjacent bins, masking a much weaker component. Multitaper averaging with carefully selected bandwidth can suppress some of that leakage while producing a more stable background estimate. Nevertheless, if the desired weak line lies inside the multitaper smoothing bandwidth of a strong line, the method can still blur the distinction. The correct question is not whether multitaper is better in the abstract, but whether a particular taper set and bandwidth provide acceptable bias and detection power for the specific spectral separation. The researcher should test with injected tones of known amplitude and frequency before relying on the method in a contested measurement. [C9-21; C9-18]

A practical verification should compare three outcomes from the same retained raw record: a Hann-window single periodogram, Welch-averaged periodograms, and a multitaper spectrum. For each output, provide the analysis bandwidth, coherent or density normalization, effective degrees of freedom, and controlled-injection recovery error. For a stationary white-noise simulation, record empirical variance over many independent seeds. For a coloured process, test whether the fitted background and taper adaptation distort a weak local line. For a short transient, move the transient through the record and quantify the sensitivity of each method to time location. A method that performs admirably on stationary noise may be a poor discovery tool for a rare emission. [C9-18; C9-21; C9-23]

Copyright 2026, James M. Atkinson

The statistical inference must also separate exploratory and confirmatory stages. If a researcher tries ten time-bandwidth products, several adaptive weights, many frequency ranges and different thresholds before selecting the most favourable picture, the selection is part of the experiment. A small nominal p value derived as though that final configuration had been fixed in advance is not reliable. A stronger protocol identifies a discovery set and an independent validation set, or uses a pre-registered method on an archived acquisition. Even where the measurement is not a formal hypothesis test, reporting all materially different processing choices helps a later reviewer evaluate robustness. [C9-21; C9-24]

The consequence for a technical textbook is a clearer doctrine of estimator choice. Multitaper belongs in the toolkit for stationary-spectrum inference and line detection, but its status as an advanced method does not excuse failure to specify the physical measurand, acquisition continuity, taper family, bandwidth, calibration and uncertainty. Every spectral estimator is an answer to a stated question under a set of assumptions. A disciplined investigator learns to move between methods without allowing their attractive graphical differences to decide which one must be true. [C9-18; C9-22]

Copyright 2026, James M. Atkinson

9.22 Transient-spectrum analysis, time gating, and the interpretation of spectrograms

Spectrum analysers increasingly combine frequency-domain measurements with time-domain selection. This is valuable because many RF systems do not transmit continuously: digital radios share channels in time, radar returns are pulses, control systems emit bursts, and faults may produce sporadic interference. Traditional sweep measurements can combine successive states into one trace without revealing that the state changed during acquisition. Time-gated spectral analysis narrows the interval from which samples contribute to the estimate. A gate can isolate one time slot of a repeating system, exclude an unrepresentative switching transient, or focus analysis on the interior of a pulse. It cannot, however, turn a poorly specified observation into a complete record of the source. The gate's origin, delay, duration, trigger uncertainty and edge effects must be preserved. [C9-01; C9-02; C9-10]

Suppose two transmitters alternately occupy a common channel, each for one millisecond. A swept analyser that visits frequencies over many alternations can display a composite spectrum. A gate synchronized to the first transmitter may isolate its signal under the condition that the slot timing is stable and the analyser observes enough repeats. A triggered FFT capture may instead analyse a particular slot directly, assuming that its instantaneous acquisition bandwidth covers the feature and its duration is sufficient for the desired resolution. If the slots drift or fail to repeat, an accumulated gated sweep may mix states unexpectedly. The operator should therefore specify whether the reported spectrum is based on

Copyright 2026, James M. Atkinson

repeated equivalent bursts or on one native time record. These are distinct types of evidence. [C9-01; C9-02; C9-04]

The short-time Fourier transform produces a sequence of windowed spectra whose centres progress through time. The spectrogram is a visualisation of a squared magnitude or power estimate as a function of time and frequency. Its time-frequency trade-off is not simply a graphics setting: a shorter window gives better localisation of rapid changes but broader spectral responses, while a longer window improves narrowband discrimination but smears temporal boundaries. Overlap can make the image look fluid while leaving its independent information essentially unchanged. A colour scale adds yet another transformation; logarithmic compression can reveal small components but can also distort intuitive impressions of relative energy. Captions should give time resolution, frequency resolution, overlap, colour quantity and dynamic range. [C9-10; C9-18; C9-23]

A spectrogram is often treated as a moving picture of an RF environment. That metaphor is helpful but dangerous. A pixel represents the result of a finite windowed computation, not an infinitesimal event. Energy may bleed into neighbouring time and frequency cells because of the analysis kernel. A narrow carrier switching on midway through a window can appear to have started earlier; a short pulse can occupy several frequency bins despite being narrowband in its instantaneous carrier. Conversely, an emission that lies outside the receiver's instantaneous capture band is absent from the spectrogram regardless of how alarming the outside world might have been at that moment. A properly described spectrogram is therefore a map of a

Copyright 2026, James M. Atkinson

particular acquisition and computation, not a universal chronicle of the ether. [C9-10; C9-11]

When the measurement concerns rare events, trigger strategy is part of the scientific method. An amplitude trigger can miss a weak frequency-specific spur hidden under broadband noise; a frequency-mask trigger may be more selective, provided the analyser processes the entire relevant instantaneous band without gaps and the event exceeds the specified duration and amplitude. Trigger thresholds create selection bias: events below the threshold will not enter the retained set, and the stored population therefore cannot be mistaken for the complete population of events. To estimate event rates, a separate account of monitored time, trigger dead time and excluded intervals is necessary. [C9-10; C9-12; C9-28]

A rigorous field record should preserve the complex samples when practical, the original spectrogram settings, an unaltered copy of the detection log, and a mapping from every analysis frame to input sample indices. A review script should be capable of recomputing selected frames and demonstrating the effect of alternative window lengths. If a finding depends entirely on a narrow colour-scale choice or one gate position, the conclusion should say so. The best forensic outcome is not necessarily the most persuasive image; it is a result that survives reasonable perturbations of an explicitly justified analysis plan. [C9-18; C9-26]

Copyright 2026, James M. Atkinson

9.23 Real-time spectrum analysis, overlapping FFT engines, and probability of intercept

The expression real time has become a technical selling point, but a scholarly treatment must replace marketing terminology with a testable acquisition contract. The practical distinction is not merely how frequently a spectrum graph is repainted. An analyser may present an impressive stream of visual updates while its processor discards samples between transform frames, or it may acquire continuously yet store only sparse derived summaries. The relevant questions are whether every sample in a specified instantaneous bandwidth is acquired, whether the digital processing can maintain that throughput indefinitely, whether triggering operates on all relevant samples, and whether the stored record retains enough information to reconstruct the detected event. Real-time bandwidth is the width of the frequency band over which these conditions hold under the stated instrument configuration, not necessarily the full tuning range printed on the instrument's front panel. [C9-10; C9-11; C9-28]

A mathematical expression for the overlap of consecutive Fourier records helps identify the limitations. Let N be the number of samples in each transform and H the hop length between successive transforms. The overlap fraction is $r = 1 - H/N$ for $0 < H \leq N$. For a sample frequency f_s, the nominal transform arrival rate is f_s/H transforms per second, assuming no scheduling gaps. A 1,024-sample transform operating at 102.4 MS/s with a hop of 256 samples produces 400,000 overlapping transform opportunities per second. This arithmetic does not alone establish uninterrupted input acquisition or a guaranteed event-detection threshold; the front-end filters,

Copyright 2026, James M. Atkinson

window weighting, analysis bandwidth, trigger algorithm, processing backlog and memory pathway must be considered. If a vendor specifies a minimum detectable duration for a particular resolution bandwidth and span, that specification applies to that stated configuration, not to all possible settings. [C9-10; C9-12; C9-30]

Probability of intercept deserves especially careful definition. The phrase can refer to a statistical probability under an assumed random event arrival process, or to a manufacturer's guaranteed detection criterion for events meeting specified amplitude and duration conditions. These are not equivalent. A randomly arriving burst may be detected with some probability determined by the ratio of observed to unobserved intervals when its onset is uniformly distributed and the receiver's duty cycle is stable. A guaranteed trigger statement requires stronger engineering assumptions. It must show that every qualifying event, regardless of arrival phase, lasts long enough to be detected under the actual window, overlap, threshold and instantaneous bandwidth. The Tektronix literature provides illustrative instrument-specific duration tables; a textbook must teach the logic of interpreting those tables rather than transplanting one model's values into a universal law. [C9-12; C9-30]

For a hypothetical periodic acquisition system, suppose a 1 ms observation is followed by a 3 ms blind interval. An instantaneous event with uniformly random onset and negligible duration has an approximate intercept probability of one quarter, under the stated simplifying assumptions. A longer burst that can intersect an observation window has a greater probability, but the calculation must account for its duration and the periodic boundary conditions. This idealised duty-cycle computation should

Copyright 2026, James M. Atkinson

not be confused with a real-time analyser that continuously samples a bounded band yet retains only events satisfying its trigger. In the latter case, the sampling duty cycle may be unity while the *reporting* duty cycle is selective. A complete claim requires both acquisition coverage and decision-rule coverage. [C9-10; C9-28]

Spectral persistence displays, sometimes called digital phosphor or density displays, accumulate counts or intensities corresponding to repeated spectral observations. Their principal value is that rare emissions can become visible as faint traces or density clouds which a conventional maximum or average display might conceal. Yet display persistence itself introduces an aggregation process. A colour intensity is meaningful only when its counting period, transform rate, amplitude binning, reference correction and normalisation are known. A density hotspot does not automatically provide the event rate per hour; it may reflect different dwell periods, gain changes or unequal acquisition coverage. If two sessions are to be compared, the operator must establish a common denominator of valid observation time and comparable instrument states. [C9-10; C9-12]

A robust validation exercise injects pulses of varying duration and amplitude into a terminated and calibrated RF path. The instructor specifies a fixed analysis bandwidth and a set of RBW and trigger configurations. Students record the fraction of deliberately injected events detected under each condition, then distinguish an empirical detection frequency from a manufacturer's guaranteed minimum-duration specification. They should also inspect false triggers caused by background fluctuations and compute the consequences of increasing trigger sensitivity. The exercise ends with a bounded acceptance statement: within a declared band, observation time,

Copyright 2026, James M. Atkinson

source range and detection threshold, the system intercepted a stated fraction of events of specified duration. It does not end with the assertion that no unseen transmitter could have escaped observation. [C9-12; C9-18]

9.24 Spectral confidence intervals, model adequacy, and the danger of a single smooth curve

A periodogram estimate of power spectral density is a random variable, even when the underlying process is stationary. A plotted point is therefore not the spectrum itself; it is an estimate whose variability depends on the number of effectively independent observations and on the process distribution. Under a simplified complex Gaussian model, the squared magnitude of a single properly normalised Fourier coefficient behaves approximately like an exponential variable at many frequencies. Averaging independent periodograms can reduce variance, and a scaled chi-square approximation can yield confidence intervals. But the approximation requires assumptions about stationarity, independence, estimator bandwidth and sometimes asymptotic behaviour that must be stated. Colour, line smoothness or the absence of a visible error bar supplies none of those assumptions. [C9-18; C9-19; C9-24]

For ν effective degrees of freedom, the form ν S_hat(f) / S(f) approximately follows a chi-square distribution under the appropriate model. A two-sided confidence interval for the unknown S(f) is then constructed by dividing ν S_hat(f) by suitable upper and lower chi-square quantiles. The direction of the inequalities is important, and a student should verify it against a known tabulated case rather than rely on memory. The estimate S_hat(f) must be positive, and the degrees of freedom must represent actual effective information rather than the raw number of overlapping FFT frames. If confidence intervals are formed at thousands of frequency bins, simultaneous coverage and multiple-testing questions arise. A nominal 95

Copyright 2026, James M. Atkinson

per cent interval for each bin is not a guarantee that 95 per cent of an entire plotted curve lies within all displayed bounds at once. [C9-18; C9-22]

The difficulty intensifies for coloured noise. Adjacent frequency samples can be correlated by the window response, while the underlying power density may vary across the equivalent bandwidth. In that situation a simple white-noise model can understate bias, and an apparently narrow interval can be centred on a systematically inaccurate value. Instruments may also include detector corrections, smoothing, preselection, trace averaging and logarithmic conversion before showing a result. Each of those transformations can change the estimator's distribution. The aim of statistical verification is not to decorate a graph with standard errors but to establish whether its uncertainty statement corresponds to the actual calculation and physical process. [C9-18; C9-23]

A useful forensic example concerns an apparent weak line standing 6 dB above a fluctuating background. A peak selected because it is the tallest among ten thousand searched bins is not statistically equivalent to a pre-specified bin tested at one frequency. Even when every individual noise bin follows the assumed distribution, the maximum across many bins is expected to be larger than a typical one. The correct null model is the distribution of the selected maximum or a multiple-comparison procedure, not an unadjusted single-bin tail probability. If the analyst also varied window length, taper, threshold and time position until the line became conspicuous, the search space is larger still. Independent validation with a fresh acquisition and a fixed method is often more persuasive than an elaborate nominal probability calculated after the fact. [C9-18; C9-21; C9-24]

Copyright 2026, James M. Atkinson

Confidence in a spectral finding should also be stratified by the kind of claim. The presence of a spectral feature above the instrument's internal background may be established with modest evidence. Its existence at the antenna terminal requires calibration and external-state checks. Its assignment to an external transmitter requires receiver-artifact challenges and localisation evidence. Its attribution to a particular person, device or purpose requires an entirely different evidential chain. Statistical confidence intervals for power density are relevant to only the first parts of that progression. They are not an automatic bridge from a line in a plot to a forensic attribution. [C9-26; C9-27]

The recommended reporting standard therefore presents a primary estimate, the estimator family, effective bandwidth, actual number and dependence of records, chosen confidence method, validation tests, and any sensitivity analysis performed. It may also report a robust median or trimmed alternative for descriptive purposes, provided the difference in estimand is explained. Where assumptions fail, the analyst should resist producing a mathematically precise but conceptually fictitious interval. An honest range of plausible values, tied to stated calibration limitations and explicitly missing information, may be more scientifically useful. [C9-18; C9-24]

9.25 Cross-spectral analysis, coherence, and causal restraint in multichannel measurements

Two measurement channels can observe related signals without establishing that one caused the other. The cross-power spectral density $S_{xy}(f)$ describes frequency-dependent joint second-order behaviour between $x(t)$ and $y(t)$. The magnitude-squared coherence $C_{xy}(f) = |S_{xy}(f)|^2 / (S_{xx}(f)S_{yy}(f))$ lies between zero and one for a physically valid ensemble spectral matrix, with appropriate qualifications for finite estimates and numerical roundoff. High coherence indicates a strong linear relationship in the analysed ensemble and band. It does not, by itself, distinguish direct coupling from a common source, reveal the propagation path, prove the signals originated at the same physical location, or establish that an emission was deliberate. [C9-18; C9-24]

The phase of a cross-spectrum can support a delay estimate when the channels share a coherent source and their relative phase responses have been calibrated. Under a pure-delay model $y(t) = x(t - \tau)$, the cross-spectrum carries an approximately linear phase term with frequency; the slope determines delay, subject to the sign convention chosen for conjugation. If cable lengths, sample-clock offsets, group-delay ripple or frequency-dependent front-end filters are not corrected, an apparent delay may be an instrument property. Moreover, phase unwrapping is not unique when the bandwidth is too narrow or signal-to-noise ratio is poor. A reported delay should therefore include frequency range, coherence support, phase convention, uncertainty and the channel calibration record. [C9-18; C9-25]

Copyright 2026, James M. Atkinson

Consider two receivers in adjacent rooms that show a similar narrowband signal at the same time. Their spectra may be correlated because a building-wide electrical system radiates into both channels, because a common antenna splitter connects them, because their oscillators share a spurious reference product, or because an external transmitter illuminates both positions. Coherence helps establish common temporal or spectral structure; it does not distinguish these physical alternatives automatically. A good challenge programme changes one path at a time, adds calibrated attenuation, inserts a known terminating load where authorised, varies independent reference clocks, and examines whether the correlation survives. If the signal disappears under a change that should affect only internal coupling, the original external-source theory requires revision. [C9-01; C9-10; C9-26]

The estimation method should preserve complex products until averaging is complete. Computing cross-spectral magnitude separately for each short record and then averaging magnitudes generally produces a different answer from averaging complex cross-spectral products first. The latter retains phase cancellation that is essential to a coherent relationship. Likewise, coherence based on one unaveraged Fourier pair can become trivially unity under certain definitions, giving the appearance of a perfect relationship without genuine replication. Independent or at least properly modelled ensembles are necessary. The textbook should teach students to distrust coherence numbers stripped of their averaging protocol. [C9-19; C9-24]

A valuable multi-instrument laboratory exercise begins with one calibrated signal generator feeding two known paths through a splitter. Students

Copyright 2026, James M. Atkinson

measure the complex transfer ratio, obtain a cross-spectrum and estimate relative delay. They then add a short length of cable, a filter with frequency-dependent group delay, and a small independent noise contribution. Finally, they repeat with the two inputs terminated and an independently observed environmental signal. They must explain what changed in magnitude, phase and coherence and what the changes do not prove. The expected written result is a table that separates instrument calibration, physical path, statistical estimate and causal claim. [C9-06; C9-18]

Multichannel claims become especially delicate when the observer combines samples taken at different times. A pair of receivers may be disciplined to a common frequency reference yet not aligned in sample epoch; a third system may be separately accurate in frequency but have an unknown phase history. Cross-channel spectral statistics without time alignment can be biased or meaningless for fast transients. A complete record therefore includes clock source, frequency alignment, sample-index offset, buffering delay, correction coefficients and the uncertainty of each. The existence of a common ten-megahertz reference alone does not establish coherent sampling. [C9-25; C9-28]

9.26 Phase noise, close-in skirts, and the limits of interpreting narrow spectral features

A spectrum surrounding a stable carrier may contain phase-noise skirts, amplitude modulation, discrete reference spurs, intermodulation products and external signals. Distinguishing them requires a model that respects the instrument's own oscillator and conversion system. A swept or FFT spectrum analyser can introduce close-in noise through its local oscillator and sampling clock, sometimes obscuring a source's true performance. A narrow line close to a strong carrier may also arise from modulation or power-supply coupling rather than a second independent transmitter. Therefore, the phrase nearby emission is a description of the display, not an attribution. [C9-01; C9-06; C9-25]

For a sinusoidal carrier with small phase fluctuation φ(t), the single-sideband phase-noise function L(f) is often reported in dBc/Hz at positive offset f from the carrier, under a specified convention and small-noise approximation. The conversion between a phase-fluctuation power spectral density and L(f) depends on one-sided versus two-sided definitions. A student should never apply a factor of two or a decibel correction from memory without writing the adopted convention. Near the carrier, flicker processes, drift, finite acquisition duration and reference instability further complicate the assumption of stationary noise. NIST guidance on frequency stability provides the appropriate broader context for considering phase noise alongside Allan deviation and other time-domain measures. [C9-25; C9-24]

One elementary check uses the instrument's own floor. Terminate the RF input appropriately and observe the response under a valid self-noise

Copyright 2026, James M. Atkinson

condition. Introduce a stable known carrier at a safe level and measure the apparent skirt. Repeat using another source or reference arrangement, and change attenuation by a controlled amount. A residual that scales with the injected source may be external to one stage; a component that follows the analyser's frequency plan may be internally generated. None of these tests alone provides absolute proof, but their combined pattern can distinguish hypotheses. Particular care is required when increasing source power in an attempt to improve signal-to-noise ratio, because a strong carrier can drive nonlinear or reciprocal-mixing behaviour in the analyser itself. [C9-01; C9-06]

The use of phase-noise markers deserves its own uncertainty budget. A marker may integrate or estimate density across a filter whose equivalent noise bandwidth differs from its nominal resolution setting. It may remove or retain discrete spurs according to an undocumented algorithm. Its reported dBc/Hz value is meaningful only relative to a specified carrier power, offset frequency and density conversion. A report should record the instrument state and whether residual instrument noise was measured or subtracted. Subtraction in decibels is not a valid generic operation on powers; if subtraction is physically justified, the analyst must move to consistent linear quantities and propagate the associated uncertainties. [C9-01; C9-25]

A thought experiment shows the danger of visual certainty. Two oscillators have apparently identical close-in skirts on one analyser; a second instrument produces a different ordering of their phase-noise performance. The discrepancy could reflect different internal oscillator floors, correlation properties, measurement bandwidths or calibration. Before declaring one instrument defective, the analyst should compare the complete

Copyright 2026, James M. Atkinson

measurement chains and select a reference method capable of discriminating the oscillator under test from instrument limitations. For high-precision work, a dedicated cross-correlation phase-noise instrument may be more appropriate than a general-purpose spectrum display, but the comparison must still respect its statistical and calibration assumptions. [C9-06; C9-25]

Phase noise is thus a meeting point between instrument engineering and statistical signal processing. A beautiful close-in spectrum cannot rescue an unknown measurement configuration. The expert records the source and instrument contributions, frequency and time reference, offset range, density definition, estimation method and conditions under which the result ceases to be valid. [C9-25; C9-18]

9.27 Noise-floor measurement, gain distribution, and the difference between a displayed floor and an environmental floor

The noise floor of a spectral display is not the minimum possible signal at the antenna. It is a result of input loss, internal noise, frequency filtering, detector choice, averaging, display correction and the source conditions during observation. In a properly calibrated matched system at about 290 kelvin, the thermal reference density is approximately -174 dBm per hertz. A first-order estimate of noise power in bandwidth B is $N_{dBm} \approx -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF$, where NF is the applicable noise figure in decibels and B is the equivalent noise bandwidth. The formula presumes a stationary thermal reference and appropriate impedance. Its simplicity is useful for hand calculations; its assumptions are frequently violated in field RF surveys. [C9-01; C9-02; C9-18]

For example, with an equivalent noise bandwidth of 1 kHz and a 12 dB receiver noise figure, the simplified internal reference floor is -174 + 30 + 12 = -132 dBm. A tenfold decrease in equivalent bandwidth should reduce white-noise power by approximately 10 dB, all else being equal. If the displayed floor does not behave that way, the cause may be external interference, coloured receiver noise, an offset introduced by a detector, gain compression, or a change in the instrument's auto-coupled configuration. The operator should not force the measured number to match the thermal approximation by arbitrary offsets; the discrepancy is valuable evidence about the measurement system. [C9-07; C9-18]

Copyright 2026, James M. Atkinson

An external low-noise amplifier can improve receiver-system sensitivity only if its gain and noise performance are understood in relation to losses preceding it and to the rest of the receiver chain. Friis's cascade relation quantifies this interaction for appropriate linear matched conditions. But greater gain can reduce blocker tolerance, allowing a strong out-of-band source to create intermodulation products that resemble weak in-band emissions. A preselector can suppress those blockers at the cost of loss; moving it before the amplifier can change the noise figure and compression balance. The optimal configuration therefore depends on both weak-signal sensitivity and the maximum plausible aggregate power, rather than the desired line alone. [C9-01; C9-02; C9-06]

Displayed average noise level, often abbreviated DANL, is typically defined under specified instrument conditions. It must not be transcribed into an environmental noise measurement without the appropriate antenna factor, cable loss, external gain, impedance, detector and bandwidth corrections. A portable antenna outdoors may receive atmospheric noise, broadcast signals and impulsive man-made interference that dominate the analyser's internal reference. In a shielded chamber, the same instrument may show primarily its own system floor. Both traces can be accurate descriptions of their respective systems, but they answer different questions. [C9-07; C9-26]

A strong laboratory procedure repeats noise measurements with a matched termination, with an approved calibrated noise source, with the actual antenna path, and with controlled changes to input attenuation. Each observation should record whether the front end was preamplified, the reference plane, the instrument temperature and the stability of the sample clock or local oscillator where relevant. The resulting report compares

Copyright 2026, James M. Atkinson

expected and observed noise changes in linear units and decibels. It also documents any discrete spurs or nonstationary impulses, since a single median-noise number may conceal precisely the phenomenon a TSCM survey seeks to understand. [C9-01; C9-18]

A negative result should finally be expressed as a bounded sensitivity statement. The investigator can report that no component exceeding a stated level under defined dwell, detector and bandwidth conditions was observed at the measured plane during a named interval. The result does not warrant a universal statement that no emitter exists, especially if the instrument swept intermittently, its input experienced compression, or the emission could have been outside the selected band. [C9-26; C9-27]

The numerical value labelled resolution bandwidth is not, by itself, the bandwidth that multiplies a white-noise spectral density. For a filter with power transfer response |H(f)| squared and passband reference f_0, define the equivalent noise bandwidth as B_ENBW = [integral |H(f)| squared df]/|H(f_0)| squared; the result is measured in hertz. The 3 dB bandwidth characterises a pair of amplitude-response points, whereas B_ENBW characterises admitted noise power relative to the stated reference gain. One documented family of near-Gaussian analyser filters has B_ENBW approximately 1.05 to 1.13 times its nominal 3 dB bandwidth. A nominal 10 kHz filter in that family therefore admits the same white-noise power as a 10.5 to 11.3 kHz ideal rectangular filter. That manufacturer- and implementation-conditioned range cannot be transferred automatically to a digital window, an EMI receiver or an arbitrary IF filter.

For the specified near-Gaussian filter family, a density calculation normalised to 10,000 Hz from observations made over 10,500 to 11,300 Hz

Copyright 2026, James M. Atkinson

uses the power correction 10 log10(10,000/B_ENBW), giving approximately −0.212 to −0.531 dB. The correction changes when the actual response departs from the assumed shape. It is conceptually distinct from the change caused by averaging a logarithmic envelope instead of linearly averaged power. Thus one must identify, in order, the analogue or digital filter response, detector statistic, order of averaging, gain calibration and final display transformation. A 2.5 dB logarithmic-noise correction is conditional upon the particular Rayleigh/Gaussian and detector model used in the relevant instrument guidance; neither that figure nor the bandwidth adjustment is a universal property of a trace labelled dBm.

9.28 Multiple comparisons, threshold design, and weak-line detection in a searched spectrum

A spectrum search usually evaluates many frequencies, time intervals, antenna positions and instrument configurations. Even when the background model is correct, selecting the largest observed excursion creates a different statistical problem from testing one pre-registered frequency. This selection effect must be addressed whenever a claim relies on a weak peak near the noise floor. A rule declaring a detection whenever one periodogram ordinate exceeds a threshold will generate false alarms whose expected number increases with the number of effectively independent tests. Correlation between neighbouring FFT bins, overlap between time records, and searching different window functions complicate the count, but they do not make the issue disappear. [C9-18; C9-19; C9-24]

If a single noise-only test exceeds its threshold with probability α, then M independent such tests have probability 1 - (1 - α)^M of at least one exceedance. For α = 0.001 and M = 1,000 independent tests, the family-wise probability is approximately 0.632. Thus, a criterion that sounds very stringent per bin can become weak when applied to a large blind search. The independence assumption is deliberately simplified; it serves to reveal the scale of the problem. In real spectra, leakage couples nearby bins and may reduce the effective number of tests, while repeated choices of time windows, detectors and thresholds may increase the true search space. A defensible assessment should state which tests were planned in advance and how selection was handled. [C9-18; C9-20]

Copyright 2026, James M. Atkinson

A practical approach uses discovery and confirmation. The discovery phase may employ sensitive detectors, broad searches, multiple windows and adaptive analysis in order to find candidate signals. The analyst records the full discovery history and does not describe its resulting peak as an independently validated probability statement. The confirmation phase then fixes the frequency band, window, detector, threshold, sample duration and calibration before examining new data. If independent data are unavailable, the report should state the limitation and use appropriately cautious descriptive language. The distinction is particularly important when a weak line is later used to justify an intrusive investigative conclusion. [C9-18; C9-26]

Detection also depends on the target class. A continuous narrow carrier is well suited to long coherent integration if its phase and frequency are sufficiently stable. A frequency-hopping emission may require time-frequency search, greater instantaneous bandwidth and a detector that integrates a trajectory rather than one stationary bin. A short chirp has a different time-frequency footprint; a pulsed emission with uncertain occurrence time calls for windowed or triggered approaches that respect its duty factor. There is no universal best threshold without a target model and a cost assigned to missed detections and false alarms. [C9-10; C9-12; C9-28]

A rigorous synthetic exercise begins with a fixed noise model and a seeded pseudorandom generator. Students inject a line at a known frequency and amplitude into only some trials; they then run two detection algorithms over pre-specified windows. They construct empirical receiver-operating-characteristic curves relating probability of detection and false alarm, and assess sensitivity to record length, RBW, input attenuation and phase

Copyright 2026, James M. Atkinson

instability. Each class must distinguish the true positive rate measured under the laboratory model from the confidence that an unknown field signal has any particular provenance. Instrument detection is only one link in the evidentiary chain. [C9-18; C9-24]

Where regulatory or compliance thresholds are involved, the test configuration and acceptance limit may be specified by a standard rather than selected solely by statistical optimisation. The operator must then respect the required detector, bandwidth, dwell and test method. A research threshold that is excellent for discovery may not correspond to a legally defined compliance detector. Conversely, a compliance scan may not be optimised for finding the rarest weak emission. Reporting should identify the governing standard where applicable and separate its prescribed decision rule from exploratory spectral analysis. [C9-26; C9-29]

Copyright 2026, James M. Atkinson

9.29 Parametric spectral estimation: when a model buys apparent resolution

A conventional periodogram deliberately makes few assumptions about the observed process. Parametric spectral estimation proceeds differently. It supposes that the data are adequately described by a particular family of stochastic or deterministic models and then estimates the parameters of that family. In an autoregressive model of order p, the present value of a stationary sequence is expressed as a weighted sum of p preceding values plus a driving innovation. If the coefficients are a_1 through a_p and the innovation variance is σ_e squared, the resulting spectral density has the rational form $S_x(f) = \sigma_e^2$ divided by the squared magnitude of 1 minus the sum of $a_k \exp(-j2\pi fk/f_s)$. This formula may produce a smooth, sharply defined estimate using a comparatively short record. It does not create additional experimental observations. Its apparent precision depends upon the adequacy of the chosen model, its stationarity assumptions, the order p and the numerical conditioning of the estimation. [C9-24]

The elementary autoregressive estimator is often obtained through the Yule–Walker equations linking sample autocovariances to the coefficients. A least-squares estimate instead minimises one-step prediction residuals. Burg's method is a forward-and-backward prediction procedure that imposes a stable autoregressive structure under appropriate conditions; it can be useful for short records, but it is not immune to producing artificial narrow peaks when the model order is excessive. Levinson–Durbin recursion exploits the Toeplitz structure of the autocorrelation equations and gives an efficient route to successive model orders. All three

Copyright 2026, James M. Atkinson

approaches can return different spectra from the same finite record because they optimise different finite-sample objectives and handle boundary data differently. They must be reported with the model order, the covariance or prediction method, regularisation, residual diagnostics and stability test. [C9-24]

Moving-average models construct a stationary process by filtering an innovation through a finite impulse-response polynomial; autoregressive-moving-average models combine poles and zeros. A line-like peak in a fitted AR spectrum is not necessarily evidence for an external oscillator. A broadband process passing through a resonant RF front end can produce a similar spectral shape, while an unmodelled transient can force the parameter estimator to fit a fictitious narrow resonance. The analyst should therefore test whiteness of the residual innovations, examine the prediction error on held-out samples, inspect sensitivity to model order, and compare a nonparametric density estimate produced from the same calibrated raw data. When the fitted and nonparametric spectra disagree, the difference is evidence of model sensitivity, not a reason to select whichever curve looks more impressive. [C9-18; C9-24]

This distinction matters in forensic receiver work. A short acquisition contaminated by receiver gain changes, clock discontinuities or intermittently active transmitters is not well described by a single stationary ARMA model. Rather than applying a high-order fit to the entire record, divide it into physically justified states, preserve the boundaries, and test the parametric model within each. Report negative results no more broadly than the observed states and the model actually examined. Parametric estimators belong in postgraduate treatment because their conditional

Copyright 2026, James M. Atkinson

sharpness can be valuable; their fragility belongs in that same treatment because an attractive narrow peak is not proof of a physical spectral line. [C9-24; C9-18]

Copyright 2026, James M. Atkinson

9.30 Sinusoids in noise, model order and the limits of super-resolution

Line-spectral estimation begins with a different question from density estimation: how many coherent sinusoidal components are present, what are their frequencies and complex amplitudes, and what noise model makes those estimates identifiable? A useful model is $x[n] = \sum_{k=1}^{K} c_k \exp(j2\pi f_k n/f_s) + e[n]$, where K is the number of components, c_k their complex amplitudes, f_k their frequencies and $e[n]$ a noise or interference process. The model assumes that the frequencies remain stable during the observation and that phase coherence exists over the period used for inference. If an emitter hops, chirps, changes modulation state or suffers phase discontinuity, a static sinusoidal model becomes an approximation whose validity must be demonstrated. [C9-24]

Nonlinear least squares fits the sinusoids directly and can obtain high precision when the signal-to-noise ratio, model order and starting values are favourable. The frequency parameters make the optimisation nonlinear, so local minima and component swapping must be considered. A simple FFT peak can supply an initial estimate, but one should then examine the residual spectrum and vary the starting point. The maximum-likelihood interpretation additionally requires a specified probability law for the disturbance. Under a misspecified coloured-noise model, a small residual sum of squares may coexist with a biased uncertainty statement. An estimator can be numerically repeatable and still scientifically wrong. [C9-24]

Methods commonly grouped under subspace analysis exploit the eigenstructure of a sample covariance matrix. The MUSIC method examines

Copyright 2026, James M. Atkinson

an orthogonality relation between candidate sinusoidal steering vectors and an estimated noise subspace; ESPRIT uses rotational relationships between displaced subarrays or delayed sample structures. The minimum-norm and Pisarenko approaches are historically related but have different requirements and failure modes. These methods can distinguish components closer than the nominal DFT-bin spacing when their assumptions are met, but the resolution is not guaranteed by the name of the algorithm. High coherence, small sample numbers, incorrect source count, mutual coupling, correlated noise, numerical ill-conditioning and rapid frequency drift can destroy the supposed super-resolution advantage. [C9-24]

The source-count problem must precede a claim about precisely resolved frequencies. Information criteria such as AIC or MDL, eigenvalue-gap procedures and cross-validated prediction error may suggest a model order; none replaces an experimental challenge. Where a suspected weak carrier is found beside a strong emission, perform controlled injections and compare the detection threshold with that of a windowed FFT. The conclusion should report the source-count selection method, sample count, covariance dimension, any smoothing or regularisation, the estimated frequencies, their uncertainty and whether the same candidate survives materially different estimators. High-resolution mathematical inference becomes evidentially useful only when its prerequisites can be inspected. [C9-24; C9-18]

Copyright 2026, James M. Atkinson

9.31 Filter-bank analysis, Capon spectra and aperture-dependent selectivity

A bank of bandpass filters is a physical and mathematical alternative to the familiar FFT display. Each filter produces an estimate at a selected centre frequency or frequency interval, with a defined response, equivalent noise bandwidth, group delay and settling behaviour. A conventional FFT can itself be interpreted as a bank of windowed matched filters, but more general filter-bank approaches permit adaptive weights, unequal bandwidths and time-dependent responses. That flexibility is useful when a signal occupies a narrow but shifting part of a much broader acquisition. It also requires the analyst to disclose which filter outputs were observed and when they were observed. The name of a filter does not establish that its output is a calibrated power measurement. [C9-24; C9-23]

The Capon, or minimum-variance distortionless-response, estimator chooses weights that maintain unit response to a selected steering vector while minimising estimated output power. For a complex covariance matrix R and steering vector a(f), the familiar spectral form is proportional to 1 divided by a(f)^H R^(-1) a(f), subject to the adopted normalisation. This can suppress interference and sharpen an apparent peak, but inversion of a poorly estimated covariance matrix can magnify numerical noise. Diagonal loading and other regularisation can improve stability at the cost of changing the estimator's effective response. The covariance length, loading rule, training data and sample support therefore belong in the measurement record. [C9-24]

Copyright 2026, James M. Atkinson

A Capon peak should never be mistaken for the same kind of display ordinate as a power density from a properly normalised periodogram. Adaptive cancellation can suppress energy that a conventional display shows, or create high apparent contrast at frequencies selected by the covariance geometry. An analyst comparing the methods should specify whether each ordinate expresses power, inverse adaptive residual power, a pseudo-spectrum, or another statistic. An overlay without those definitions can mislead even a highly educated reader. Equally, the use of a common training record to select and then validate an adaptive filter makes the resulting confidence claim circular unless the selection uncertainty is accounted for. [C9-24; C9-18]

For the laboratory, use a weak line adjacent to a stronger interferer, repeat the acquisition with controlled phase and frequency drift, and compare a Hann-window estimate, a fixed filter bank and a loaded adaptive estimator. Measure false detections on independent noise-only records and record the point at which the adaptive method becomes unstable. This experiment turns an appealing mathematical method into a demonstrated engineering trade-off. [C9-24]

Copyright 2026, James M. Atkinson

9.32 Frequency stability, oscillator noise and the distinction between drift and random phase

A spectral peak with a broad skirt can arise from the transmitter, the receiver local oscillator, modulation, vibration, amplitude noise, or a combination of mechanisms. A single spectrum therefore rarely identifies the physical origin of close-in noise. For single-sideband phase noise L(f_m), expressed in dBc/Hz at offset f_m from a carrier, the usual small-angle approximation relates L(f_m) to one-half the one-sided phase-fluctuation density, subject to convention. The instrument's own reference and conversion chain can contribute noise. A measurement report must state the offset frequency, measurement bandwidth, carrier level, detector or cross-correlation configuration, instrument floor and correction method. [C9-06; C9-25]

Time-domain frequency stability methods answer related but different questions. Fractional frequency deviation y(t) is the instantaneous frequency error divided by nominal frequency. Allan variance forms the expectation of one-half the squared difference between adjacent average frequency deviations over an averaging interval tau. Modified Allan variance, total variance and other statistics alter the weighting and confidence characteristics to improve discrimination among noise types or finite-record behaviour. A spectrum measured over seconds and an Allan deviation measured over hours cannot be treated as duplicate descriptions of the same phenomenon without an explicit transformation and compatible noise model. The record length, sample interval, gaps, outlier handling and type of variance estimator must all be reported. [C9-25]

Copyright 2026, James M. Atkinson

An FFT with an unusually narrow resolution bin can make a drifting oscillator look like a broader stationary source, because a finite observation integrates motion across the selected window. Shorter records may resolve the oscillator's instantaneous carrier more clearly but have less frequency discrimination. A spectrogram reveals motion over time yet introduces its own time-frequency smoothing. When an attribution depends upon oscillator stability, compare complementary windows and independent references, then ask whether the observed phase noise could be the receiver's own. A reference oscillator and phase detector may provide deeper phase-noise measurement than a direct spectrum trace, but only when the reference's noise and loop transfer functions are established. [C9-06; C9-25]

The instructional test should include a calibrated synthesiser and a second traceable reference, with intentionally programmed small frequency steps and controlled phase perturbations. Students calculate frequency error, reproduce a phase-noise offset value from the appropriate linear quantities, and compare Allan deviation under at least two averaging times. They must then explain why an impressive narrow spectral trace is not proof of long-term timekeeping accuracy. [C9-25]

Copyright 2026, James M. Atkinson

9.33 Spurious-response searches, hybrid sweep-and-FFT acquisition, and search-time economics

A spurious-emissions search normally combines a very wide frequency range with a stringent amplitude threshold. A narrow resolution bandwidth may be needed to distinguish low-level components from noise, while the same narrow bandwidth lengthens a classical swept measurement because each frequency position must be visited and the filter allowed to settle. This is an engineering scheduling problem rather than simply a request for a high-resolution display. Some modern instruments accelerate portions of the search by processing wide instantaneous bands through FFT techniques and then stepping or sweeping the front end to cover frequencies outside that band. The resulting performance depends upon the instantaneous processing bandwidth, filter skirts, overlap between tuning positions, detector behaviour and final validation method. [C9-08; C9-01]

There are at least three distinct time scales. Acquisition time is the time for which the input is actually sampled at a given frequency. Processing time is the interval required to transform, detect and store that acquisition. Scan time is the elapsed wall-clock interval to cover the requested search range, including tuning, settling, data transfer and any verification rescan. An instrument may reduce processing time while leaving blind intervals between disjoint tuning positions; it may also maintain continuous acquisition within one processed band yet pause when shifting the analogue front end. The analyst should record each time scale separately when asserting that a frequency range was continuously monitored. [C9-08; C9-10]

Copyright 2026, James M. Atkinson

A defensible spurious search therefore adopts two stages. The initial discovery pass uses bandwidth and timing settings that cover the specified range economically, while retaining enough metadata to identify candidate responses. The confirmatory pass narrows the span, measures amplitude with the required detector and RBW, tests for internally generated mixer images or intermodulation, and repeats in a controlled input state. The candidate list must include negative results only for the actually qualified frequency-time cells. A fine-looking stitched spectrum, however complete it appears across its horizontal axis, does not prove that every frequency was observed at every instant. [C9-01; C9-08]

The laboratory should require students to measure the wall-clock search time for two methods, compute the total observable dwell per frequency interval and document any retune gaps. They should then insert a brief known carrier during a deliberately unobserved interval and confirm that the failure to record it is consistent with the declared acquisition model. This converts an instrument speed claim into an evidence-coverage statement. [C9-08; C9-10]

The frequently quoted classical sweep-time heuristic T_s proportional to S/B squared requires qualification at the architectural boundary. Here S is the searched span in hertz, B is the selected resolution-filter bandwidth in hertz, and a proportionality factor absorbs settling criterion, filter shape, detector operation and sweep strategy. It describes a class of swept-filter measurements, not a universal timing law for every modern spectral receiver. FFT-based analysis covers an instantaneous acquisition band through finite records and may stitch multiple tunings; its computational complexity, record duration, retune settling and unobserved intervals are

Copyright 2026, James M. Atkinson

separate constraints. A defensible comparison therefore records the observation time per frequency cell, the number and overlap of processed acquisitions, the computational latency and the wall-clock completion time. Neither a short displayed sweep time nor a fast FFT alone demonstrates uninterrupted interception of a transient emission.

Copyright 2026, James M. Atkinson

9.34 Pulsed RF, gating, coherent repetition and missing transient evidence

A pulsed carrier is not a steady sinusoid merely because its instantaneous frequency is fixed. Multiplication of a continuous carrier by a finite envelope convolves the carrier's spectral line with the spectrum of that envelope. A rectangular pulse of duration T produces a sinc-shaped amplitude envelope in the idealisation, with frequency features governed by the inverse pulse duration. A periodic pulse train produces a comb-like structure whose line spacing depends upon the pulse repetition frequency, while the overall envelope depends upon pulse width and shape. A short burst can therefore appear much wider than its underlying carrier modulation, and changing the pulse duty factor changes average power without necessarily changing peak envelope power. [C9-17; C9-10]

Peak and average power must be kept separate. If a transmitter emits constant power P_on for a fraction d of the wall-clock period and emits negligible power otherwise, the average power is approximately d times P_on, and the decibel difference between mean and on-state power is 10 log10(d). This relation assumes stable on-state power, a defined duty factor and an averaging interval containing enough repetitions. It does not by itself specify the result of a peak detector, an RMS detector with finite time response or a gated channel-power algorithm. A proper test distinguishes the time window over which the instrument reports power from the time window over which the physical signal exists. [C9-17; C9-06]

When bursts repeat, an instrument may synchronise and accumulate many nominally identical intervals to improve sensitivity. This is useful only if

Copyright 2026, James M. Atkinson

repetition timing, amplitude and phase are stable to the degree required by the method. A single missed sample, an unrecorded clock adjustment or an unnoticed variation of duty cycle can bias the result. If the source is a one-off emission, repetition-averaged methods are not applicable. Record the trigger source, pre-trigger samples, gate start and end, clock calibration, missing-sample flags and whether the displayed spectrum was reconstructed from one event or many equivalent events. [C9-10; C9-17; C9-28]

The classical literature remains valuable because it exposes the measurement physics independently of modern touchscreen conveniences. Its analytical rules must nevertheless be translated through the modern instrument's actual digital IF filters, triggers and detector conventions. A historical pulsed-RF application note can justify a method to investigate, not the uncritical reuse of settings on an instrument with a different acquisition architecture. [C9-15; C9-17; C9-01]

Copyright 2026, James M. Atkinson

9.35 EMI receivers, quasi-peak detection, time-domain scan and measurement compliance

Electromagnetic-compatibility measurements and general-purpose spectrum discovery are related but not identical enterprises. Compliance receivers may use prescribed bandwidths, detector time constants, dwell requirements, preselection and scan procedures derived from the applicable standard. A quasi-peak detector weights repeated disturbances in a manner different from a simple peak or RMS estimator; a rapid repetition pattern may yield a different indication from an isolated impulse of the same instantaneous amplitude. This behaviour is intentional within the relevant compliance regime. An analyst must not present an ordinary peak-hold trace as if it were a quasi-peak compliant result merely because the image resembles one. [C9-29; C9-06]

Time-domain scanning can accelerate the collection of wideband emissions data by capturing a broad time record and performing spectral calculations digitally. The method must still reproduce the required detector behaviour, measurement bandwidth, overload performance, scan completeness and calibration. A fast FFT is not by itself proof of regulatory equivalence. The analyst should keep the acquisition and processing contract traceable to the standard actually being applied, record any settings that were outside the standard method, and distinguish engineering diagnostics from accredited compliance measurement. [C9-29; C9-02]

A spectrogram can be particularly valuable when emissions are state-dependent: a motor drive, switching supply or digital controller may emit only during a particular phase of operation. The display permits an engineer

Copyright 2026, James M. Atkinson

to align interference events with the device state. The hazard is that the same colour image can contain spectral leakage, interpolation artifacts, nonuniform temporal weighting or gaps caused by retuning. It should therefore be accompanied by the native waveform where available, declared frequency and time scales, uncertainty or threshold basis, and a clear description of which portions of the operational cycle were actually sampled. [C9-29; C9-10]

The laboratory should compare peak, average and quasi-peak detector results on the same controlled disturbance, using a properly specified receiver or emulation whose detector parameters are known. Students must justify which measurement is appropriate for diagnosis and which might qualify for a regulatory submission. The lesson is to distinguish an instrument capability from authority to make a compliance claim. [C9-29]

Copyright 2026, James M. Atkinson

9.36 Automated monitoring, event provenance and networked spectrum-survey architecture

Continuous RF monitoring extends the spectral measurand into the temporal and operational domains. A monitoring system is no longer one instrument and one human operator. It may comprise several remotely controlled receivers, preselectors, reference clocks, antennas, storage nodes, event detectors and automated notifications. The central engineering question becomes which observations survive failures of the network, power, software and human workflow. The system must define what it means by a detection, which intervals were searched, which settings were active, which data were retained and which events were missed or deferred. An apparently complete historical dashboard can conceal long intervals of silent failure unless health status is recorded with the measurements. [C9-13; C9-14; C9-26]

A robust architecture separates the raw-observation plane from the derived-event plane. The former contains native samples or instrument traces, timestamps, equipment states and calibration records; the latter contains threshold crossings, classified features, alarms and reports. The relationship should be reversible: a reviewer must be able to follow a reported event back to the original record and reproduce the derived quantity from documented settings. If data are retained selectively, the selection criteria and dropped-event counters must be recorded as evidence, because an absent event record may mean that the event did not occur, that it was below threshold, that storage failed, or that the monitored receiver was simply not observing the frequency at the relevant moment. [C9-13; C9-26]

Copyright 2026, James M. Atkinson

Geographically distributed observations require clock-quality and frequency-reference metadata. A common time label is not necessarily proof of synchronous sampling. Propagation delay, sample-clock drift, front-end delay, cable calibration and interpolation error can all affect a comparison among receivers. The network transport may introduce variable delivery latency, which must not be confused with the physical time at which a radio event was acquired. Store the acquisition timestamp near the sampling hardware, identify its clock source and uncertainty, and preserve the original data ordering and loss masks. A later network time-synchronisation correction can be offered as a derived product, not silently substituted for the primary record. [C9-13; C9-25]

The instructional exercise is a simulated remote-monitoring outage. Students run an authorised bench signal source while a separate logger records the source duty schedule, then intentionally interrupt only the communications link to the remote receiver. They compare local acquisition, transmitted event logs and dashboard summaries, identifying exactly which evidential claims survive. The exercise teaches that a monitoring system needs both spectral competence and computer-network forensic discipline. [C9-13; C9-14]

Copyright 2026, James M. Atkinson

9.37 Higher-order spectra, spectral kurtosis and departures from Gaussian noise

Ordinary second-order spectral estimates are powerful because they characterise the distribution of variance with frequency under familiar stationarity assumptions. They do not distinguish every physically interesting process. Two signals can possess similar second-order spectra while differing substantially in phase coupling, impulsiveness, higher-order moments or modulation structure. Higher-order statistics and related techniques are therefore useful in selected diagnostic contexts, but only after the analyst has stated why the second-order model is insufficient. An abrupt burst within noise can raise fourth-order moments; a nonlinear system can create phase-coupled harmonics that are not explained by independently generated spectral lines. [C9-24; C9-18]

A bispectrum is derived from a third-order cumulant or from an expectation involving three Fourier factors whose frequencies sum according to a specified convention. Under ideal Gaussian assumptions, higher-order cumulants beyond second order vanish, so nonzero structure can indicate non-Gaussian behaviour or phase coupling. Yet finite-sample bispectral estimates can be noisy, require many averaging intervals and produce spurious peaks when the process changes during acquisition. Their normalisation, symmetries, leakage control and statistical threshold must be stated. The detection of a bispectral feature does not, without corroboration, identify the physical source or prove malicious intent. [C9-24]

Spectral kurtosis approaches examine departures from the distribution predicted for a selected noise model within time-frequency cells. Such

Copyright 2026, James M. Atkinson

measures can identify intermittent interference hidden in a broadband average, but their thresholds depend on the accumulation scheme, sample dependence, detector statistics and the assumed noise law. A receiver whose front end compresses intermittently can also create non-Gaussian artifacts. Accordingly, an apparently informative impulsiveness map should be compared with raw time samples, overload logs and an independently controlled source. [C9-18; C9-24]

An advanced laboratory can compare a Gaussian-noise record, a Gaussian record with rare injected impulses and a record passed through a controlled nonlinear element. Students compute ordinary PSDs and an appropriately calibrated higher-order statistic, then determine whether the latter adds genuine discrimination. The educational goal is not to pronounce a sophisticated statistic universally superior, but to demonstrate precisely which difference in physical behaviour it measures and under which assumptions the inference holds. [C9-24]

Copyright 2026, James M. Atkinson

9.38 Digital radiometry, quadratic spectral estimators and uncertainty budgets

Spectral estimation becomes metrology when the numerical estimator itself is treated as a source of measurement bias and uncertainty. A digital radiometer calculates spectral power from calibrated time-series samples, yet finite windows, nonideal sampling, covariance structure and processing choices can alter the estimate. One convenient mathematical framework is the quadratic form $x^H Q(f) x$, where x is a finite complex data vector and $Q(f)$ is a Hermitian estimator matrix determined by the chosen method. The conventional windowed periodogram is a special case, but other nonnegative quadratic estimators can be constructed with different bias, variance and computational cost. The critical metrological question is whether the estimator's bias relative to the intended spectrum is acceptable for the application. [C9-18]

Bias and variance trade against one another. A narrow effective analysis kernel may preserve line resolution while producing a highly variable random-power estimate; heavier smoothing may reduce variance while blending neighbouring components. The familiar mean-squared-error criterion is the sum of squared bias and variance for a scalar estimator, under a particular statistical expectation. Its minimisation depends upon the unknown or modelled signal distribution and an explicit loss function. Thus an estimator optimised for one radiometric background is not automatically optimal for a transient interference search. The operator must name the spectrum class, estimator family, training evidence and uncertainty evaluation used to justify the choice. [C9-18]

Copyright 2026, James M. Atkinson

A complete uncertainty budget should distinguish calibration uncertainty of the analogue front end, clock and sampling errors, processing bias, finite-record variance, reference-impedance uncertainty and repeatability under changed operating state. These terms are not necessarily independent. A shared reference frequency can create common errors across bins, while overlapping windows generate dependence among estimates drawn from the same record. Summing individual variances as though every term were independent can therefore produce an unrealistically narrow interval. Where correlations are significant, use an appropriate covariance expression or a validated simulation. [C9-18; C9-25]

The classroom application is to compare two windowed estimators on simulated white noise, coloured noise and a weak line. Estimate empirical bias and variance over independent realisations, then repeat the exercise when each realisation is artificially subdivided into overlapping windows. Students should explain why the increased number of plotted periodograms does not create a corresponding number of independent experiments. The instructor should insist on a written uncertainty statement tied to the actual acquisition and processing model. [C9-18]

An “optimal” spectral window is optimal only relative to an explicit estimation problem. In a quadratic estimate $x^H Q(f)x$, x is the finite sampled record and Q(f) represents the weighting and spectral measurement operator; the admissible family of Q, the assumed spectrum subspace, record length, target bandwidth and loss function delimit the optimisation. Mean-squared error balances variance against local and broadband bias, but a taper that suppresses remote leakage can also widen the response to neighbouring tones or reduce the effective number of independent

Copyright 2026, James M. Atkinson

estimates. The 2024 digital-radiometry analysis by Gu, Rezac, Lu and Kuester studies precisely such conditional bias-and-variance choices. It does not establish one universally best taper for intermittent emissions, weak-line searches, coherent amplitude measurement and stationary radiometric noise simultaneously. Every assertion of optimum performance should therefore state the signal class, prior model, estimator family, reference response and the independent experiment used to verify the claimed advantage.

Copyright 2026, James M. Atkinson

9.39 Spectrum-monitoring surveys, occupancy statistics and evidential limits

Spectrum monitoring is commonly undertaken to answer questions about occupancy, interference, use of allocated frequencies or the compliance of observed emissions with a defined regulatory regime. These questions are not identical. A momentary signal detection may establish that energy above a particular threshold was observed at a frequency and time, but it does not necessarily identify a transmitter, infer a communication service or establish an ongoing violation. The survey design must distinguish frequency coverage, geographic coverage, observation periods, antenna selection, receiver sensitivity and threshold policy. Administrative and legal findings require an authority and method appropriate to the jurisdiction. [C9-26; C9-27]

A channel-occupancy statistic might be written as the number of time-frequency cells meeting a declared detection rule divided by the number of cells actually observed. This expression is meaningful only if the denominator excludes intervals when the receiver was not collecting valid samples. If a scanned receiver revisits a channel once every several seconds, a brief transmission may occur entirely between visits. Counting the intervening time as verified unoccupied time would underestimate occupancy. A survey should therefore report duty-cycle sensitivity, gap policy, confidence bounds and the meaning of any interpolation between measured intervals. [C9-26; C9-10]

When spectral observations support interference resolution, the analyst should seek repeatability under changes that can distinguish receiver

Copyright 2026, James M. Atkinson

artifacts from external sources. Suitable challenges include path attenuation, input termination, preselector change, alternate receiver, reference-clock substitution and controlled source isolation. A legitimate external signal may change under propagation and antenna conditions; an internally generated spur may respond primarily to receiver tuning or overload state. The resulting case record should preserve both positive findings and unsuccessful challenges rather than selecting only the images that support an initial theory. [C9-01; C9-26]

A university or military-school field exercise may compare a conducted laboratory reference, an RF-isolated chamber and an authorised outdoor range, with emission permissions and safety controls established beforehand. Students should formulate the limits of any occupancy claim, explain why a frequency plan matters, and demonstrate that the forensic trace of a reported event is reproducible from a known recording. This is the link between mathematical Chapter 9 and operational monitoring doctrine. [C9-26; C9-13]

Copyright 2026, James M. Atkinson

9.40 Ten fully specified spectral-estimation exercises with numerical checks

Example 1: noise-bandwidth scaling. Assume the equivalent noise bandwidth changes from 100 Hz to 1,000 Hz while the density of stationary white noise is unchanged. The expected ratio of admitted noise powers is 1,000/100 = 10. In decibels the change is 10 log10(10) = 10 dB. The result depends on equivalent noise bandwidth rather than a filter-label convention and is not valid without qualification for a coherent tone. [C9-01; C9-23]

Example 2: record duration and nominal bin spacing. For a sample rate f_s = 2,000,000 samples/s and a record of N = 100,000 samples, the duration is $T = N/f_s = 0.05$ s and the unpadded DFT-bin spacing is $\Delta f = f_s/N = 20$ Hz. Padding the record to 200,000 points makes the displayed interpolation grid 10 Hz, but it does not double the physical observation duration or create independent 10 Hz resolution. [C9-23]

Example 3: coherent-gain correction. Consider a sinusoidal component whose sampled window has coherent gain $G_c = 0.5$. If the reported raw complex DFT amplitude is 0.4 V by the selected two-sided convention, the corrected coherent amplitude is 0.4/0.5 = 0.8 V. The operation requires a stable tone near the assumed bin and must not be reused to normalise random noise density. [C9-20; C9-23]

Example 4: duty-cycle power. A device emits at 10 mW only during 2% of a sufficiently long averaging interval. The mean power is approximately 0.02 × 10 mW = 0.2 mW, or 10 log10(0.2) = -6.99 dBm. The on-state power is +10 dBm. The difference, approximately 16.99 dB, reflects duty factor and does not itself describe a peak detector's response. [C9-17]

Copyright 2026, James M. Atkinson

Example 5: independent-record averaging. If eight independent exponential noise-power periodograms have the same mean μ and variance μ^2, their arithmetic mean has variance $\mu^2/8$. Under the idealised model the relative standard deviation becomes 1/sqrt(8) ≈ 0.354. If the records overlap and are correlated, the true variance reduction is smaller and depends upon the covariance among estimates. [C9-19; C9-18]

Example 6: window overlap accounting. For N = 2,048 samples per FFT and hop H = 512 samples, the overlap fraction is 1 - 512/2,048 = 0.75, or 75%. At sample rate f_s = 10.24 MS/s, the nominal transform initiation rate is f_s/H = 20,000 per second. This does not establish that the analogue front end, memory or processor is gap-free; those components require independent verification. [C9-10; C9-12]

Example 7: marker difference. A first marker lies at 433.920 MHz with amplitude -41.2 dBm and a second at 434.350 MHz with amplitude -37.8 dBm. The frequency difference is 0.430 MHz = 430 kHz. The amplitude difference is (-37.8) - (-41.2) = +3.4 dB. These are relative display values until path corrections and uncertainties are evaluated. [C9-01; C9-06]

Example 8: calibration-plane correction. An analyser measures -65 dBm at its input, and an independently characterised cable presents 2.5 dB insertion loss between the declared source terminal and that input. Assuming compatible impedance and no additional intervening gain, the source-terminal estimate is -65 + 2.5 = -62.5 dBm. If an external amplifier of 10 dB precedes the same cable, the corresponding source-plane correction changes; the whole path must be recorded in order. [C9-01; C9-02]

Copyright 2026, James M. Atkinson

Example 9: frequency-error fraction. A synthesiser set to 1 GHz is measured 10 Hz high against a qualified reference. The fractional frequency error is y = 10 / 1,000,000,000 = 1 × 10^-8. This number represents a particular measurement interval, not an Allan deviation over all averaging times or a phase-noise specification. [C9-25]

Example 10: observed-time occupancy. An instrument observes a channel for 300 valid seconds across a 600-second wall-clock survey, and valid cells above threshold sum to 45 seconds. Occupancy relative to observed time is 45/300 = 15%. A naïve 45/600 = 7.5% statement would misclassify the unobserved half of the survey as empty. The report must disclose the scan coverage and any time-weighting assumptions before presenting an occupancy estimate. [C9-26]

Copyright 2026, James M. Atkinson

Chapter Summary

FFT analysis is an estimator built from finite records. Window, averaging, synchronization, and nonstationarity controls determine whether spectral structure is environmental, processing-induced, or shared through the instrument chain.

Model 9W separates coherent line amplitude from noise-density scaling by using the actual window coefficients and their different sums. Correct side conventions preserve DC and Nyquist contributions. Zero padding refines the evaluation grid without adding observations or narrowing the window response. Exact energy closure checks normalization while retaining the window's position-dependent weighting of a transient.

Model 9C requires paired records, compatible scaling and common nonnegative weights. Its coherence bound and least-squares residual describe that finite construction. Conjugation determines phase sign; shared disturbances, cancellation and changing states limit causal interpretations. A single nonzero pair fits perfectly, and an SNR interpretation requires additional justified assumptions about the input and disturbance.

A defensible result preserves samples, preprocessing, coefficient vectors, timing and channel calibration with its plots. Compare alternate windows and inspect event-resolved data when averaging hides activity. Validate the intended estimator on known signals and held-out observations. Acquisition continuity and usable event coverage remain separate requirements that favorable spectral arithmetic cannot establish.

Chapter 9 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C09-MCQ-001. What directly supports an FFT spectral estimate?

A. A window-independent picture of the source

B. A continuous observation of every possible frequency

C. A finite sampled record with declared processing

D. An assumption that every input is periodic

Answer: C. Record duration, sampling, window, and processing condition the estimate. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Why the selected alternative fits: A finite sampled record with declared processing.

Distinguishing consideration: compare this with option A, “A window-independent picture of the source”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Discrete Records and Spectral Estimates.

Review: Chapter 9 — Discrete Records and Spectral Estimates.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-002. An unpadded 4096-sample record is acquired at 40960 samples per second. What is its nominal bin spacing?

A. 5 Hz

B. 100 Hz

C. 10 Hz

D. 20 Hz

Answer: C. Unpadded spacing is sample rate divided by sample count, here 40960/4096. Source: §9.8 Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation (p. 5073)

Why the selected alternative fits: 10 Hz.

Distinguishing consideration: compare this with option A, “5 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Review: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-003. Which parameter determines the represented Nyquist interval for a sampled record?

A. Coherent window gain alone

B. Sample rate

C. Zero-padding length alone

D. Number of averages alone

Answer: B. Record length affects bin spacing; sample rate sets the represented Nyquist interval. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Why the selected alternative fits: Sample rate.

Distinguishing consideration: compare this with option A, “Coherent window gain alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Discrete Records and Spectral Estimates.

Review: Chapter 9 — Discrete Records and Spectral Estimates.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-004. An observed tone does not complete an integer number of cycles in the record. Which inference is unsafe?

A. The finite window influences its spectrum

B. Its energy must appear in only one DFT bin

C. Its apparent sidelobes depend on the window

D. Its peak can lie between displayed bins

Answer: B. A non-bin-centered component generally produces a distributed finite-window response. Source: §9.2 Spectral Leakage and Window Selection (p. 5027)

Why the selected alternative fits: Its energy must appear in only one DFT bin.

Distinguishing consideration: compare this with option A, “The finite window influences its spectrum”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Spectral Leakage and Window Selection.

Review: Chapter 9 — Spectral Leakage and Window Selection.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-005. Why inspect time samples in addition to one transform?

A. A single spectrum can represent a tone, drift, transient, or windowed fragment

B. A transform always identifies the time of every event uniquely

C. A second view proves that clipping never occurred

D. The time record removes all window corrections

Answer: A. Time inspection helps distinguish constructions that can have similar spectral displays. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Why the selected alternative fits: A single spectrum can represent a tone, drift, transient, or windowed fragment.

Distinguishing consideration: compare this with option B, “A transform always identifies the time of every event uniquely”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Discrete Records and Spectral Estimates.

Review: Chapter 9 — Discrete Records and Spectral Estimates.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-006. Which retained record supports later checking of acquisition clipping?

A. Original samples and overflow flags with acquisition parameters

B. Only the maximum displayed spectral level

C. Only a window name without sample values

D. Only a normalized spectrum image

Answer: A. Native samples and flags retain evidence that a spectral image may hide. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Why the selected alternative fits: Original samples and overflow flags with acquisition parameters.

Distinguishing consideration: compare this with option B, “Only the maximum displayed spectral level”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Discrete Records and Spectral Estimates.

Review: Chapter 9 — Discrete Records and Spectral Estimates.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-007. What is a characteristic rectangular-window tradeoff?

A. Automatic rejection of all negative-frequency images

B. Low sidelobes and no scalloping for every frequency

C. Narrow main lobe with relatively high sidelobes for off-bin components

D. A main lobe that narrows when zeros are appended

Answer: C. The rectangular window can separate coherent tones well but leaks strongly for off-grid components. Source: §9.2 Spectral Leakage and Window Selection (p. 5027)

Why the selected alternative fits: Narrow main lobe with relatively high sidelobes for off-bin components.

Distinguishing consideration: compare this with option A, “Automatic rejection of all negative-frequency images”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Spectral Leakage and Window Selection.

Review: Chapter 9 — Spectral Leakage and Window Selection.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-008. What normally accompanies reduced sidelobes from tapering?

A. Unchanged main-lobe width with no correction changes

B. A wider main lobe and altered amplitude/noise normalization

C. A guarantee that nearby tones are resolved

D. Elimination of the finite-record duration limit

Answer: B. Tapering redistributes the window response; lower sidelobes have costs relevant to the measurand. Source: §9.2 Spectral Leakage and Window Selection (p. 5027)

Why the selected alternative fits: A wider main lobe and altered amplitude/noise normalization.

Distinguishing consideration: compare this with option A, “Unchanged main-lobe width with no correction changes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Spectral Leakage and Window Selection.

Review: Chapter 9 — Spectral Leakage and Window Selection.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-009. Which criterion should guide window selection?

A. The largest zero-padded transform regardless of record length

B. The intended amplitude, noise, separation, or transient measurement

C. The greatest possible displayed peak alone

D. One window name used for every measurement

Answer: B. No window is universally best; its tradeoffs serve a declared question.

Source: §9.2 Spectral Leakage and Window Selection (p. 5027)

Why the selected alternative fits: The intended amplitude, noise, separation, or transient measurement.

Distinguishing consideration: compare this with option A, “The largest zero-padded transform regardless of record length”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Spectral Leakage and Window Selection.

Review: Chapter 9 — Spectral Leakage and Window Selection.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-010. Why process the same samples with two different windows as a challenge?

A. The two outputs become independent acquisitions

B. It doubles the physical observation duration

C. A component and leakage from a stronger component can respond differently

D. Agreement proves a unique external source

Answer: C. The controlled processing change probes leakage interpretation without creating new observations. Source: §9.2 Spectral Leakage and Window Selection (p. 5027)

Why the selected alternative fits: A component and leakage from a stronger component can respond differently.

Distinguishing consideration: compare this with option A, “The two outputs become independent acquisitions”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Spectral Leakage and Window Selection.

Review: Chapter 9 — Spectral Leakage and Window Selection.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-011. Why does coherent-tone normalization use the sum of weights rather than their squared sum?

A. Tone powers from all samples are necessarily independent

B. The window's noise bandwidth equals every bin spacing

C. Coherently aligned amplitudes add before squaring

D. The square sum is always zero for a coherent tone

Answer: C. The coherent tone produces amplitude times S_1; white-noise covariance instead leaves S_2 in expected squared magnitude. Source: §9.3.1 Define the record before interpreting the display (p. 5029)

Why the selected alternative fits: Coherently aligned amplitudes add before squaring.

Distinguishing consideration: compare this with option A, “Tone powers from all samples are necessarily independent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the record before interpreting the display.

Review: Chapter 9 — Define the record before interpreting the display.

V011-C09-MCQ-012. Which window sum enters the white-noise expected squared transform magnitude?

A. Only the square of the sum S_1

B. The maximum window coefficient alone

C. The count of padded zeros

D. The sum of squared weights S_2

Answer: D. Uncorrelated sample cross terms vanish, leaving variance times the squared-weight sum. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: The sum of squared weights.

Distinguishing consideration: compare this with option A, “Only the square of the sum”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

V011-C09-MCQ-013. With voltage samples and dimensionless weights, what are the units of the unnormalized windowed DFT coefficient?

A. Volts

B. Volts per hertz

C. Watts

D. Volts squared per hertz

Answer: A. The finite sum changes scale but introduces no time or frequency unit factor. Source: §9.3.1 Define the record before interpreting the display (p. 5029)

Why the selected alternative fits: Volts.

Distinguishing consideration: compare this with option B, “Volts per hertz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the record before interpreting the display.

Review: Chapter 9 — Define the record before interpreting the display.

V011-C09-MCQ-014. What condition permits the density denominator in Model 9W?

A. S_1 exactly zero only

B. S_2 greater than zero

C. The transform length equal to one

D. Every weight equal to one

Answer: B. A nonzero squared-weight sum and positive sample rate define density even when coherent gain is zero. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: greater than zero.

Distinguishing consideration: compare this with option A, “exactly zero only”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

V011-C09-MCQ-015. What additional condition is required for the model's coherent-gain normalization?

A. All frequencies confined to DC

B. All samples statistically independent

C. A Gaussian amplitude distribution

D. S_1 not equal to zero

Answer: D. Division by S_1 is undefined for a zero-sum window even if density normalization is valid. Source: §9.3.1 Define the record before interpreting the display (p. 5029)

Why the selected alternative fits: not equal to zero.

Distinguishing consideration: compare this with option A, “All frequencies confined to DC”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the record before interpreting the display.

Review: Chapter 9 — Define the record before interpreting the display.

V011-C09-MCQ-016. A bin-centered complex tone has coefficient a times S_1. How is its complex amplitude recovered?

A. Divide by the padded transform length

B. Divide that coefficient by S_1

C. Divide by S_2 regardless of S_1

D. Double its magnitude and discard phase for every signal

Answer: B. The stated complex-tone derivation uses the coherent weight sum and retains complex amplitude. Source: §9.3.1 Define the record before interpreting the display (p. 5029)

Why the selected alternative fits: Divide that coefficient by.

Distinguishing consideration: compare this with option A, “Divide by the padded transform length”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the record before interpreting the display.

Review: Chapter 9 — Define the record before interpreting the display.

V011-C09-MCQ-017. When is twice the positive-bin magnitude divided by the magnitude of S_1 an exact real-sinusoid peak amplitude in the stated derivation?

A. Whenever S_2 is positive regardless of the image

B. Whenever the tone is coherent for any arbitrary window and bin

C. Whenever a one-sided display is selected

D. When the frequency condition holds and the negative-image term vanishes

Answer: D. The real signal has a negative-frequency image; its window contribution must vanish or be negligibly bounded. Source: §9.3.1 Define the record before interpreting the display (p. 5029)

Why the selected alternative fits: When the frequency condition holds and the negative-image term vanishes.

Distinguishing consideration: compare this with option A, “Whenever is positive regardless of the image”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the record before interpreting the display.

Review: Chapter 9 — Define the record before interpreting the display.

V011-C09-MCQ-018. Why are DC and the even-length Nyquist bin not ordinary positive-frequency sinusoid bins?

A. Their voltages must always be zero

B. They do not have distinct opposite-frequency partners to fold

C. They always require the same doubling as interior bins

D. They have no contribution to mean square

Answer: B. Doubling those endpoints would count their contributions twice. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: They do not have distinct opposite-frequency partners to fold.

Distinguishing consideration: compare this with option A, “Their voltages must always be zero”; that competing statement does not meet the question’s stated requirement.

V011-C09-MCQ-025. What covariance condition gives expected D_2 equal to variance divided by sample rate?

A. Zero-mean samples with zero off-diagonal covariance and common variance

B. Any colored covariance with the same diagonal variance

C. Any deterministic tone regardless of window

D. Every sample identical to the first

Answer: A. The white covariance makes the squared-transform cross terms vanish.

Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: Zero-mean samples with zero off-diagonal covariance and common variance.

Distinguishing consideration: compare this with option B, “Any colored covariance with the same diagonal variance”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Noise density uses a different denominator.

V011-C09-MCQ-026. Is Gaussianity necessary for the model's expected white-noise density calculation?

A. Yes, without it Parseval fails

B. No, because no covariance assumption is needed

C. No, the stated second-order covariance is sufficient

D. Yes, otherwise every cross term is nonzero

Answer: C. The expectation uses means and covariances, not the full Gaussian distribution. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: No, the stated second-order covariance is sufficient.

Distinguishing consideration: compare this with option A, “Yes, without it Parseval fails”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Noise density uses a different denominator.

V011-C09-MCQ-027. For a real record, how are interior positive-frequency density values converted to a one-sided display?

A. Double every retained bin including endpoints

B. Double them while retaining DC and even-length Nyquist unchanged

C. Discard negative frequencies without any adjustment

D. Halve the interior bins and double endpoints

Answer: B. Correct folding retains total finite-record energy without double-counting endpoints. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: Double them while retaining DC and even-length Nyquist unchanged.

Distinguishing consideration: compare this with option A, “Double every retained bin including endpoints”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

V011-C09-MCQ-028. For odd sample count, how is the highest retained positive-frequency bin treated?

A. It is never doubled because it is last on the display

B. It is divided by two because no negative partner exists

C. It is discarded as an undefined frequency

D. It is doubled because it is not a Nyquist endpoint

Answer: D. Odd-length real records have no Nyquist sample; the highest retained positive bin has a distinct partner. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why the selected alternative fits: It is doubled because it is not a Nyquist endpoint.

Distinguishing consideration: compare this with option A, “It is never doubled because it is last on the display”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Noise density uses a different denominator.

V011-C09-MCQ-031. What does the integrated density equal for an arbitrary finite record in Model 9W?

A. The squared-window-weighted mean square divided by S_2

B. Always the unweighted sample mean square

C. Always the square of the sample mean

D. Only the mean square of a periodic extension

Answer: A. The exact sum retains window-position weighting; it need not equal unweighted record energy per sample. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why the selected alternative fits: The squared-window-weighted mean square divided by.

Distinguishing consideration: compare this with option B, “Always the unweighted sample mean square”; that competing statement does not meet the question’s stated requirement.

V011-C09-MCQ-047. A 0.100 V peak sinusoid is across a stipulated 50 ohm resistive load. What is its mean power?

A. 0.000200 W

B. 0.000050 W

C. 0.005 W

D. 0.000100 W

Answer: D. Its mean square is peak squared divided by two; dividing 0.005 V squared by 50 ohms gives 0.0001 W. Source: §9.3.4 Ten worked applications of the normalization model (p. 5039)

Why the selected alternative fits: 0.000100 W.

Distinguishing consideration: compare this with option A, “0.000200 W”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of the normalization model.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-MCQ-048. A 1 V impulse is at the center of a 16-point periodic Hann record with S_2 = 6. What is the integrated windowed density?

A. One sixth V squared

B. One sixteenth V squared

C. One V squared

D. One eighth V squared

Answer: A. The squared center weight is one, so weighted energy divided by S_2 is 1/6. Source: §9.3.4 Ten worked applications of the normalization model (p. 5039)

Why the selected alternative fits: One sixth V squared.

Distinguishing consideration: compare this with option B, “One sixteenth V squared”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of the normalization model.

Review: Chapter 9 — Ten worked applications of the normalization model.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-049. What does subtracting the mean do to the constant-record DC example?

A. It repairs a missing factor-of-two endpoint correction

B. It leaves the original DC measurement unchanged

C. It converts DC to a Nyquist component

D. It removes that processed DC component

Answer: D. Preprocessing changes the measurand; it must be documented rather than treated as normalization. Source: §9.3.4 Ten worked applications of the normalization model (p. 5039)

Why the selected alternative fits: It removes that processed DC component.

Distinguishing consideration: compare this with option A, “It repairs a missing factor-of-two endpoint correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of the normalization model.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-MCQ-050. Why is specifying only the name Hann insufficient for short records?

A. Every Hann implementation uses random coefficients

B. The difference disappears exactly for all N greater than two

C. The name specifies only a detector, not a window

D. Periodic and endpoint-symmetric coefficient vectors have different sums

Answer: D. The generation convention matters appreciably at short N and must be unambiguous. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why the selected alternative fits: Periodic and endpoint-symmetric coefficient vectors have different sums.

Distinguishing consideration: compare this with option A, “Every Hann implementation uses random coefficients”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

V011-C09-MCQ-051. Which average combines squared spectral magnitudes for stationary random-power estimates?

A. Averaging individual logarithmic spectral levels

B. Taking only the largest record

C. Linear power averaging

D. Vector averaging of complex coefficients

Answer: C. Power averaging addresses the power statistic; complex averaging preserves phase and answers a different question. Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: Linear power averaging.

Distinguishing consideration: compare this with option A, “Averaging individual logarithmic spectral levels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-052. What does vector averaging retain that power averaging discards?

A. A guarantee of external source origin

B. An unbiased occurrence probability

C. Coherent phase

D. Every independent noise realization separately

Answer: C. A coherent component can survive complex averaging while uncorrelated components tend to cancel under suitable conditions. Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: Coherent phase.

Distinguishing consideration: compare this with option A, “A guarantee of external source origin”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-MCQ-053. How does exponential averaging differ from equal-weight record averaging?

A. It necessarily averages logarithms

B. It selects only record maxima

C. It makes overlapping records independent

D. It gives greater weight to recent records

Answer: D. The temporal weights differ; the name does not itself imply a logarithmic estimator. Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: It gives greater weight to recent records.

Distinguishing consideration: compare this with option A, “It necessarily averages logarithms”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-054. Why might a percentile or max-hold result reveal a burst missed in an ordinary average?

A. A percentile creates missing bursts from unobserved intervals

B. Max hold proves all frequencies coexisted

C. A simple average always overstates rare-event power

D. Rare high records can be diluted by the many quiet records

Answer: D. Different summaries answer different questions about occurrence and magnitude. Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: Rare high records can be diluted by the many quiet records.

Distinguishing consideration: compare this with option A, “A percentile creates missing bursts from unobserved intervals”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-MCQ-055. What does an average count fail to establish when records overlap?

A. The fact that a calculation was performed

B. Effective independent information

C. The existence of a chosen window

D. The literal number of stored estimates

Answer: B. Correlation changes statistical uncertainty; count alone is not an independence measure. Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: Effective independent information.

Distinguishing consideration: compare this with option A, “The fact that a calculation was performed”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-056. How should a burst occurring in one of a hundred records be retained for occurrence analysis?

A. Discard the rare record as incompatible with stationarity

B. Treat its max-hold level as a 100 percent occurrence rate

C. Report only the one overall power average

D. Keep the distribution or event-resolved measurements as well as summaries

Answer: D. Per-record information preserves intermittency that a single aggregate can hide. Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: Keep the distribution or event-resolved measurements as well as summaries.

Distinguishing consideration: compare this with option A, “Discard the rare record as incompatible with stationarity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-MCQ-057. A line grows prominent under vector averaging. What alternative to an environmental source must remain open?

A. A mathematically impossible Fourier artifact

B. A necessarily random-phase external burst

C. Only uncorrelated thermal noise

D. A coherent internal spur

Answer: D. Coherence is a processing property, not a guarantee of external origin.

Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: A coherent internal spur.

Distinguishing consideration: compare this with option A, “A mathematically impossible Fourier artifact”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-MCQ-058. What is the benefit of multiple declared summaries of the same per-record measurements?

A. They are independent acquisitions by definition

B. They prove a unique source when their plots look similar

C. They expose different power, peak, and occurrence properties

D. They eliminate the need to freeze analysis choices

Answer: C. Complementary summaries can reveal state changes; their relationship to source records and selection must remain clear. Source: §9.4 Averaging and Statistical Stability (p. 5052)

Why the selected alternative fits: They expose different power, peak, and occurrence properties.

Distinguishing consideration: compare this with option A, “They are independent acquisitions by definition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Averaging and Statistical Stability.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-MCQ-059. Which records should enter the paired spectra used for coherence?

A. Only the records maximizing each channel separately

B. Independently selected records optimized for each spectrum

C. Corresponding aligned X and Y records with common weights

D. Unmatched records from different acquisition times

Answer: C. The bound and interpretation depend on one paired construction, not arbitrary combinations of spectra. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: Corresponding aligned X and Y records with common weights.

Distinguishing consideration: compare this with option A, “Only the records maximizing each channel separately”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-060. If either autospectrum is zero, what is coherence under the stated ratio?

A. Zero by definition

B. The value of the other autospectrum

C. One by definition

D. Undefined

Answer: D. The denominator fails; assigning zero would add an unsupported physical interpretation. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: Undefined.

Distinguishing consideration: compare this with option A, “Zero by definition”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

V011-C09-MCQ-061. With voltage input and current output, what are cross-spectrum units?

A. Amperes per volt

B. Volt ampere per hertz

C. Volts squared per hertz for every channel pair

D. Dimensionless

Answer: B. The cross-product carries both channel units and the common density normalization. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: Volt ampere per hertz.

Distinguishing consideration: compare this with option A, “Amperes per volt”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-062. What happens when the entire cross-spectrum convention is conjugated?

A. Both phase and coherence signs reverse

B. Its phase sign reverses while magnitude-squared coherence is unchanged

C. Its autospectra become negative

D. Its fitted physical delay becomes uniquely unambiguous

Answer: B. Magnitude is unchanged by conjugation, but phase-based delay requires the declared convention. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: Its phase sign reverses while magnitude-squared coherence is unchanged.

Distinguishing consideration: compare this with option A, “Both phase and coherence signs reverse”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-063. What ensures the finite coherence ratio lies between zero and one?

A. A logarithmic display of the ratio

B. Any three separately summarized spectra with the same units

C. One consistently paired estimate with common nonnegative weights and positive autospectra

D. A large record count regardless of selection

Answer: C. The Cauchy–Schwarz proof applies to a common weighted pair of coefficient vectors. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: One consistently paired estimate with common nonnegative weights and positive autospectra.

Distinguishing consideration: compare this with option A, “A logarithmic display of the ratio”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-064. When does the finite paired estimate attain coherence one?

A. One complex gain relates Y to X on every positive-weight record, with nonzero vectors

B. Whenever the average record count exceeds the bin count

C. Whenever X and Y share a nominal sample rate

D. Whenever the two autospectra have equal units

Answer: A. Equality is a proportional-vector condition; it does not identify a physical causal path. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: One complex gain relates Y to X on every positive-weight record, with nonzero vectors.

Distinguishing consideration: compare this with option B, “Whenever the average record count exceeds the bin count”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-065. Why can the algebraic coherence bound hold without a valid confidence interval?

A. The bound itself proves independent samples

B. Any value between zero and one is an exact probability

C. The bound does not require record independence, while uncertainty needs additional assumptions

D. More digits in the ratio remove sampling uncertainty

Answer: C. The finite inequality and a statistical uncertainty claim have different premises. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: The bound does not require record independence, while uncertainty needs additional assumptions.

Distinguishing consideration: compare this with option A, “The bound itself proves independent samples”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

V011-C09-MCQ-066. In the chapter's estimator, what operation precedes taking the cross-spectrum magnitude squared?

A. Average the complex cross-products

B. Select the largest positive product

C. Average the per-record normalized magnitudes

D. Take each product's magnitude and discard its phase

Answer: A. Complex averaging preserves cancellation and phase relationships that magnitude-first processing would erase. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: Average the complex cross-products.

Distinguishing consideration: compare this with option B, “Select the largest positive product”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-067. For a single nonzero paired coefficient, what is the normalized coherence ratio?

A. A unique measure of causal probability

B. Undefined for every complex pair

C. Zero unless the two coefficients are identical

D. One regardless of whether a repeatable relationship is established

Answer: D. Any nonzero one-pair vectors admit a perfect scalar fit; unity is then not evidence of repeatable coupling. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why the selected alternative fits: One regardless of whether a repeatable relationship is established.

Distinguishing consideration: compare this with option A, “A unique measure of causal probability”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-MCQ-068. What can happen if each of the three spectra uses different retained records?

A. Only the phase changes, never the magnitude

B. The common paired-estimate bound need not survive

C. The denominator automatically restores pairing

D. The ratio necessarily becomes more conservative

Answer: B. Changing the record set breaks the common inner-product construction on which the bound rests. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: The common paired-estimate bound need not survive.

Distinguishing consideration: compare this with option A, “Only the phase changes, never the magnitude”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

V011-C09-MCQ-069. Separate medians of X powers, Y powers, and cross-products give 1, 1, and 10 in the chapter's example. What ratio results?

A. 0.1, because the cross-product must be inverted

B. 0, because medians remove every shared component

C. 1, because all coherence ratios are clipped by algebra

D. 100, exposing the loss of the weighted-mean construction

Answer: D. The formal substitution gives 10 squared divided by 1; separate robust summaries do not inherit the mean-based proof. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why the selected alternative fits: 100, exposing the loss of the weighted-mean construction.

Distinguishing consideration: compare this with option A, “0.1, because the cross-product must be inverted”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

V011-C09-MCQ-071. What is the best fitted complex gain for the declared output-on-input projection?

A. The square root of coherence alone

B. P_{xy} divided by P_{xx}

C. The magnitude of P_{xy} divided by P_{xx} with phase discarded

D. P_{xy} divided by P_{yy}

Answer: B. Completing the residual square gives the complex gain, with units of output per input. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why the selected alternative fits: divided by.

Distinguishing consideration: compare this with option A, “The square root of coherence alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-072. What is the minimum residual density in that fit?

A. P_{yy} divided by coherence

B. P_{yy} times one minus coherence

C. The magnitude of P_{xy} alone

D. P_{xx} times coherence

Answer: B. The unexplained output sum of squares is the output autospectrum minus squared cross-spectrum over input autospectrum. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why the selected alternative fits: times one minus coherence.

Distinguishing consideration: compare this with option A, “divided by coherence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-075. Why can equal coherence arise from different output SNRs?

A. Noise can enter the measured input and output in different allocations

B. The density normalization alone determines noise location

C. The coherence formula has units of decibels

D. Every finite fit has identical residual variance

Answer: A. The noisy-input expression contains both input and output disturbance terms; coherence alone does not identify them. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why the selected alternative fits: Noise can enter the measured input and output in different allocations.

Distinguishing consideration: compare this with option B, “The density normalization alone determines noise location”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — The projection interpretation and its boundary.

V011-C09-MCQ-080. Equal-weight records have X all ones and Y signs +, +,minus,minus. What happens on pooling?

A. Coherence is zero although each same-sign state has coherence one

B. Coherence stays one because every per-record ratio is one

C. The cross-spectrum must be positive

D. The autospectra become zero

Answer: A. Opposite state gains cancel in the complex mean; pooling changes the relationship being estimated. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why the selected alternative fits: Coherence is zero although each same-sign state has coherence one.

Distinguishing consideration: compare this with option B, “Coherence stays one because every per-record ratio is one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-MCQ-083. Why does coherence invariance to fixed nonzero channel gains not remove calibration requirements?

A. Every gain change leaves the physical delay calibration identical

B. The fitted amplitude and phase can change even when coherence does not

C. A zero channel gain preserves the denominator

D. Coherence also supplies absolute voltage automatically

Answer: B. The normalized ratio can cancel fixed gain factors while gain and phase measurands still depend on them. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why the selected alternative fits: The fitted amplitude and phase can change even when coherence does not.

Distinguishing consideration: compare this with option A, “Every gain change leaves the physical delay calibration identical”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-084. For P_{xx} = 4, P_{yy} = 5, and P_{xy} = 3 + j in compatible density units, what is coherence?

A. 0.75

B. 0.25

C. 0.4

D. 0.5

Answer: D. The cross magnitude squared is 10 and the autospectral product is 20.

Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why the selected alternative fits: 0.5.

Distinguishing consideration: compare this with option A, “0.75”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-085. For those same spectra, what is the minimum output residual density in output squared units per hertz?

A. 1

B. 5

C. 2.5

D. 3

Answer: C. The residual is P_{yy} times (1-C), or 5 times 0.5. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why the selected alternative fits: 2.5.

Distinguishing consideration: compare this with option A, “1”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-MCQ-086. With X conjugated in the cross-spectrum, a delay gives Y = exp(minus j two pi f tau) X. What is its phase slope sign for positive delay?

A. Zero whenever coherence is one

B. Undefined solely because the gain magnitude is one

C. Negative on the stated continuous branch

D. Positive under every convention

Answer: C. The declared exponential and conjugation convention determine the sign; branch ambiguity remains. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why the selected alternative fits: Negative on the stated continuous branch.

Distinguishing consideration: compare this with option A, “Zero whenever coherence is one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-MCQ-087. What prevents a single-bin phase from establishing a unique absolute propagation delay?

A. Integer-cycle ambiguity in addition to channel calibration limits

B. The fact that phase is always unrelated to delay

C. Coherence must be zero at one bin

D. A one-sided spectrum has no phase

Answer: A. Several delays differ by whole cycles at one frequency; the chosen branch and timing evidence matter. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why the selected alternative fits: Integer-cycle ambiguity in addition to channel calibration limits.

Distinguishing consideration: compare this with option B, “The fact that phase is always unrelated to delay”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-MCQ-088. Which challenge directly investigates a possible recorder-mediated coherence path?

A. Selecting only the frequency bin with greatest coherence

B. Increasing the coherence display's averaging count alone

C. Channel swapping, independent terminations, and known injected references

D. Replacing phase by magnitude before averaging

Answer: C. Controlled path changes probe alternatives such as shared references and cable leakage. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

Why the selected alternative fits: Channel swapping, independent terminations, and known injected references.

Distinguishing consideration: compare this with option A, “Selecting only the frequency bin with greatest coherence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis.

Review: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis.

V011-C09-MCQ-089. High coherence collapses after isolated-digitizer substitution and an injected reference reveals clock leakage. What is supported?

A. Coherence is mathematically meaningless in all instruments

B. The room contains no possible coupling under any condition

C. The original recorder has a contaminating path that limits the room-coupling inference

D. Every original spectral line was absent

Answer: C. The specific challenge identifies a mechanism without proving universal absence of another path. Source: §9.10 Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation (p. 5076)

Why the selected alternative fits: The original recorder has a contaminating path that limits the room-coupling inference.

Distinguishing consideration: compare this with option A, “Coherence is mathematically meaningless in all instruments”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Review: Chapter 9 — Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

V011-C09-MCQ-090. Why preserve sensitivity and receiver state during a path challenge?

A. Otherwise a changed indication may reflect changed capability rather than removal of the path

B. Only geometry matters for the comparison

C. Any lower noise floor guarantees a fair comparison

D. A different gain state never affects coherence interpretation

Answer: A. A causal interpretation of the challenge requires comparable measurement capability and declared conditions. Source: §9.10 Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation (p. 5076)

Why the selected alternative fits: Otherwise a changed indication may reflect changed capability rather than removal of the path.

Distinguishing consideration: compare this with option B, “Only geometry matters for the comparison”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Review: Chapter 9 — Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

V011-C09-MCQ-095. Increasing record length improves nominal spacing but introduces what consideration?

A. A longer interval over which stationarity may be assumed

B. A guarantee that every transient is resolved

C. An automatic doubling of independent averages

D. A reduction of sample rate by definition

Answer: A. More observation time can improve spacing while mixing changes that shorter records would separate. Source: §9.8 Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation (p. 5073)

Why the selected alternative fits: A longer interval over which stationarity may be assumed.

Distinguishing consideration: compare this with option B, “A guarantee that every transient is resolved”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Review: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

V011-C09-MCQ-096. Two tones are 20 Hz apart and nominal bins are about 15.26 Hz apart. What is justified?

A. Their separation is impossible to estimate under any processing

B. They may remain unresolved because window response and estimator matter

C. They become resolved merely by eightfold padding

D. They must be resolved because they occupy different numerical frequencies

Answer: B. Bin spacing alone is not actual two-tone resolution. Source: §9.8 Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation (p. 5073)

Why the selected alternative fits: They may remain unresolved because window response and estimator matter.

Distinguishing consideration: compare this with option A, “Their separation is impossible to estimate under any processing”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Fill-in-the-Blank Questions

V011-C09-FIB-001. An FFT starts from a _____ sampled record rather than an infinite observation.

Answer: finite. Record length and preprocessing bound what the estimate represents. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Why this term is required: “finite” completes the stated technical proposition.

Question context: An FFT starts from a _____ sampled record rather than an infinite observation

Basis and qualification: Chapter 9 — Discrete Records and Spectral Estimates.

Review: Chapter 9 — Discrete Records and Spectral Estimates.

Copyright 2026, James M. Atkinson

V011-C09-FIB-002. For an unpadded record, nominal frequency spacing is sample rate divided by sample _____.

Answer: count. The record length N appears in the bin-spacing formula. Source: §9.8 Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation (p. 5073)

Why this term is required: “count” completes the stated technical proposition.

Question context: For an unpadded record, nominal frequency spacing is sample rate divided by sample _____

Basis and qualification: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Review: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

V011-C09-FIB-024. Under the stipulated white covariance, expected squared transform magnitude equals variance times _____.

Answer: S_2. The off-diagonal covariance terms vanish in the expansion. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: "The off-diagonal covariance terms vanish in the expansion" completes the stated technical proposition.

Question context: Under the stipulated white covariance, expected squared transform magnitude equals variance times _____

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-025. The Kronecker-delta covariance assumption makes distinct sample cross terms have _____ expectation.

Answer: zero. This is the second-order reason for the white density expectation.

Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “zero” completes the stated technical proposition.

Question context: The Kronecker-delta covariance assumption makes distinct sample cross terms have _____ expectation

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-026. The white-noise density expectation does not require a _____ probability distribution.

Answer: Gaussian. The stated mean and covariance suffice for the calculation.

Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “Gaussian” completes the stated technical proposition.

Question context: The white-noise density expectation does not require a _____ probability distribution

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-027. With S_1 nonzero and D_2 greater than zero, Q2 divided by D_2 equals equivalent noise _____.

Answer: bandwidth. The identity is recordwise and is not restricted to white noise.

Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “bandwidth” completes the stated technical proposition.

Question context: With nonzero and greater than zero, Q2 divided by equals equivalent noise _____

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-028. Interior positive bins of a real-record density are _____ in a one-sided fold.

Answer: doubled. They combine equal positive and negative contributions. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “doubled” completes the stated technical proposition.

Question context: Interior positive bins of a real-record density are _____ in a one-sided fold

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-029. The zero-frequency endpoint is commonly called _____.

Answer: DC. It is retained without the interior-bin doubling. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “DC” completes the stated technical proposition.

Question context: The zero-frequency endpoint is commonly called _____

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-030. For even N, the other undoubled endpoint is the _____ bin.

Answer: Nyquist. It has no distinct opposite-frequency partner in the finite transform. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “Nyquist” completes the stated technical proposition.

Question context: For even N, the other undoubled endpoint is the _____ bin

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-031. An odd-length real record has no sampled _____ endpoint.

Answer: Nyquist. Its highest positive bin is an interior contribution and is doubled.

Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “Nyquist” completes the stated technical proposition.

Question context: An odd-length real record has no sampled _____ endpoint

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-032. Complex records generally lack the conjugate _____ used for real one-sided folding.

Answer: symmetry. Their positive and negative spectra need not be equal. Source: §9.3.2 Noise density uses a different denominator (p. 5033)

Why this term is required: “symmetry” completes the stated technical proposition.

Question context: Complex records generally lack the conjugate _____ used for real one-sided folding

Basis and qualification: Chapter 9 — Noise density uses a different denominator.

Review: Chapter 9 — Noise density uses a different denominator.

Copyright 2026, James M. Atkinson

V011-C09-FIB-033. Exact density integration gives a window-weighted mean _____.

Answer: square. The squared weights remain in the finite-record energy identity.

Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “square” completes the stated technical proposition.

Question context: Exact density integration gives a window-weighted mean _____

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-034. To integrate a discrete density, multiply ordinates by frequency-grid _____.

Answer: spacing. A density is per hertz; summation requires the bin interval. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “spacing” completes the stated technical proposition.

Question context: To integrate a discrete density, multiply ordinates by frequency-grid _____

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-035. The window-weighted mean square need not equal the _____ sample mean square for a particular transient.

Answer: unweighted. The transient's location in the coefficient vector matters.

Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “unweighted” completes the stated technical proposition.

Question context: The window-weighted mean square need not equal the _____ sample mean square for a particular transient

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-036. Fourier energy closure is often associated with _____ identity.

Answer: Parseval's. Closure checks consistent transform arithmetic and normalization. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “Parseval's” completes the stated technical proposition.

Question context: Fourier energy closure is often associated with _____ identity

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

V011-C09-FIB-041. The endpoint-symmetric Hann uses N minus _____ in its cosine denominator.

Answer: one. Its finite sums differ from the periodic convention, especially for short records. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “one” completes the stated technical proposition.

Question context: The endpoint-symmetric Hann uses N minus _____ in its cosine denominator

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-042. Scaling all window weights by the same nonzero real constant leaves normalized density _____.

Answer: unchanged. The coefficient magnitude squared and S_2 scale together.

Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “unchanged” completes the stated technical proposition.

Question context: Scaling all window weights by the same nonzero real constant leaves normalized density _____

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-043. The equivalent-noise-bandwidth lower bound follows from the _____ inequality used on window sums.

Answer: Cauchy–Schwarz. The squared sum is no greater than N times the squared-weight sum. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “Cauchy–Schwarz” completes the stated technical proposition.

Question context: The equivalent-noise-bandwidth lower bound follows from the _____ inequality used on window sums

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-044. A zero-sum window makes coherent-gain normalization _____.

Answer: undefined. Division by S_1 is not meaningful when S_1 is zero. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “undefined” completes the stated technical proposition.

Question context: A zero-sum window makes coherent-gain normalization _____

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-045. That zero-sum window can still define density if S_2 is _____.

Answer: positive. Density uses the squared-weight sum and positive sample rate rather than S_1. Source: §9.3.4 Ten worked applications of the normalization model (p. 5039)

Why this term is required: “positive” completes the stated technical proposition.

Question context: That zero-sum window can still define density if is _____

Basis and qualification: Chapter 9 — Ten worked applications of the normalization model.

Review: Chapter 9 — Ten worked applications of the normalization model.

Copyright 2026, James M. Atkinson

V011-C09-FIB-046. Adding zeros after a record increases transform length without adding _____.

Answer: observations. It samples the same finite-record transform on a denser grid. Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “observations” completes the stated technical proposition.

Question context: Adding zeros after a record increases transform length without adding _____

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-047. With padding to M, displayed spacing is sample rate divided by _____.

Answer: M. The integral uses this grid while normalization retains original sums.

Source: §9.3.3 Energy closure and its limits (p. 5036)

Why this term is required: “M” completes the stated technical proposition.

Question context: With padding to M, displayed spacing is sample rate divided by _____

Basis and qualification: Chapter 9 — Energy closure and its limits.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-FIB-048. An eightfold padding leaves the original equivalent noise bandwidth _____ in hertz.

Answer: unchanged. The observed coefficients and window vector have not changed. Source: §9.3.4 Ten worked applications of the normalization model (p. 5039)
Why this term is required: “unchanged” completes the stated technical proposition.
Question context: An eightfold padding leaves the original equivalent noise bandwidth _____ in hertz
Basis and qualification: Chapter 9 — Ten worked applications of the normalization model.
Review: Chapter 9 — Ten worked applications of the normalization model.

Copyright 2026, James M. Atkinson

V011-C09-FIB-049. Using padded length as though it were observed N can falsely narrow the estimated noise _____.

Answer: bandwidth. The chapter's example shows an eightfold density error from that substitution. Source: §9.3.4 Ten worked applications of the normalization model (p. 5039)

Why this term is required: “bandwidth” completes the stated technical proposition.

Question context: Using padded length as though it were observed N can falsely narrow the estimated noise _____

Basis and qualification: Chapter 9 — Ten worked applications of the normalization model.

Review: Chapter 9 — Ten worked applications of the normalization model.

Copyright 2026, James M. Atkinson

V011-C09-FIB-050. For the periodic Hann example, adjacent tone bins are part of the same window _____.

Answer: response. They should not be counted as independent physical lines without further evidence. Source: §9.3.4 Ten worked applications of the normalization model (p. 5039)

Why this term is required: “response” completes the stated technical proposition.

Question context: For the periodic Hann example, adjacent tone bins are part of the same window _____

Basis and qualification: Chapter 9 — Ten worked applications of the normalization model.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-FIB-078. The finite coherence upper bound follows from a weighted _____-product inequality.

Answer: inner. Cauchy–Schwarz bounds the paired coefficient vectors. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why this term is required: “inner” completes the stated technical proposition.

Question context: The finite coherence upper bound follows from a weighted _____-product inequality

Basis and qualification: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-FIB-079. For unity coherence, one complex _____ must relate every positive-weight pair.

Answer: gain. Proportional nonzero vectors attain equality in the bound. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why this term is required: “gain” completes the stated technical proposition.

Question context: For unity coherence, one complex _____ must relate every positive-weight pair

Basis and qualification: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-FIB-080. Separate robust medians need not preserve the paired _____-matrix construction.

Answer: Gram. The chapter's median example produces a substituted ratio above one despite nonnegative inputs. Source: §9.5.1 Define the ensemble before normalizing (p. 5055)

Why this term is required: “Gram” completes the stated technical proposition.

Question context: Separate robust medians need not preserve the paired _____-matrix construction

Basis and qualification: Chapter 9 — Define the ensemble before normalizing.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-FIB-081. The least-squares gain estimate divides P_{xy} by _____.

Answer: P_{xx}. The declared projection estimates output from input, not the reverse regression. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why this term is required: "The declared projection estimates output from input, not the reverse regression" completes the stated technical proposition.

Question context: The least-squares gain estimate divides by _____

Basis and qualification: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-082. The minimum residual is output autospectrum times one minus _____.

Answer: coherence. It is the unexplained output spectral sum of squares for the fitted gain. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why this term is required: “coherence” completes the stated technical proposition.

Question context: The minimum residual is output autospectrum times one minus ____

Basis and qualification: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-083. If output autospectrum is 12 and coherence is 0.75, the minimum residual is _____.

Answer: 3. The stated fit gives 12 times (1-0.75), in output squared units per hertz.

Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why this term is required: “3” completes the stated technical proposition.

Question context: If output autospectrum is 12 and coherence is 0.75, the minimum residual is _____

Basis and qualification: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-084. If P_{xx} is 2 and P_{xy} is 1 plus j, the fitted gain is _____ plus 0.5j.

Answer: 0.5. Dividing the complex cross-spectrum by the real input autospectrum preserves phase. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why this term is required: “0.5” completes the stated technical proposition.

Question context: If is 2 and is 1 plus j, the fitted gain is _____ plus 0.5j

Basis and qualification: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-085. A fitted relationship does not by itself establish causal _____.

Answer: direction. Common excitation and alternative physical paths can share a spectral matrix. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)
Why this term is required: “direction” completes the stated technical proposition.
Question context: A fitted relationship does not by itself establish causal _____
Basis and qualification: Chapter 9 — The projection interpretation and its boundary.
Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-086. The simple coherence-to-SNR expression requires exact observation of the _____.

Answer: input. Noise in the measured input changes the relation. Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why this term is required: “input” completes the stated technical proposition.

Question context: The simple coherence-to-SNR expression requires exact observation of the _____

Basis and qualification: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-087. The additive output disturbance must have zero _____-spectrum with the input in that SNR model.

Answer: cross. The absence of this cross term gives the stated decomposition.

Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why this term is required: “cross” completes the stated technical proposition.

Question context: The additive output disturbance must have zero _____-spectrum with the input in that SNR model

Basis and qualification: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-088. With coherence 0.8 under that specific model, output SNR is _____ as a linear ratio.

Answer: 4. The ratio is $\frac{0.8}{0.2}$*;* it is not valid merely because coherence was measured.

Source: §9.5.2 The projection interpretation and its boundary (p. 5058)

Why this term is required: “4” completes the stated technical proposition.

Question context: With coherence 0.8 under that specific model, output SNR is _____ as a linear ratio

Basis and qualification: Chapter 9 — The projection interpretation and its boundary.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-FIB-089. Equal coherence can leave the location of measurement _____ unresolved.

Answer: noise. Different input/output allocations can produce the same normalized value. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why this term is required: “noise” completes the stated technical proposition.

Question context: Equal coherence can leave the location of measurement _____ unresolved

Basis and qualification: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-FIB-090. Equal shared components with opposite signs can _____ in the cross-spectrum.

Answer: cancel. Autospectra can remain positive while the cross mean is zero.

Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why this term is required: “cancel” completes the stated technical proposition.

Question context: Equal shared components with opposite signs can _____ in the cross-spectrum

Basis and qualification: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-FIB-091. Pooling states with gains plus one and minus one can erase perfect within-state _____.

Answer: coherence. The complex products can cancel when states are mixed.

Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why this term is required: “coherence” completes the stated technical proposition.

Question context: Pooling states with gains plus one and minus one can erase perfect within-state _____

Basis and qualification: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-FIB-092. State rules should be specified independently of the desired _____.

Answer: result. Selecting states to manufacture coherence biases the claimed interpretation. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why this term is required: “result” completes the stated technical proposition.

Question context: State rules should be specified independently of the desired _____

Basis and qualification: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-FIB-093. Fixed nonzero channel gains cancel from coherence but not necessarily from the fitted gain and _____.

Answer: phase. Normalized invariance does not replace calibration of other measurands. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why this term is required: “phase” completes the stated technical proposition.

Question context: Fixed nonzero channel gains cancel from coherence but not necessarily from the fitted gain and _____

Basis and qualification: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-FIB-094. A single-bin delay estimate retains integer-_____ ambiguity.

Answer: cycle. Multiple delays produce the same phase at a single frequency.

Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Why this term is required: “cycle” completes the stated technical proposition.

Question context: A single-bin delay estimate retains integer-_____ ambiguity

Basis and qualification: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-FIB-095. Shared references and direct cable coupling can create coherence without an environmental _____.

Answer: field. Controlled path challenges are needed before source attribution.

Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

Why this term is required: “field” completes the stated technical proposition.

Question context: Shared references and direct cable coupling can create coherence without an environmental _____

Basis and qualification: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis.

Review: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis.

Copyright 2026, James M. Atkinson

V011-C09-FIB-096. Short-time Fourier analysis divides samples into overlapping _____.

Answer: windows. The duration and placement condition the evolving estimates.

Source: §9.6 Time-Frequency and Nonstationary Methods (p. 5071)

Why this term is required: “windows” completes the stated technical proposition.

Question context: Short-time Fourier analysis divides samples into overlapping _____

Basis and qualification: Chapter 9 — Time-Frequency and Nonstationary Methods.

Review: Chapter 9 — Time-Frequency and Nonstationary Methods.

Copyright 2026, James M. Atkinson

V011-C09-FIB-097. Time-frequency features should be checked in raw data, alternate windows, and held-_____ data.

Answer: out. Held-out evaluation helps distinguish robust findings from tuned processing choices. Source: §9.6 Time-Frequency and Nonstationary Methods (p. 5071)
Why this term is required: “out” completes the stated technical proposition.
Question context: Time-frequency features should be checked in raw data, alternate windows, and held-_____ data
Basis and qualification: Chapter 9 — Time-Frequency and Nonstationary Methods.
Review: Chapter 9 — Time-Frequency and Nonstationary Methods.

Copyright 2026, James M. Atkinson

V011-C09-FIB-098. Before held-out evaluation, the chapter directs that processing parameters be _____.

Answer: frozen. This prevents selecting the evaluation procedure to fit the desired result. Source: §9.7 Estimator Validation and Reporting (p. 5072)

Why this term is required: “frozen” completes the stated technical proposition.

Question context: Before held-out evaluation, the chapter directs that processing parameters be _____

Basis and qualification: Chapter 9 — Estimator Validation and Reporting.

Review: Chapter 9 — Estimator Validation and Reporting.

Copyright 2026, James M. Atkinson

V011-C09-FIB-099. Plots remain traceable to source samples and executable analysis _____.

Answer: scripts. The data-to-image transformation must be reproducible. Source: §9.7 Estimator Validation and Reporting (p. 5072)

Why this term is required: “scripts” completes the stated technical proposition.

Question context: Plots remain traceable to source samples and executable analysis _____

Basis and qualification: Chapter 9 — Estimator Validation and Reporting.

Review: Chapter 9 — Estimator Validation and Reporting.

Copyright 2026, James M. Atkinson

V011-C09-FIB-100. Correct spectral arithmetic cannot alone establish usable event _____.

Answer: coverage. Acquisition continuity and receiver-state validity are separate requirements. Source: §9.7 Estimator Validation and Reporting (p. 5072)

Why this term is required: “coverage” completes the stated technical proposition.

Question context: Correct spectral arithmetic cannot alone establish usable event _____

Basis and qualification: Chapter 9 — Estimator Validation and Reporting.

Review: Chapter 9 — Estimator Validation and Reporting.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C09-ESSAY-001. Derive the two different window sums needed for coherent complex-tone amplitude and white-noise density.

- Opening: Present a thesis that answers this precise question: Derive the two different window sums needed for coherent complex-tone amplitude and white-noise density. Identify which evidence would falsify the proposed conclusion Source: §9.3.2 Noise density uses a different denominator (p. 5033)
- Core terminology and scope: Define window, sums, coherent in the question's particular technical setting; explain how amplitude, white-noise, density differ if that distinction would change the analysis of "Derive the two different window sums needed for coherent complex-tone amplitude and white-noise density" Source: §9.3.2 Noise density uses a different denominator (p. 5033)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Substitute a bin-centered complex tone into the unnormalized DFT to obtain a times Expand squared magnitude under zero-mean white covariance to obtain variance times Identify units Source: §9.3.2 Noise density uses a different denominator (p. 5033)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the two different window sums needed for coherent complex-tone amplitude and white-noise density to the claimed result, following "Windowed DFT normalization: line amplitude, noise density, and finite-record energy"; name the intermediate states and measurable outputs

Discussion Questions

[Discussion instructions: For each discussion question, prepare approximately 500 spoken words for delivery over 2.5–3 minutes (approximately 167–200 words per minute). Address the ten subject prompts below in their stated order. Use the opening to frame the issue and the closing to synthesise the principal findings, conclusions and unresolved questions.]

Copyright 2026, James M. Atkinson

V011-C09-DISCUSSION-001. A colleague treats a denser padded spectrum as evidence of newly resolved carriers. What should the review establish?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A colleague treats a denser padded spectrum as evidence of newly resolved carriers. What should the review establish?” Put this particular dispute to the panel: A colleague treats a denser padded spectrum as evidence of newly resolved carriers. What should the review establish. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

- 02. Student A, terminology and scope: Agree the operational meanings of treats, padded, newly and resolved, carriers, review in “A colleague treats a denser padded spectrum as evidence of newly resolved carriers. What should the review establish”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A colleague treats a denser padded spectrum as evidence of newly resolved carriers; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §9.3.5 Measurement consequence (p. 5050)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Measurement consequence”. Request raw record, N, M, window, SNR, and a two-tone validation Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §9.3.5 Measurement consequence (p. 5050)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A colleague treats a denser padded spectrum as evidence of newly resolved carriers; explain what each record can establish State what the existing record

Copyright 2026, James M. Atkinson

establishes, what it does not establish, and which further measurement would change your opinion. Source: §9.16 Long-duration multiresolution spectrum retention and the limits of thirty-hertz FFT bins (p. 5091)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Measurement consequence”. Request raw record, N, M, window, SNR, and a two-tone validation Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §9.3.5 Measurement consequence (p. 5050)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Distinguish grid interpolation from the unchanged finite-window response and observation duration Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A colleague treats a denser padded spectrum

Copyright 2026, James M. Atkinson

as evidence of newly resolved carriers: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A colleague treats a denser padded spectrum as evidence of newly resolved carriers; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §9.16 Long-duration multiresolution spectrum retention and the limits of thirty-hertz FFT bins (p. 5091)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A colleague treats a denser padded spectrum as evidence of newly resolved carriers: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative

Copyright 2026, James M. Atkinson

that could survive the proposed test. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A colleague treats a denser padded spectrum as evidence of newly resolved carriers, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §9.3.5 Measurement consequence (p. 5050)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A colleague treats a denser padded spectrum as evidence of newly resolved carriers: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Copyright 2026, James M. Atkinson

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A colleague treats a denser padded spectrum as evidence of newly resolved carriers. Preserve any improved peak-location estimate while rejecting unsupported separation claims Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §9.16 Long-duration multiresolution spectrum retention and the limits of thirty-hertz FFT bins (p. 5091)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A colleague treats a denser padded spectrum as evidence of newly resolved carriers, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §9.3.5 Measurement consequence (p. 5050)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A colleague treats a denser padded spectrum as evidence of newly resolved carriers. Preserve any improved peak-location estimate while rejecting unsupported separation claims

Copyright 2026, James M. Atkinson

Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §9.16 Long-duration multiresolution spectrum retention and the limits of thirty-hertz FFT bins (p. 5091)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A colleague treats a denser padded spectrum as evidence of newly resolved carriers and What should the review establish; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §9.12 Spectral confidence intervals and why averaging is not the same as independence (p. 5081)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A colleague treats a denser padded spectrum as evidence of newly resolved carriers”, addressing “What should the review establish”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §9.1 Discrete Records and Spectral Estimates (p. 5025)

Copyright 2026, James M. Atkinson

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A colleague treats a denser padded spectrum as evidence of newly resolved carriers. What should the review establish”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “A colleague treats a denser padded spectrum as evidence of newly resolved carriers. What should the review establish”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion.

V011-C09-DISCUSSION-025. What should constitute acceptance of a multichannel spectral method intended for intermittent survey work?

- 01. Moderator, opening proposition: Introduce the exact dispute, “What should constitute acceptance of a multichannel spectral method intended for intermittent survey work?” Put this particular dispute to the panel: What should constitute acceptance of a multichannel spectral method intended for intermittent survey work. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

- 02. Student A, terminology and scope: Agree the operational meanings of multichannel, method, intended and intermittent, survey, work in “What should constitute acceptance of a multichannel spectral method intended for intermittent survey work”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of What should constitute acceptance of a multichannel spectral method intended for intermittent survey work; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §9.7 Estimator Validation and Reporting (p. 5072)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Estimator Validation and Reporting”. Discuss artifact challenges and report scope Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §9.7 Estimator Validation and Reporting (p. 5072)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of What should constitute acceptance of a multichannel spectral method intended for intermittent survey work; explain what each record can establish

Copyright 2026, James M. Atkinson

State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §9.3.3 Energy closure and its limits (p. 5036)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Estimator Validation and Reporting”. Discuss artifact challenges and report scope Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §9.7 Estimator Validation and Reporting (p. 5072)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Require correct normalization, paired records, clock/skew calibration, uncertainty limits, representative transient and channel references, held-out tests, and usable sample coverage Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving What should constitute acceptance of a multichannel spectral method intended for intermittent survey work: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of What should constitute acceptance of a multichannel spectral method intended for intermittent survey work; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §9.3.3 Energy closure and its limits (p. 5036)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving What should constitute acceptance of a multichannel spectral method intended for intermittent survey work: specify the altered receiver state or source

condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving What should constitute acceptance of a multichannel spectral method intended for intermittent survey work, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §9.7 Estimator Validation and Reporting (p. 5072)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving What should constitute acceptance of a multichannel spectral method intended for intermittent survey work: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead

Copyright 2026, James M. Atkinson

the panel to retain, qualify or reject the conclusion. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for What should constitute acceptance of a multichannel spectral method intended for intermittent survey work. No single attractive spectrum, coherence value, or energy check replaces this combined evidence Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §9.3.3 Energy closure and its limits (p. 5036)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving What should constitute acceptance of a multichannel spectral method intended for intermittent survey work, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §9.7 Estimator Validation and Reporting (p. 5072)

Copyright 2026, James M. Atkinson

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for What should constitute acceptance of a multichannel spectral method intended for intermittent survey work. No single attractive spectrum, coherence value, or energy check replaces this combined evidence Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §9.3.3 Energy closure and its limits (p. 5036)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about What should constitute acceptance of a multichannel spectral method intended for intermittent survey work and Require correct normalization, paired records, clock/skew calibration, uncertainty limits, representative…; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §9.5.3 Ten worked applications of Equation 18 and its paired-spectrum realization (p. 5060)

Copyright 2026, James M. Atkinson

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “What should constitute acceptance of a multichannel spectral method intended for intermittent survey work”, addressing “Require correct normalization, paired records, clock/skew calibration, uncertainty limits, representative…”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §9.5 Cross-Spectra, Coherence, and Multichannel Analysis (p. 5053)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “What should constitute acceptance of a multichannel spectral method intended for intermittent survey work”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “What should constitute acceptance of a multichannel spectral method intended for intermittent survey work”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion. Chapter 9 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C09-ESSAY-001 — Substitute a bin-centered complex tone into the unnormalized DFT to obtain a times S_1. Expand squared magnitude under zero-mean white covariance to obtain variance times S_2. Identify units, nonzero denominator conditions, and why Gaussianity is unnecessary for the expectation. Explain why substituting one sum for the other changes the measurand.

Review: Chapter 9 — Noise density uses a different denominator.

V011-C09-ESSAY-002 — Retain both frequency images and derive the contribution of W at twice the tone bin. Require the stated frequency condition and a vanishing or bounded image term before using doubled magnitude over the coherent sum. Treat DC, Nyquist, and off-grid cases separately; coherent gain is not a universal correction.

Review: Chapter 9 — Define the record before interpreting the display.

V011-C09-ESSAY-003 — Start with the two-sided density, fold equal conjugate contributions, double interior positive bins, retain DC and even-length Nyquist once, and double the last positive bin for odd N. Use actual grid spacing. Show that the sum equals the squared-window-weighted mean square, not necessarily unweighted mean square.

Review: Chapter 9 — Energy closure and its limits.

V011-C09-ESSAY-004 — Retain the original coefficient vector, S_1, S_2, and N while increasing transform length M. Use $\frac{f_s}{M}$ in density integration. Explain peak interpolation and the unchanged response width, and derive the error from replacing N by M in a window bandwidth formula. State the limit on resolving overlapping components.

Review: Chapter 9 — Energy closure and its limits.

Copyright 2026, James M. Atkinson

V011-C09-ESSAY-005 — Use the squared coefficient at each position and divide by S_2. For the stated 16-point periodic example, compare zero and $\frac{1}{6}$ V squared with unweighted $\frac{1}{16}$ V squared. Explain why all satisfy exact energy closure and why capture opportunity and window placement require separate validation.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-ESSAY-006 — Retain the same native samples while applying declared alternate windows, compare sidelobe and main-lobe behavior, and inspect time evolution and repeated records. Calibrate amplitude with actual sums and account for off-grid effects. Use appropriate known tones and held-out observations; changed window response alone does not identify physical origin.

Review: Chapter 9 — Spectral Leakage and Window Selection.

V011-C09-ESSAY-007 — Explain that adjacent bins are part of one finite-window response, not independent powers. Convert Q to D with equivalent noise bandwidth, multiply by actual grid spacing, and sum. Reproduce the 0.0075 times $\frac{46.875}{70.3125}$ = 0.005 V squared example. Preserve side conventions and impedance if converting to power.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-ESSAY-008 — Give their distinct cosine conventions and finite S_1 and S_2 values. At N = 16 and f_s = 1600 Hz, obtain 150 and 160 Hz bandwidths. Explain the complex-amplitude error from using 8 instead of 7.5 as coherent sum and the separate density error from mixing bandwidths. Do not silently substitute a real tone without its image condition.

Review: Chapter 9 — Ten worked applications of the normalization model.

Copyright 2026, James M. Atkinson

V011-C09-ESSAY-009 — State the recordwise weighted-energy identity and correct frequency spacing. Explain its validity for colored covariance and transient records. Separate arithmetic normalization from stationarity, alias-free sampling, calibration, source attribution, overload, and usable observation intervals. Propose additional tests for those distinct claims.

Review: Chapter 9 — Energy closure and its limits.

V011-C09-ESSAY-010 — Retain samples, sample rate, observed N, transform length, coefficient convention, side folding, units, impedance, and preprocessing. State linear, logarithmic, vector, or weighted averaging and record overlap/dependence. Identify corrections already applied and the distinction between logarithm of expected power and expected log display. Link plots to executable analysis.

Review: Chapter 9 — Measurement consequence.

V011-C09-ESSAY-011 — Form vectors from square-root nonnegative weights times the paired coefficients. Apply Cauchy–Schwarz with common positive density scaling and positive autospectra. Give the proportional-vector equality condition. Explain that independence is not needed for this algebraic bound but is relevant to uncertainty, and that different record selections break the construction.

Review: Chapter 9 — Define the ensemble before normalizing.

V011-C09-ESSAY-012 — Show that each nonzero one-pair ratio is one. Use X = (1,1) and Y = (1,minus 1) to obtain zero averaged complex cross-product and zero proper coherence despite unit per-record ratios. Identify the lost phase cancellation and distinguish this exact processing error from rounding or finite-sample uncertainty.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-ESSAY-013 — Calculate autospectral medians 1 and 1 and cross median 10, yielding 100. Contrast common means yielding 400/10201. Explain the loss of one paired Gram construction rather than negative weights or floating-point error. Do not claim that every robust method fails or that a named coherence routine necessarily uses this separate-median construction.

Review: Chapter 9 — Define the ensemble before normalizing.

V011-C09-ESSAY-014 — Expand the weighted squared residual, complete the square, and obtain $\frac{P_{xy}}{P_{xx}}$ and P_{yy} minus squared cross magnitude over P_{xx}. Give gain and residual units and the explained-fraction interpretation. Separate a finite fit from causal direction, residual independence, and extrapolation to other states.

Review: Chapter 9 — The projection interpretation and its boundary.

V011-C09-ESSAY-015 — State exact input observation, linear gain, and zero input-disturbance cross-spectrum. Derive $\frac{C}{(1-C)}$. Compare the chapter's equal-coherence cases with different input/output noise allocations and output SNRs. Explain why a measured value alone cannot locate noise or supply an input-noise correction.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-ESSAY-016 — Use X = S + D and Y = S minus D with uncorrelated components. Derive autospectra as sums and cross-spectrum as a difference. Show exact cancellation for equal spectra and the $\frac{1}{81}$ case when spectra are 1 and 0.8. Recommend complex-spectrum inspection and coupling challenges rather than treating low coherence as proof of independent physical causes.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-ESSAY-017 — Use opposite gains and equal weights to show canceled cross-spectrum with positive autospectra. Then weight states three quarters and one quarter to obtain coherence one quarter. Define a defensible state rule independently of the desired result and retain state-resolved records. Discuss what the pooled estimator actually describes.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-ESSAY-018 — State which channel is conjugated, the signal delay exponential, phase sign, calibrated skew, sample alignment, clock behavior, and phase branch. Use the stated 1000 Hz and 125 microsecond example to obtain minus 45 degrees under X conjugate Y. Explain integer-cycle ambiguity and why coherence alone does not calibrate absolute delay.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-ESSAY-019 — Preserve comparable sensitivity and state while using channel swaps, independent terminations, separation, and injected references. Record clock and synchronization paths. Interpret a revealed recorder path as a mechanism that limits the original claim, without asserting universal absence of room coupling. Retain both original and challenged native records.

Review: Chapter 9 — Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

V011-C09-ESSAY-020 — Distinguish bin spacing from window response, SNR, and estimator resolution. Explain how longer duration improves nominal spacing while increasing exposure to drift or state mixing. Compare alternate lengths on known and held-out signals, preserve time data, and choose the interval that supports the intended measurand.

Review: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

V011-C09-ESSAY-021 — Declare window and segment lengths, overlap, normalization, thresholds, interpolation, and color mapping. Validate known bursts and chirps, inspect raw records and alternate settings, freeze parameters before held-out evaluation, and retain excluded intervals. Require a quantified detection rule rather than treating a compelling image as direct physical evidence.

Review: Chapter 9 — Time-Frequency and Nonstationary Methods.

Copyright 2026, James M. Atkinson

V011-C09-ESSAY-022 — Define each summary's relevant statistic or weighting. Explain how ordinary averaging can hide rare bursts, how coherent internal spurs can survive vector averaging, and why peak or percentile summaries do not establish simultaneous occurrence or independent trials. Retain per-record distributions and select summaries according to the question.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-ESSAY-023 — Use weights 1, minus 1, 1, minus 1 to obtain S_1 = 0 and S_2 = 4. Show valid density for positive sample rate and the stated white expectation, but undefined Q and equivalent noise bandwidth in that definition. Explain why an arbitrary numerical correction cannot restore a canceled coherent tone.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-ESSAY-024 — Compare the common latent-source construction with an alternative direct linear representation having an uncorrelated residual. State which autospectra, cross-spectrum, and coherence agree. Explain that algebraic equivalence does not select causality or unique path, and identify controlled acquisition/path evidence needed beyond the matrix.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-ESSAY-025 — Separate Model 9W scaling, Model 9C relationships, and continuity/timing requirements. Require correct actual coefficients, side conventions, sample provenance, paired weighting, calibration, state controls, and representative held-out tests. State limitations on source attribution and negative findings even when both algebraic models pass their checks.

Review: Chapter 9 — Estimator Validation and Reporting.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-C09-DISCUSSION-001 — Distinguish grid interpolation from the unchanged finite-window response and observation duration. Request raw record, N, M, window, SNR, and a two-tone validation. Preserve any improved peak-location estimate while rejecting unsupported separation claims.

Review: Chapter 9 — Energy closure and its limits.

V011-C09-DISCUSSION-002 — Identify their measurands, main-lobe/sidelobe tradeoffs, amplitude and density normalization, and transient weighting. Require exact coefficients and clear claims. Agreement on reproducible inputs and limits matters more than imposing a universal preferred window.

Review: Chapter 9 — Spectral Leakage and Window Selection.

V011-C09-DISCUSSION-003 — Use window-position weighting to explain valid arithmetic with poor event opportunity. Discuss actual capture windows, valid samples, and alternate window placement. Do not use Parseval success to dismiss the missed transient or to certify coverage.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-DISCUSSION-004 — Explain the change to DC and other processed-record meanings. Require explicit preprocessing and comparison with the intended measurand. A useful detrend may be justified, but it must not be represented as a mere normalization fix.

Review: Chapter 9 — Define the record before interpreting the display.

Copyright 2026, James M. Atkinson

V011-C09-DISCUSSION-005 — Recover coefficients or the generation convention if possible, recompute S_1 and S_2, and examine short-record sensitivity. Avoid selecting the convention that happens to match the desired result. Report unresolved normalization limits if the actual vector cannot be established.

Review: Chapter 9 — Ten worked applications of the normalization model.

V011-C09-DISCUSSION-006 — Check units, coefficient vector, side convention, and equivalent noise bandwidth. Use Q = Be D to compare like quantities. Distinguish an algebraically consistent representation from proof of calibration or white input assumptions.

Review: Chapter 9 — Noise density uses a different denominator.

V011-C09-DISCUSSION-007 — Discuss common sources, shared clocks or references, direct cable leakage, and state-conditioned fit. Request paired data, calibration, and controlled path changes with comparable sensitivity. Preserve the relationship evidence while limiting causal attribution.

Review: Chapter 9 — Cross-Spectra, Coherence, and Multichannel Analysis.

V011-C09-DISCUSSION-008 — Use shared-source cancellation and state mixing as concrete alternatives. Inspect complex cross-spectra and independent state rules, and propose configuration challenges. Low coherence can describe the pooled fit without proving physical independence.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

Copyright 2026, James M. Atkinson

V011-C09-DISCUSSION-009 — Show that a single pair always permits a complex scalar fit. Discuss repeatability, ensemble definition, uncertainty, and competing paths. Require meaningful multiple observations and controls before drawing a physical relationship conclusion.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-DISCUSSION-010 — Demonstrate the phase-cancellation example and distinguish averaging complex products from averaging already normalized magnitudes. Keep the proper estimator and explain it clearly. If another statistic is retained, give it an accurate separate definition and do not inherit the coherence proof.

Review: Chapter 9 — Define the ensemble before normalizing.

V011-C09-DISCUSSION-011 — Discuss the loss of a common paired construction and the counterexample above one. Require a valid estimator definition, domain, and uncertainty assessment. Avoid generalizing the specific failure to every robust method or claiming that clipping an invalid ratio repairs it.

Review: Chapter 9 — Define the ensemble before normalizing.

V011-C09-DISCUSSION-012 — Explain the role of input noise and disturbance allocation. Require calibrated autospectra and justified model assumptions before applying $\frac{C}{(1-C)}$. Equal normalized coherence need not identify equal SNR or noise location.

Review: Chapter 9 — The projection interpretation and its boundary.

Copyright 2026, James M. Atkinson

V011-C09-DISCUSSION-013 — Ask whether the state rule was specified independently of the desired result and corresponds to a meaningful operating condition. Preserve pooled and state-resolved estimates and their weights. Reject postselection that merely manufactures proportional vectors.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-DISCUSSION-014 — Separate normalized relationship from absolute amplitude, fitted gain, and phase/delay quantities. Discuss nonzero-gain assumptions and calibration residuals. Coherence invariance does not validate the full multichannel measurement chain.

Review: Chapter 9 — Ten worked applications of Equation 18 and its paired-spectrum realization.

V011-C09-DISCUSSION-015 — Distinguish nonnegative autospectra from complex cross-spectra encoding relative phase. State conjugation and units, inspect the paired construction, and avoid interpreting a negative real cross term as negative physical mean power.

Review: Chapter 9 — Define the ensemble before normalizing.

V011-C09-DISCUSSION-016 — Identify the contaminating mechanism and qualify the inference supported by original high coherence. Preserve evidence, test remaining paths with comparable sensitivity and state, and avoid declaring universal absence of environmental coupling solely because one instrument artifact was found.

Review: Chapter 9 — Hypothetical Case Adjudication: FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

Copyright 2026, James M. Atkinson

V011-C09-DISCUSSION-017 — Discuss thresholds, interpolation, color mapping, window lengths, and selection effects. Require raw-record corroboration and intended-use references. The image can motivate a hypothesis, but detection claims need an explicit tested rule.

Review: Chapter 9 — Time-Frequency and Nonstationary Methods.

V011-C09-DISCUSSION-018 — Explain each statistic and preserve event-resolved frequency and duration information. Use multiple declared summaries for power and occurrence, without treating max hold as mean power or simultaneous coexistence. Report the behavior that actually answers the survey question.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-DISCUSSION-019 — Discuss drift, nonstationarity, changing states, and transient dilution. Balance resolution against the time interval over which the signal is comparable. Validate chosen lengths against intended references rather than maximizing N automatically.

Review: Chapter 9 — Quantitative Model for FFT Analyzers, Windowing, Averaging, and Spectral Estimation.

V011-C09-DISCUSSION-020 — Explain the algebraic bound separately from sampling variation, overlap, independence, and record selection. A bounded estimator is not automatically an exact probability or confidence statement. Identify evidence needed for the uncertainty claim.

Review: Chapter 9 — Define the ensemble before normalizing.

Copyright 2026, James M. Atkinson

V011-C09-DISCUSSION-021 — Retain original samples, both exact processing paths, settings, and relevant controls. Compare predicted leakage behavior and time structure, then test on independent records. Avoid deleting the less convenient interpretation or claiming processing variation identifies the physical source by itself.

Review: Chapter 9 — Spectral Leakage and Window Selection.

V011-C09-DISCUSSION-022 — Use conjugate-pair counting and energy closure to explain endpoint treatment. Distinguish odd and even N and preserve the actual quantity. Consistent physics requires different endpoint handling rather than visually uniform arithmetic.

Review: Chapter 9 — Noise density uses a different denominator.

V011-C09-DISCUSSION-023 — State the statistic each method retains and examine per-record phase and magnitude. Use controlled receiver/path challenges, since coherent persistence alone does not prove an external source. Retain both methods as declared diagnostics if they answer different questions.

Review: Chapter 9 — Averaging and Statistical Stability.

V011-C09-DISCUSSION-024 — Distinguish visual recreation from data-to-estimate reproducibility. Require samples, preprocessing, coefficients, units, exclusions, and executable analysis. State what the surviving image supports while identifying missing evidence instead of inventing a reconstruction.

Review: Chapter 9 — Estimator Validation and Reporting.

Copyright 2026, James M. Atkinson

V011-C09-DISCUSSION-025 — Require correct normalization, paired records, clock/skew calibration, uncertainty limits, representative transient and channel references, held-out tests, and usable sample coverage. Discuss artifact challenges and report scope. No single attractive spectrum, coherence value, or energy check replaces this combined evidence.

Review: Chapter 9 — Estimator Validation and Reporting.

Copyright 2026, James M. Atkinson

Chapter Glossary

AUTOSPECTRUM: A spectral estimate formed from weighted squared magnitudes of a channel's Fourier coefficients. Its units follow the measured quantity and density normalization. The chapter's coherence ratio requires both autospectra to be positive and to use the same paired record population and compatible weighting as the cross-spectrum.

CHANNEL SKEW: A relative timing offset between measurement channels caused by acquisition or processing paths. It can introduce a frequency-dependent phase difference into paired analysis. Phase and delay conclusions therefore require alignment and calibration of the relevant channel paths, together with the common-clock and geometry conditions used in the comparison.

COHERENCE: Normalized spectral measure of linear relationship between two signals under stated averaging conditions.

COHERENCE RESIDUAL: The minimum weighted spectral residual $P_{yy}(1-C)$ for a single complex-gain fit, conditional on positive autospectra and the declared estimator.

COHERENT GAIN: Window-dependent amplitude scaling for a sinusoid centered on a transform bin.

COHERENT WEIGHT SUM: The signed sum of the actual window coefficients. For the chapter's coherent complex tone it is the factor multiplying that tone's complex amplitude in the selected transform coefficient. Coherent-amplitude normalization requires this sum to be nonzero; it must not be confused with the sum of squared weights.

Copyright 2026, James M. Atkinson

COMPLEX CROSS-PRODUCT AVERAGING: Averaging the complex paired-channel products before taking the magnitude used in a coherence calculation. Opposing phases can cancel in this operation. Averaging the individual normalized magnitude ratios instead loses that information and gives unity for every nonzero single pair, regardless of a repeatable relationship.

CONJUGATE SPECTRAL SYMMETRY: The relationship in which the negative-frequency coefficient of a real windowed record is the complex conjugate of its positive-frequency counterpart. Their squared magnitudes are equal, allowing the stated one-sided folding. A general complex record need not satisfy this relationship, so the same doubling rule cannot be applied automatically.

CROSS-SPECTRAL CONJUGATION CONVENTION: The declared choice of which channel coefficient is complex-conjugated in each cross-product. Reversing that choice conjugates the resulting cross-spectrum, reverses its phase and leaves magnitude-squared coherence unchanged. A delay inference must retain the selected convention and any remaining phase-branch ambiguity.

CROSS-SPECTRUM: A complex spectral estimate formed from products of corresponding Fourier coefficients from two aligned channels, with a stated conjugation direction, common weights and compatible normalization. Its magnitude and phase describe a second-order relationship under that construction. Neither a nonzero value nor its phase alone identifies a unique physical coupling path.

Copyright 2026, James M. Atkinson

CROSS-SPECTRUM CANCELLATION: Reduction or disappearance of an averaged complex cross-spectrum because admitted shared components contribute opposing signs or phases. Both channels can still contain substantial shared power. The chapter's two-source and changing-state examples show why low coherence does not by itself establish that the channels have no common contribution.

DC BIN: The zero-frequency transform coefficient. It represents the retained record's weighted constant component under the stated preprocessing. It is not doubled in the one-sided power sum, and subtracting a mean before transformation can remove it by changing the analyzed record rather than merely changing normalization.

DETRENDING: Removal of a specified fitted or fixed trend from the retained samples before spectral estimation. Even constant detrending can eliminate the DC component. The chapter's finite-window model assumes no detrending unless explicitly stated, so a software default that removes a mean changes the model input and must be accounted for.

DFT BIN SPACING: The separation between adjacent frequencies at which a discrete Fourier transform is evaluated. It is the sample rate divided by transform length, with the record length used when no padding is applied. This grid spacing does not by itself establish the ability to resolve nearby components through the actual window response.

EQUIVALENT NOISE BANDWIDTH: Rectangular-filter bandwidth passing the same noise power as a processing window or filter.

Copyright 2026, James M. Atkinson

FINITE-RECORD ENERGY CLOSURE: The exact agreement between the correctly normalized discrete spectral integral and the corresponding window-weighted time-domain mean square. It checks transform scaling, side conventions and frequency spacing. It does not establish white noise, adequate sampling, physical calibration, source identity or valid observation of every transient.

NYQUIST BIN: The transform bin at one half of the sample rate when the transform has even length. For a real record it is its own conjugate-frequency partner and is counted once in the chapter's one-sided power sum. An odd-length transform has no bin exactly at that endpoint.

ONE-SIDED SPECTRUM: A frequency representation that combines the conjugate positive- and negative-frequency contributions of a real record under a declared folding rule. Interior positive-frequency powers are doubled, while DC and an even-length Nyquist bin are retained once. Complex records generally lack the symmetry required for this construction.

PAIRED SPECTRAL ESTIMATE: Autospectral and cross-spectral sums formed from the same paired records with compatible weights and normalization.

PERIODIC WINDOW CONVENTION: A coefficient-vector convention intended for periodic DFT use; for Hann it uses N in the cosine denominator, unlike the endpoint-symmetric $N-1$ form.

RECORD LENGTH: The number of acquired samples retained for a stated finite analysis before any zero padding. Together with the sample rate it defines the observation duration. Changing this length can change leakage, nominal bin spacing and the interval over which statistical or signal-state assumptions must hold.

Copyright 2026, James M. Atkinson

SCALLOPING LOSS: The reduction in a selected bin's response when a tone lies between the transform's evaluation frequencies instead of at the stated coherent location. Its magnitude depends on the actual window and offset. A coherent-gain correction alone does not remove this error, while denser evaluation can help locate an isolated response peak.

SHORT-TIME FOURIER TRANSFORM: Sequence of transforms applied to overlapping time segments to estimate spectral evolution.

SPECTRAL DENSITY NORMALIZATION: Scaling squared transform magnitude by the sample rate and the actual squared window-weight sum so that the ordinate has input-squared units per hertz. Under the chapter's white-covariance premise its expectation is flat. Integrating this finite-record density gives the stated window-weighted mean square even without that whiteness assumption.

SPECTRAL GRAM MATRIX: The matrix formed from consistently weighted paired spectral vectors, with autospectra on its diagonal and conjugate cross-spectra off the diagonal. Common nonnegative weights give the positivity structure behind the coherence bound. Separately chosen medians need not retain that structure and can produce a substituted ratio above one.

SPECTRAL LEAKAGE: Distribution of energy into neighboring transform bins caused by finite observation and windowing.

Copyright 2026, James M. Atkinson

SPECTRAL PREPROCESSING: The declared operations applied to acquired samples before the analyzed transform, such as mean subtraction or other detrending. These operations can change which physical or statistical components remain in the analyzed record. Reproducibility requires their order and parameters alongside the window, sample rate and retained data.

SQUARED WINDOW-WEIGHT SUM: The sum of the squared real window coefficients, which is positive unless every coefficient is zero. It sets the chapter's noise-density normalization and window-weighted energy denominator. Using a coherent weight sum or sums calculated from a different coefficient vector changes the estimated quantity.

STATE-CONDITIONED COHERENCE: A paired spectral result calculated within observations assigned to a defined state instead of pooling different transfer conditions. Opposing within-state gains can produce low pooled coherence even when each state is perfectly related. The state rule must be independently defensible, rather than selected merely to obtain a preferred relationship.

SYMMETRIC WINDOW CONVENTION: A coefficient-vector convention with matching endpoints, distinguished from the periodic form used in many spectral calculations. The chapter's symmetric Hann window uses the record length minus one in its cosine denominator. For short records its weight sums and equivalent noise bandwidth differ materially from the periodic form.

TONE-NORMALIZED SQUARED SPECTRUM: The squared windowed transform divided by the squared coherent weight sum, with side conventions specified. Its units are those of input mean square, but summing its ordinates requires bandwidth correction.

Copyright 2026, James M. Atkinson

TRANSFORM LENGTH: The number of values supplied to the discrete transform, including any appended zeros. It determines the displayed frequency grid. When it exceeds the acquired record length, normalization must retain the sums of the original window coefficients; a longer transform does not represent more acquired observation time.

TWO-SIDED SPECTRUM: A spectral representation retaining both positive and negative frequencies in the chosen sampled-frequency interval. The chapter's density model begins with this convention before any justified folding for real data. Its ordinate units and integration spacing must remain explicit, especially when comparing a complex baseband record with a one-sided real-signal display.

VECTOR AVERAGING: Combining complex spectral coefficients while retaining their phase relationships. A phase-aligned component can persist while varying components partly cancel. The resulting quantity differs from an average of nonnegative powers, and its usefulness depends on the stated alignment, stationarity and meaning of the retained records.

WINDOW COEFFICIENT VECTOR: The complete sequence of real, dimensionless weights multiplied into the retained samples before transformation. Its values determine coherent gain, density scaling and the weighting of transient energy. A window name alone is insufficient when endpoint conventions, normalization or coefficient generation can differ.

WINDOW MAIN LOBE: The central region of a window's frequency response around a tone's shifted center. Its width affects separation of neighboring components and differs from the transform-bin spacing. Reducing sidelobes generally changes this central response, so the relevant tradeoff follows the quantity and interference conditions being measured.

Copyright 2026, James M. Atkinson

WINDOW SCALING INVARIANCE: The property that multiplying all window coefficients by one nonzero real constant leaves the chapter's normalized squared spectrum, density and equivalent noise bandwidth unchanged when all associated sums are changed consistently. It does not permit mixing a transform from one vector with normalization sums from another.

WINDOW SIDELOBE: A secondary region of a finite window's frequency response away from its main lobe. A strong component can therefore contribute an indication at other frequencies even without another physical tone. Window choice and controlled reprocessing help test this leakage explanation, with amplitude and noise normalizations kept consistent.

WINDOW-WEIGHTED MEAN SQUARE: The ratio $\frac{\sum_{n=0}^{N-1} w_n^{\ 2} \left| x_n \right|^2}{\sum_{n=0}^{N-1} w_n^{\ 2}}$. It is the integrated density of the stated finite-record normalization and can depend strongly on transient position.

ZERO PADDING: Appending zeros to an acquired, windowed record before calculating its transform. It evaluates the same finite-record transform on a denser frequency grid. It does not narrow the underlying window response, create independent observations or replace the original window sums in amplitude and density normalization.

Chapter 10. Software-Defined Radios, Sampling, Quantization, DDC, and Channelization

Copyright 2026, James M. Atkinson

10.1 SDR Boundary and Partitioning

A software-defined radio moves functions traditionally performed by analog hardware into configurable digital processing. The boundary can occur at audio, baseband, IF, or direct RF sampling. Analog protection, filtering, gain, clocking, and converter performance remain essential even when tuning, filtering, detection, and demodulation are implemented in software. The practitioner documents where the analog chain ends, where samples are formed, and which functions are performed by firmware, programmable logic, driver, host software, and analysis script.[1]

An SDR configuration is executable measurement logic. Center frequency, sample rate, analog bandwidth, gain distribution, decimation, digital oscillator, filter coefficients, data type, scaling, and packet format determine the samples. Configuration files, device serial number, gateware, driver, software build, and calibration data should accompany a significant capture. A generic label such as 20 MS/s I/Q is insufficient when hidden decimation or analog filtering changes the actual bandwidth.

1 United States Navy, Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles, NAVEDTRA 14189 (September 1998), 2-10–2-14, reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388–8392; title and edition at page 8345. These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

Copyright 2026, James M. Atkinson

10.2 Sampling, Aliasing, and Band Selection

Sampling maps input spectrum into periodic replicas around multiples of sample rate. A band-limited real signal requires adequate anti-alias filtering, while complex sampling can represent a selected band with different symmetry. Undersampling may intentionally translate a higher-frequency band into a lower Nyquist zone, but noise, harmonics, converter bandwidth, and filter response also fold. An aliased component can look stable and repeatable while being assigned to the wrong external frequency.

Copyright 2026, James M. Atkinson

Figure 55. ADC aliasing and preselection.

Aliasing challenges include changing sample rate, analog center frequency, front-end filter, and tuner plan. A genuine RF component maps predictably through those changes. A component fixed in digital frequency may be generated after sampling, while one moving according to a different Nyquist

Copyright 2026, James M. Atkinson

relationship may be an alias. These tests are recorded before a software display is treated as a physical spectrum.

Copyright 2026, James M. Atkinson

Figure 56. Software-defined radio signal path.

Copyright 2026, James M. Atkinson

10.3 Quantization, Clipping, and Converter Performance

An analog-to-digital converter represents amplitude with finite codes. Quantization noise is one contributor among thermal noise, clock jitter, aperture error, differential and integral nonlinearity, reference noise, distortion, and digital truncation. The ideal relationship between bit depth and signal-to-quantization-noise ratio is a planning limit for a full-scale sinusoid, not a guarantee of effective performance.

Copyright 2026, James M. Atkinson

Figure 57. ADC effective bits, clipping and jitter.

Clipping is especially damaging because it generates broad harmonics and intermodulation. A trace can appear normal after digital scaling even when the ADC has clipped. Overflow flags, sample histograms, peak-to-full-scale ratio, and repeated captures with changed analog attenuation are needed.

Copyright 2026, James M. Atkinson

Effective number of bits varies with input frequency and sample rate. The converter's analog input bandwidth can pass out-of-band energy that aliases even when the selected digital span is narrow.

Copyright 2026, James M. Atkinson

10.4 Digital Downconversion and Channelization

A digital downconverter multiplies samples by a numerically controlled oscillator, filters the translated band, and decimates to a lower sample rate. Numerically controlled oscillator phase and tuning word, filter response, decimation ratio, arithmetic precision, and scaling determine the result. Half-band, polyphase, finite impulse response, cascaded-integrator-comb, and multistage filters have different passband, alias rejection, group delay, and transient behavior.

Channelizers divide a wideband stream into many subchannels using filter banks or FFT structures. They are efficient for monitoring, but channel boundaries, oversampling, scalloping, leakage, and per-channel gain must be understood. A narrow signal near a boundary can split between outputs or appear at different levels as the channel grid changes. Verification uses known tones across channel centers and edges.

Copyright 2026, James M. Atkinson

10.5 Model 10B for digital mixing filtering and decimation

A recorded channel is defined by its transformation from the original samples. A center-frequency label and an output rate leave amplitude, phase, rejected-band contamination, and time origin unspecified. The useful starting point is an explicit mixer, finite impulse response filter, and retained-sample rule. The three-stage architecture is established in the original manufacturer explanation cited here. The derivation and numerical applications below use stipulated signals and filters; they are not measurements of a named receiver.[2]

Let $F_s > 0$ be the input sampling frequency in hertz, n the integer input index, and $x[n]$ a real or complex sample expressed in calibrated volts. Let f_n be the NCO frequency in hertz and φ_0 its initial phase in radians. Use the negative complex exponential convention, with $j^2 = -1$. The mixed sequence $v[n]$, also in volts, is

$$v[n] = x[n] \exp\{-j[\frac{2\pi f_n n}{F_s} + \varphi_0]\}$$

For a causal FIR filter, $h[k]$ is the dimensionless coefficient at integer lag k, and $L \geq 1$ is its integer length. Coefficients outside $0 \leq k < L$ are zero. The filtered sequence $w[n]$ and retained output $y[m]$ are

$$w[n] = \sum_{k=0}^{L-1} h[k] v[n-k]$$

2 Joint Committee for Guides in Metrology, International vocabulary of metrology: Basic and general concepts and associated terms, VIM3 online edition, entries 2.48, 2.49 and 2.53, https://jcgm.bipm.org/vim/en/2.48.html, https://jcgm.bipm.org/vim/en/2.49.html and https://jcgm.bipm.org/vim/en/2.53.html, read November 2, 2026. These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

$$y[m]=w[mM+p], F_o=\frac{F_s}{M}$$

Here m is the integer output index, $M \geq 1$ is the integer decimation factor, p is the retained input phase with $0 \leq p < M$, and F_o is the output sampling frequency in hertz. The phase p is an index residue, not an angle. Both w and y retain voltage units. These relations assume exact linear arithmetic, fixed coefficients, and a continuous input clock. They exclude saturation, coefficient rounding, gaps, clock error, and undocumented state resets. A finite record also requires an initial filter-state rule; zero padding is one possible rule, not a statement that the physical signal was zero before recording.

For a steady complex tone, define $A \geq 0$ as its voltage amplitude, f as its signed input frequency in hertz, and θ as its phase in radians. Set $\omega=\frac{2\pi \backslash(f-f_n \backslash)}{F_s}$, in radians per input sample. Then

$$x[n]=A\exp\{j[\frac{2\pi f n}{F_s}+\theta]\}$$

$$H(\omega)=\sum_{k=0}^{L-1} h[k]\exp(-j\omega k)$$

$H \backslash(\omega \backslash)$ is the dimensionless complex filter response. Substitution into the convolution factors out the common tone and leaves H as the weighted sum of its delayed phases. Substituting $n=mM+p$ then gives the complete steady-state result

$$y[m]=A\,H(\omega)\exp\{j[\theta-\varphi_0+\omega p+M\omega m]\}$$

The output phase increment is $M\omega$ radians per output sample. Its signed frequency representative f_o is therefore $f-f_n$ modulo F_o, chosen in the half-

Copyright 2026, James M. Atkinson

open interval $-\frac{F_o}{2} \leq f_o < \frac{F_o}{2}$. Amplitude is $A \mid H \backslash(\omega \backslash) \mid$. Keeping every Mth value introduces no automatic factor $\frac{1}{M}$ in that tone amplitude. Frequency-domain alias-sum formulas must be interpreted with the corresponding frequency scaling; their prefactor is not a voltage-loss rule for an individual retained sinusoid.[3]

The response H must be evaluated at the translated frequency before sample deletion. Different translated tones separated by an integer multiple of F_o can reach the same output frequency while receiving different gains from this filter. Once those contributions have combined in a retained sequence, a subsequent linear filter cannot separate them solely by their former frequencies. The model also starts after sampling: its frequency translation does not identify which analog member of an existing alias class produced $x[n]$.

10.6 Ten worked applications of Model 10B

Each application states a separate test condition. Frequencies are referenced to the input of the stated stage, and MS/s means one million samples per second. Unity or specified gains below are assumptions used to isolate a mechanism. A physical acceptance result requires the actual coefficients, gain conventions, state handling, and measured errors.

Copyright 2026, James M. Atkinson

10.7 Application 10B1 Mixer sign and the output frequency label

Use a complex 9 MHz input tone, $F_s = 48\ \mathrm{MS/s}$, $f_n = 8\ \mathrm{MHz}$, $M = 8$, $p = 0$, and $\varphi_0 = 0$. The translated frequency is 1 MHz and $F_o = 6\ \mathrm{MS/s}$. With H at 1 MHz equal to one, the output retains amplitude A and advances by $\frac{2\pi}{6}$ radians per output sample. The same voltage sequence must be interpreted on the 6 MS/s clock. If the mixer sign is reversed, the intermediate frequency becomes 17 MHz; its representative after unfiltered deletion is \$(17 - 3 \times 6\$) $\mathrm{MHz} = -1\ \mathrm{MHz}$. A low-pass filter can instead reject that misplaced tone. Neither outcome is explained by changing only a display label. Record the complex sign convention before assigning an output offset to RF frequency.

Copyright 2026, James M. Atkinson

10.8 Application 10B2 Real input and complex amplitude normalization

Let $x[n]$ be a 2 V peak real cosine at 10 MHz, with $F_s = 48\ \mathrm{MS/s}$ and $f_n = 9\ \mathrm{MHz}$. Euler expansion produces two mixed components: +1 MHz and −19 MHz, each with a 1 V complex coefficient. Assume a filter with unit gain at +1 MHz and zero response at −19 MHz, followed by $M = 8$. The retained complex tone has amplitude 1 V. Its mean square $|y|^2$ is 1 V², whereas the original real cosine has mean square 2 V². This explicitly defined comparison is −3.0103 dB. The coefficient amplitude is half the original real peak, giving $20\log_{10}\backslash(\frac{1}{2}\backslash)\ \mathrm{dB} \approx -6.0206\ \mathrm{dB}$. These are different normalization questions.

Multiplying the complex output by two recovers a 2 V analytic-signal amplitude but gives 4 V² complex mean square. Without image rejection, the −19 MHz component would alias to −1 MHz at the 6 MS/s output. A claimed conversion loss is uninterpretable until peak, branch, complex mean-square, and full-scale references are identified.

Copyright 2026, James M. Atkinson

10.9 Application 10B3 An irreversible blocker combination

At the mixer output, stipulate two equal-amplitude complex tones at 1 MHz and 7 MHz with the same initial phase. Take $F_s = 48\ \mathrm{MS/s}$, $M = 8$, and $p = 0$. Bare deletion maps both to +1 MHz at $F_o = 6\ \mathrm{MS/s}$, because their input phase difference at $n = 8m$ is $2\pi m$. Their equal coefficients add to twice one coefficient. Instead place a filter before deletion with real gains of 1 at 1 MHz and 0.001 at 7 MHz in this stipulated example. The desired coefficient is retained and the blocker coefficient is 60 dB lower in amplitude ratio, leaving a combined coefficient 1.001 times the original desired value. A filter applied only after bare deletion sees the single combined tone and cannot reconstruct the two original coefficients. This is an information-loss counterexample, not a proposed realizable two-point filter specification.

Copyright 2026, James M. Atkinson

10.10 Application 10B4 Allocate attenuation across actual stage frequencies

Consider two decimation stages: $M_1 = 2$ reduces 48 MS/s to 24 MS/s, then $M_2 = 4$ reduces 24 MS/s to 6 MS/s. Both retain phase zero. A 1 MHz desired tone remains at 1 MHz with unit gain in both stages. A 13 MHz blocker becomes −11 MHz after the first deletion and +1 MHz after the second. Suppose the first filter attenuates its 13 MHz input by 30 dB and the second attenuates its −11 MHz input by 50 dB. Their magnitude ratios multiply, so the total attenuation is 80 dB. A second blocker initially at 7 MHz remains at 7 MHz after the first deletion and also ends at +1 MHz. If the two filters give only 5 dB and 60 dB at this path, its total is 65 dB.

Use a common mean-square reference of 1 V^2 and define a level as $10 \log_{10} \backslash(\frac{P}{1\ \mathrm{V}^2} \backslash)$, where P is the tone mean square. For either blocker initially at −5 dB relative to that reference, an allowed contribution of −85 dB requires 80 dB attenuation. The 13 MHz path reaches that limit; the 7 MHz path leaves −70 dB and misses it by 15 dB. These are individual blocker contributions; a combined limit additionally requires their relative phases or a justified power-combination rule. The calculation concerns digital alias contamination and says nothing about earlier analog or converter overload. Each stage needs a frequency-specific rejection ledger on its own sampling clock.

Copyright 2026, James M. Atkinson

10.11 Application 10B5 A moving-average null is not a rejection band

Choose the exact four-tap filter $h[k]=\frac{1}{4}$ for $k=0,1,2,3$ at $F_s=48\ \mathrm{MS/s}$, followed by $M=4$. Summing the finite geometric series gives

$$H(\omega)=\exp\left(\frac{-j3\omega}{2}\right)\frac{\sin(2\omega)}{4\sin\left(\frac{\omega}{2}\right)}$$

The removable singularity at $\omega=0$ has limit one. At a translated 12 MHz, $\omega=\frac{\pi}{2}$ and the response is exactly zero. At 6 MHz, however, $|H|\approx 0.653281$, or −3.69799 dB. At 15 MHz, $|H|\approx 0.212608$, or −13.4484 dB; that component maps to +3 MHz on the 12 MS/s output clock. Thus a successful rejection test at the exact null does not establish rejection of a neighboring alias band. The 6 MHz value lies at the output half-rate boundary and is used here only as a filter-response diagnostic, not as an admissible general passband endpoint. Acceptance must cover the intended band and the frequencies capable of entering it.

Copyright 2026, James M. Atkinson

10.12 Application 10B6 Group delay and first complete filter history

A real symmetric FIR of length $L=33$ has coefficients symmetric about input lag 16. Away from response zeros its linear-phase group delay is 16 input samples, or $\frac{16}{48\times10^6\ \mathrm{s}^{-1}}\approx333.333\ \mathrm{ns}$ at $F_s=48\ \mathrm{MS/s}$. For $M=8$ this is two output sample intervals. With retained phase $p=3$, an output at index m corresponds to the filter center time

$$t_{center}[m]=\frac{mM+p-16}{F_s}$$

The result is in seconds relative to input sample zero. For $m=2$ the retained input index is 19, while the filter center is index 3, giving 62.5 ns. Labeling this value only with the retained-index time would omit the 333.333 ns filter delay. If acquisition begins at $n=0$ and both end coefficients are nonzero, a complete 33-sample history first exists at $n\geq32$. The first retained index meeting that condition is 35, at $m=4$, whose center is $\frac{19}{48\times10^6\ \mathrm{s}^{-1}}\approx395.833\ \mathrm{ns}$. Group delay and startup support answer different questions. Symmetry alone supplies neither flat amplitude nor a passband error tolerance.[4]

Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. These sources distinguish receiver noise from source and path contributions; the scalar assumptions and synthetic cases are stated in Model 2B.

Copyright 2026, James M. Atkinson

10.13 Application 10B7 Retained phase creates a coherent offset

Compare two otherwise identical settled channels for a translated 1 MHz tone at $F_s = 48\ \mathrm{MS/s}$ and $M = 8$. Let one retain $p = 0$ and the other $p = 3$, with the same NCO phase and filter. At a common output index, their phase difference is $\omega \times 3 = \frac{2\pi \times 3}{48}\ \mathrm{rad} = \frac{\pi}{8}\ \mathrm{rad}$, or 22.5°. Their physical retained-time origins differ by $\frac{3}{48 \times 10^6\ \mathrm{s}^{-1}} = 62.5\ \mathrm{ns}$. Both report a 6 MS/s rate and a 1 MHz tone, yet direct sample-by-sample phase comparison includes that offset. It is not evidence of a different propagation path. The tone-specific correction follows from the known frequency; a broadband alignment needs the actual timing and filtering relationship, not one constant phase correction for every frequency.

Copyright 2026, James M. Atkinson

10.14 Application 10B8 Tuning resolution and accumulated phase error

For an ideal b-bit phase accumulator clocked at F_s, let K be the integer phase-increment word, f_t the requested frequency, and f_n the generated frequency, both in hertz. Nearest-word tuning uses

$$K = round\left[\frac{2^b f_t}{F_s}\right], f_n = \frac{K F_s}{2^b}$$

The frequency grid is $\frac{F_s}{2^b}$ and the nearest-word error is at most half a grid interval. With $b = 32$, $F_s = 48\ \mathrm{MS/s}$, and $f_t = 9.1\ \mathrm{MHz}$, $K = 814254217$. The generated frequency is 9,100,000.005215406 Hz, an error of +0.005215406 Hz; the grid is 0.011175871 Hz. Over 10 s the NCO phase leads the requested oscillator by $\backslash(360 \times 0.005215406 \times 10\backslash)^\circ \approx 18.7755^\circ$. The negative-exponential mixer consequently adds a −18.7755° baseband phase drift relative to an ideal requested-frequency mixer. Fine frequency resolution can therefore matter in a long coherent comparison. This calculation assumes an exact clock and evaluates only accumulator quantization. Truncated phase addresses, waveform-table amplitudes, arithmetic, and clock instability need separate error models; bit width alone does not establish spur performance.[5]

The full paper was not accessed; Model 2B supplies its own stated derivation and working conventions.

Copyright 2026, James M. Atkinson

10.15 Application 10B9 Polyphase computation preserves the specified filter

Partition the convolution lag as $k = sM + r$, with branch index $r = 0, \ldots, M-1$ and nonnegative integer s. Continue h by zeros outside its finite support. Regrouping, without approximating, gives

$$y[m] = \sum_{r=0}^{M-1} \sum_{s \geq 0} h[sM + r] v[M(m-s) + p - r]$$

For $M = 3$, $p = 0$, $L = 6$, choose $h = \frac{[1,2,3,4,5,6]}{21}$. Use the local input sequence $v[n] = n \ \mathrm{V}$ for $n = 1$ through 6 and evaluate $m = 2$. Direct filtering at retained index 6 gives $\frac{6+10+12+12+10+6}{21} \ \mathrm{V} = \frac{56}{21} \ \mathrm{V} = \frac{8}{3} \ \mathrm{V}$. The three branch contributions are $\frac{6+12}{21}$, $\frac{10+10}{21}$, and $\frac{12+6}{21} \ \mathrm{V}$, respectively, and sum to the same $\frac{8}{3}$ V. The ramp is a finite arithmetic test, not a bounded steady-state tone. Polyphase organization can avoid computing filtered samples that would be discarded. It does not improve the rejection of unchanged coefficients. If a deployed implementation rounds branch products or sums differently, equality must be checked under that specified arithmetic, including state and commutator order.

Copyright 2026, James M. Atkinson

10.16 Application 10B10 A block reset can imitate a phase event

Use $F_s = 48\ \mathrm{MS/s}$, $f_n = 9\ \mathrm{MHz}$, $M = 8$, and $p = 0$. Process consecutive blocks of $B = 1000$ input samples. A continuous NCO advances $\frac{9 \times 1000}{48} = 187.5$ cycles per block, leaving a half-cycle phase change modulo one cycle. If software instead restarts its NCO at zero at every block, its mixed samples differ from the continuous-NCO result by $\exp\backslash(\frac{j2\pi f_n c B}{F_s}\backslash) = \backslash(-1\backslash)^c$ in block c, where c is a nonnegative block index. Thus alternate blocks acquire an artificial 180° sign reversal even though the input samples are continuous.

Each block contains 125 retained samples and lasts 20.8333 μs. The corresponding sign is exact before filtering and after the filter history lies wholly within a block. Near boundaries, a preserved FIR state also contains samples mixed under the preceding phase, so its transient must be evaluated from the full convolution. Resetting that state adds a separate startup artifact. A correct streaming reproduction carries both NCO phase and FIR history, along with the retained-phase schedule. A file with uninterrupted sample counters can still contain a processing-induced phase discontinuity.

Copyright 2026, James M. Atkinson

10.17 Interpretation of the DDC evidence

A reproducible channel record links original sample indices to output indices, identifies the signed mixer convention and NCO state, supplies coefficients and scaling for every rate-changing stage, and records any discarded startup interval. These facts permit a second analyst to predict the channel response and to distinguish retained environmental content from a transformation artifact. They do not establish analog-source uniqueness or physical calibration by themselves. A channelizer extends this problem to several interacting selected bands; its common prototype, channel grid, overlap, and branch phase relationships require a separate analysis.

The unit-magnitude complex oscillator in Model 10B translates a complex component without an automatic amplitude factor. A real input cosine contributes half its peak amplitude to each complex-frequency component, as Application 10B2 makes explicit. Model 4A and Model 6A use their declared real-mixer and peak-envelope scalings, so an amplitude comparison must carry the selected sideband and any explicit reconstruction factor between conventions. A decimation factor is not that reconstruction factor. When the selected channel is subsequently aligned to symbol references, Model 7A supplies the finite-record fitting and EVM definitions; the DDC output alone does not define them.

Copyright 2026, James M. Atkinson

10.18 Model 10C for a polyphase analysis channelizer

A channelizer applies a family of related filters to one sampled input. Separate output labels do not imply separate sources, disjoint information, equal gain, or independent noise. The common prototype and the timing convention determine how those outputs relate. The MIT lecture cited here develops modulated filter banks and their polyphase and Fourier-transform realization. The following derivation fixes a causal lag convention explicitly and extends Model 10B to a complete analysis bank. Its calculations are stipulated digital examples, not measurements of a deployed receiver.[6]

6 International Electrotechnical Commission, CISPR 16-1-1:2019, Specification for Radio Disturbance and Immunity Measuring Apparatus and Methods, Part 1-1: Radio Disturbance and Immunity Measuring Apparatus: Measuring Apparatus, 5th ed. (May 22, 2019), official publication scope, https://webstore.iec.ch/en/publication/60774, checked November 1, 2026. The public scope identifies the 9 kHz–18 GHz apparatus range and EMI receivers and spectrum analyzers. No access to or clause-by-clause compliance review of the complete standard is claimed.

Copyright 2026, James M. Atkinson

Figure 58. Polyphase filter-bank channelisation.

In this model, $M \geq 1$ is the integer number of channels and D is the integer decimation factor, with $1 \leq D \leq M$. These roles are deliberately separated; M was the decimation factor in Model 10B. Let $F_s > 0$ be the input sampling frequency in hertz, n the integer input index, and $x[n]$ the complex input

Copyright 2026, James M. Atkinson

voltage. Let $h[\ell]$ be a dimensionless, possibly complex FIR coefficient at integer lag ℓ, with nominal length $L \geq 1$ and zero coefficients outside $0 \leq \ell < L$. A real input is a special case, but its conjugate-frequency relationships must then be retained. Channel index k runs from zero through $M-1$. Define its angular center ω_k, in radians per input sample, and the output sampling frequency F_o by

$$\omega_k = \frac{2\pi k}{M}, F_o = \frac{F_s}{D}$$

The signed center frequency is the representative of $\frac{k F_s}{M}$ in the half-open interval $[\frac{-F_s}{2}, \frac{F_s}{2}\backslash)$. The grid spacing is $\frac{F_s}{M}$ hertz. Let m be the integer output index and p a fixed retained input-index residue, $0 \leq p < D$, so the absolute retained input index is $n_m = m D + p$. With $j^2 = -1$, each channel first mixes by a negative complex exponential, then applies the same prototype and retains the specified indices:

$$y_k[m] = \sum_{\ell=0}^{L-1} h[\ell] x[n_m - \ell] \exp\{-j \omega_k (n_m - \ell)\}$$

The result $y_k[m]$ remains in volts. The equation assumes a known uninterrupted input clock, exact linear arithmetic, fixed coefficients, and a specified filter history. It excludes clipping, finite-word rounding, dropped samples, and undocumented resets. A finite recording requires an initial-state rule; the settled-tone calculations below use a tone extending through the required history. The formula does not identify the analog source of an already sampled alias.

Copyright 2026, James M. Atkinson

Write a complex tone as $x[n]=A\exp[j(\omega n+\theta)]$, where $A\geq 0$ is voltage amplitude, θ is phase in radians, and $\omega=\frac{2\pi f}{F_s}$ is the angular frequency corresponding to signed digital-input frequency f in hertz. Define the channel offset $\delta_k=\omega-\omega_k$. The prototype response and output are

$$H(\delta_k)=\sum_{\ell=0}^{L-1} h[\ell]\exp(-j\delta_k\ell)$$

$$y_k[m]=A\,H(\delta_k)\exp\{j[\theta+\delta_k(mD+p)]\}$$

H is dimensionless and periodic with period 2π. Output amplitude is $A\,|\,H(\delta_k)\,|$, and its phase advances by $D\delta_k$ radians per output sample. Its frequency in hertz is $f-\frac{kF_s}{M}$ modulo F_o, represented in $[\frac{-F_o}{2},\frac{F_o}{2})$. The prototype response must be evaluated before that output-frequency reduction. Two inputs sharing an output-frequency label need not receive the same prototype gain.

Copyright 2026, James M. Atkinson

10.19 Causal polyphase grouping and the transform convention

Partition the filter lag as $\ell = qM + r$, where r is an integer branch index from zero through $M-1$ and q is a nonnegative integer. Zero extension of h makes the following sum finite. Define the branch value $s_r[m]$, in volts, by

$$s_r[m] = \sum_{q \geq 0} h[qM + r]\, x[n_m - qM - r]$$

Substitution into the direct sum gives $\exp[j\omega_k \backslash(qM + r\backslash)] = \exp\backslash(\frac{j2\pi kr}{M}\backslash)$, because the factor $\exp\backslash(j2\pi kq\backslash)$ equals one. Hence the exact analysis-bank identity is

$$y_k[m] = \exp(-j\omega_k n_m) \sum_{r=0}^{M-1} s_r[m] \exp(\frac{j2\pi kr}{M})$$

The inner sum uses the positive exponential sign. Define an inverse DFT here with the positive exponential and a normalization of $\frac{1}{M}$. The inner sum is then M times that inverse DFT. A negative-exponential FFT applied to this same ordered branch vector requires the output-bin mapping $k \mapsto \backslash(-k \bmod M\backslash)$; the outer phase still uses the desired channel k. Reversing branch order is a different implementation choice and must be traced explicitly. Neither the word FFT nor the name polyphase fixes sign, order, or amplitude normalization.

When $D = M$ and $p = 0$, $\exp\backslash(-j\omega_k n_m\backslash) = 1$. For $D < M$ that simplification generally fails. In addition, the input residue used by branch r is $\backslash(mD + p - r\backslash)$ modulo M and changes with m. Its schedule repeats after $\frac{M}{\gcd\backslash(M, D\backslash)}$ output steps, where gcd denotes the greatest common divisor.

Copyright 2026, James M. Atkinson

This algebraic grouping therefore does not authorize an unchanged critically sampled commutator for an oversampled implementation. The manufacturer algorithm reference separately describes output rates, transform arrangements, and phase correction for an oversampled bank.[7]

Critical sampling means $D = M$, so the sum of the M output sample rates equals F_s. Oversampling means $D < M$, giving an aggregate rate $\frac{M F_s}{D}$ and a ratio $\frac{M}{D}$ relative to the input rate. This rate accounting establishes neither a passband specification nor invertibility. The analysis bank may retain redundant information, suppress information, or admit a synthesis inverse, depending on its actual coefficients and timing. A receiver implementation also needs its own state, scaling, and phase comparison. The current manufacturer HDL documentation explicitly describes a phase difference from its other channelizer implementation and a configuration-dependent correction; that example supports checking conventions, not a universal phase value for other equipment.[8]

current analyzer.

Copyright 2026, James M. Atkinson

10.21 Application 10C1 Signed channel centers and residual frequency

Take $F_s = 64\ \mathrm{MS/s}$ and $M = D = 8$. The signed center list for $k = 0, \ldots, 7$ is $[0, 8, 16, 24, -32, -24, -16, -8]\ \mathrm{MHz}$. A complex input at −13 MHz lies 3 MHz above channel 6, whose positive-grid center 48 MHz represents −16 MHz on the input clock. Its unreduced difference from 48 MHz is −61 MHz; reducing modulo F_s gives +3 MHz. For $h[\ell] = \frac{1}{8}$ at $\ell = 0, \ldots, 7$, the channel response is therefore H\($\frac{2\pi \cdot 3}{64}$\). The output rate is 8 MS/s, and the retained tone is at +3 MHz, with phase increment $\frac{3\pi}{4}\ \mathrm{rad}$ per output sample. Channel 7 instead has residual −5 MHz before output reduction, which also becomes +3 MHz at 8 MS/s. Their matching displayed output frequencies do not make the channel centers identical: their amplitudes and phases are evaluated at different prototype offsets. Record both the channel index and the residual frequency when reconstructing a frequency label.

Copyright 2026, James M. Atkinson

10.22 Application 10C2 Transform sign and amplitude normalization

Use $M=D=L=4$ and $h=\frac{[1,1,1,1]}{4}$. At retained index $n_m=4$, stipulate the newest-to-oldest input vector $[x[4],x[3],x[2],x[1]]=[1,2,3,4]\ \mathrm{V}$. The branch vector is $s=\frac{[1,2,3,4]}{4}\ \mathrm{V}$ and the outer phase is one. The required channel vector, ordered by increasing k, is

$$y=[2.5,-0.5-j0.5,-0.5,-0.5+j0.5]\ \mathrm{V}$$

A normalized inverse DFT applied directly to s produces $[0.625,-0.125-j0.125,-0.125,-0.125+j0.125]\ \mathrm{V}$, one quarter of the required voltage. Multiplication by $M=4$ restores the defined gain. A negative-exponential FFT of s instead interchanges channels 1 and 3. These are observable errors even when magnitude-only plots hide the interchange. The sum of squared output magnitudes is 7.5 V^2, equal to $\frac{1^2+2^2+3^2+4^2}{4}\ \mathrm{V}^2$. This is a block-energy identity under the stated normalization, not an RF power measurement into an unspecified impedance.

Copyright 2026, James M. Atkinson

10.23 Application 10C3 One tone at a channel boundary

Return to $F_s = 64\ \mathrm{MS/s}$, $M = D = L = 8$, and $h[\ell] = \frac{1}{8}$. A 1 V complex tone at 4 MHz lies halfway between the centers of channels 0 and 1. Their prototype offsets are $+\frac{\pi}{8}$ and $-\frac{\pi}{8}$ rad per input sample. A finite geometric sum gives $H(\frac{\pi}{8}) \approx 0.125 - j\,0.628417437$ and $H(\frac{-\pi}{8})$ as its conjugate. Both magnitudes are $\frac{1}{8\sin(\frac{\pi}{16})} \approx 0.640728862$, or −3.86651 dB relative to unit voltage gain.

Each output has mean square 0.410533475 V^2. The two contributions total 0.821066949 V^2; the remaining six channels carry the rest of the 1 V^2 sum for this rectangular bank.

On the 8 MS/s output clock, the two offsets lie at opposite half-rate endpoints and both generate an alternating exponential, with different complex coefficients. One input tone thus yields two strong boundary responses. Counting those traces as two emitters is not supported by this transformation. Conversely, adding their powers without the specified gain convention is not automatically a calibrated estimate of input power. The complete response vector and the channel grid explain the duplication.

Copyright 2026, James M. Atkinson

10.24 Application 10C4 A single-channel alias and a distinguishable full bank

Keep the same eight-channel rectangular bank. A 1 MHz input and a 9 MHz input both appear at +1 MHz in channel 0 after decimation. Their channel-0 responses are $H_1 \approx 0.917898901 - j\,0.328429478$ and $H_9 \approx 0.111746556 + j\,0.005489756$, where the subscripts denote the input frequency in megahertz for this application. Their magnitudes are 0.974886821 and 0.111881322. The ratio $\left|\frac{H_9}{H_1}\right|$ is 0.114763396, or −18.80393 dB. A 9 MHz complex coefficient $C = \frac{H_1}{H_9}$ volts, approximately \(8.050297987 - j\,3.334542607 \) V, produces exactly the same channel-0 sequence as the 1 V, zero-phase 1 MHz tone. Here C includes initial phase as well as amplitude.

The full bank distinguishes these inputs. For their unscaled unit-voltage tones, channel 1 has respective magnitudes 0.141991302 and 0.974886821. More generally define $b_r[m] = x[8m - r]$, in volts, for $r = 0, \ldots, 7$. With this particular length-eight rectangular prototype, the complete output vector is the normalized inverse DFT of b, so the negative-exponential DFT of all eight outputs reconstructs b exactly for each fully observed block. The two tone-response vectors are orthogonal over this block, because their input-frequency difference spans one complete Fourier cycle across eight lags. Saving only channel 0 discards that distinction. This inverse is specific to the stated block prototype and complete set of channels; it is not a perfect-reconstruction claim for every critically sampled filter bank.

Copyright 2026, James M. Atkinson

10.25 Application 10C5 Oversampling changes the required channel phase

Choose $M=L=8$, $D=4$, $p=0$, and $h[\ell]=\frac{1}{8}$. Drive the input with $x[n]=\exp\left(\frac{j\pi n}{4}\right)\ \mathrm{V}$, a channel-1 center tone. Its offset δ_1 is zero, so the direct mixer-filter definition gives $y_1[m]=1\ \mathrm{V}$ for all settled outputs. The raw positive-exponential transform of the branch vector instead gives $\exp(j\pi m)\ \mathrm{V}$, or $[1,-1,1,-1,\ldots]\ \mathrm{V}$. The outer phase $\exp(-j\omega_1 4m)=(-1)^m$ restores the constant output. At $F_s=64\ \mathrm{MS/s}$ the output rate is 16 MS/s, so omitting this factor places a channel-center tone at the output half-rate boundary. The branch residue schedule also repeats every $\frac{8}{\gcd(8,4)}=2$ output steps. A code path copied from $D=M$ without those phase and schedule changes does not implement the stated oversampled bank.

Copyright 2026, James M. Atkinson

10.26 Application 10C6 Oversampling and the complete recording rate

For $F_s = 64\ \mathrm{MS/s}$, $M = 8$, and $D = 4$, each channel emits 16 million complex samples per second and the bank emits 128 million. Suppose a stored complex sample contains one signed 16-bit I value and one signed 16-bit Q value, totaling four bytes. The sample payload is 512 million bytes per second, or 512 MB/s in decimal units. Sixty seconds requires 30.72 GB before headers, alignment, timestamps, and continuity records. With $D = 8$, the corresponding payload is 256 MB/s and 15.36 GB per minute. The factor of two follows from $\frac{M}{D}$; it does not establish twice as much independent environmental information. Selecting fewer stored channels reduces the payload but can remove distinctions such as those in Application 10C4. A recording claim must therefore identify which channels and samples were actually retained.

10.27 Application 10C7 White input can give correlated simultaneous channels

Stipulate zero-mean complex input with $\mathrm{E}[x[t]x^*[u]]=\sigma^2$ when $t=u$ and zero otherwise, where t and u are integer sample indices, the star means complex conjugation, E denotes expectation, and σ^2 is input mean-square voltage in V². This is a second-order white-input assumption; it does not assert independent samples. For two channel indices a and b observed at the same retained input index n, define $C_{ab}\backslash(n\backslash)=\mathrm{E}[y_a y_b^*]$ in V² and $\Delta\omega_{ab}=\omega_a-\omega_b$ in radians per input sample. Expanding the two finite sums leaves only terms sharing the same input sample:

$$C_{ab}(n)=\sigma^2\exp(-j\Delta\omega_{ab}n)\sum_{\ell=0}^{L-1}|h[\ell]|^2\exp(j\Delta\omega_{ab}\ell)$$

Choose $M=D=4$, $p=0$, $h=\frac{[1,2,2,1]}{6}$, and $\sigma^2=1\ \mathrm{V}^2$. Each channel variance is $\frac{1+4+4+1}{36}\ \mathrm{V}^2=\frac{5}{18}\ \mathrm{V}^2$. At $n=4m$, $C_{01}=\frac{1-4j-4+j}{36}\ \mathrm{V}^2=\frac{-1-j}{12}\ \mathrm{V}^2$. Its normalized complex correlation is $\frac{C_{01}}{\backslash(\frac{5}{18}\backslash)\ \mathrm{V}^2}=-0.3-j0.3$, with magnitude 0.424264069.

The opposite-channel covariance C_{02} is zero. Distinct center frequencies therefore do not guarantee uncorrelated simultaneous outputs. Equal input variance without the stated white cross-moments would not even justify this calculation. Zero covariance alone would still be insufficient to claim independence without a suitable joint distribution; proper jointly complex Gaussian variables provide one such additional condition.

Copyright 2026, James M. Atkinson

10.28 Application 10C8 Same-frame decorrelation does not remove time overlap

Use $M=4$, $D=2$, $p=0$, $h=\frac{[1,1,1,1]}{4}$, and the same zero-mean white-input second moments with $\sigma^2=1\ \mathrm{V}^2$. At each output time the channel covariance matrix is diagonal, with every variance $\frac{1}{4}\ \mathrm{V}^2$, because the four equal tap energies have zero nonzero-bin DFT coefficients. Yet adjacent frames share two input samples. In the same channel, those common samples have the same mixer phases in both frames, so their two contributions give

$$E[y_k[m+1]y_k{}^*[m]]=\frac{2}{16}\sigma^2=\frac{1}{8}V^2$$

The adjacent-frame normalized correlation is $\frac{\frac{1}{8}}{\frac{1}{4}}=\frac{1}{2}$. For an explicit cross-channel, cross-time calculation, $y_0[1]$ and $y_1[0]$ share input indices 0 and -1. Their phase-weighted covariance $\mathrm{E}[y_0[1]y_1^*[0]]$ is $\frac{1-j}{16}\ \mathrm{V}^2$ and normalized magnitude $\frac{\sqrt{2}}{4}\approx 0.353553391$. These results assume available prehistory, not a zero-padded acquisition boundary. Treating each frame and channel as a new independent noise observation would discard this known overlap. The same-frame diagonal covariance describes one slice of the record, not the independence of entire channel streams.

Copyright 2026, James M. Atkinson

10.29 Application 10C9 Critical sampling can retain a complete blind residue

Set $M=D=4$, $p=0$, and $h=\frac{[1,1,1,0]}{3}$ with nominal length four. Let $x[1]=A$, with nonzero A in volts, and every other input sample be zero. A contribution at retained index $4m$ requires lag $\ell=4m-1$ within $0,\ldots,3$. The only possibility is $m=1$ and $\ell=3$, whose coefficient is zero. Every channel output is consequently zero at every output time. The same reasoning applies to any input supported on indices congruent to 1 modulo four. Although the prototype has $H\backslash(0\backslash)=1$ and the aggregate output rate equals the input rate, the bank loses that entire sample residue. Unit DC gain and critical rate accounting therefore do not establish injectivity, the property that distinct admissible inputs give distinct complete outputs.

Copyright 2026, James M. Atkinson

10.30 Application 10C10 Oversampling repairs this blind residue with unequal energy coverage

Keep $M=4$ and $h=\frac{[1,1,1,0]}{3}$, but change D to two. For the same isolated sample $x[1]=A$, the only nonzero retained frame is $m=1$, with $n_m=2$ and lag $\ell=1$. The complete channel vector is $\frac{[A,-jA,-A,jA]}{3}$, in volts, so the previously invisible sample is observed. Every odd-index input sample now occurs once among the nonzero taps of the retained windows, and every even-index sample occurs twice. For a finite-energy input and complete observation of all affected frames, Fourier orthogonality within each frame yields

$$E_y=\frac{4}{9}(2E_e+E_o)$$

Here E_y is the sum of $|y_k[m]|^2$ over every channel and frame, E_e is the sum of $|x[n]|^2$ over even n, and E_o is the corresponding odd-index sum; all three are discrete sums in V², without a time-interval multiplier. The input sum is $E_x=E_e+E_o$. Thus $\frac{4}{9}E_x\leq E_y\leq\frac{8}{9}E_x$. The positive lower bound excludes a nonzero finite-energy input with all outputs zero for this exact bank, while the unequal bounds show that its energy gain depends on sample placement. They are not a time-integrated electrical-energy calibration. Oversampling repairs the particular blind residue in Application 10C9; it does not prove that every oversampled prototype is invertible or that a truncated recording preserves the complete-frame bound.

10.31 Interpretation and reproducibility of the channelized record

The strongest comparison starts from the defined direct mixer-filter sum, then checks the implemented polyphase scheduling, transform order, normalization, and output phase against it. A complete record identifies the input clock, signed grid, retained phase, actual coefficients, initial history, selected output channels, and arithmetic scaling. Center and boundary tones, a finite nonsymmetric input vector, and a sparse impulse exercise different failure mechanisms. Their expected responses must be computed from the actual configuration before hardware observations are interpreted.

Model 10C provides a defined exact-arithmetic channelizer reference. Its covariance and energy relations explain the specified configurations; they do not establish general statistical detection performance or complete filter-bank synthesis. Model 10D develops fixed-point arithmetic and saturation with explicit coefficient, product, accumulator, and transform scaling. Comparing that implementation with the exact-arithmetic reference distinguishes numerical processing errors from analog receiver behavior.

Copyright 2026, James M. Atkinson

10.32 Model 10D for fixed point channelizer arithmetic

Copyright 2026, James M. Atkinson

Figure 60. Fixed-point overflow: wrapping versus saturation.

The exact bank in Model 10C supplies a comparison standard, but a stored channel value also depends on where an implementation changes numerical representation. Rounding coefficients changes the filter. Rounding branch sums changes the arithmetic. Overflow can destroy a result before a later output scale brings its displayed value into range. This

Copyright 2026, James M. Atkinson

treatment therefore specifies each conversion and derives a deterministic error bound. Its numerical records are stipulated tests, not observations from a commercial receiver. The numerical-overflow comparison is illustrated in Figure 46.

Use the channel count M, decimation D, lag length L, retained index $n_m = mD + p$, angular center $\omega_k = \frac{2\pi k}{M}$, and imaginary unit j from Model 10C. All counts and indices are integers; angles are radians per input sample. Introduce a positive calibration factor V_* in volts and a dimensionless complex sequence $u[n] = \frac{x[n]}{V_*}$. The present prototype coefficients $h[\ell]$ are real and dimensionless. The input samples are already represented exactly on their stated digital grid; analog conversion error belongs to the preceding acquisition model. Preserve the same absolute sample indices and initial history in the exact and finite-word calculations.

Copyright 2026, James M. Atkinson

10.33 Signed formats and explicit conversion points

Write $S\backslash(W,F\backslash)$ for a signed two's-complement format with $W \geq 2$ total bits and $F \geq 0$ fractional bits. W and F are dimensionless integer counts. Its stored integer code c represents $c\,2^{-F}$, giving step $\Delta = 2^{-F}$ and the asymmetric interval below. This notation avoids the differing conventions attached to a bare Q-format label. The same representation applies separately to real and imaginary components.

$$\Delta = 2^{-F}, -2^{W-F-1} \leq c\Delta \leq 2^{W-F-1} - \Delta$$

Let $R\backslash(t\backslash)$ select the nearest integer to the real number t, with exact halfway cases assigned to the even integer. Define $Q_{W,F}\backslash(v\backslash)$ by rounding $2^F v$, clamping that integer to the allowed code interval, and restoring the factor 2^{-F}. Clamping is saturation; write sat_W for this integer-code clamp. When the rounded code lies within range, the real error is at most $\frac{\Delta}{2}$. Once saturation occurs, that bound is unavailable. Wrapping is a different operation, defined below for integer c; it discards multiples of the code range and can reverse the sign of an over-range result.

$$Q_{W,F}(v) = 2^{-F} sat_W[R(2^F v)]$$

$$wrap_W(c) = [(c + 2^{W-1}) mod\, 2^W] - 2^{W-1}$$

For fixed-point multiplication, an exact signed real product can be carried with $W_p = W_x + W_h$ bits and $F_p = F_x + F_h$ fractional bits, where subscripts x, h, and p identify input, coefficient, and product formats. Aligned additions need a range sufficient for every intermediate sum. Assignment to a narrower format is itself an arithmetic operation and must be specified even when no explicit rounding instruction appears in source code. The

Copyright 2026, James M. Atkinson

manufacturer reference illustrates these distinctions; the numerical construction here defines its own tie and overflow rules.[9]

Round each coefficient once to $\hat{h}[\ell]$ using format $S\backslash(W_h, F_h\backslash)$. Compute products and the finite branch sum $a_r[m]$ exactly using those quantized coefficients, then round each real and imaginary component once to the branch format $S\backslash(W_b, F_b\backslash)$. The resulting branch value is $b_r[m]$. Coefficients outside the original support remain zero. Let Q_b^{C} denote this componentwise branch conversion and let $\Delta_b = 2^{-F_b}$.

$$a_r[m] = \sum_{q \geq 0} \hat{h}[qM + r]\, u[n_m - qM - r],\; b_r = Q_b^{\,C}(a_r)$$

Next compute the positive-exponent transform and the outer phase exactly, producing dimensionless $w_k[m]$. Apply one recorded nonnegative integer shift s, then convert each component once to output format $S\backslash(W_z, F_z\backslash)$, with step $\Delta_z = 2^{-F_z}$. Subscript z identifies the output format and its componentwise conversion Q_z^{C}. The stored value is $v_k[m]$, while the recovered voltage $\hat{y}_k[m]$ multiplies it by V_* and 2^s. Recovery must use an adequately wide representation.

$$w_k[m] = \exp(-j\omega_k n_m) \sum_{r=0}^{M-1} b_r[m] \exp\left(\frac{j2\pi kr}{M}\right)$$

$$v_k = Q_z^{\,C}(2^{-s} w_k),\; \hat{y}_k = V_* 2^s v_k$$

---

Its historical radiometer thresholds are not adopted as acceptance limits for the present constructed receiver.

Copyright 2026, James M. Atkinson

For $M = 4$, all transform weights and outer phases are among 1, -1, j, and $-j$. Widened addition, subtraction, component exchange, and sign change can therefore realize the stipulated exact transform without irrational twiddle coefficients. Negating the most negative signed code still requires sufficient width. The ten applications below use this four-channel construction. The algebraic error bound also applies to an exact transform of any M, but a larger finite-word FFT usually adds twiddle and intermediate-rounding errors that must be budgeted separately.

Copyright 2026, James M. Atkinson

10.34 Range and error are separate obligations

Range proof precedes the rounding bound. For any real branch, suppose every input component lies in $[u_{\min}, u_{\max}]$, with $u_{\min} \le 0 \le u_{\max}$. Let G_r^+ be the sum of its positive quantized coefficients and G_r^- the sum of its negative coefficients. Zero coefficients contribute nothing. Maximizing or minimizing each independent product over the interval gives the following branch limits. The same argument applies separately to I and Q because the prototype is real. A component bound is not a bound on complex magnitude.[10]

$$a_{min} = G_r^{+¿} u_{min} + G_r^{-} u_{max} ¿$$

$$a_{max} = G_r^{+¿} u_{max} + G_r^{-} u_{min} ¿$$

With exact products, an accumulator can retain $F_a = F_x + F_h$ fractional bits. Choose its integer code range to contain both endpoints multiplied by 2^{F_a}. Because the permitted input interval contains zero, each partial coefficient subset has extrema no farther from zero than those of the complete branch. Thus the same interval bound protects a direct accumulation with no other operations. A transformed, scaled, or feedback topology needs its own intermediate analysis. Test the positive endpoint explicitly, since a signed format has one fewer positive code.

These are identified examples of preselection, gain placement, and protection, not a universal front-end architecture or an instrument-independent limit.

Copyright 2026, James M. Atkinson

To bound error, assume no coefficient, branch, transform, or output overflow, exact products and accumulations, and the two stated rounding locations. Let $B \geq 0$ bound $|u[n]|$ over all required history. Define $\delta h[\ell] = \hat{h}[\ell] - h[\ell]$. The coefficient contribution to any output is bounded by B times the sum of $|\delta h[\ell]|$, since each mixer factor has unit magnitude. Each rounded complex branch contributes at most $\frac{\Delta_b}{\sqrt{2}}$, obtained by combining two component errors bounded by $\frac{\Delta_b}{2}$. The unscaled transform sums M such contributions; the outer phase preserves magnitude. Restoring the output shift magnifies its final rounding error by 2^s. Hence

$$|\hat{y}_k - y_k| \leq E = V_* \left[B \sum_{\ell=0}^{L-1} |\delta h[\ell]| + \frac{M \Delta_b}{\sqrt{2}} + \frac{2^s \Delta_z}{\sqrt{2}}\right]$$

Here E is a nonnegative voltage bound and $|\hat{y}_k - y_k|$ is complex error magnitude in volts at the same channel and retained index. The bound is conservative and deterministic. It assumes neither a white spectrum nor independent, uniform, or zero-mean errors. If coefficient rounding is also unsaturated, the sum of coefficient errors is at most $\frac{L \Delta_h}{2}$, where $\Delta_h = 2^{-F_h}$. Exact binary coefficients, exact branch sums, or exact output values allow their corresponding actual error terms to vanish. Recorded residuals can tighten the envelope, but cannot validate unobserved operating ranges.

Real implementations need architecture-specific accounting. AMD's July 2026 PG109 distinguishes unscaled, scheduled, and block-floating scaling, and states that its convergent option does not cover every internal reduction. It also describes wrap overflow for the relevant scaled FFT interface. Those details demonstrate why a named rounding setting is

Copyright 2026, James M. Atkinson

insufficient to establish this model's two-conversion architecture; they are not asserted as universal behavior of FFT hardware.[11]

11 Rohde & Schwarz, R&S ESW EMI Test Receiver User Manual, 1177.6298.02, version 18 (2025), §§9.7.1.2–9.7.1.3, 193–94, https://scdn.rohde-schwarz.com/ur/pws/dl_downloads/pdm/cl_manuals/user_manual/1177_6298_01/ESW_UserManual_en_18.pdf. The manual identifies firmware 3.20 and higher; the cited architecture is a specific instrument example.

Copyright 2026, James M. Atkinson

10.35 Ten worked applications of Model 10D

All ten tests set $V_* = 1\ \mathrm{V}$. A numerical value described as dimensionless becomes volts only after the stated calibration and scale restoration. Unless an application deliberately exercises failure, products, sums, phase operations, and output storage have sufficient range and precision. Input vectors are ordered newest to oldest, coefficients are ordered by increasing lag, and the output vector is ordered by increasing channel index k.

Copyright 2026, James M. Atkinson

10.36 Application 10D1 Coefficient rounding can preserve DC and change rejection

Take $M=D=L=4$, $h=[0.1,0.2,0.3,0.4]$, and coefficient format $S\backslash(5,4\backslash)$, whose step is $\frac{1}{16}$. Nearest-even rounding gives $\hat{h}=[\frac{1}{8},\frac{3}{16},\frac{5}{16},\frac{3}{8}]$. Both coefficient sums equal one, so their DC gains agree exactly. At angular offset π, however, the ideal response is $0.1-0.2+0.3-0.4=-0.2$, while the quantized response is $\frac{2-3+5-6}{16}=-0.125$. Their difference is +0.075. For a unit-magnitude alternating input and otherwise exact arithmetic, the coefficient error reaches the bound $\sum_{\ell=0}^{L-1}|\delta h[\ell]|=0.075$. Its magnitude response changes from 0.2 to 0.125, a ratio of 0.625 or −4.08240 dB. A successful DC gain test therefore does not test the implemented frequency response at this offset.

Copyright 2026, James M. Atkinson

10.37 Application 10D2 Size a branch accumulator from its signed endpoints

Let one branch contain coefficients $[\frac{3}{4},\frac{-1}{2},\frac{1}{4}]$, represented exactly in $S\backslash(3,2\backslash)$, and let each real input component use $S\backslash(4,3\backslash)$, with range $[-1,\frac{7}{8}]$. The positive coefficient sum is one and the negative sum is $-\frac{1}{2}$. Therefore $a_{\min}=-1-\frac{7}{16}=-\frac{23}{16}$ and $a_{\max}=\frac{7}{8}+\frac{1}{2}=\frac{11}{8}$. Full product precision requires $F_a=3+2=5$ fractional bits. The endpoint codes are −46 and 44. Six total bits allow only −32 through 31 and fail; seven allow −64 through 63 and suffice, including every partial direct sum. The minimum is attained by input components $[-1,\frac{7}{8},-1]$ assigned to those three lags. Using the coefficient signs saves width compared with blindly adding guard bits, while retaining an explicit range proof.

Copyright 2026, James M. Atkinson

10.38 Application 10D3 The negative rail creates a positive product

Choose input and coefficient values both equal to −1 in $S\backslash(4,3\backslash)$. Their exact product is +1. $S\backslash(8,6\backslash)$, the full product format, stores this as code 64 without overflow. Narrowing to $S\backslash(7,6\backslash)$ permits only codes −64 through 63, so +1 is not representable. Saturation returns $\frac{63}{64}=0.984375$; wrap returns $-\frac{64}{64}=-1$. The respective errors are $\frac{-1}{64}$ and −2. A subsequent gain adjustment cannot determine which value was lost from the stored code alone. This endpoint calculation explains why a product-width rule must include signed asymmetry rather than rely on the informal assertion that two magnitudes no greater than one produce an in-range fraction.

Copyright 2026, James M. Atkinson

10.39 Application 10D4 Rounding once and rounding each product differ

Consider two products in the same branch, each formed from coefficient $\frac{5}{16}$ and input $\frac{1}{4}$. Each exact product is $\frac{5}{64}$. Their exact sum is $\frac{5}{32}$. With branch step $\Delta_b = \frac{1}{8}$, rounding once after accumulation produces $\frac{1}{8}$ because $\frac{5}{32}$ is closer to $\frac{1}{8}$ than to $\frac{1}{4}$. Rounding each product first instead gives $\frac{1}{8} + \frac{1}{8} = \frac{1}{4}$. The two implementations differ by $\frac{1}{8}$ even though they use the same coefficients and nominal branch format. For this test their errors relative to the exact sum are $\frac{-1}{32}$ and $+\frac{3}{32}$. Model 10D admits the first placement. The second requires a separate per-product error budget and may not borrow the single-rounding branch term.

Copyright 2026, James M. Atkinson

10.40 Application 10D5 Intermediate saturation makes association consequential

Use a fixed accumulator $S\backslash(4,2\backslash)$, whose range is $[-2,\frac{7}{4}]$, and successive exactly represented products $[\frac{3}{2},\frac{3}{2},\frac{-3}{2}]$. The exact total is $\frac{3}{2}$. Adding the first two products and saturating gives $\frac{7}{4}$; adding the last then gives $\frac{1}{4}$. Combining the last two products first gives zero, followed by the correct $\frac{3}{2}$. Thus saturation has made two algebraically equivalent associations disagree by $\frac{5}{4}$. Wrapping this particular sequential sum produces -1 after the first overflow and then $\frac{3}{2}$ after another wrap, accidentally recovering the final modular result. That coincidence does not prove absence of internal overflow. Preserve stage flags and use a sufficient-width accumulator when the exact-linear comparison is required.

Copyright 2026, James M. Atkinson

10.41 Application 10D6 Transform normalization is part of voltage gain

At n_m divisible by four, set the rounded branch vector to $b=[\frac{1}{4},\frac{1}{2},\frac{-1}{4},0]$. The outer phase equals one. The required positive-exponent unscaled transform is $w=[\frac{1}{2},\frac{1}{2}+\frac{j}{2},\frac{-1}{2},\frac{1}{2}-\frac{j}{2}]$. A normalized inverse DFT instead returns $\frac{w}{4}$. Without an explicitly recorded restoration by four, each nonzero amplitude is smaller by $20\log_{10}\backslash(4\backslash)\ \mathrm{dB}\approx 12.0412\ \mathrm{dB}$. The sum of squared branch magnitudes is $\frac{3}{8}$, and the unscaled output sum is $\frac{3}{2}$, exactly four times greater. This equality checks the chosen transform convention. It is a discrete voltage-squared identity and does not supply electrical power without a load and calibration model.

Copyright 2026, James M. Atkinson

10.42 Application 10D7 Restoring a shift also restores its coarse spacing

Stipulate an exact real transform component $w=\frac{5}{16}$ and output format $S\backslash(4,3\backslash)$, with $\Delta_z=\frac{1}{8}$. Without a shift, nearest-even rounding maps $\frac{5}{16}$, halfway between $\frac{1}{4}$ and $\frac{3}{8}$, to $\frac{1}{4}$; voltage error is $\frac{-1}{16}$ V. With $s=2$, the stored input is $\frac{5}{64}$, which rounds to $\frac{1}{8}$. Restoring the shift gives $4\times\frac{1}{8}\ \mathrm{V}=\frac{1}{2}\ \mathrm{V}$, an error of $\frac{+3}{16}$ V. The restored real-component error limit is $\frac{2^2\Delta_z}{2}\ \mathrm{V}=\frac{1}{4}\ \mathrm{V}$. The shift can provide headroom for other values but increases the restored output step to $\frac{1}{2}$ V. Merely multiplying the stored numbers back to the desired display range does not restore the discarded low bits.

Copyright 2026, James M. Atkinson

10.43 Application 10D8 Exact codes still require phase order and history

Take $M=L=4$, $D=2$, $p=0$, $h[\ell]=\frac{1}{4}$, and the exactly represented center tone $u[n]=\frac{j^n}{2}$. The positive transform in channel 1 is $\frac{\backslash(-1\backslash)^m}{2}$. The required outer phase is also $\backslash(-1\backslash)^m$, leaving the correct constant output $\frac{1}{2}$ V. Omitting that phase produces alternating $\frac{+1}{2}$ and $\frac{-1}{2}$ V, with a 1 V discrepancy on odd frames despite exact arithmetic. A negative-exponent transform without the required bin remapping instead places this tone in channel 3. Neither defect is fixed by adding fractional bits.

For a separate history test, use $M=D=4$, $p=0$, eight taps all equal to $\frac{1}{8}$, and constant $u[n]=\frac{1}{2}$. A settled bank gives channel 0 equal to $\frac{1}{2}$ V and other channels zero. Resetting the history immediately before input sample zero makes the first output at $n=0$ equal to $\frac{1}{16}$ V in every channel. At $n=4$, channel 0 is $\frac{5}{16}$ V and each other channel is $\frac{1}{16}$ V; by $n=8$ the full history has restored the settled result. These values follow directly from one, five, and then eight available taps. The hardware channelizer documentation separately identifies valid-input handling, resets, and phase options, so such control settings belong in a reproducible numerical comparison.[12]

10.44 Application 10D9 A constant error does not become white noise

Use $M=D=L=4$, $h[\ell]=\frac{1}{4}$, and constant input $u[n]=\frac{5}{8}$ with complete history. Every exact branch value is $\frac{5}{32}$. Branch step $\Delta_b=\frac{1}{8}$ rounds each to $\frac{1}{8}$, giving channel 0 equal to $\frac{1}{2}$ V instead of the exact $\frac{5}{8}$ V. The error is the constant $\frac{-1}{8}$ V; the three other channels remain zero. Its variance about its own mean is zero, while its mean-square error is $\frac{1}{64}$ V². Averaging more identical frames retains the same bias. A formula that distributes independent uniform rounding noise across channels would misdescribe this deliberately coherent record, even though every branch conversion obeys its half-step error bound.

---

recovery law.

10.45 Application 10D10 Audit a complete finite word output vector

Return to the coefficients and coefficient format of Application 10D1. Use $M=D=L=4$, $p=0$, n_m divisible by four, and input vector $u=[\frac{3}{4},\frac{-1}{2},\frac{1}{4},\frac{-3}{4}]$ in $S\backslash(4,2\backslash)$. Exact filtering with the original coefficients gives $y=[\frac{-1}{4},\frac{j}{5},\frac{11}{20},\frac{-j}{5}]$ V. The quantized coefficients give branch products $[\frac{3}{32},\frac{-3}{32},\frac{5}{64},\frac{-9}{32}]$. These products are carried exactly in $S\backslash(9,6\backslash)$. Converting once to $S\backslash(6,5\backslash)$ changes only $\frac{5}{64}$: it is halfway between codes two and three and rounds to the even code two. Thus $b=\frac{[3,-3,2,-9]}{32}$.

$$\hat{y}=[-\frac{7}{32},\frac{1}{32}+j\frac{3}{16},\frac{17}{32},\frac{1}{32}-j\frac{3}{16}]V$$

Store the unscaled result in $S\backslash(8,5\backslash)$, with $s=0$; every displayed component is exact on that output grid. Channel errors are $\frac{+1}{32}$, $\frac{1}{32}-\frac{j}{80}$, $\frac{-3}{160}$, and $\frac{1}{32}+\frac{j}{80}$ volts. Their largest magnitude is $\frac{\sqrt{29}}{160}$ V ≈ 0.0336572800 V. The general envelope uses $B=\frac{3}{4}$, $\sum_{\ell=0}^{L-1}|\delta h[\ell]|=\frac{3}{40}$, and $\Delta_b=\Delta_z=\frac{1}{32}$, giving $E\approx 0.166735435$ V. Inspecting the actual residuals tightens this to $\backslash(0.05625+0.015625+0\backslash)$ V $=0.071875$ V: the coefficient term retains its worst-case bound, only one branch incurs rounding, and output rounding vanishes. Both bounds contain all four observed errors. The tighter result is an audit of this specified vector, not a uniform guarantee for another input range or conversion schedule.

10.46 What the arithmetic comparison establishes

These examples turn numerical reproducibility into a finite specification: signed formats at every conversion, actual quantized coefficients, product and accumulator widths, rounding locations and ties, overflow policy and status, transform sign and normalization, scale exponents, channel order, and preserved history. An exact-code implementation can be checked against Model 10C before its hardware output is interpreted. Passing these stipulated vectors establishes agreement only for the tested arithmetic cases. A deployed pipeline still requires its actual stage graph, twiddle formats, timing controls, overflow telemetry, and input-range evidence. The deterministic envelope does not certify receiver sensitivity, false-alarm performance, or absence of a source.

Copyright 2026, James M. Atkinson

10.47 Data Transport, Gaps, and Reproducible Recording

High-rate I/Q recording depends on device buffers, bus throughput, packet transport, operating-system scheduling, storage, and file format. Dropped samples, repeated packets, timestamp discontinuities, USB resets, network loss, or disk throttling can create spectral splatter and false transients. Many formats store samples without complete metadata, while others embed center frequency, sample rate, time, scaling, and device state.

The capture system monitors sequence numbers, overflow indicators, time stamps, storage margin, and clock lock. A known reference or loopback tests continuity. Native samples are preserved before conversion or compression, and processing scripts record exact parameters and software versions. When a gap is filled with zeros or interpolated, the change is explicitly logged because it changes the spectrum.

Copyright 2026, James M. Atkinson

10.48 Model 10E for absolute sample continuity and retained processing state

The arithmetic in Models 10B through 10D presumes an identified input history. A recording can violate that premise while retaining plausible amplitudes, a convenient file length, and an apparently stable spectrum. Model 10E therefore treats continuity as a mapping from stored positions to original sample indices. It then asks whether each retained output has all the inputs and state required by its stated calculation. The model concerns sample behavior inside a declared clock segment. Chapter 15 addresses the separate obligations of survey coverage, record custody, access, and reproducible evidence handling.

Assume one complex input stream with a fixed sampling frequency over the segment, no unmodeled change of sample format, and an unwrapped integer source counter. The counter is associated with the sampling event, not with a host buffer arrival. A clock reset, unresolved counter wrap, rate change, or incompatible source-index declaration ends this segment until a new mapping is established. Numerical examples below are constructed calculations with stated inputs. They are not measurements of a receiver or claims about deployed transport reliability.

Copyright 2026, James M. Atkinson

10.49 Source indices, stored offsets, and time anchors

Let $x[n]$ be the original complex sample in volts at integer source index n. Let $z[k]$ be the stored sample at integer file-sample offset k. Block r has stored start s_r, source start n_r, and positive integer length N_r, all measured in samples. Its internal index i takes the integer values 0 through $N_r - 1$. A faithful block satisfies the following relation; contiguous file placement alone says nothing about source continuity.

$$z[s_r + i] = x[n_r + i], 0 \le i < N_r$$

For adjacent blocks in the declared source ordering, define the signed boundary discrepancy G_r. A positive value counts source positions between this pair, zero identifies adjoining indices, and a negative value identifies an overlap. The positive interval is missing only if no other accepted block supplies it; resolve overlapping coverage before declaring a global gap. A negative result does not establish that overlapping payloads agree. Blocks received out of order must first be associated with their declared indices; arrival order cannot silently replace source order.

$$G_r = n_{r+1} - (n_r + N_r)$$

A recording format can preserve this distinction explicitly. In SigMF 1.2.6, sample_start identifies the capture position in the stored dataset, whereas global_index identifies its position in the original stream. The capture datetime anchors the indicated sample. The specified default equating an absent global_index to sample_start is a decoding rule, not evidence that the physical acquisition lost no samples. Segment metadata must carry the values that apply to that segment. The mathematical continuity decisions

Copyright 2026, James M. Atkinson

here require verified declarations, not merely a syntactically valid metadata file.[13]

Let f_s be the declared positive sampling frequency in samples per second. An anchor associates source index n_a with time t_a in seconds on a declared time scale. Under the constant-rate assumption, the sample time is obtained from the index difference. A timestamp describing buffer delivery or file creation is a different event and cannot be substituted without an established relationship to sampling.

$$t(n) = t_a + \frac{n - n_a}{f_s}$$

The receiving implementation also matters. UHD receive metadata identifies the time of the first sample, distinguishes packet fragmentation through fragment offsets, and reports overflow or sequence conditions. Its out_of_sequence field helps distinguish a sequence error from a receive-buffer overflow.

These indicators guide reconstruction, but an error flag alone does not supply the exact number of absent source samples. A short application receive buffer can divide one packet into fragments without causing a gap. Inspect the returned sample counts, index or time declarations, and error context together.[14]

10.50 A continuity condition for finite filtering and decimation

The processing contract uses a complex mixer followed by a causal finite impulse response filter and decimation. Let j satisfy $j^2=-1$. The mixer frequency f_0 is in hertz, its angular increment ω_0 equals $\frac{2\pi f_0}{f_s}$ radians per input sample, and its phase at source index zero is φ_0 radians. The fixed coefficients $h[\ell]$ are dimensionless and have declared length L, a positive integer. The lag ℓ ranges from zero to $L-1$. The output sample $y[m]$ remains in volts. Its source-grid index $n_m=n_0+mD$, where n_0 is a fixed integer epoch, D is the positive integer decimation factor, and m is an integer output index.

$$n_m=n_0+mD\,,\omega_0=\frac{2\pi f_0}{f_s}$$

$$y[m]=\sum_{\ell=0}^{L-1} h[\ell]x[n_m-\ell]\exp\left(-j[\varphi_0+\omega_0(n_m-\ell)]\right)$$

This expression fixes both the waveform history and the phase convention. An arbitrary file-block boundary changes neither. For a channelizer, apply the same construction at each channel frequency while retaining the established output epoch and branch ordering of Model 10C. The present continuity model assumes exact linear arithmetic for its counterfactual comparisons. Model 10D supplies the separate rounding, range, saturation, and implementation-graph qualifications; a continuity flag does not certify those numerical properties.

14 Walt Kester, MT-080, Mixers and Modulators, rev. 0 (Analog Devices, October 2008), 1–2 and 5, including the multiplier model and “Image Response,” https://www.analog.com/media/en/training-seminars/tutorials/mt-080.pdf. The ideal product identities are developed in Model 4A; its candidate spur locations do not establish the amplitudes of real mixer products.

Copyright 2026, James M. Atkinson

Define the coefficient support H as the set of lags whose declared coefficients are nonzero. Exclude the identically zero filter from this discussion. Let $v[n]$ equal one only when source sample n is uniquely resolved and available, or when its prehistory is legitimately known by the stated experiment. Otherwise let $v[n]$ equal zero. An absent sample and an unresolved conflicting duplicate both fail this availability condition. The output continuity indicator $\kappa[m]$ is the product of these binary inputs over the coefficient support.

$$\kappa[m] = \prod_{\ell \in H} v[n_m - \ell], v[n] \in \{0,1\}$$

For unrestricted unknown missing values, $\kappa[m]$ equals one exactly when the output is independent of those unknowns. Each nonzero coefficient multiplies a distinct source sample, and the mixer has unit magnitude. Consequently, an unknown sample with a nonzero coefficient can change the output even if the particular observed waveform happens to conceal its effect. This is a dependency test, not a probability of correctness. A valid dependency mask does not establish calibration accuracy, the truth of a timestamp, or the authenticity of a source counter.

A finite filter can be evaluated in blocks while retaining state equivalent to its required input history. One implementation example is SciPy lfilter: its documented zi argument supplies initial delay state, an omitted initial state means rest, and zf returns the final delay state when initial state was supplied. That implementation uses a direct form II transposed realization. Its delay-state coordinates should not be confused with a raw list of

Copyright 2026, James M. Atkinson

preceding samples; transfer the documented state of the same realization or reconstruct the equivalent history correctly.[15]

When every lag from zero through $L-1$ is nonzero and a single missing interval spans the inclusive source indices a through b, the potentially affected output source indices span a through $b+L-1$. Suppose the declared output record contains integer indices $m_{\min}$ through $m_{\max}$. Intersecting this interval with the retained decimation grid gives the first and last affected output indices below. Ceiling means the least integer not smaller than its argument; floor means the greatest integer not larger.

$$m_{lo}=max\left(m_{min},\lceil\frac{a-n_0}{D}\rceil\right)$$

$$m_{hi}=min\left(m_{max},\lfloor\frac{b+L-1-n_0}{D}\rfloor\right)$$

$$C=max\left(0,m_{hi}-m_{lo}+1\right)$$

Here C is the number of affected retained outputs, a nonnegative count. If the intersection is empty, C is zero. The full interval construction is exact for a contiguous nonzero support; a sparse filter instead uses the actual support in $\kappa[m]$. Several missing intervals can overlap after filtering, so add the affected sets by union rather than summing counts that double-count an output. A finite history becomes independent of an old gap after the required known samples have entered it. This finite recovery rule does not

15 Walt Kester, MT-080, Mixers and Modulators, rev. 0 (Analog Devices, October 2008), 1–2 and 5, especially the multiplier scaling and “Image Response,” https://www.analog.com/media/en/training-seminars/tutorials/mt-080.pdf. The ideal normalization and synthetic cases here are explicitly derived and do not quote a device conversion-loss specification.

extend automatically to recursive filters, adaptive coefficients, gain-control loops, or phase-tracking loops.

Copyright 2026, James M. Atkinson

10.51 Gap representations, phase, and the limits of timing claims

Zero filling creates a derived sequence on the original index grid while preserving a separate validity mask. Let $\tilde{x}[n]$ equal the available value where $v[n]$ is one and equal zero where it is zero. Let $\tilde{y}[m]$ be the result of applying the same declared processing to that sequence. Let U_m be the subset of supported lags for which $v[n_m-\ell]$ is zero. Relative to the counterfactual complete record, the output error $e[m]=\tilde{y}[m]-y[m]$. Subtracting the two finite sums gives the missing-input contribution directly.

$$e[m]=-\sum_{\ell \in U_m} h[\ell]x[n_m-\ell]\exp\left(-j[\varphi_0+\omega_0(n_m-\ell)]\right)$$

If a justified bound B in volts limits the magnitude of each missing input contributing to this output, the triangle inequality yields the following conditional deterministic bound. The bound is not a noise variance, and the zero-filled output remains marked invalid even when the bound is small. If no input bound is justified, this model supplies no finite numerical error limit. Interpolation introduces another assumed sequence and requires its own error assumptions.

$$|\, e[m] \,| \leq B \sum_{\ell \in U_m} |\, h[\ell] \,|$$

Deleting missing positions instead compresses the index axis. It changes which physical samples become neighbors in the filter history, unless a separate reconstruction restores the original grid. It also changes a numerically controlled oscillator if the oscillator advances by stored offset rather than source index. Let $g=n-k$, the difference between the source index and its compressed stored index after a gap. At that sample, a mixer

Copyright 2026, James M. Atkinson

using k instead of n has the following multiplicative phase error relative to the correct mixer.

$$\frac{\exp(-j[\varphi_0+\omega_0 k])}{\exp(-j[\varphi_0+\omega_0 n])}=\exp(j\omega_0 g), g=n-k$$

Both oscillators in this ratio use the same phase constant φ_0. When g is constant across an entire filter support, this is a constant output rotation when corresponding source instants are compared. A decimator advancing on compact k selects the intended source grid only when its mapped n is congruent to n_0 modulo D. A nonzero gap residue otherwise changes the retained source instants. Across a gap boundary, different retained samples can have different deficits, so a single rotation does not repair the altered convolution. The first sample after G missing samples is $G+1$ sampling intervals after the last retained sample. Computing phase from absolute indices avoids confusing this interval with the number of missing positions.

Continuity of indices also leaves a distinct clock-rate question. Suppose the true constant sampling frequency is f_s\($1+\varepsilon$\), the signed fractional rate error is ε, its magnitude is bounded by $\varepsilon_{\max}<1$, and anchor-time uncertainty is bounded by A seconds. Let $t_{\text{true}}[n]$ be the actual sample time and $t_{\text{nom}}[n]$ the time calculated from the declared rate and anchor. Subtracting the reciprocal rates and using the smallest allowed denominator gives this conservative elapsed-time bound.

$$|t_{true}[n]-t_{nom}[n]| \le A+\frac{|n-n_a|\,\varepsilon_{max}}{f_s(1-\varepsilon_{max})}$$

The absolute index distance is measured in samples, so the second term has units of seconds. The bound includes neither stochastic clock wander nor an unmodeled time step. Those require a richer timing model or a new

Copyright 2026, James M. Atkinson

segment. The applications below exercise one continuity model at different points in the same recording and processing chain; they do not declare separate comprehensive treatments of transport protocols, clock synchronization, or recursive-state recovery.

Copyright 2026, James M. Atkinson

10.52 Application 10E.1: a file offset that conceals forty missing samples

Take $f_s = 1,000,000$ samples per second and an anchor at source index 1,000,000 with $t_a = 0$ seconds. A first block contains 128 samples beginning at that source index. The next block begins at source index 1,000,168 but is stored immediately after the first, at file-sample offset 128. The gap relation gives 1,000,168 minus (1,000,000 plus 128), or 40 missing samples. The next block begins at 168 microseconds on the source clock, not the 128 microseconds implied by its compact file offset.

Seven positions into the second block, the stored offset is 135 while the source index is 1,000,175 and the time is 175 microseconds. Using the file offset as elapsed sample count makes the time 40 microseconds early. The last retained sample before the gap was at source index 1,000,127; its separation from the next retained sample is 41 microseconds. Forty missing positions therefore produce forty-one intervals between the bounding retained samples. A correct block map preserves both the gap count and that endpoint distinction.

Copyright 2026, James M. Atkinson

10.53 Application 10E.2: overlap, duplicate indices, and conflicting payloads

A block beginning at source index 2,000 contains 64 samples. A second block begins at 2,032 and also contains 64. Their boundary discrepancy is minus 32, so the stored 128 values cover only 96 distinct source indices, from 2,000 through 2,095. With a two-megasample-per-second clock anchored at the first sample, the second block starts 16 microseconds later. Its compact stored offset of 64 would suggest 32 microseconds if source identity were ignored.

Agreement of the 32 overlapping values permits a declared duplicate-resolution policy to retain one value per source index. Disagreement requires investigation or an invalidity flag; averaging the conflicting values manufactures a third value without resolving which observation belongs to the source event. Repetition of a periodic waveform at different source indices is not a duplicate index. The overlap calculation is about declared sample identity, so waveform resemblance cannot replace the counter and timing evidence.

Copyright 2026, James M. Atkinson

10.54 Application 10E.3: a continuous record with uncertain elapsed time

Let the declared rate be 5,000,000 samples per second. A separation of 40,000,000 source indices corresponds nominally to eight seconds. Assume a constant fractional rate error bounded by 20 parts per million and an anchor uncertainty of two microseconds. The timing bound is two microseconds plus eight seconds multiplied by 0.000020 and divided by 0.999980. The result is approximately 162.0032 microseconds.

At exactly 20 parts per million fast, the elapsed-time difference from nominal is approximately minus 159.9968 microseconds; at the same fractional rate error slow, it is approximately plus 160.0032 microseconds. The extra two microseconds permits the anchor error in either direction. No sample need be missing for either case to occur. The calculation is a bounded timing statement under a constant-rate assumption, not a probability distribution, an assertion of clock performance, or a reason to insert missing samples.

Copyright 2026, James M. Atkinson

10.55 Application 10E.4: an ordinary block boundary preserves filter history

For Applications 10E.4 through 10E.8, set $f_0 = 0$ and $\varphi_0 = 0$. Applications 10E.4 through 10E.7 additionally use $D = 1$ and $n_0 = 0$. Use the three-tap FIR coefficients one-half, one-quarter, and one-quarter, with explicitly known zero prehistory. Input samples at indices zero through three are 2, 4, 6, and 8 volts. Process indices zero and one as the first block. Their outputs are 1 and 2.5 volts. Retaining the equivalent history for the second block produces 4.5 volts at index two and 6.5 volts at index three.

Resetting the filter to rest at index two instead produces 3 volts and then 5.5 volts. Those errors, minus 1.5 volts and minus 1 volt, arise despite complete input continuity. A transport or file partition has been mistaken for a physical startup. Passing implementation state or the equivalent preceding input history gives the full-record result. Knowing that the experiment began at rest does not authorize imposing a new rest condition at every later buffer boundary.

Copyright 2026, James M. Atkinson

10.56 Application 10E.5: zero filling preserves the grid and exposes a finite tail

Keep that filter and extend the complete synthetic input to 2, 4, 6, 8, 10, and 12 volts. Suppose source sample two is absent. In this constructed counterfactual its value was 6 volts, but an actual missing record would not disclose that value. Zero filling only source position two gives outputs of 1.5, 5, 7, and 10.5 volts at indices two through five. The complete-record outputs at those positions are 4.5, 6.5, 8.5, and 10.5 volts.

The errors are minus 3, minus 1.5, minus 1.5, and zero volts. The dependency mask rejects outputs two, three, and four; output five has recovered because all its contributing input positions are known. If the missing input is independently bounded by 12 volts, the corresponding magnitude bounds are 6, 3, and 3 volts. These are conservative limits, not estimates of the actual errors. Filling the gap has made the calculation executable while leaving its uncertainty visible.

Copyright 2026, James M. Atkinson

10.57 Application 10E.6: deleting the same gap changes a different operator

Delete source sample two instead of reserving its position. The compact sequence becomes 2, 4, 8, 10, and 12 volts. Applying the same three coefficients to this new sequence gives 5.5 volts at compact index two, which corresponds to source index three. The complete-record output at source index three was 6.5 volts, so the error is minus 1 volt. At compact index three, corresponding to source index four, the result is 8 volts instead of 8.5 volts.

At compact index four the result is 10.5 volts and the finite filter history again matches source index five. Nevertheless, a timestamp obtained by dividing the compact index by the sample rate remains one sampling interval early. Zero filling had produced 5 volts at source index three, not the 5.5 volts produced by deletion. The two procedures are therefore different transformations even when both eventually recover the same local finite history. Retain the original source map with either derived representation.

Copyright 2026, James M. Atkinson

10.58 Application 10E.7: a zero coefficient changes the validity pattern

Choose a three-position filter with coefficients one-half, zero, and one-half. Keep the six-input sequence from Application 10E.5 and lose source sample two. The declared coefficient support contains only lags zero and two. Output two depends on the missing sample at lag zero, and output four depends on it at lag two. Output three uses the known samples at source indices three and one, giving one-half times 8 plus one-half times 4, or 6 volts.

Thus output three remains continuity-valid even though the contiguous-length envelope spans outputs two through four. The exact support mask avoids discarding that usable result. This reasoning requires an exactly zero coefficient in the stated implementation. A small nonzero coefficient still creates a dependency, although a justified amplitude bound may limit its consequence. Changing coefficients merely to avoid an invalidity indication would define a different filter and require a separate declared processing result.

Copyright 2026, James M. Atkinson

10.59 Application 10E.8: decimation retains two outputs from a longer gap tail

Use seven nonzero FIR coefficients, an output epoch $n_0 = 1$, and decimation factor $D = 4$. Suppose input indices ten through twelve are missing. The finite-filter dependency interval extends from ten through eighteen. Nearby retained output source indices are nine, thirteen, seventeen, and twenty-one. Only thirteen and seventeen fall inside the interval.

The lower affected output index is the ceiling of (10 minus 1) divided by 4, which is 3. The upper is the floor of (12 plus 6 minus 1) divided by 4, which is 4. Provided the output record includes those indices, C equals 4 minus 3 plus 1, or two outputs. Input index nineteen is the first source time after the contiguous dependency tail, while the first retained output after that tail is at twenty-one. Retaining the original decimation epoch makes this distinction reproducible.

Copyright 2026, James M. Atkinson

10.60 Application 10E.9: absolute phase survives three missing positions

Set the mixer frequency to one-eighth of the sampling rate, so ω_0 equals $\frac{\pi}{4}$ radians per sample, and let $\varphi_0 = 0$. For the unit-amplitude complex tone $x[n] = \exp\backslash(\frac{j\pi n}{4}\backslash)$ volts, the correctly indexed mixer gives one volt. After deleting three positions, a compact counter has $k = n - 3$. Its mixer instead produces $\exp\backslash(\frac{j3\pi}{4}\backslash)$ volts, approximately $-0.707107 + j0.707107$ volts.

The magnitude of its difference from the correct one-volt result is the square root of (2 plus the square root of 2), approximately 1.847759 volts. If source index nine is followed by thirteen, the correct oscillator advances through four sample intervals, or π radians. Advancing through one interval misses $\frac{3\pi}{4}$ radians. The constant-rotation interpretation applies once a whole filter support shares the same index deficit; it cannot restore a support assembled from samples on both sides of a compressed gap. If $D = 4$ and the intended source epoch is zero, selecting compact indices divisible by four after this three-sample gap selects source indices congruent to three modulo four. A constant phase correction cannot replace the missing output instants on the intended grid.

Copyright 2026, James M. Atkinson

10.61 Application 10E.10: one missing input appears in idle channels

Construct a four-channel bank with channel frequencies $\omega_k = \frac{2\pi k}{4}$ for integer channel labels k from zero through three, phase $\varphi_0 = 0$, output epoch zero, decimation by four, and an eight-tap prototype whose coefficients all equal one-eighth. This k is a channel label local to the example, not the earlier stored-file index. Let every input sample be one volt, with known prior history. At output source indices divisible by four, the complete channel vector is $[1,0,0,0]$ volts. This elementary prototype is chosen for transparent arithmetic and makes no practical selectivity claim.

Lose source sample one hundred and zero-fill that position. At output source index one hundred it contributes through lag zero; at one hundred four it contributes through lag four. Its phase factor is one in every channel, so each affected channel output loses one-eighth volt. The vector becomes $[\frac{7}{8},\frac{-1}{8},\frac{-1}{8},\frac{-1}{8}]$ volts at both retained outputs. All four outputs at each time are invalid under the common support mask. At source index one hundred eight the full vector returns because the gap has left the finite history. The apparent activity in the three previously idle channels is a consequence of the recording discontinuity, without any additional transmitted tone.

Copyright 2026, James M. Atkinson

10.62 Interpretation and continuation boundary for Model 10E

This bounded model supplies a reproducible way to distinguish source chronology, stored position, and processing state. Its ten applications show why a cleanly parsed file, continuous output array, or plausible spectrum cannot by itself establish a continuous observation. Preserve the sample map and uncertainty mask through derived processing, retain the correct phase and output epoch, and interpret only the dependency-valid results under their separate amplitude and timing qualifications. General recursive-state recovery, clock-wander estimation, counter-wrap reconciliation, and empirical transport testing remain extensions requiring additional assumptions and evidence.

Dependency-valid output samples are candidates for usable acquisition windows, not a complete signal-validity certificate. Before applying Model 15A, establish that the signal lies within the accepted channel response, that control and overload recovery have ended, and that the sample timing meets the event criterion. Preserve contiguous record boundaries when forming the overlap intervals. Model 12A supplies deterministic clock, phase, and delay conventions, and Model 12B treats the separate stochastic phase and coherence questions under its specified covariance assumptions. These additional qualifications do not repair an invalid source dependency; they define when a dependency-valid interval supports the intended observation.

Copyright 2026, James M. Atkinson

10.63 SDR Acceptance and Supply-Chain Controls

SDR acceptance covers analog response, filters, gain states, ADC range, sample-rate accuracy, alias rejection, DDC response, channelizer boundaries, sample continuity, timestamp behavior, and software reproducibility. Firmware, gateware, driver, and application hashes are recorded with device identity. An update is treated as a configuration change requiring regression testing.

Unknown or modified software is not permitted to become the only evidence path. Reference recordings are processed through independent tools where practical, and the device is challenged with noise-only and known-source data. A technically attractive open architecture still requires supply-chain, rights, security, and reproducibility controls before field deployment.

Copyright 2026, James M. Atkinson

10.64 Framework 10F for bounded SDR acceptance

Acceptance establishes that a particular receiver configuration satisfies stated requirements under a stated examination. Its object is the configured measurement path, including the software that interprets the samples. A release label, a successful installation, and an attractive spectrum display establish different facts. None specifies, by itself, which input levels, sample rates, gain states, channels, or recording conditions were examined. The useful result is a bounded claim that another examiner can evaluate against the same criteria.

Framework 10F organizes that claim without assigning a numerical confidence score to incomplete evidence. It joins artifact identity, configuration identity, test applicability, and technical results through mandatory criteria. The ten applications are constructed acceptance cases, not observations of a commercial receiver. Their numerical limits are expressly chosen for the examples and are not universal SDR specifications. Chapter 15 remains the home of legal authority, retention, access, and evidentiary governance; the present section concerns which technical behavior an acceptance result actually supports.

10.65 Define the case before testing

Begin with a declared use and a finite configuration envelope. Identify the receiving channels, analog input reference plane, admitted frequency band, permitted input levels, gain and filter states, clock and time sources, sample formats, rate changes, processing stages, and recording destination. Include environmental and host-load conditions when they can affect a requirement. An acceptance case for one channel at one rate is legitimate if that narrow scope is useful. It cannot be relabeled as acceptance of every channel and rate after the tests are complete.

Give each criterion a stable identifier and a proposition that can be satisfied or contradicted. A useful criterion identifies its subject, allowed configuration, stimulus or documentary examination, required observable, decision rule, and evidence. For example, a declared sample-format test can require exact recovery of specified integer code words; an analog-response test needs a reference plane, frequency points, gain state, uncertainty treatment, and allowed error. A statement such as works normally supplies neither a discriminating observation nor a boundary for the conclusion.

Determine applicability separately from the result. A criterion explicitly outside the declared case may be excluded only with a recorded technical rationale. Transmit spectral purity can be outside a receive-only acceptance case when no transmitting operation is being claimed; the exclusion does not establish that transmission is disabled or harmless. If the operating modes, signal path, or requirement interpretation are not yet known, applicability is unresolved. Do not remove a difficult requirement by

Copyright 2026, James M. Atkinson

marking it nonapplicable after an unfavorable result. A changed scope creates a new case whose narrower claim must be stated.

For every mandatory applicable criterion, retain one of three evidence states. Satisfied means that adequate, applicable evidence meets its stated rule. Contradicted means that adequate evidence demonstrates a breach of that rule. Unresolved means that the necessary evidence, its applicability, or its interpretation is insufficient. An invalid test does not demonstrate either compliant or noncompliant receiver behavior. A failed signature check, however, can contradict a requirement for successful verification without establishing why the check failed or what the receiver would do. Evidence of a breach must be attributable to the case. If observations conflict, examine their subjects, conditions, and validity; a favorable repetition does not erase an earlier valid breach of a criterion that permits none.

Table 10F1 Decision states for mandatory applicable criteria

Evidence state	Meaning for one criterion	Effect on the acceptance case
Satisfied	Applicable evidence meets the declared rule.	Required for every mandatory applicable criterion.
Contradicted	Applicable evidence demonstrates a breach.	The case fails; retain any other unresolved matters.
Unresolved	Evidence or applicability is insufficient.	Acceptance is not demonstrated unless the matter is resolved.

The decision follows directly from the conjunction of requirements. If any mandatory applicable criterion is contradicted, the case fails. If none is contradicted but a required result or applicability decision remains unresolved, acceptance is not demonstrated. Acceptance is supported only

Copyright 2026, James M. Atkinson

when all mandatory applicable criteria are satisfied and every exclusion has a defensible rationale. An empty set of criteria, an undefined envelope, or an exclusion without justification cannot produce acceptance. Numerous favorable results cannot compensate for a failed mandatory condition, and unresolved conditions are not assigned fractional passes.

This logic is deliberately conditional. It does not calculate the probability that the receiver is secure, the chance of an undetected fault, or the frequency of future data loss. A test suite can omit a relevant failure mode even when every listed test passes. The completeness and relevance of the criteria therefore need technical review independently of the mechanical aggregation of their results. Record the remaining boundaries of an accepted case as carefully as its successful observations.

Copyright 2026, James M. Atkinson

10.66 Separate signed artifacts from operating configurations

Code signing authenticates signed content under a verification and trust policy. The verifier must use appropriate trust anchors and validate the relevant signature, certificate, and time information. NIST also identifies the possibility that unauthorized or malicious code is itself signed. Thus a valid signature is evidence about integrity and the signing source, not a measurement of filter response, sample scaling, or numerical correctness. Those behavioral propositions need their own examination.[16]

A build attestation requires more than a visible signature symbol. SLSA version 1.2 calls for checking the artifact digest against the attestation subject, the provenance type, trusted builder identity, and expected build information. Its verification guidance includes the source repository, buildType, and externalParameters, and recommends rejection of unrecognized external parameters. The receiver acceptance case must state which of these expectations it actually checks; a general statement that provenance was present is insufficient.[17]

Bind these documentary results to the executable files, loaded modules, firmware, gateware, calibration data, and configuration that the test used. A digest identifies declared bytes under the selected hash algorithm. It does not show that those bytes were loaded, that all executable dependencies were included, or that a compromised reporting component described its state honestly. Record whether each identity came from a file examination, a loader record, a device response, or a stronger authenticated mechanism. Do not describe ordinary version strings as attestation.

Image selection can be part of the configuration. UHD documents different loading arrangements among device families, including runtime loading and images held in device storage. Its image downloader obtains images compatible with the host software, and its image-search configuration can include multiple ordered paths. These are concrete reasons to distinguish the downloaded file, the file selected for loading, and the image operating in the device. The applicable device documentation determines which observations can support that association.[18]

A configuration manifest should use explicit field names, units, channel identifiers, and unambiguous values. Retain actual values as well as requests. UHD documents that set_rx_rate can coerce a requested rate and directs the caller to get_rx_rate for the resulting value. It similarly distinguishes requested and actual tuning or gain values. A successful call is

18 United States Navy, Navy Electricity and Electronics Training Series, Module 12: Modulation, NAVEDTRA 14184 (September 1998), 1-43–1-45 and 2-8–2-13, reproduced in SIGINTRADARTSCM.pdf, compilation pages 7308–7310 and 7349–7354. The cited passages distinguish sinusoidal AM envelope and sideband structure from frequency deviation and modulation rate. Classification and attribution limits here are methodological conclusions, not claims that the source proves an emitter’s identity or purpose.

Copyright 2026, James M. Atkinson

therefore not sufficient evidence that the requested operating point was established.[19]

The interface boundary also matters. UHD distinguishes the CPU sample format, the over-the-wire format, additional stream arguments, and channel mapping. Host-memory and transport representations are not interchangeable descriptions. A separate recording serializer introduces another format contract. Fix the sign convention, numerical scaling, byte order where applicable, I/Q order, and channel order at the boundary actually being tested.[20]

---

19 United States Navy, Navy Electricity and Electronics Training Series, Module 12: Modulation, NAVEDTRA 14184 (September 1998), 1-43–1-45, reproduced in SIGINTRADARTSCM.pdf, PDF pages 7308–7310; title and edition at compilation page 7254. The cited treatment concerns the sinusoidal AM envelope and sidebands, not a current regulatory allocation.

10.67 Choose evidence that can discriminate the required behavior

A functional test needs an expected result derived independently enough to expose the proposed failure. Known integer vectors can distinguish data-format mistakes that a smooth waveform conceals. Analytically selected tones can distinguish channel permutation, frequency-sign reversal, and an incorrect decimation epoch. Reference processing from Models 10B through 10E can supply the appropriate finite-record assumptions and state conventions. Reusing those established derivations avoids replacing a precise test oracle with an undocumented display comparison.

An analog test additionally needs a known applied stimulus and a characterized path to the declared reference plane. State which source uncertainty, cable correction, mismatch effect, receiver repeatability, and drift are included in the decision. A displayed amplitude alone does not separate receiver error from stimulus or fixture error. For a frequency grid, distinguish acceptance at the tested points from a claim over the continuous interval between them. Neither interpolation nor a smooth plot supplies a worst-case bound without an additional justified model.

Choose the decision rule before examining the results. One conservative example is to accept a bounded error interval only when the entire interval lies inside the allowed region, declare a contradiction when the entire interval lies outside it, and otherwise retain an unresolved result. The interval must have the interpretation stated in the test. An expanded uncertainty is not automatically a deterministic bound, and a stated coverage probability is not a certainty. Chapter 14 develops the

Copyright 2026, James M. Atkinson

measurement-uncertainty and decision-risk treatment; the example below uses a stipulated bound only.

Test names also have boundaries. The UHD R&D testing chapter expressly distinguishes development tests from manufacturing or production tests. Its devtests exercise basic functionality, while the FPGA functional procedure examines data flow at specified rates and channel configurations using benchmark_rate. The procedure names error indications and device-specific exceptions. Passing such a procedure supports its stated conditions; it does not silently validate an unexercised recording destination, analog acceptance limit, or mission workload.[21]

Evidence must remain applicable through the end of the test. Changing a driver, FPGA image, coefficient file, calibration correction, clock source, packet setting, or recording program can invalidate a prior result. Assess the dependencies of each criterion rather than assuming that only the component named in a release note can be affected. A data-type conversion can change amplitude, clipping, and file interpretation simultaneously. An uncertain dependency is a reason to retain an unresolved result or expand testing, not a reason to declare the old result unaffected.

Component provenance must also be usable after an update. NIST SSDF version 1.1 calls for release-integrity information, protected release

21 Range Commanders Council, Telemetry Standards, IRIG Standard 106-05 (2005), appendix A, “Frequency Considerations for Telemetry,” sec. 5.2.3.3, A-12, eq. A-4 and the stated limitation on correspondence with 99-percent power bandwidth, https://irig106.org/docs/106-05/appendixA.pdf. The engineering estimate is used here without adopting the document’s historical frequency allocations or implying current regulatory guidance.

Copyright 2026, James M. Atkinson

material, and maintained provenance for software components, including through an SBOM. Here that information supports comparison of the tested and proposed configurations. An inventory records the components within its declared scope; it does not itself prove absence of vulnerabilities or establish the identity of hardware or firmware omitted from that scope.[22]

22 Keysight Technologies, Digital Modulation in Communications Systems, application note 5965-7160E (July 5, 2024), 38–39 and 41–43, https://www.keysight.com/us/en/assets/7018-09093/application-notes/5965-7160.pdf. These passages describe carrier and symbol-clock recovery and comparison with an ideal reference waveform. The historical system examples and dated claims about adoption of EVM standards are not adopted. Model 7A fixes its own finite-record normalization and alignment permissions.

10.68 Ten worked applications of Framework 10F

Each application supplies hypothetical evidence and a declared rule. Satisfied, contradicted, and unresolved refer to the stated criterion, not to a universal product rating. Unless an application says otherwise, the remaining mandatory criteria are assumed satisfied so that the consequence of the particular issue is explicit. Hexadecimal bytes are written in their stored order. No case represents an actual device test, security incident, or vendor certification.

Copyright 2026, James M. Atkinson

10.69 Application 10F.1 A familiar filename with different bytes

A release manifest identifies the accepted application file by a full digest. The installation directory contains the same filename and release label, but a direct computation gives a different digest. The mandatory identity criterion requires equality with the authenticated manifest entry. It is contradicted: matching names do not satisfy the byte-identity rule. A normal-looking spectrum from that installation cannot repair the failed comparison, because it does not establish which release was executed.

The case fails without an inference that an attacker modified the file. A packaging change, a local rebuild, or an unintended download could also explain the difference. Resolution requires a separately justified artifact identity and the corresponding acceptance work. Replacing the expected digest with the observed value merely to clear the failure would change the criterion after the result and would not authenticate the new artifact.

Copyright 2026, James M. Atkinson

10.70 Application 10F.2 A valid signature with an unacceptable build claim

A hypothetical receiver application has an authentic attestation whose subject matches its file digest. The declared policy permits one builder, one source repository, and a release build with a fixed set of external parameters. The attestation instead identifies a laboratory fork and an additional parameter enabling a diagnostic path. Signature verification is satisfied, but the source and parameter expectations are contradicted. The combined provenance requirement fails, so the acceptance case fails despite the valid signature.

The failure concerns the declared production configuration; it does not prove that the diagnostic path is malicious. A laboratory case might explicitly admit that fork and parameter, but it would need its own requirements and tests. Conversely, an unavailable attestation would leave verification unresolved rather than proving that the software was modified. This distinction separates missing evidence from an observed policy mismatch.

Copyright 2026, James M. Atkinson

10.71 Application 10F.3 The verified image was never shown to be loaded

An examiner verifies the expected FPGA image in a download directory and records a successful device connection. The loading mechanism searches two image directories, and the connection report gives only a compatibility number shared by several image builds. The criterion requires association of the tested device session with the intended image. File verification is satisfied, but the loaded-image association is unresolved. The evidence does not show that the intended file won the search or that the compatibility label uniquely identifies its contents.

The examiner establishes the actual selected image path through the applicable loading procedure, verifies that file, and repeats the session initialization with the controlled selection. Where the device cannot provide authenticated runtime identity, the report states the narrower assurance supplied by the observed loading process. It does not invent a runtime attestation. Tests performed before that association was established are not automatically transferred to the newly identified session.

Copyright 2026, James M. Atkinson

10.72 Application 10F.4 A requested sample rate is not the established rate

The hypothetical acceptance rule permits an actual receive rate from 9.999 to 10.001 megasamples per second. An application requests 10 megasamples per second, but the documented readback for the established configuration is 9.6 megasamples per second. The difference is 0.4 megasamples per second, or 4 percent of the request, far beyond the allowed 0.001-megasample-per-second deviation. The operating-point criterion is contradicted. No inference about clock accuracy follows from a readback alone; that is a separate measurement criterion.

Even if the samples are continuous, labeling them with the requested rate misstates their time axis. Using those nominal configured rates, a digital feature at one-tenth of the readback rate is labeled 0.96 megahertz, while use of the requested rate would label it 1 megahertz. The correction is to establish an admitted rate or create an explicitly different acceptance case, then use the actual rate consistently. An unresolved clock-reference measurement cannot be replaced by this arithmetic check.

Copyright 2026, James M. Atkinson

10.73 Application 10F.5 A serialization error survives successful installation

At a declared file boundary, three real test samples are signed 16-bit two’s complement codes in little-endian byte order, with values 1, 256, and minus 256. The stored byte pairs are 01 00, 00 01, and 00 FF. A reader using big-endian interpretation returns 256, 1, and 255. The criterion requires exact recovery of all three code values, so it is contradicted in every position. The values are integer codes, not voltages; no analog calibration is implied.

A zero-only vector would have passed both interpretations and concealed the defect. The asymmetric positive and negative vector discriminates byte order and sign handling without relying on a plausible waveform shape. This example specifies a recording format independently of UHD transport packing. A verified driver package does not establish that a separate serializer and reader agreed on their interface. Correct the format boundary and repeat the reference-vector and affected scaling tests.

Copyright 2026, James M. Atkinson

10.74 Application 10F.6 A bounded amplitude result near an acceptance limit

At one stated frequency and gain state, the allowed amplitude error is from minus 0.50 to plus 0.50 decibel, including both endpoints. The test stipulates a justified deterministic error-bound half-width of 0.18 decibel, including the declared source and fixture contributions. A corrected estimate of plus 0.30 decibel therefore permits errors from plus 0.12 to plus 0.48 decibel. Every permitted value lies inside the allowed interval, so this criterion is satisfied under the stated conservative rule.

With the same bound, an estimate of plus 0.42 decibel permits plus 0.24 through plus 0.60 decibel. The interval overlaps the acceptance boundary, so the result is unresolved, even though the estimate itself is inside. An estimate of plus 0.74 decibel permits plus 0.56 through plus 0.92 decibel, entirely outside, and contradicts the criterion. If the stated half-width were only a coverage interval, these classifications would require the corresponding probabilistic decision rule. None of the three outcomes establishes performance at untested frequencies or gain states.

Copyright 2026, James M. Atkinson

10.75 Application 10F.7 A streaming pass leaves the recording path unresolved

A hypothetical rule requires a continuous sixty-second, two-channel recording at 20 megasamples per second per channel, through the designated disk-writing application under a declared host workload. A benchmark streams the two channels for sixty seconds with no reported errors, but discards the received buffers. It exercises a different endpoint from the required recording. The benchmark result may satisfy its own streaming criterion; the complete recording criterion remains unresolved.

For the declared interval, the expected count is 1,200,000,000 complex samples per channel, or 2,400,000,000 across both channels. With two signed 16-bit components per complex sample, the payload alone is 9,600,000,000 bytes, before headers or metadata. These counts help define the test but do not establish continuity: duplicated samples can replace missing samples without changing file length. The completed test must exercise the actual writer, examine the relevant error indications, and apply the source-index and state checks of Model 10E. No error-free finite run establishes a future loss probability of zero.

Copyright 2026, James M. Atkinson

10.76 Application 10F.8 Two agreeing programs share the same fault

The criterion requires an independent reference check of a four-channel output ordering. Two applications agree on every output, but both call the same conversion library and use the same channel-map table. Their agreement is not independent evidence for that mapping. The required independent reference check remains unsupplied, so that criterion is unresolved. The assertion that these two implementations are independent is contradicted by their known common dependency. Their agreement remains a narrower reproducibility observation.

For a constructed single-channel basis test, the declared oracle is the ordered vector $[0,1,0,0]$ in normalized dimensionless units. Both applications instead return $[0,0,0,1]$. Comparison with the explicit oracle now contradicts the mapping criterion. A tone of equal amplitude in every channel would not have exposed the permutation. After correction, different software names are still insufficient: document the implementation or analytical independence actually used for the comparison.

Copyright 2026, James M. Atkinson

10.77 Application 10F.9 An inventory omits a required component

A supplier provides a signed software inventory for the host application and its libraries. The acceptance case separately requires provenance for the FPGA image and the calibration file used by the receiver session. Those two artifacts are absent from the inventory and no separate evidence is supplied. The inventory may be valid within its stated software scope; the two required provenance criteria remain unresolved. Neither the signature nor the inventory length converts absence of evidence into verified coverage.

The remedy is to obtain applicable component evidence or explicitly revise the claimed configuration and its acceptance scope before retesting. Calling the missing artifacts hardware would not justify exclusion when their contents influence required sample processing or correction. Likewise, a statement that the listed software has no reported vulnerability does not establish absence of defects in unlisted components. The result remains an incomplete acceptance case, without a claim that the omitted artifacts are defective.

Copyright 2026, James M. Atkinson

10.78 Application 10F.10 An update closes a precisely bounded case

A hypothetical receive-only case has eight mandatory applicable criteria: artifact identity, provenance policy, loaded-image association, actual configuration, sample representation, analog response, recording continuity, and reference independence. A driver update changes the artifact and provenance evidence and may affect configuration, conversion, and recording behavior. The reviewer also reopens loaded-image association because the driver participates in loading, bringing the reopened set to six criteria. Analog response and reference independence are retained only after a documented dependency review establishes that their subjects and conditions did not change; uncertainty about any dependency would reopen it as well.

The first update examination produces seven satisfied criteria and unresolved recording continuity. Acceptance is not demonstrated. After the complete recording-path test supplies applicable evidence, all eight are satisfied. A transmit-only criterion is excluded with the established receive-only scope and an explicit rationale, not counted as a ninth pass. The resulting acceptance statement identifies the exact updated configuration, tested frequency and gain conditions, and recording workload. It does not extend to another rate, channel count, or transmitting mode. A later permitted configuration change starts a new applicability and impact review rather than inheriting this conclusion by release-name similarity.

Copyright 2026, James M. Atkinson

10.79 Acceptance as a reproducible technical argument

The strength of this framework lies in keeping evidence attached to the proposition it can support. Identity evidence constrains which artifact was examined; configuration evidence constrains what was operating; a valid test constrains behavior under its stimulus and conditions. Their conjunction can support a useful acceptance claim while leaving broader claims unmade. A rejected or unresolved case should identify the specific contradiction or missing association so that further work can change the result through evidence, rather than through a more favorable description.

Copyright 2026, James M. Atkinson

10.80 Quantitative Model for Software-Defined Radios, Sampling, Quantization, DDC, and Channelization

Equation 1. Nyquist condition for a baseband signal

$$f_s > 2\,B_{\text{signal}}$$

For a real baseband signal band-limited to B_{signal} hertz, sample rate f_s must exceed twice that bandwidth to avoid spectral overlap in the ideal model. Practical anti-alias filters require transition margin, and band-pass or complex-sampling cases use different conditions.

The ten sampling-equivalence applications in this chapter make Equation 19's signal-class condition explicit. The inequality is a sufficient separation condition for the stated real baseband class, not a general identification rule for an arbitrary analog tone or a substitute for the front-end admission model.

Copyright 2026, James M. Atkinson

10.81 Sampling equivalence, admissible bands, and receiver interpretation

Uniform sampling constrains frequency through an equivalence relation. Let $x(t) = A\cos(2\pi f t + \varphi)$, where A is peak voltage, f is frequency in hertz, t is time in seconds and φ is phase in radians. An ideal real sampler observes $x[n] = A\cos(\frac{2\pi f n}{f_s} + \varphi)$ at integer n, with positive rate f_s in samples per second. Adding $k f_s$ to f, for integer k, adds $2\pi k n$ to the sampled phase and leaves every sample unchanged. Replacing f by $-f$ changes the sign convention for phase; a cosine with frequency $-f$ and phase $-\varphi$ is the original waveform. Consequently a magnitude spectrum cannot distinguish f from any member of $\{k f_s \pm f\}$. This is an algebraic ambiguity before finite record length, noise or converter defects enter the problem.

$$x[n] = A\cos\left(\frac{2\pi f n}{f_s} + \varphi\right)$$

Define the signed representative $r = f - f_s \operatorname{floor}(\frac{f}{f_s} + \frac{1}{2})$, lying in $[\frac{-f_s}{2}, \frac{f_s}{2})$. The representative folded frequency for a real magnitude spectrum is the absolute value of r. At an exact half-rate boundary the signed representative convention is arbitrary, because the two endpoints describe the same sampled exponential. For real sinusoids the boundary is more serious: at $f = \frac{f_s}{2}$, $x[n] = A(-1)^n \cos\varphi$. The samples do not separately determine A and φ; with $\varphi = \frac{\pi}{2}$ every sample is zero. Thus the strict inequality in Equation 19 deliberately avoids an endpoint ambiguity for unrestricted sinusoidal phase. It is not merely a numerical preference.

Copyright 2026, James M. Atkinson

$$r = f - f_s floor\left(\frac{f}{f_s} + \frac{1}{2}\right), f_a = |r|$$

$$x[n] = A(-1)^n \cos\varphi \; when \; f = \frac{f_s}{2}$$

A reconstruction claim adds an admissible signal class. Let B denote the positive upper baseband frequency in hertz. If an ideal real signal has no spectral content outside $|f| \leq B$ and $f_s > 2B$, its translated spectra are separated. A physical receiver must provide evidence that unwanted components reaching the sampler are sufficiently attenuated; knowledge of the desired signal's nominal bandwidth alone is insufficient. The source tutorial describes analog filtering and zone translation. The derivations and hypothetical cases below are independent applications, not measured converter results.[23]

The rate-change challenge in the earlier prose is therefore a test of candidate explanations, not a uniqueness theorem. Before changing a rate, list the analog bands admitted by the front end and all intervening mixers. Predict the signed or folded mapping under each acquisition configuration. Reject candidates whose predictions contradict the observed movement, but retain multiple candidates when their mappings coincide. Automatic software retuning can change both the frequency conversion and the rate; that experiment is not equivalent to changing only the sampler clock.

Instrument-specific exceptions and metric settings must be checked before comparing a reported value with the declared finite-vector model.

Copyright 2026, James M. Atkinson

Likewise, a stable displayed frequency does not prove generation after sampling.

Copyright 2026, James M. Atkinson

10.82 Ten worked sampling applications

All inputs, filters and clocks in these applications are hypothetical. Rates and tone frequencies refer to the sampler input rather than an RF label after undocumented frequency conversion. Ideal point samples are assumed unless an explicit limitation is introduced.

Copyright 2026, James M. Atkinson

10.83 Sampling application 1 Baseband transition allowance

A real desired band extends from DC to 4 MHz and the rate is 12 MS/s. Equation 19 is satisfied because $12 > 8$. The nearest image band that folds into the retained 0–4 MHz interval begins at $f_s - B = 8\ \text{MHz}$, so the available analog transition interval from 4 to 8 MHz is 4 MHz. At 10 MS/s it narrows to 4–6 MHz, only 2 MHz. Writing W for the transition width in hertz, this calculation locates the first unwanted band relevant to the retained channel; it does not determine filter order or the allowed ripple. An interferer near 6 MHz at 12 MS/s lies outside the retained 4 MHz band, but could still overload the converter before digital rejection.

$$W = f_s - 2B = (12 - 8)\,MHz = 4\,MHz$$

Copyright 2026, James M. Atkinson

10.84 Sampling application 2 The half-rate phase failure

Let $f_s = 20\ \mathrm{MS/s}$ and $f = 10\ \mathrm{MHz}$. With $A = 1\ \mathrm{V}$ and $\varphi = 0$, the samples alternate +1 and −1 V. With the same amplitude but $\varphi = \frac{\pi}{2}$, all samples are zero. More generally any pair satisfying $A\cos\varphi = c$ gives the same alternating amplitude c. A zero sequence cannot distinguish this quadrature sinusoid from no input. Choosing 24 MS/s removes this particular boundary degeneracy for the 10 MHz tone, although it does not exclude higher admitted aliases.

$$x[n] = (-1)^n\ \mathrm{V} \quad \text{or} \quad x[n] = 0\ \mathrm{V}$$

Copyright 2026, James M. Atkinson

10.85 Sampling application 3 A folded upper-zone tone

At 16 MS/s, a 21 MHz cosine has $r = \backslash(21 - 16\backslash)\ \mathrm{MHz} = 5\ \mathrm{MHz}$ and $f_a = 5\ \mathrm{MHz}$. A 5 MHz cosine of the same phase gives identical ideal samples. A tone at 11 MHz has $r = -5\ \mathrm{MHz}$; choosing its phase as the negative of the 5 MHz tone's phase again gives the same real samples. Input filtering must distinguish these analog candidates before conversion if the later record is to identify their origin. The folded magnitude itself supplies no attenuation estimate.

$r(21\ \mathrm{MHz}) = 5\ \mathrm{MHz}; r(11\ \mathrm{MHz}) = -5\ \mathrm{MHz}$

Copyright 2026, James M. Atkinson

10.86 Sampling application 4 A useful rate change

Retain a 21 MHz tone but increase the rate from 16 to 18 MS/s, keeping the analog path fixed. Its folded position moves from 5 MHz to 3 MHz because $21-18=3$. A true 5 MHz input would remain at 5 MHz at both rates. These two candidates are distinguishable by this challenge in the ideal model. Their relative amplitudes need not remain equal in a physical receiver if gain, aperture response or analog bandwidth changes with the new configuration.

$f_a(21,16)=5\,MHz\,;f_a(21,18)=3\,MHz$

Copyright 2026, James M. Atkinson

10.87 Sampling application 5 A failed two-rate uniqueness claim

Compare 10 MHz and 110 MHz zero-phase cosines. At 100 MS/s, $110 = 100 + 10$, so both fold to 10 MHz with identical samples. At 120 MS/s, $110 = 120 - 10$; cosine evenness again makes their samples identical. Thus observing 10 MHz at both rates does not establish the lower-frequency origin. The ambiguity survives records of arbitrary length under these stipulated phases. An independently justified analog input limit below 50 MHz would eliminate 110 MHz, but that information comes from the admitted-band specification rather than the two records alone.

$110 = 100 + 10 = 120 - 10 \quad \backslash(\mathrm{MHz}\backslash)$

Copyright 2026, James M. Atkinson

10.88 Sampling application 6 Band location and spectral reversal

Suppose the only admitted real band is 31–33 MHz and $f_s = 20\ \mathrm{MS/s}$. This band lies inside the 30–40 MHz Nyquist zone. The folded map is $40\ \mathrm{MHz} - f$, sending 31 MHz to 9 MHz and 33 MHz to 7 MHz. Its 2 MHz width is retained with reversed order. Moving the band to 29–31 MHz crosses the 30 MHz boundary: both 29 and 31 MHz fold to 9 MHz. Merely noting that 20 MS/s exceeds twice the 2 MHz bandwidth fails to detect this overlap. Band placement, not bandwidth alone, controls this particular undersampling plan.

$f_a(31\,MHz) = 9\,MHz\,;\, f_a(33\,MHz) = 7\,MHz$

Copyright 2026, James M. Atkinson

10.89 Sampling application 7 Complex coordinates retain a sign

Let j denote the imaginary unit, with $j^2 = -1$. For ideal complex samples $z[n] = A \exp \backslash(\frac{j 2 \pi f n}{f_s} \backslash)$, an 11 MHz input sampled at 16 MS/s has signed representative −5 MHz. It is not the +5 MHz sequence: at $n = 1$ their imaginary parts have opposite signs. If only the real part is retained, that distinction is lost after suitable phase interpretation. This calculation explains why a complex channel's signed frequency convention must be recorded. It does not establish that a physical I/Q receiver has perfect quadrature or image rejection.

$r = 11 - 16 = -5 \text{ MHz}$

Copyright 2026, James M. Atkinson

10.90 Sampling application 8 Required pre-sampling attenuation

At 20 MS/s, an 18 MHz interferer folds to 2 MHz. Suppose the desired 2 MHz input is −80 dBm, the interfering input is −20 dBm, and the permitted aliased contribution is at most −90 dBm, all referred to the same matched input and unit desired-band transmission. Writing L for filter attenuation in decibels, the filter needs at least 70 dB attenuation at 18 MHz because \$(-20\ \text{dBm}\$)-70\ \text{dB}=-90\ \text{dBm}$. A measured 60 dB would leave −80 dBm, equal to the desired level. The arithmetic assumes a linear non-overloaded path; an attenuated output spectrum cannot repair intermodulation generated upstream.

$$L \geq (-20)-(-90)=70\ \text{dB}$$

Copyright 2026, James M. Atkinson

10.91 Sampling application 9 Coherent aliases can cancel

At 16 MS/s choose $x(t)=[\cos(2\pi\cdot 5\ \text{MHz}\cdot t)-\cos(2\pi\cdot 21\ \text{MHz}\cdot t)](1\ \text{V})$, with each tone having 1 V peak. At every sample the two cosine arguments differ by $2\pi n$, so $x[n]=0$. The corresponding plus sign gives a 2 V peak sampled cosine. Adding the two analog tone powers would miss both results because these distinct analog frequencies become coherent at the same discrete frequency. Uncorrelated random components permit a different mean-power argument, but that assumption is absent here.

$$\cos\left(\frac{2\pi\cdot 21n}{16}\right)=\cos\left(\frac{2\pi\cdot 5n}{16}\right)$$

Copyright 2026, James M. Atkinson

10.92 Sampling application 10 Clock error shifts a folded result

Stipulate an exact 21 MHz tone and a true sampling rate $f_s = 16\ \text{MHz}\backslash(1+\varepsilon\backslash)$, where ε is the dimensionless fractional clock offset and $|\varepsilon| \leq 10$ parts per million. The signed alias remains on the same branch and is $5\ \text{MHz} - 16\ \text{MHz}\ \varepsilon$. Its physical-rate frequency therefore lies from 4,999,840 to 5,000,160 Hz. If software instead labels frequency using the nominal 16 MHz clock, it reports $[\frac{21\ \text{MHz}}{f_s} - 1] \cdot 16\ \text{MHz}$; that expression has a different error dependence. A frequency-axis uncertainty budget must specify which clock establishes the displayed hertz. The calculations concern constant clock offset, not random aperture jitter.

$$f_a = 5{,}000{,}000 - 16{,}000{,}000\,\varepsilon\ Hz$$

$$f_{display} = \left(\frac{21\,MHz}{f_s} - 1\right) \times 16\,MHz$$

Equation 2. Ideal quantization SNR

$$\text{SNR}_{\text{Q,dB}} \approx 6.02\,N_{\text{bits}} + 1.76$$

For an ideal N-bit converter driven by a full-scale sinusoid with uniformly distributed quantization error, signal-to-quantization-noise ratio is approximately $\backslash(6.02\,N + 1.76\backslash)\ \text{dB}$. Effective performance is lower when jitter, noise, nonlinearity, or reduced amplitude is present.

The quantization treatment and its ten applications derive the domain of Equation 20. The ideal full-scale sine-wave estimate is conditional on the stipulated error model; code alignment, clipping, correlation, dither, and

Copyright 2026, James M. Atkinson

admitted channel bandwidth can change the result. It is not a measured converter specification.

Copyright 2026, James M. Atkinson

10.93 Quantization margin and channel bandwidth

A code count determines amplitude spacing, whereas a noise claim also requires a distribution and a bandwidth. Let F be the nominal peak-to-peak input span in volts, N the integer bit count, and $\Delta = \frac{F}{2^N}$ volts the ideal interior code spacing. The nominal positive peak $\frac{F}{2}$ is a reference amplitude; the actual finite-code endpoint convention must be checked separately before driving a converter to its rail. For a rounding quantizer away from overload, define the error $e = Q(x) - x$. Its bound $|e| \leq \frac{\Delta}{2}$ does not alone establish its mean, variance, correlation with x, or spectrum. A constant input at a code center has zero error; another constant input can have a fixed error. Neither record becomes white noise merely because the converter has many bits.

$$\Delta = \frac{F}{2^N}, \; |e| \leq \frac{\Delta}{2}$$

The familiar planning model stipulates error uniformly distributed over an interval of width Δ centered on zero. Direct integration gives $\mathrm{E}[e] = 0$ and $\mathrm{E}[e^2] = \frac{\Delta^2}{12}$. For a zero-mean sinusoid with peak amplitude $\frac{aF}{2}$, its mean square is $\frac{a^2 F^2}{8}$, provided the sampled record adequately represents the sinusoid's phase. Dividing these quantities gives a signal-to-error-power ratio of $\frac{3}{2} a^2 2^{2N}$, or $20 N \log_{10}(2) + 10 \log_{10}(\frac{3}{2}) + 20 \log_{10}(a)$ decibels. This

Copyright 2026, James M. Atkinson

derivation is conditional on the uniform-error model; the power ratio is not a universal property of every sequence passed through a quantizer.[24]

$$E[e]=0, E[e^2]=\frac{\Delta^2}{12}$$

$$\mathrm{SQNR}=20N\log_{10}(2)+10\log_{10}\left(\frac{3}{2}\right)+20\log_{10}(a)$$

A further assumption is needed to predict noise in a channel. If the sampled error is white with variance $\frac{\Delta^2}{12}$, its one-sided density over zero to $\frac{f_s}{2}$ is $\frac{\Delta^2}{6f_s}$, in volts squared per hertz. For a digital filter with unit reference gain and one-sided equivalent noise bandwidth B_e, the output error power is $\frac{\Delta^2 B_e}{6f_s}$. This follows by integrating the density against squared filter magnitude. The improvement relative to full-Nyquist error is $10\log_{10}[\frac{f_s}{2B_e}]$. It requires anti-alias filtering before decimation and retained signal gain. Merely selecting every Dth sample does not reduce the variance of independent samples. Neither the white-error premise nor this bandwidth calculation applies automatically to deterministic quantization lines.[25]

These introductory passages distinguish bit and symbol rates while explicitly excluding

Copyright 2026, James M. Atkinson

$$S_e = \frac{\Delta^2}{6 f_s}, P_e = \frac{\Delta^2 B_e}{6 f_s}$$

$$G = 10 \log_{10}[\frac{f_s}{2 B_e}]$$

Here f_s is the sampling frequency and B_e the one-sided equivalent noise bandwidth, both in hertz; S_e is the one-sided error spectral density in volts squared per hertz, P_e is error mean square in volts squared, and G is the improvement in decibels. These symbols describe the stated error model, not independent measured specifications.

The original tutorial cited here derives the uniform-error estimate and distinguishes correlated errors from a broad noise spectrum. Its formula describes an ideal model, not a calibration certificate. The following calculations are independent examples derived from the stated assumptions; they do not import plot coordinates or equipment observations.

---

synchronization and error-correction overhead. Model 7B independently derives its finite coding, framing, time and duplicate-payload accounting under the stated premises; no commercial performance or error-probability claim is imported.

Copyright 2026, James M. Atkinson

10.94 Application 1 Voltage spacing and error budget

A hypothetical 10-bit channel has a 2 V nominal span. $\Delta = \frac{2\ \mathrm{V}}{1024} = 1.953125\ \mathrm{mV}$.

Uniform error would have RMS $\frac{\Delta}{\sqrt{12}} \approx 0.563819\ \mathrm{mV}$, whereas the deterministic magnitude bound is 0.9765625 mV. A specification requiring an error smaller than 0.7 mV for every sample is not met merely because the model RMS is below that value. The distinction is between a mean-square prediction and a maximum-error requirement.

Copyright 2026, James M. Atkinson

10.95 Application 2 A small signal in a fixed range

A nominal 10-bit sine at one quarter of the reference peak has ideal SQNR $[61.9669 + 20\log_{10}\backslash(\frac{1}{4}\backslash)]\ \mathrm{dB} \approx 49.9257\ \mathrm{dB}$. Keeping Δ fixed while halving amplitude once more removes another 6.0206 dB. Increasing digital gain after conversion scales both signal and error and restores neither lost amplitude distinctions nor their ratio.

Copyright 2026, James M. Atkinson

10.96 Application 3 Crest-factor headroom

Suppose a non-sinusoidal signal has peak-to-RMS ratio four and its peak is limited to $\frac{F}{2}$. Its mean square is $\frac{F^2}{64}$. Relative to a full-reference sine, whose mean square is $\frac{F^2}{8}$, it loses $10\log_{10}\backslash(8\backslash)\ \mathrm{dB} \approx 9.0309\ \mathrm{dB}$ of model margin at the same peak. For $N = 10$, its ratio is therefore 52.9360 dB if the uniform error assumption still holds. Peak control alone does not specify RMS margin.

Copyright 2026, James M. Atkinson

10.97 Application 4 Filtered noise power

Let $f_s = 8\ \text{MHz}$ and $B_e = 125\ \text{kHz}$, with unity signal gain. The retained white-error fraction is $\frac{2B_e}{f_s} = \frac{1}{32}$. Its RMS is reduced by $\sqrt{32}$, and its signal-to-error ratio improves by 15.0515 dB. This is an integration over squared response, so substituting a filter's nominal 3 dB bandwidth for B_e without verification can misstate the result.

Copyright 2026, James M. Atkinson

10.98 Application 5 Minimum integer code count

A quarter-reference sine needs at least 60 dB of model SQNR over the full Nyquist band. Solving $N \geq \frac{60 - 10\log_{10}\left(\frac{3}{2}\right) - 20\log_{10}\left(\frac{1}{4}\right)}{20\log_{10}(2)}$ gives a numerical threshold of approximately 11.6733 for the bit count, hence at least 12 bits. Eleven bits give 55.9463 dB; twelve give 61.9669 dB. This is an ideal necessary planning choice under the model, not sufficient acceptance of a physical converter.

Copyright 2026, James M. Atkinson

10.99 Application 6 Exact code-center counterexample

For an unsaturated rounding quantizer $Q(x) = \Delta \operatorname{round}(\frac{x}{\Delta})$, choose the deterministic record $\frac{x}{\Delta} = [-2, -1, 0, 1, 2]$. Every output equals its input, so all five errors and their mean square are exactly zero. Substituting $\frac{\Delta^2}{12}$ would be incorrect for this record. A favorable code-center test is therefore not evidence that other input levels have no quantization error.

Copyright 2026, James M. Atkinson

10.100 Application 7 A periodic error sequence

Let $\frac{x}{\Delta}=[\frac{1}{4},\frac{3}{4},\frac{1}{4},\frac{3}{4}]$, repeated. Rounding gives $\frac{Q\backslash(x\backslash)}{\Delta}=[0,1,0,1]$, hence $\frac{e}{\Delta}=[\frac{-1}{4},\frac{1}{4},\frac{-1}{4},\frac{1}{4}]$. Its mean is zero, mean square is $\frac{\Delta^2}{16}$, and lag-one correlation is negative rather than zero. All error energy lies in the alternating component. A broad-band white-noise allocation would distribute that error into channels incorrectly.

Copyright 2026, James M. Atkinson

10.101 Application 8 Mean-square error is not always variance

The constant input $x = \frac{\Delta}{4}$ rounds to zero. Error is $-\frac{\Delta}{4}$, variance around its own mean is zero, and mean-square error relative to the original input is $\frac{\Delta^2}{16}$. Removing DC from both input and output before comparing them can hide this bias. The relevant metric depends on whether the measurement seeks an AC waveform or an absolute input level.

Copyright 2026, James M. Atkinson

10.102 Application 9 Averaging correlated versus independent errors

Four independent zero-mean errors of common variance $\frac{\Delta^2}{12}$ have average variance $\frac{\Delta^2}{48}$. Four identical errors instead retain variance $\frac{\Delta^2}{12}$, because all covariance terms contribute. Independence thus yields 6.0206 dB improvement, while perfect correlation yields none. The constant-bias record in Application 8 retains its bias under averaging regardless of sample count.

Copyright 2026, James M. Atkinson

10.103 Application 10 Decimation without filtering

Take independent zero-mean white errors of variance $\frac{\Delta^2}{12}$ and keep every fourth sample. Each retained sample has the same distribution and variance; the output rate becomes $\frac{f_s}{4}$. A mistaken use of a fourfold process gain would predict $\frac{\Delta^2}{48}$, which belongs to a suitable averaging/filtering operation, not bare sample deletion. In a physical chain, out-of-band components can additionally alias into the retained band.

Table 1. Chapter 10 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Analog-digital boundary	Protection, filters, gain, converter range, clock, and calibration	Defines what the samples physically represent	Software cannot recover information lost before conversion
Sampling and alias control	Sample rate, Nyquist zone, analog bandwidth, filters, and rate-change tests	Maps digital frequency to possible RF origins	Stable aliases can be misattributed
DDC and channelizer	NCO, filters, decimation, scaling, channel grid, and transient state	Creates efficient selected-band data	Boundary and alias behavior can change amplitude and timing
Recording path	Buffers, packet sequence, timestamps, overflow, file format, storage, and hashes	Preserves sample continuity and data lineage	Dropped or repeated samples generate false spectral features

10.104 Hypothetical Applied Calculation: Software-Defined Radios, Sampling, Quantization, DDC, and Channelization

A 14-bit ADC has an ideal full-scale sinusoidal quantization SNR near 86.0 dB. If the signal uses only one eighth of full-scale amplitude, its power is 18.1 dB lower while quantization step size is unchanged, reducing the ideal relative margin to about 67.9 dB before other converter impairments.

Copyright 2026, James M. Atkinson

10.105 Hypothetical Case Adjudication: Software-Defined Radios, Sampling, Quantization, DDC, and Channelization

An SDR recording shows periodic broadband impulses every 1.024 s. The same interval appears in the USB packet sequence log as buffer overflows, and changing the storage destination removes both the overflow and the impulses. These observations support a recording-path explanation and require checking sample continuity and the processing of affected records before using those impulses as evidence of an environmental transmitter. The stated observations do not by themselves establish that no environmental burst was present.

Copyright 2026, James M. Atkinson

10.106 Converter and Waveform-Recorder Validation Boundary

IEEE 1241-2023 provides current terminology and test methods for analog-to-digital converters sampled at known time intervals. IEEE 1057-2017 separately governs digitizing waveform recorders.[26] A complete SDR or receiver result depends upon the converter, clock, analog front end, digital downconverter, firmware, host interface, dropped-sample behavior, scaling, metadata, and software processing. Converter compliance alone does not validate the receiver system.[27]

10.107 Worked Example 10A.1. Ideal Quantization Signal-to-Noise Ratio

Engineering question. Estimate the ideal full-scale sine-wave quantization signal-to-noise ratio for a nominal 12-bit converter.

Variables and units. $N = 12$ bits; $\mathrm{SNR}_{\mathrm{ideal}}$ is in decibels.

$$\mathrm{SNR}_{\mathrm{ideal,dB}} \approx 6.02\,N + 1.76$$

Calculation. $\mathrm{SNR}_{\mathrm{ideal}} \approx \backslash(6.02 \times 12 + 1.76\backslash)\ \mathrm{dB} = 74.0\ \mathrm{dB}$.

Dimensional check. Bit count is dimensionless and the coefficients produce a logarithmic result in decibels.

Uncertainty and valid range. The relation is an ideal quantization limit for a full-scale sine wave. It excludes aperture jitter, thermal noise, nonlinearity, missing codes, clock phase noise, front-end distortion, clipping, spurs, and digital processing.

Practical meaning. A 12-bit label does not establish 74 dB of usable dynamic range. Effective number of bits and system-level tests must be measured for the actual sampling condition.

Copyright 2026, James M. Atkinson

10.108 Parallel ADC arrays, correlated quantisation error and claims of synthetic resolution

Parallel ADCs can reduce certain noise contributions through averaging, or extend time sampling through deliberately offset aperture phases, but the two architectures solve different problems. Suppose M simultaneously sampling channels measure the same bounded analogue voltage x(t) with individual additive errors e_i(t). The average sample y(t) = (1/M) sum_i [x(t) + e_i(t)] retains the signal while averaging the errors. Its error variance is (1/M squared) times the sum of every pairwise error covariance. Only under independent, zero-mean, equal-variance errors does this reduce to sigma squared divided by M. Quantisation errors may be highly correlated when all channels share the same input and thresholds, so independence cannot be asserted from separate package serial numbers. An input dither or deliberate threshold offset may alter the dependence, but introduces other calibration and dynamic-range obligations.

For M = 16 independent equal-noise channels, averaging reduces random error variance by a factor of sixteen and standard deviation by four. The ideal improvement in amplitude-related signal-to-noise ratio is 20 log10(4) = 12.041 dB, often colloquially equivalent to approximately two additional bits under an appropriately defined quantisation-limited ENOB model. Sixteen nominal 14-bit converters do not thereby become one physical 224-bit converter, nor is 14 plus 14 a justified 28-bit accuracy claim. Shared reference errors, analogue nonlinearity, threshold integral nonlinearity, clock jitter, power-supply coupling and finite input bandwidth can remain

Copyright 2026, James M. Atkinson

unchanged under averaging. The useful figure is measured signal fidelity under stated conditions, not a sum of nominal label widths.

A time-interleaved array uses staggered aperture times to increase the aggregate sample-event rate. For four channels each sampling at 250 MS/s with ideal quarter-period placement, the aggregate sequence can provide a nominal 1 GS/s set of sample times. Yet it does not increase the signal-to-noise ratio by the simultaneous averaging law because each channel observes a different instant. Timing skew, offset, gain mismatch and frequency-response mismatch produce structured spurs. At input frequency f_{in}, a small rms aperture timing uncertainty σ_t yields an idealised jitter-limited ratio $SNR_j = -20 \log_{10}(2 \pi f_{in} \sigma_t)$, provided the small-error approximation applies and the error model is appropriate. For 100 MHz and 1 ps, the calculated limit is about 64.04 dB. Any other distortion or noise will worsen system performance; this is not the achieved ENOB of the array.

Engineering qualification should therefore begin with a declared architecture: simultaneous coherent averaging, time interleaving, spatial sampling, or a hybrid. Characterise each channel's analogue transfer, converter linearity, aperture timing and output statistics, then verify the combined signal with known multi-tone and pulse stimuli across the intended frequency and amplitude range. Preserve the raw per-channel records before combining them; otherwise a spurious improvement cannot be independently explained. IEEE 1241-2023 provides terminology and ADC evaluation methods, while waveform-recording performance must additionally be assessed as a system. The public standard abstracts do not

Copyright 2026, James M. Atkinson

certify a particular implementation or justify assigning a new nominal word length without a traceable experiment.

Copyright 2026, James M. Atkinson

10.109 Advanced technical expansion. Converter-array resolution and physical information limits

The nominal bit width of an ADC describes a digital encoding arrangement, not a guarantee of equal physical accuracy. Quantisation error may be approximated as uniform and uncorrelated with the input only under specified conditions; differential and integral nonlinearity, aperture jitter, reference-voltage variation, harmonic distortion and correlated front-end noise limit realised performance. IEEE 1241-2023 provides public terminology and test-method scope for converters sampling at known intervals, but individual device compliance and performance require actual measurements and the applicable complete standard. The technical argument must therefore distinguish nominal code precision, SINAD-based effective resolution, dynamic range in a stated bandwidth and the reproducibility of a particular waveform estimate. A display reporting a 32-bit floating-point sample has not thereby created 32 bits of analogue knowledge.

Consider N simultaneous converters measuring the same stable input and providing individually calibrated samples with independent, equal-variance, zero-mean random errors. Their arithmetic average has error variance $sigma^2/N$, so ideal SNR improves by 10 log10(N) decibels, equivalent to 0.5 $log_2(N)$ extra bits under the restrictive assumptions of a suitable noise-limited comparison. Sixteen channels yield 12.04 dB or two ideal effective bits. However, if error covariance has nonzero off-diagonal terms, the variance of the average becomes $(1/N^2)$ times the sum of all entries of the covariance matrix, and an uncalibrated common error may remain

Copyright 2026, James M. Atkinson

unchanged by averaging. This explicit covariance formula is the correct replacement for the alluring but false proposition that concatenating the output words of two 14-bit converters yields a physical 28-bit measurement.

Time interleaving is a different architecture. Multiple converters sample at staggered instants and can increase aggregate temporal sampling rate, but each converter's offset, gain, aperture skew and bandwidth difference produces periodic artefacts. A two-channel interleaver with a relative time skew delta_t introduces a small frequency-dependent phase error approximately 2 pi f delta_t at physical frequency f. At 100 MHz, a 10-ps skew corresponds to 0.006283 radians or about 0.36 degrees. The result grows with frequency; a correction fitted only at baseband may not remain applicable near the upper useful input band. Oversampling also does not repeal the analogue bandwidth, anti-aliasing, timing and memory-throughput limits that determine which physical information was ever admitted.

Aperture jitter is often assessed using the ideal sinusoidal relation SNR_jitter approximately -20 log10(2 pi f_in sigma_t), where f_in is sinusoidal input frequency and sigma_t is RMS timing uncertainty under the defined jitter model. This relation arises because small sampling-time errors create voltage errors proportional to waveform slope; it is not a universal SINAD model including every distortion source. For a hypothetical 100-MHz sine wave and 100-fs RMS jitter, 2 pi f sigma_t is approximately 6.283 × 10^-5 and the corresponding ideal upper SNR is about 84.04 dB. This says nothing about reference spurs, thermal noise, harmonic distortion or whether the jitter was correlated across multiple converter channels. The full receiver chain needs independent measurement of those other effects.

Copyright 2026, James M. Atkinson

Parallel converter claims should be accepted through a controlled test whose reference system is superior in the quantities under examination. Measure each channel's input transfer, spur levels, gain and offset, clock relationships and response to amplitude and frequency changes. Form the array estimator only after recording its weights and calibration, then evaluate on held-out signals not used to fit the correction. Compare the result with both the best individual channel and a suitably calibrated reference instrument. Include large blockers and brief pulses, because an average that performs well for a slowly varying sine may smear a transient or reproduce a shared overload. Preserve the individual-channel raw records so an apparent gain cannot be manufactured by selecting only favourable channels after seeing the desired outcome.

The digital downconverter and channeliser must also be represented as measurements with state and bandwidth. Frequency translation, filtering and decimation can preserve a selected complex band if the alias rejection and filter response meet the intended requirements. Once spectral content has been rejected, no subsequent interpolation restores it. Quantisation inside a fixed-point filter can change noise and spur behaviour according to word length, scaling and saturation policy; floating-point processing has different numerical boundaries, not automatic physical fidelity. Reproducibility requires sample ordering, numerical format, complex sign convention, filter coefficients, overflow handling and software revision. Engineering precision and forensic trust converge in the ability to reconstruct exactly which acquired information each output retained.

Copyright 2026, James M. Atkinson

10.110 Complex I/Q acquisition: physical meaning, signed frequency, calibration and defensible identification

A recorded complex signal consists of two simultaneously indexed coordinate sequences, conventionally called in-phase and quadrature, rather than two independent radio transmissions. The receiver forms these coordinates by projecting the incident real-valued RF waveform upon approximately orthogonal reference oscillations, low-pass filtering and sampling. In an ideal sign convention, mixing with cosine produces I(t) and mixing with the negative sine produces Q(t), so that $z(t)=I(t)+jQ(t)$ represents an analytic equivalent about a declared reference frequency. The sign of Q, the local-oscillator reference convention, anti-alias filter response and sample-clock rate determine the meaning of positive and negative digital frequency. Interchanging I and Q, reversing the Q sign, or changing the complex-oscillator sign mirrors or rotates a spectrum; a silent convention change can convert an apparently positive carrier offset into a negative one. The unambiguous quantity is not a display colour but the complete recorded mapping of RF frequency onto complex sample frequency.

Write the ideal complex-baseband observation as $z[n]=g\, s(nT_s-\tau) \exp\{j(2\pi\Delta f\, nT_s+\varphi_0)\}+d+\eta[n]$, where n is an integer sample index, T_s is the sample period in seconds, s is the incident complex waveform referred to a named input plane, g is a complex conversion gain, τ is a physical and computational delay, Δf is residual frequency offset in hertz, φ_0 is initial phase in radians, d is a fixed or slowly varying complex DC term and η is receiver-added noise plus any excluded residual. This is a local model for a specified fixed state, not a universal law through compression, missing

Copyright 2026, James M. Atkinson

buffers or automatic-gain transitions. It demonstrates why waveform classification is conditional: the same emitter waveform can have different digitised phases, offsets, amplitude scaling and carrier placements on two instruments. Before comparing them, estimate or bound the nuisance parameters with an independent calibration or a transparent joint estimator.

An uncalibrated I/Q imbalance is conveniently written in a widely linear form $z_{obs}[n]=\alpha\, z_{ideal}[n]+\beta\, \mathrm{conj}(z_{ideal}[n])+d+\eta[n]$. Here α is the wanted complex response and β multiplies the conjugate, representing image leakage under the local model. Their ratio controls how a mirror-frequency feature can imitate a second emitter. For a single isolated complex tone, the image-rejection ratio is approximately $20 \log10(|\alpha|/|\beta|)$ dB when other terms are negligible. An apparent pair of equal and opposite digital-frequency lines therefore does not necessarily indicate two radios. Test with a known single-sideband reference at several offsets, gain states and sample rates. Correcting one observed image with an arbitrary notch can destroy the evidence needed to reconstruct the original converter imbalance.

Amplitude, instantaneous phase, differential phase, complex autocorrelation, cyclic spectral coherence, occupied bandwidth, pulse-repetition structure and modulation-specific statistics can all be derived from I/Q. None singly constitutes a unique transmitter fingerprint. A raised-cosine symbol envelope or a particular cyclic frequency may suggest a waveform family, but multiple implementations can share it. Likewise, a stable oscillator offset can arise from reference mismatch or frequency translation in the measurement chain. Class labels should be expressed as

Copyright 2026, James M. Atkinson

hypotheses supported by measured features, a specified classifier or tested likelihood, and comparison data from other plausible signal classes. Distinguish waveform-family identification from an inference about the physical emitter, geographic source, intended recipient or carried content.

Signal extraction begins with defining the objective and available acquisition. After verifying original sample continuity, sample rate, gain, timing and frequency convention, apply a frequency translation, a known filter and a justified decimation only when the desired waveform fits the preserved passband and the out-of-band rejection is sufficient. If decimation reduces sample rate by D, the retained Nyquist region shrinks accordingly. A narrow extracted channel is a derivative of a wider record; it does not restore anything that analog preselection, clipping or original capture never admitted. Preserve a cryptographic digest of the source chunk, the exact input-sample index interval, filter coefficients, processing code revision, complex-oscillator phase convention and output transformation. A derived audio file, constellation plot or decoded packet is not a substitute for those original coordinates.

A full validation combines authorised synthetic signals with field-like noise, blockers and deliberately ambiguous waveforms. Acquire controlled positive and negative frequency offsets, stable tones, frequency-agile bursts, AM, SSB, FM, phase-coded pulses and a known null case. Test the complete conversion and extraction chain using withheld signal instances, not merely the training signals with a new name. For every inferred signal report detection opportunity, extracted bandwidth, actual receiver state, occupied time span, classification confidence if calibrated, unresolved alternatives and any information that was discarded. Where legal collection authority is

Copyright 2026, James M. Atkinson

limited to technical characteristics, decoding arbitrary communication content is not an automatic or necessary part of signal identification.

10.111 Eight-, twelve-, fourteen-, sixteen- and twenty-four-bit complex sample representations

Sample width must be separated into analogue converter resolution, effective noise-and-distortion performance and file representation. A converter advertised with N physical output bits can exhibit fewer effective bits because of thermal noise, aperture jitter, differential and integral nonlinearity, reference errors, interleaving mismatch or analogue distortion. A signed complex sample stored with twenty-four bits each for I and Q is simply a numerical representation unless a calibrated analogue path demonstrates corresponding information content. Padding a fourteen-bit ADC result into a twenty-four-bit integer does not create ten extra physically meaningful bits, just as averaging sixteen channels does not manufacture sixteen independent observations of one transient without noise independence and temporal coincidence.

For an ideal full-scale sinusoid and uniform independent quantisation error, the conventional approximate signal-to-quantisation-noise ratio is $SQNR \approx 6.02N+1.76$ dB, where N is the quantiser's nominal bit count. The ideal figures are 49.9, 74.0, 86.0, 98.1 and 146.2 dB for 8, 12, 14, 16 and 24 bits, respectively. These are teaching upper benchmarks under the stated sinusoidal and quantisation assumptions, not measured converter specifications, and they say nothing about sensitivity when analogue noise dominates. Effective number of bits inferred from SINAD is conditional upon test waveform, frequency, amplitude, bandwidth, clock and method. IEEE 1241-2023 supplies public terminology and methods for ADC assessment; its

Copyright 2026, James M. Atkinson

publication scope is not evidence that any particular proposed converter meets those ideals.

Eight-bit complex samples are economical for high-rate occupancy analysis and event triggers, but insufficient analogue headroom can make small signals disappear behind quantisation or large-signal clipping. Twelve-bit packed recording gives a better nominal resolution-to-bandwidth balance, provided samples are truly packed into three bytes per complex pair rather than promoted to two sixteen-bit words. Fourteen-bit packed samples nominally use 3.5 bytes per complex pair; practical interfaces may pad them to four bytes or impose lane alignment, which must appear in ingestion budgets. Sixteen-bit I and sixteen-bit Q offer convenient arithmetic and interoperable file formats, but the additional transport width cannot be treated as additional analogue precision when the source converter has fewer meaningful bits. Twenty-four-bit fixed-point I and Q can be useful for accumulated gain corrections or preserving high-dynamic-range processed results, at a six-byte payload per complex sample; it makes no promise about physical input ENOB. Floating-point processing changes the numerical range and rounding behaviour further without undoing earlier clipping or lost information.

Data-rate calculations require both components. If R is the aggregate rate of valid complex samples in samples per second and b is the stored bits per I or Q component, an ideally packed payload needs R(2b)/8 bytes per second. For R=40×10^9 complex samples/s, the five formats require 80, 120, 140, 160 and 240 GB/s, respectively, using decimal gigabytes. Across 14,400 seconds, their exact ideal raw payloads are 1.152, 1.728, 2.016, 2.304 and 3.456 PB. This simplification assumes aggregate complex sample rate equals

Copyright 2026, James M. Atkinson

the intended 40 GHz total useful passband, with no oversampling, guard bands, receiver overlap, framing or loss. Physical implementation normally requires additional spectral margins and may need more aggregate samples. It is incorrect to multiply forty gigahertz of coverage by every channel's independent sample rate without first identifying overlap and total represented passband.

The expected input to the GPU differs from the disk representation. An FPGA might perform sign extension and convert packed fourteen-bit I/Q to sixteen-bit lanes for a general-purpose I/O interface, or even float32 pairs for frequency-domain processing. In the latter case, the internal buffer traffic becomes eight bytes per complex point, giving 320 GB/s for a hypothetical aggregate 40 Gsamples/s. Copying each block host-to-device and back doubles or triples some fabric movements. The bandwidth claim must therefore be made for every segment of the path, including ADC link, FPGA lanes, network encapsulation, PCIe or other device fabric, GPU ingress, memory read/write traffic, and storage. GPUDirect transfers can avoid some host-memory copies on supported topologies, but they do not remove the source rate or the need to measure sustained rather than headline peak throughput.

A verification fixture should generate a weak controlled tone alongside a stronger blocker and measure noise floor, clipping frequency, spurious-free dynamic range, missing-sample rate and output spectral bias in every packing mode. Repeat at temperature and with the same analogue gain state. Show whether an observed difference is caused by the converter, FPGA bit-shifting, scaling, arithmetic precision, or transport layout. Archive sample-packing test vectors containing negative full-scale, zero, positive full-

Copyright 2026, James M. Atkinson

scale and sign-boundary values; a single endian error or mistaken offset-binary interpretation can turn ordinary noise into an apparent spectral line or a correlated complex-plane feature.

Chapter Summary

An SDR is a configurable analog and digital measurement chain. Sample-rate challenges, converter-state checks, channelizer verification, and continuity metadata are required before software-derived spectra or decodes are assigned to the environment.

Sampling leaves frequency equivalence classes that must be restricted by the admitted analog band and supported conversion plan. Ideal quantization estimates require stated error distributions; filtering gains require additional spectral assumptions. Digital mixing, filtering and channelization preserve meaning only when signs, coefficient vectors, normalization, retained phases and output labels are explicit.

Finite arithmetic adds its own conversion schedule, range proof and rounding bounds. Output rescaling cannot repair earlier clipping or lost precision. Continuity then ties stored positions to source indices, valid filter history and clock segments. Zero filling, deletion and state resets change different aspects of the operation and must remain visible.

Framework 10F binds the tested behavior to actual loaded artifacts, configuration and applicable criteria. A valid signature, successful installation or agreeing software outputs cannot replace the relevant technical evidence. Acceptance requires every mandatory applicable criterion to be satisfied; unresolved conditions retain that status, and changes trigger review of the affected dependencies.

Chapter 10 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C10-MCQ-001. Why is an SDR configuration described as executable measurement logic?

A. It makes all digital outputs independent of firmware state

B. It determines the transformations and meaning of the stored samples

C. It replaces the need to characterize the analog input path

D. It guarantees every software label identifies an RF source

Answer: B. Rates, gain, coefficients, scaling, and formats define the actual measurement path. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

Why the selected alternative fits: It determines the transformations and meaning of the stored samples.

Distinguishing consideration: compare this with option A, “It makes all digital outputs independent of firmware state”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — SDR Boundary and Partitioning.

Review: Chapter 10 — SDR Boundary and Partitioning.

V011-C10-MCQ-002. Which condition can digital amplitude scaling conceal without repairing?

A. Clipping that already occurred at the ADC

B. An unchanged sample-counter origin

C. The documented multiplication factor itself

D. A known linear conversion of intact samples

Answer: A. Clipped information is lost before rescaling; examine flags, histograms, and gain-step behavior. Source: §10.3 Quantization, Clipping, and Converter Performance (p. 5684)

Why the selected alternative fits: Clipping that already occurred at the ADC.

Distinguishing consideration: compare this with option B, “An unchanged sample-counter origin”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Quantization, Clipping, and Converter Performance.

Review: Chapter 10 — Quantization, Clipping, and Converter Performance.

V011-C10-MCQ-003. With negative-exponential mixing, a 9 MHz complex tone and an 8 MHz NCO produce what translated frequency before filtering?

A. Minus 1 MHz

B. Minus 17 MHz

C. Plus 1 MHz

D. Plus 17 MHz

Answer: C. The declared mixer subtracts NCO frequency from the input frequency.

Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: Plus 1 MHz.

Distinguishing consideration: compare this with option A, “Minus 1 MHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

V011-C10-MCQ-004. A DDC takes every eighth filtered sample. Does this automatically divide a settled tone's voltage amplitude by eight?

A. No; amplitude remains the input amplitude times the filter-response magnitude

B. Yes; every retained tone loses a factor of eight in voltage

C. Yes; but only complex tones lose that factor

D. No; decimation instead multiplies every tone voltage by eight

Answer: A. Sample selection changes rate and phase progression, not an automatic individual-tone amplitude scale. Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)

Why the selected alternative fits: No; amplitude remains the input amplitude times the filter-response magnitude.

Distinguishing consideration: compare this with option B, “Yes; every retained tone loses a factor of eight in voltage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Model 10B for digital mixing filtering and decimation.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation.

V011-C10-MCQ-005. What does retained phase p denote in the DDC model?

A. An oscillator angle in radians

B. The number of independent channels

C. An input-index residue within the decimation interval

D. The filter's passband ripple

Answer: C. The output samples are taken at input indices mM+p; p is an index, not an angle. Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)

Why the selected alternative fits: An input-index residue within the decimation interval.

Distinguishing consideration: compare this with option A, “An oscillator angle in radians”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Model 10B for digital mixing filtering and decimation.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-006. At what frequency should the pre-decimation filter response be evaluated for a tone?

A. Only the analog RF label without conversion history

B. The nearest channel center regardless of offset

C. Only its final folded output label

D. Its translated frequency on that filter's input clock

Answer: D. Different pre-deletion frequencies can fold together while receiving different filter gains. Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)

Why the selected alternative fits: Its translated frequency on that filter's input clock.

Distinguishing consideration: compare this with option A, “Only the analog RF label without conversion history”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Model 10B for digital mixing filtering and decimation.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation.

V011-C10-MCQ-007. Two tones have already combined at the same complex output frequency after unfiltered decimation. What can a later linear filter do?

A. Recover both original coefficients solely by narrowing its passband

B. Apply one response to the combined sequence, without separating former frequencies alone

C. Undo the combination automatically if output rate is known

D. Reject only the former blocker by using its original RF label

Answer: B. The retained sequence no longer carries separate frequency coordinates for those contributions. Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)

Why the selected alternative fits: Apply one response to the combined sequence, without separating former frequencies alone.

Distinguishing consideration: compare this with option A, “Recover both original coefficients solely by narrowing its passband”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Model 10B for digital mixing filtering and decimation.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation.

V011-C10-MCQ-008. A 2 V peak real cosine is multiplied by a unit-amplitude complex exponential, with no additional factor-two scaling, and one sideband is retained through unit gain. What is its complex coefficient amplitude?

A. One eighth V solely because decimation is eight

B. 1 V

C. 4 V

D. 2 V

Answer: B. A real cosine has two complex coefficients, each half its peak amplitude; normalization must remain explicit. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: 1 V.

Distinguishing consideration: compare this with option A, “One eighth V solely because decimation is eight”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-009. Why must a multistage rejection ledger use each stage's actual input frequency?

A. Final folded frequency uniquely specifies each earlier gain

B. Earlier rate changes can move a blocker before later filtering

C. The attenuation at the original RF frequency applies unchanged at every stage

D. All filters have identical frequency coordinates

Answer: B. Stage gains multiply along the actual frequency path, including intermediate folding. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: Earlier rate changes can move a blocker before later filtering.

Distinguishing consideration: compare this with option A, “Final folded frequency uniquely specifies each earlier gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

V011-C10-MCQ-010. A filter rejects a test tone exactly at one moving-average null. What has been demonstrated?

A. Uniform rejection throughout the entire stopband

B. Rejection at that tested frequency, not the surrounding alias band

C. Perfect blocker control for every decimation ratio

D. Absence of earlier analog overload

Answer: B. A narrow zero does not establish neighboring response; the actual alias-entry band needs testing. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: Rejection at that tested frequency, not the surrounding alias band.

Distinguishing consideration: compare this with option A, “Uniform rejection throughout the entire stopband”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

V011-C10-MCQ-011. Why is FIR group delay insufficient to choose the startup discard interval?

A. One output interval is sufficient for every linear-phase filter

B. A symmetric FIR has no startup behavior

C. Startup depends on coefficient support, initial history, retained phase, and error criterion

D. Group delay always equals the number of missing input samples

Answer: C. Settled phase slope and complete history are different properties.

Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: Startup depends on coefficient support, initial history, retained phase, and error criterion.

Distinguishing consideration: compare this with option A, “One output interval is sufficient for every linear-phase filter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-012. A symmetric 33-tap FIR at 48 MS/s has ordinary linear-phase delay away from zeros. What is that delay?

A. 16 input samples, about 333.33 ns

B. 32 input samples, about 666.67 ns

C. Zero because symmetry removes delay

D. 33 output samples regardless of decimation

Answer: A. The center lag is $\frac{(33-1)}{2}$ = 16; startup support remains a separate question. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: 16 input samples, about 333.33 ns.

Distinguishing consideration: compare this with option B, “32 input samples, about 666.67 ns”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-013. Two otherwise identical settled channels retain phases p=0 and p=3 for a 1 MHz tone at 48 MS/s. What phase difference is introduced at a common output index?

A. 3 degrees

B. 180 degrees

C. 60 degrees

D. 22.5 degrees

Answer: D. Three input intervals produce 360 times $\frac{1}{48}$ times 3 degrees, with a 62.5 ns time-origin difference. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: 22.5 degrees.

Distinguishing consideration: compare this with option A, “3 degrees”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-014. What does a b-bit ideal NCO accumulator determine directly under the stated exact-clock model?

A. A guarantee of zero phase drift over arbitrary duration

B. A universal measured spur-free dynamic range

C. The analog anti-alias filter rejection

D. A frequency grid of input sample rate divided by two to the b

Answer: D. Accumulator word quantization sets tuning resolution; other truncation, arithmetic, and clock effects remain separate. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: A frequency grid of input sample rate divided by two to the b.

Distinguishing consideration: compare this with option A, “A guarantee of zero phase drift over arbitrary duration”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

V011-C10-MCQ-015. Why can a small constant NCO frequency error matter in a long coherent comparison?

A. It changes the FIR coefficients automatically

B. It vanishes when the output rate is lower

C. Its phase error accumulates with elapsed time

D. It necessarily reduces every sample magnitude to zero

Answer: C. Frequency error integrates into phase; fine tuning resolution does not make the accumulated error negligible. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: Its phase error accumulates with elapsed time.

Distinguishing consideration: compare this with option A, “It changes the FIR coefficients automatically”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10B.

Review: Chapter 10 — Ten worked applications of Model 10B.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-016. Does exact polyphase regrouping improve rejection of unchanged coefficients?

A. Yes; branch count directly multiplies stopband attenuation

B. Only if the same coefficients are written in a different order without tracing indices

C. Yes; discarded computations remove additional blockers

D. No; it preserves the original input-output relation

Answer: D. Efficiency changes do not create a new filter response; finite arithmetic differences require separate checking. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: No; it preserves the original input-output relation.

Distinguishing consideration: compare this with option A, "Yes; branch count directly multiplies stopband attenuation"; that competing statement does not meet the question's stated requirement.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-018. A 9 MHz NCO at 48 MS/s is reset every 1000 input samples. What artifact can this create relative to continuous phase?

A. A guaranteed integer-cycle continuation

B. Alternating block sign reversal

C. An automatic reduction of tone amplitude by 1000

D. A change only in the file timestamp

Answer: B. Each block spans 187.5 NCO cycles; resetting discards a half-cycle progression and creates a phase discontinuity. Source: §10.6 Ten worked applications of Model 10B (p. 5691)

Why the selected alternative fits: Alternating block sign reversal.

Distinguishing consideration: compare this with option A, “A guaranteed integer-cycle continuation”; that competing statement does not meet the question’s stated requirement.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-025. Why can a critically sampled implementation not be reused unchanged for D less than M?

A. The outer phase and branch-residue schedule generally change

B. The prototype coefficients alone force the old commutator schedule to remain correct

C. Oversampling only changes the displayed sample-rate label

D. All oversampled outer phases are one

Answer: A. The direct mixer-filter definition requires both correct timing and phase for oversampled outputs. Source: §10.19 Causal polyphase grouping and the transform convention (p. 5707)

Why the selected alternative fits: The outer phase and branch-residue schedule generally change.

Distinguishing consideration: compare this with option B, “The prototype coefficients alone force the old commutator schedule to remain correct”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Causal polyphase grouping and the transform convention.

Review: Chapter 10 — Causal polyphase grouping and the transform convention.

V011-C10-MCQ-026. A single tone lies at a channel boundary and appears strongly in two adjacent outputs. What is supported?

A. The outputs must have independent noise

B. Two emitters are established by the two traces

C. One source can produce both responses through the prototype

D. Adding their uncalibrated powers always gives exact input power

Answer: C. The full response vector and gain convention explain boundary duplication. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: One source can produce both responses through the prototype.

Distinguishing consideration: compare this with option A, “The outputs must have independent noise”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-027. Two different input tones give the same sequence in one retained channel. What may preserve their distinction?

A. The complete bank response when the specified bank is invertible

B. A smaller file format containing fewer channels

C. Repeated copies of that same single-channel sequence

D. The single-channel output frequency label alone

Answer: A. The chapter's rectangular-bank example retains distinctions across the full vector that one channel discards. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: The complete bank response when the specified bank is invertible.

Distinguishing consideration: compare this with option B, “A smaller file format containing fewer channels”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-028. What does oversampling ratio $\frac{M}{D}$ establish by itself?

A. A flat calibrated channel passband

B. Aggregate output rate relative to input rate

C. Perfect reconstruction for every prototype

D. Statistical independence of output samples

Answer: B. Rate accounting alone says neither injectivity nor response quality.

Source: §10.19 Causal polyphase grouping and the transform convention (p. 5707)

Why the selected alternative fits: Aggregate output rate relative to input rate.

Distinguishing consideration: compare this with option A, “A flat calibrated channel passband”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Causal polyphase grouping and the transform convention.

Review: Chapter 10 — Causal polyphase grouping and the transform convention.

V011-C10-MCQ-029. For 64 MS/s input, eight channels, D=4, and four bytes per complex sample, what is aggregate payload rate?

A. 128 MB/s

B. 64 MB/s

C. 256 MB/s

D. 512 MB/s in decimal units

Answer: D. Eight channels each emit 16 million samples per second, each stored in four bytes. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: 512 MB/s in decimal units.

Distinguishing consideration: compare this with option A, “128 MB/s”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-030. Does white input guarantee independent output channel streams?

A. Yes; different center labels guarantee independence

B. No; tap energies and overlapping histories can create correlation

C. Yes; zero mean alone establishes joint independence

D. Only critical sampling automatically makes every stream independent

Answer: B. Second-order whiteness is not full independence, and the bank can share weighted samples across channels and times. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: No; tap energies and overlapping histories can create correlation.

Distinguishing consideration: compare this with option A, "Yes; different center labels guarantee independence"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-031. A bank has diagonal same-frame covariance but overlapping frames. What may remain?

A. A universal single-record confidence interval

B. Guaranteed independence of all channel streams

C. Zero overlap in source indices

D. Correlation across output times

Answer: D. Same-frame decorrelation describes one slice; common samples can correlate adjacent frames. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: Correlation across output times.

Distinguishing consideration: compare this with option A, “A universal single-record confidence interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-032. Why can unit DC gain and critical aggregate rate fail to establish invertibility?

A. A zero coefficient has no effect on any input history

B. An input-index residue can be multiplied only by zero coefficients

C. Unit DC gain means every impulse is retained equally

D. Critical rate always adds independent missing information

Answer: B. The stated critical-bank counterexample has an entire blind residue despite those two favorable properties. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: An input-index residue can be multiplied only by zero coefficients.

Distinguishing consideration: compare this with option A, “A zero coefficient has no effect on any input history”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-033. What must be retained to apply the chapter's stated oversampled energy bound?

A. The exact coefficients and arithmetic, every channel, and all affected frames

B. Only frames wholly inside a truncated file

C. Only the strongest channel in each frame

D. Any oversampled prototype with the same rate ratio

Answer: A. The bound is configuration- and coverage-specific; omitted outputs can remove its premises. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: The exact coefficients and arithmetic, every channel, and all affected frames.

Distinguishing consideration: compare this with option B, “Only frames wholly inside a truncated file”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-034. What does a positive lower energy bound for the complete stated bank exclude?

A. All variation in energy gain with sample placement

B. A nonzero admissible finite-energy input with all outputs zero

C. Any need for voltage calibration

D. All numerical implementation error

Answer: B. A positive lower bound supports injectivity in that model while unequal bounds permit unequal energy weighting. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: A nonzero admissible finite-energy input with all outputs zero.

Distinguishing consideration: compare this with option A, “All variation in energy gain with sample placement”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-035. Which test particularly exposes channel order and transform-sign mistakes?

A. A zero-only vector only

B. Equal amplitude in every output channel only

C. A magnitude plot that discards channel labels

D. A finite nonsymmetric input vector with predicted complex outputs

Answer: D. Asymmetric complex reference outputs discriminate permutations and sign conventions that symmetric tests can hide. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why the selected alternative fits: A finite nonsymmetric input vector with predicted complex outputs.

Distinguishing consideration: compare this with option A, “A zero-only vector only”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-MCQ-036. Why is total bit count insufficient to interpret a fixed-point channel value?

A. Every stored code is already volts

B. The recorded output exponent affects only storage size

C. Fractional bits, signedness, calibration, transform normalization, and scale also matter

D. All formats with equal width have equal steps

Answer: C. The numerical representation and physical conversion jointly define the value. Source: §10.33 Signed formats and explicit conversion points (p. 5725)

Why the selected alternative fits: Fractional bits, signedness, calibration, transform normalization, and scale also matter.

Distinguishing consideration: compare this with option A, “Every stored code is already volts”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Signed formats and explicit conversion points.

Review: Chapter 10 — Signed formats and explicit conversion points.

V011-C10-MCQ-038. Does the half-step nearest-rounding error bound survive saturation?

A. Only when the saturation flag is omitted

B. Yes; if the final display is rescaled

C. Yes; clamping always reduces error below half a step

D. No; a separate range proof is required

Answer: D. The bound applies to an in-range unbounded rounded code, not an arbitrary clipped value. Source: §10.33 Signed formats and explicit conversion points (p. 5725)

Why the selected alternative fits: No; a separate range proof is required.

Distinguishing consideration: compare this with option A, “Only when the saturation flag is omitted”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Signed formats and explicit conversion points.

Review: Chapter 10 — Signed formats and explicit conversion points.

V011-C10-MCQ-039. What makes the four-channel exact-transform example special?

A. Its every input is Gaussian

B. Weights are only plus/minus one and plus/minus j

C. Its coefficients cannot be quantized incorrectly

D. Its outputs need no accumulation width

Answer: B. Widened sums, sign changes, and component exchanges can implement these weights without irrational twiddle rounding. Source: §10.33 Signed formats and explicit conversion points (p. 5725)

Why the selected alternative fits: Weights are only plus/minus one and plus/minus j.

Distinguishing consideration: compare this with option A, “Its every input is Gaussian”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Signed formats and explicit conversion points.

Review: Chapter 10 — Signed formats and explicit conversion points.

V011-C10-MCQ-040. Two implementations have identical quantized FIR coefficients but different outputs. Which explanation remains plausible?

A. Only their filenames can explain the result

B. The coefficients uniquely determine every finite-word computation regardless of architecture

C. Different conversion points, accumulation order, overflow rules, or state

D. Exact coefficients remove all need to check history

Answer: C. Finite-word behavior depends on the entire conversion and state schedule. Source: §10.35 Ten worked applications of Model 10D (p. 5731)

Why the selected alternative fits: Different conversion points, accumulation order, overflow rules, or state.

Distinguishing consideration: compare this with option A, “Only their filenames can explain the result”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-MCQ-041. Why is restoring an output shift part of the error budget?

A. It recovers all discarded low bits

B. It changes only units without changing error magnitude

C. It eliminates earlier saturation

D. It magnifies stored output rounding error by the same scale factor

Answer: D. Scale restoration also restores the coarse spacing of the saved code grid. Source: §10.35 Ten worked applications of Model 10D (p. 5731)

Why the selected alternative fits: It magnifies stored output rounding error by the same scale factor.

Distinguishing consideration: compare this with option A, “It recovers all discarded low bits”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-MCQ-042. Does nearest-even rounding establish a zero-mean white error process?

A. Yes; every tie rule creates independent errors

B. Only if output rescaling is applied

C. No; repeated inputs can produce deterministic bias

D. Yes; sufficiently many identical frames make error white

Answer: C. The deterministic rounding rule supplies no distribution or independence assumption. Source: §10.35 Ten worked applications of Model 10D (p. 5731)

Why the selected alternative fits: No; repeated inputs can produce deterministic bias.

Distinguishing consideration: compare this with option A, "Yes; every tie rule creates independent errors"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-MCQ-043. What can a correct final value conceal in a wrapping accumulator?

A. Intermediate overflow that happens to cancel modulo the code range

B. A valid half-step error bound at every stage

C. A proof that saturation would give the same result

D. A guarantee that all intermediate values were in range

Answer: A. An accidentally correct modular endpoint does not establish the intended exact arithmetic. Source: §10.35 Ten worked applications of Model 10D (p. 5731)

Why the selected alternative fits: Intermediate overflow that happens to cancel modulo the code range.

Distinguishing consideration: compare this with option B, “A valid half-step error bound at every stage”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-MCQ-044. Why explicitly test the positive range endpoint of a two's-complement format?

A. It has one fewer positive code than the corresponding negative magnitude

B. Symmetric input bounds imply symmetric stored endpoints

C. The negative endpoint is never representable

D. Positive codes always have twice the resolution

Answer: A. Signed range asymmetry can make a product of two negative rails overflow positively. Source: §10.34 Range and error are separate obligations (p. 5728)

Why the selected alternative fits: It has one fewer positive code than the corresponding negative magnitude.

Distinguishing consideration: compare this with option B, “Symmetric input bounds imply symmetric stored endpoints”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Range and error are separate obligations.

Review: Chapter 10 — Range and error are separate obligations.

V011-C10-MCQ-045. Two values of minus one multiply exactly to plus one. What happens if stored in S(7,6) with saturation?

A. It becomes zero

B. It becomes $\frac{63}{64}$

C. It remains exactly plus one

D. It becomes minus one under saturation

Answer: B. S(7,6) has maximum $\frac{63}{64}$; wrap would be a different operation returning minus one in this example. Source: §10.35 Ten worked applications of Model 10D (p. 5731)

Why the selected alternative fits: It becomes.

Distinguishing consideration: compare this with option A, “It becomes zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Model 10D.

Review: Chapter 10 — Ten worked applications of Model 10D.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-046. Why can rounding each product differ from rounding once after their sum?

A. Rounding commutes with addition for every input

B. Intermediate quantization changes the values being accumulated

C. The tie rule forces both schedules to agree

D. Only the final fractional width matters

Answer: B. The chapter's two-product example has distinct errors and requires a separate budget for each schedule. Source: §10.35 Ten worked applications of Model 10D (p. 5731)

Why the selected alternative fits: Intermediate quantization changes the values being accumulated.

Distinguishing consideration: compare this with option A, “Rounding commutes with addition for every input”; that competing statement does not meet the question’s stated requirement.

V011-C10-MCQ-060. What should happen when overlapping source indices carry conflicting values?

A. Treat waveform resemblance as proof of identical source identity

B. Average them and call the result the original sample

C. Select whichever value makes the spectrum smoother

D. Investigate or mark them unresolved rather than manufacture agreement

Answer: D. Conflicting payloads at one declared source event do not resolve themselves through arithmetic blending. Source: §10.53 Application 10E.2: overlap, duplicate indices, and conflicting payloads (p. 5755)

Why the selected alternative fits: Investigate or mark them unresolved rather than manufacture agreement.

Distinguishing consideration: compare this with option A, “Treat waveform resemblance as proof of identical source identity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Application 10E.2: overlap, duplicate indices, and conflicting payloads.

Review: Chapter 10 — Application 10E.2: overlap, duplicate indices, and conflicting payloads.

V011-C10-MCQ-061. What does zero filling preserve that deletion changes?

A. The original index grid, provided a separate validity mask is retained

B. The unknown physical values themselves

C. The original noise distribution at the missing samples

D. A guarantee that every processed output is valid

Answer: A. Deletion compresses chronology and changes filter neighbors, NCO phase, or retained grid; zero filling still lacks the missing values. Source: §10.51 Gap representations, phase, and the limits of timing claims (p. 5751)

Why the selected alternative fits: The original index grid, provided a separate validity mask is retained.

Distinguishing consideration: compare this with option B, “The unknown physical values themselves”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Gap representations, phase, and the limits of timing claims.

Review: Chapter 10 — Gap representations, phase, and the limits of timing claims.

V011-C10-MCQ-062. With a gap of G missing samples, how many sampling intervals separate the two bounding retained samples?

A. G plus one

B. One regardless of G

C. G

D. G minus one

Answer: A. The missing positions lie between the endpoints; there is one additional interval joining the boundaries. Source: §10.51 Gap representations, phase, and the limits of timing claims (p. 5751)

Why the selected alternative fits: G plus one.

Distinguishing consideration: compare this with option B, “One regardless of G”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Gap representations, phase, and the limits of timing claims.

Review: Chapter 10 — Gap representations, phase, and the limits of timing claims.

V011-C10-MCQ-063. What should be combined when several gaps have overlapping FIR dependency tails?

A. Only the first affected output

B. Only the longest gap's tail

C. The union of affected output sets

D. The raw sum of tail counts even when they overlap

Answer: C. A union avoids double-counting retained outputs influenced by more than one gap. Source: §10.50 A continuity condition for finite filtering and decimation (p. 5747)

Why the selected alternative fits: The union of affected output sets.

Distinguishing consideration: compare this with option A, “Only the first affected output”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — A continuity condition for finite filtering and decimation.

Review: Chapter 10 — A continuity condition for finite filtering and decimation.

V011-C10-MCQ-064. Why does the finite FIR recovery rule not automatically cover recursive loops?

A. Every recursive filter has the same finite lag set

B. A valid file length resets all loop state

C. A zero-filled sample always restores a tracking loop immediately

D. Recursive or adaptive state can retain dependencies beyond finite tap support

Answer: D. IIR, AGC, adaptive, and phase-tracking recovery require their own state models. Source: §10.50 A continuity condition for finite filtering and decimation (p. 5747)

Why the selected alternative fits: Recursive or adaptive state can retain dependencies beyond finite tap support.

Distinguishing consideration: compare this with option A, “Every recursive filter has the same finite lag set”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — A continuity condition for finite filtering and decimation.

Review: Chapter 10 — A continuity condition for finite filtering and decimation.

V011-C10-MCQ-065. A zero-filled missing constant-input sample produces responses in otherwise idle channels. What is the supported explanation in the constructed example?

A. A unit DC gain guarantees all idle channels remain zero

B. Three new transmitters must have appeared

C. The channel order alone proves external source multiplicity

D. The discontinuity breaks the bank's cancellation pattern

Answer: D. One missing input can affect all filters sharing that history and generate processing-induced spectral features. Source: §10.61 Application 10E.10: one missing input appears in idle channels (p. 5763)

Why the selected alternative fits: The discontinuity breaks the bank's cancellation pattern.

Distinguishing consideration: compare this with option A, “A unit DC gain guarantees all idle channels remain zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Application 10E.10: one missing input appears in idle channels.

Review: Chapter 10 — Application 10E.10: one missing input appears in idle channels.

V011-C10-MCQ-067. How do a verified digest mismatch and a missing authenticated digest differ?

A. Both prove malicious modification

B. The mismatch is weaker than no comparison and should be ignored

C. Both are satisfied if the filename matches

D. The mismatch contradicts the stated identity rule; missing evidence leaves it unresolved

Answer: D. These are different evidence states, neither of which alone identifies an actor or motive. Source: §10.68 Ten worked applications of Framework 10F (p. 5776)

Why the selected alternative fits: The mismatch contradicts the stated identity rule; missing evidence leaves it unresolved.

Distinguishing consideration: compare this with option A, “Both prove malicious modification”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Framework 10F.

V011-C10-MCQ-069. What does an API sample-rate readback establish directly under the stated interface?

A. Absence of aliasing in every admitted band

B. The exact physical clock frequency without a reference

C. A guarantee that the requested rate was accepted unchanged

D. The reported configured rate, not an independent clock-accuracy measurement

Answer: D. Readback can expose coercion and support labeling; physical rate accuracy has a separate measurement criterion. Source: §10.68 Ten worked applications of Framework 10F (p. 5776)

Why the selected alternative fits: The reported configured rate, not an independent clock-accuracy measurement.

Distinguishing consideration: compare this with option A, “Absence of aliasing in every admitted band”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Framework 10F.

V011-C10-MCQ-071. Does expected recording file size prove no samples were lost?

A. Only for two-channel files, because duplication is impossible there

B. Yes; if the disk write completed successfully

C. No; duplicated or padded values can preserve length

D. Yes; byte count uniquely identifies every sampling event

Answer: C. Length is a consistency condition, while source-index and state checks establish the actual chronology. Source: §10.68 Ten worked applications of Framework 10F (p. 5776)

Why the selected alternative fits: No; duplicated or padded values can preserve length.

Distinguishing consideration: compare this with option A, “Only for two-channel files, because duplication is impossible there”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked applications of Framework 10F.

V011-C10-MCQ-072. When may an old result be reused after an update?

A. Whenever the updated component is not named in the old criterion

B. Whenever one favorable test is repeated

C. Whenever the release name changes only slightly

D. When its subject, conditions, and relevant dependencies remain demonstrably applicable

Answer: D. Dependency review determines which evidence survives; unresolved impact prevents automatic reuse. Source: §10.67 Choose evidence that can discriminate the required behavior (p. 5773)

Why the selected alternative fits: When its subject, conditions, and relevant dependencies remain demonstrably applicable.

Distinguishing consideration: compare this with option A, “Whenever the updated component is not named in the old criterion”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Choose evidence that can discriminate the required behavior.

Review: Chapter 10 — Choose evidence that can discriminate the required behavior.

V011-C10-MCQ-081. Why is sampling alias equivalence stronger than finite spectral overlap?

A. A narrower FFT window always identifies the analog member

B. Only display resolution causes alias ambiguity

C. Different analog signals can produce exactly identical samples for every integer index

D. Longer records always separate an alias class

Answer: C. The ambiguity exists algebraically before noise and finite-record limitations. Source: §10.81 Sampling equivalence, admissible bands, and receiver interpretation (p. 5789)

Why the selected alternative fits: Different analog signals can produce exactly identical samples for every integer index.

Distinguishing consideration: compare this with option A, “A narrower FFT window always identifies the analog member”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation.

Review: Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-082. Does sample rate greater than twice the desired baseband bandwidth reject every unwanted analog input?

A. No; the admitted spectral support must be independently justified

B. Yes; the desired bandwidth excludes all blockers physically

C. Only if the FFT has more than two bins

D. Yes; digital rate alone acts as an analog filter

Answer: A. The sufficient reconstruction condition assumes a band-limited signal class reaching the sampler. Source: §10.81 Sampling equivalence, admissible bands, and receiver interpretation (p. 5789)

Why the selected alternative fits: No; the admitted spectral support must be independently justified.

Distinguishing consideration: compare this with option B, “Yes; the desired bandwidth excludes all blockers physically”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation.

Review: Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation.

V011-C10-MCQ-083. Why do equal 10 MHz observations at 100 and 120 MS/s not uniquely establish a 10 MHz analog input in the example?

A. The longer rate always halves every RF frequency

B. Two sample rates can never distinguish any candidate inputs

C. A 110 MHz cosine maps identically by shift at one rate and reflection at the other

D. A stable feature must have been generated digitally

Answer: C. The stated phase-compatible alias survives both rates; an admitted-band restriction is additional evidence. Source: §10.82 Ten worked sampling applications (p. 5792)

Why the selected alternative fits: A 110 MHz cosine maps identically by shift at one rate and reflection at the other.

Distinguishing consideration: compare this with option A, “The longer rate always halves every RF frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked sampling applications.

Review: Chapter 10 — Ten worked sampling applications.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-086. At exactly half the real sample rate, what can happen to a sine wave with quadrature phase?

A. Its frequency becomes uniquely reconstructible from zero samples

B. All samples can be zero despite nonzero analog amplitude

C. The signal automatically shifts to one-quarter rate

D. Every phase yields the same full peak amplitude

Answer: B. The samples depend on amplitude times cosine of phase; the strict baseband condition avoids this endpoint ambiguity. Source: §10.82 Ten worked sampling applications (p. 5792)

Why the selected alternative fits: All samples can be zero despite nonzero analog amplitude.

Distinguishing consideration: compare this with option A, “Its frequency becomes uniquely reconstructible from zero samples”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Ten worked sampling applications.

V011-C10-MCQ-094. How can mean removal conceal an absolute conversion defect?

A. It reveals every DC error automatically

B. It makes all deterministic errors independent

C. It can remove constant error bias from a variance-style comparison

D. It restores the input's absolute level

Answer: C. Centered variance can be zero while mean-square error relative to the original level is nonzero. Source: §10.93 Quantization margin and channel bandwidth (p. 5804)

Why the selected alternative fits: It can remove constant error bias from a variance-style comparison.

Distinguishing consideration: compare this with option A, “It reveals every DC error automatically”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Quantization margin and channel bandwidth.

Review: Chapter 10 — Quantization margin and channel bandwidth.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-095. What is missing from a claim that decimation alone adds effective bits?

A. A justified noise spectrum, filtering, gain, alias control, and defined metric

B. Nothing; bare deletion always reduces sample variance

C. Only a larger integer decimation label

D. Only a longer filename for the output

Answer: A. Process gain belongs to a suitable filtering/noise model, not sample deletion by itself. Source: §10.93 Quantization margin and channel bandwidth (p. 5804)

Why the selected alternative fits: A justified noise spectrum, filtering, gain, alias control, and defined metric.

Distinguishing consideration: compare this with option B, “Nothing; bare deletion always reduces sample variance”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Quantization margin and channel bandwidth.

Review: Chapter 10 — Quantization margin and channel bandwidth.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-096. For independent white errors, what does keeping every fourth sample do to each retained sample's variance?

A. It makes variance zero

B. It divides variance by four

C. It divides variance by sixteen

D. It leaves the variance unchanged

Answer: D. Bare selection changes rate, not the marginal distribution; an averaging or filtering operation is different. Source: §10.93 Quantization margin and channel bandwidth (p. 5804)

Why the selected alternative fits: It leaves the variance unchanged.

Distinguishing consideration: compare this with option A, “It makes variance zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Quantization margin and channel bandwidth.

Review: Chapter 10 — Quantization margin and channel bandwidth.

Copyright 2026, James M. Atkinson

V011-C10-MCQ-097. What does a deterministic code-center test with zero quantization error establish?

A. Absence of analog nonlinearity and jitter

B. The universal validity of the uniform-error variance

C. Zero error for the entire converter range

D. Exactness for those tested inputs, not all levels or an error distribution

Answer: D. The counterexample shows why bit count and one favorable sequence do not certify general performance. Source: §10.93 Quantization margin and channel bandwidth (p. 5804)

Why the selected alternative fits: Exactness for those tested inputs, not all levels or an error distribution.

Distinguishing consideration: compare this with option A, “Absence of analog nonlinearity and jitter”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Quantization margin and channel bandwidth.

Review: Chapter 10 — Quantization margin and channel bandwidth.

V011-C10-MCQ-098. What additional premise permits channel-band process gain for quantization error?

A. A white error spectrum with actual anti-alias filtering and retained signal gain

B. Only an unsaturated half-step bound

C. Only a constant-error record

D. Only selecting a smaller output rate in software

Answer: A. The density integration requires a spectral model beyond the uniform marginal-error assumption. Source: §10.93 Quantization margin and channel bandwidth (p. 5804)

Why the selected alternative fits: A white error spectrum with actual anti-alias filtering and retained signal gain.

Distinguishing consideration: compare this with option B, “Only an unsaturated half-step bound”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Quantization margin and channel bandwidth.

Review: Chapter 10 — Quantization margin and channel bandwidth.

V011-C10-MCQ-099. Periodic broadband impulses coincide with overflow logs and disappear after changing storage destination. What is supported?

A. Converter certification of the complete chain

B. Proof that no environmental burst could coexist

C. A recording-path explanation requiring continuity review before environmental attribution

D. A guaranteed malicious transmitter at the overflow period

Answer: C. The controlled observation identifies a relevant recording mechanism but does not establish universal environmental absence. Source: §10.105 Hypothetical Case Adjudication: Software-Defined Radios, Sampling, Quantization, DDC, and Channelization (p. 5819)

Why the selected alternative fits: A recording-path explanation requiring continuity review before environmental attribution.

Distinguishing consideration: compare this with option A, “Converter certification of the complete chain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Hypothetical Case Adjudication: Software-Defined Radios, Sampling, Quantization, DDC, and Channelization.

Review: Chapter 10 — Hypothetical Case Adjudication: Software-Defined Radios, Sampling, Quantization, DDC, and Channelization.

V011-C10-MCQ-100. Why does converter compliance alone not validate the complete SDR measurement?

A. A compliant converter makes all later software irrelevant

B. Front end, clock, DDC, firmware, transport, scaling, metadata, and analysis also contribute

C. Only the nominal bit count determines system dynamic range

D. A standard's title certifies every assembled receiver

Answer: B. The converter and complete recording/receiver systems have different validation boundaries. Source: §10.106 Converter and Waveform-Recorder Validation Boundary (p. 5820)

Why the selected alternative fits: Front end, clock, DDC, firmware, transport, scaling, metadata, and analysis also contribute.

Distinguishing consideration: compare this with option A, “A compliant converter makes all later software irrelevant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 10 — Converter and Waveform-Recorder Validation Boundary.

Review: Chapter 10 — Converter and Waveform-Recorder Validation Boundary.

V011-C10-FIB-039. White second-order input statistics do not automatically imply joint _____.

Answer: independence. A suitable distributional assumption is additional to covariance statements. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why this term is required: “independence” completes the stated technical proposition.

Question context: White second-order input statistics do not automatically imply joint _____

Basis and qualification: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

Copyright 2026, James M. Atkinson

V011-C10-FIB-040. Same-frame diagonal covariance does not eliminate correlation between overlapping _____.

Answer: frames. Shared input samples can correlate different output times. Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why this term is required: “frames” completes the stated technical proposition.

Question context: Same-frame diagonal covariance does not eliminate correlation between overlapping _____

Basis and qualification: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

Copyright 2026, James M. Atkinson

V011-C10-FIB-041. The critical-bank counterexample loses a complete input-index _____ despite unit DC gain.

Answer: residue. Its only relevant coefficient for those sample positions is zero.

Source: §10.20 Ten worked applications of Model 10C (p. 5709)

Why this term is required: “residue” completes the stated technical proposition.

Question context: The critical-bank counterexample loses a complete input-index _____ despite unit DC gain

Basis and qualification: Chapter 10 — Ten worked applications of Model 10C.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-FIB-087. The configuration manifest should retain actual values as well as requested _____.

Answer: values. A successful setting call may coerce the requested operating point.

Source: §10.66 Separate signed artifacts from operating configurations (p. 5770)

Why this term is required: “values” completes the stated technical proposition.

Question context: The configuration manifest should retain actual values as well as requested _____

Basis and qualification: Chapter 10 — Separate signed artifacts from operating configurations.

Review: Chapter 10 — Separate signed artifacts from operating configurations.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C10-ESSAY-001. Derive the settled complex-tone output of the declared mixer, FIR, and decimator.

- Opening: Present a thesis that answers this precise question: Derive the settled complex-tone output of the declared mixer, FIR, and decimator. Identify which evidence would falsify the proposed conclusion Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)
- Core terminology and scope: Define settled, complex-tone, output in the question's particular technical setting; explain how declared, mixer, decimator differ if that distinction would change the analysis of "Derive the settled complex-tone output of the declared mixer, FIR, and decimator" Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define input clock, signed input and NCO frequencies, initial phases, coefficient response, decimation, and retained residue Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the settled complex-tone output of the declared mixer, FIR, and decimator to the claimed result, following "Application 10C1 Signed channel centers and residual frequency"; name the intermediate states and measurable outputs Source: §10.21 Application 10C1 Signed channel centers and residual frequency (p. 5710)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for the settled complex-tone output of the declared mixer, FIR, and decimator. Obtain translated response magnitude and phase at mM+p, and interpret frequency modulo output rate Source: §10.21 Application 10C1 Signed channel centers and residual frequency (p. 5710)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Interpretation and reproducibility of the channelized record” that resolves the question about the settled complex-tone output of the declared mixer, FIR, and decimator; derive the relevant result with units and stated validity conditions Source: §10.31 Interpretation and reproducibility of the channelized record (p. 5721)
- Evidence and method: Specify the native observations, control records and calculations that would resolve the settled complex-tone output of the declared mixer, FIR, and decimator. Explain the absence of an automatic voltage division by decimation and the inability to identify an earlier analog alias Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)
- Worked application or illustrative case: Build a worked example of “the settled complex-tone output of the declared mixer, FIR, and decimator”, addressing this associated condition: Define input clock, signed input and NCO frequencies, initial phases, coefficient response, decimation, and.... Define input clock, signed input and NCO frequencies, initial phases, coefficient response, decimation, and retained residue Source: §10.21 Application 10C1 Signed channel centers and residual frequency (p. 5710)

Copyright 2026, James M. Atkinson

- Alternative explanations and failure modes: Construct two plausible technical explanations for “the settled complex-tone output of the declared mixer, FIR, and decimator”. Using “Interpretation and reproducibility of the channelized record”, specify a discriminator and the result expected under each explanation Source: §10.31 Interpretation and reproducibility of the channelized record (p. 5721)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to the settled complex-tone output of the declared mixer, FIR, and decimator, including the effect of missing measurements and inconsistent operating conditions Source: §10.17 Interpretation of the DDC evidence (p. 5702)
- Scholarly synthesis and implications: Explain what the result about the settled complex-tone output of the declared mixer, FIR, and decimator authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)
- Closing: Conclude by answering “Derive the settled complex-tone output of the declared mixer, FIR, and decimator” using only the demonstrated evidence; state the remaining decisive verification step Source: §10.5 Model 10B for digital mixing filtering and decimation (p. 5688)

V011-C10-ESSAY-002. Design a rejection test for a two-stage decimator that faces several blockers folding into the desired output.

- Opening: Present a thesis that answers this precise question: Design a rejection test for a two-stage decimator that faces several blockers folding into the desired output. Identify which evidence would falsify the proposed conclusion Source: §10.11 Application 10B5 A moving-average null is not a rejection band (p. 5696)
- Core terminology and scope: Define Design, rejection, test in the question's particular technical setting; explain how blockers, desired, output differ if that distinction would change the analysis of "Design a rejection test for a two-stage decimator that faces several blockers folding into the desired output" Source: §10.11 Application 10B5 A moving-average null is not a rejection band (p. 5696)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Trace each blocker on each stage's input clock, evaluate actual coefficient responses before deletion, combine stage attenuations, and compare each contribution with a common-plane limit Source: §10.11 Application 10B5 A moving-average null is not a rejection band (p. 5696)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a rejection test for a two-stage decimator that faces several blockers folding into the desired output to the claimed result, following "Application 10B3 An irreversible blocker combination"; name the intermediate states and measurable outputs Source: §10.9 Application 10B3 An irreversible blocker combination (p. 5694)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a rejection test for a two-stage decimator that faces several blockers folding into the desired output. Treat coherent combination separately from power addition and distinguish digital alias rejection from upstream analog overload Source: §10.9 Application 10B3 An irreversible blocker combination (p. 5694)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 10B4 Allocate attenuation across actual stage frequencies” that resolves the question about a rejection test for a two-stage decimator that faces several blockers folding into the desired output; derive the relevant result with units and stated validity conditions Source: §10.10 Application 10B4 Allocate attenuation across actual stage frequencies (p. 5695)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a rejection test for a two-stage decimator that faces several blockers folding into the desired output. Avoid testing only one exact filter null Source: §10.11 Application 10B5 A moving-average null is not a rejection band (p. 5696)
- Worked application or illustrative case: Build a worked example of “a rejection test for a two-stage decimator that faces several blockers folding into the desired output”, addressing this associated condition: Trace each blocker on each stage's input clock, evaluate actual coefficient responses before deletion,.... Trace each blocker on each stage's input clock, evaluate actual coefficient responses

source-index map for a recording containing out-of-order blocks, overlaps, and gaps. Reorder by declared source identity, resolve global coverage before declaring gaps, compare overlapping payloads, and distinguish repeated values from repeated indices Source: §10.53 Application 10E.2: overlap, duplicate indices, and conflicting payloads (p. 5755)

- Analytical framework: Identify the equation, calibration or evidential decision test in “Interpretation and continuation boundary for Model 10E” that resolves the question about a source-index map for a recording containing out-of-order blocks, overlaps, and gaps; derive the relevant result with units and stated validity conditions Source: §10.62 Interpretation and continuation boundary for Model 10E (p. 5764)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a source-index map for a recording containing out-of-order blocks, overlaps, and gaps. Preserve unresolved conflicts and show why continuous file offsets or total length do not establish chronology Source: §10.49 Source indices, stored offsets, and time anchors (p. 5745)
- Worked application or illustrative case: Build a worked example of “a source-index map for a recording containing out-of-order blocks, overlaps, and gaps”, addressing this associated condition: Identify stored starts, source starts, lengths, clock segment, and anchor. Identify stored starts, source starts, lengths, clock segment, and anchor Source: §10.53 Application 10E.2: overlap, duplicate indices, and conflicting payloads (p. 5755)

V011-C10-DISCUSSION-001. A team treats the SDR as software and proposes omitting analog input tests. How should the boundary be explained?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A team treats the SDR as software and proposes omitting analog input tests. How should the boundary be explained?” Put this particular dispute to the panel: A team treats the SDR as software and proposes omitting analog input tests. How should the boundary be explained. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

- 02. Student A, terminology and scope: Agree the operational meanings of treats, software, omitting and analog, tests, boundary in “A team treats the SDR as software and proposes omitting analog input tests. How should the boundary be explained”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A team treats the SDR as software and proposes omitting analog input tests; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §10.106 Converter and Waveform-Recorder Validation Boundary (p. 5820)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Converter and Waveform-Recorder Validation Boundary”. Explain information lost before sampling and how digital settings depend on it Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §10.106 Converter and Waveform-Recorder Validation Boundary (p. 5820)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A team treats the SDR as software and proposes omitting analog input tests; explain what

Copyright 2026, James M. Atkinson

each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §10.63 SDR Acceptance and Supply-Chain Controls (p. 5765)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Converter and Waveform-Recorder Validation Boundary”. Explain information lost before sampling and how digital settings depend on it Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §10.106 Converter and Waveform-Recorder Validation Boundary (p. 5820)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Identify protection, filters, gain, clock, and converter as parts of the same measurement chain Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving A team treats the SDR as software and proposes omitting analog input tests: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A team treats the SDR as software and proposes omitting analog input tests; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §10.63 SDR Acceptance and Supply-Chain Controls (p. 5765)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A team treats the SDR as software and proposes omitting analog input tests: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test

Copyright 2026, James M. Atkinson

with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A team treats the SDR as software and proposes omitting analog input tests, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §10.106 Converter and Waveform-Recorder Validation Boundary (p. 5820)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A team treats the SDR as software and proposes omitting analog input tests: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

Copyright 2026, James M. Atkinson

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A team treats the SDR as software and proposes omitting analog input tests. Retain a configuration-bound acceptance plan spanning the relevant analog and digital functions Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §10.63 SDR Acceptance and Supply-Chain Controls (p. 5765)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A team treats the SDR as software and proposes omitting analog input tests, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §10.106 Converter and Waveform-Recorder Validation Boundary (p. 5820)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A team treats the SDR as software and proposes omitting analog input tests. Retain a configuration-bound

Copyright 2026, James M. Atkinson

acceptance plan spanning the relevant analog and digital functions Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §10.63 SDR Acceptance and Supply-Chain Controls (p. 5765)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A team treats the SDR as software and proposes omitting analog input tests and How should the boundary be explained; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §10.3 Quantization, Clipping, and Converter Performance (p. 5684)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A team treats the SDR as software and proposes omitting analog input tests”, addressing “How should the boundary be explained”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the

Copyright 2026, James M. Atkinson

specific contested proposition that remains unresolved. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A team treats the SDR as software and proposes omitting analog input tests. How should the boundary be explained”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “A team treats the SDR as software and proposes omitting analog input tests. How should the boundary be explained”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion. Source: §10.1 SDR Boundary and Partitioning (p. 5679)

V011-C10-DISCUSSION-006. The team can store only a subset of channels. How should it decide what information loss is acceptable?

- 01. Moderator, opening proposition: Introduce the exact dispute, “The team can store only a subset of channels. How should it decide what information loss is acceptable?” Put this particular dispute to the panel: The team can store only a subset of channels. How should it decide what information loss is acceptable. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §10.24 Application 10C4 A single-channel alias and a distinguishable full bank (p. 5713)

- 02. Student A, terminology and scope: Agree the operational meanings of store, subset, channels and information, loss, acceptable in “The team can store only a subset of channels. How should it decide what information loss is acceptable”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §10.24 Application 10C4 A single-channel alias and a distinguishable full bank (p. 5713)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of The team can store only a subset of channels; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §10.31 Interpretation and reproducibility of the channelized record (p. 5721)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Interpretation and reproducibility of the channelized record”. Account for actual payload and metadata, and state which distinctions complete-bank retention would preserve Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §10.31 Interpretation and reproducibility of the channelized record (p. 5721)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of The team can store only a subset of channels; explain what each record can establish State

what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §10.26 Application 10C6 Oversampling and the complete recording rate (p. 5715)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Interpretation and reproducibility of the channelized record”. Account for actual payload and metadata, and state which distinctions complete-bank retention would preserve Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §10.31 Interpretation and reproducibility of the channelized record (p. 5721)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Relate selected channels to the intended question, alias distinctions, boundaries, and inversion requirements Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §10.24 Application 10C4 A single-channel alias and a distinguishable full bank (p. 5713)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving The team can store only a subset of channels: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §10.24 Application 10C4 A single-channel alias and a distinguishable full bank (p. 5713)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of The team can store only a subset of channels; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §10.26 Application 10C6 Oversampling and the complete recording rate (p. 5715)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving The team can store only a subset of channels: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion.

Copyright 2026, James M. Atkinson

Ask Student H to identify an alternative that could survive the proposed test. Source: §10.24 Application 10C4 A single-channel alias and a distinguishable full bank (p. 5713)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving The team can store only a subset of channels, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §10.31 Interpretation and reproducibility of the channelized record (p. 5721)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving The team can store only a subset of channels: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §10.24 Application 10C4 A single-channel alias and a distinguishable full bank (p. 5713)

Copyright 2026, James M. Atkinson

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for The team can store only a subset of channels. Do not treat reduced rate as proof of independent or complete coverage Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §10.26 Application 10C6 Oversampling and the complete recording rate (p. 5715)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving The team can store only a subset of channels, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §10.31 Interpretation and reproducibility of the channelized record (p. 5721)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for The team can store only a subset of channels. Do not treat reduced rate as proof of independent or complete coverage Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing

V011-C10-DISCUSSION-013. The team wants to remove gaps so downstream software receives a continuous array. What conditions should govern that derived product?

- 01. Moderator, opening proposition: Introduce the exact dispute, “The team wants to remove gaps so downstream software receives a continuous array. What conditions should govern that derived product?” Put this particular dispute to the panel: The team wants to remove gaps so downstream software receives a continuous array. What conditions should govern that derived product. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §10.62 Interpretation and continuation boundary for Model 10E (p. 5764)

- 02. Student A, terminology and scope: Agree the operational meanings of remove, gaps, downstream and array, govern, derived in “The team wants to remove gaps so downstream software receives a continuous array. What conditions should govern that derived product”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §10.62 Interpretation and continuation boundary for Model 10E (p. 5764)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of The team wants to remove gaps so downstream software receives a continuous array; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §10.61 Application 10E.10: one missing input appears in idle channels (p. 5763)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Application 10E.10: one missing input appears in idle channels”. Explain changed convolution and timing Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §10.61 Application 10E.10: one missing input appears in idle channels (p. 5763)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of The team wants to remove

gaps so downstream software receives a continuous array; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §10.51 Gap representations, phase, and the limits of timing claims (p. 5751)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Application 10E.10: one missing input appears in idle channels”. Explain changed convolution and timing Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §10.61 Application 10E.10: one missing input appears in idle channels (p. 5763)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Retain the original data/map, document deletion or filling, carry validity masks, and preserve absolute phase/output epoch Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §10.62 Interpretation and continuation boundary for Model 10E (p. 5764)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving The team wants to remove gaps so downstream software receives a continuous array: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §10.62 Interpretation and continuation boundary for Model 10E (p. 5764)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of The team wants to remove gaps so downstream software receives a continuous array; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §10.51 Gap representations, phase, and the limits of timing claims (p. 5751)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving The team wants to remove gaps so downstream software receives a continuous array: specify the altered receiver state or source condition, predicted change, test

V011-C10-DISCUSSION-024. Should a converter be selected solely because the ideal bit formula exceeds a desired dynamic range?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Should a converter be selected solely because the ideal bit formula exceeds a desired dynamic range?” Put this particular dispute to the panel: Should a converter be selected solely because the ideal bit formula exceeds a desired dynamic range. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §10.96 Application 3 Crest-factor headroom (p. 5809)

- 02. Student A, terminology and scope: Agree the operational meanings of converter, ideal, formula and exceeds, dynamic, range in “Should a converter be selected solely because the ideal bit formula exceeds a desired dynamic range”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §10.96 Application 3 Crest-factor headroom (p. 5809)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of whether a converter be selected solely because the ideal bit formula exceeds a desired dynamic range; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §10.3 Quantization, Clipping, and Converter Performance (p. 5684)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Quantization, Clipping, and Converter Performance”. Use the formula as conditional planning arithmetic Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §10.3 Quantization, Clipping, and Converter Performance (p. 5684)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of whether a converter be selected solely because the ideal bit formula exceeds a desired dynamic range; explain what each record can establish State what

Chapter 10 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C10-ESSAY-001 — Define input clock, signed input and NCO frequencies, initial phases, coefficient response, decimation, and retained residue. Obtain translated response magnitude and phase at mM+p, and interpret frequency modulo output rate. Explain the absence of an automatic voltage division by decimation and the inability to identify an earlier analog alias.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation.

V011-C10-ESSAY-002 — Trace each blocker on each stage's input clock, evaluate actual coefficient responses before deletion, combine stage attenuations, and compare each contribution with a common-plane limit. Treat coherent combination separately from power addition and distinguish digital alias rejection from upstream analog overload. Avoid testing only one exact filter null.

Review: Chapter 10 — Ten worked applications of Model 10B.

V011-C10-ESSAY-003 — Use the 33-tap symmetric example to distinguish center lag 16 from history requirement 32. Map retained index mM+p to center time and identify the first complete retained history. Discuss initial-state assumptions, response zeros, error criterion, and why a single delay number does not define a discard interval.

Review: Chapter 10 — Ten worked applications of Model 10B.

Copyright 2026, James M. Atkinson

V011-C10-ESSAY-004 — Track absolute input timing, continuous NCO phase, FIR history, and retained schedule. Use the 9 MHz/48 MS/s/1000-sample example to explain alternating sign resets. Examine boundary convolution separately from settled block interiors and distinguish NCO reset from filter reset. State the records needed to reproduce the correct stream.

Review: Chapter 10 — Ten worked applications of Model 10B.

V011-C10-ESSAY-005 — Group lag by channel count, derive the positive inner exponent, state inverse-DFT normalization and negative-FFT remapping, and retain the outer channel phase. Explain critical versus oversampled residue scheduling and why labels FFT or polyphase do not uniquely specify sign, order, or gain.

Review: Chapter 10 — Causal polyphase grouping and the transform convention.

V011-C10-ESSAY-006 — Use the prototype response for a boundary tone, preserve signed centers and residual labels, and compare the full response vector. Explain why one source can populate both channels and why unqualified power addition is not a calibrated input estimate. Validate center and boundary tones with actual coefficients and arithmetic.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-ESSAY-007 — Analyze the chapter's single-channel alias with adjusted complex coefficient and the particular complete rectangular bank's inverse. Identify which complete vector information distinguishes the inputs. Limit perfect-reconstruction claims to the specified prototype, full channels, valid history, and retained frames; discuss recording-rate tradeoffs.

Review: Chapter 10 — Ten worked applications of Model 10C.

Copyright 2026, James M. Atkinson

V011-C10-ESSAY-008 — Expand same-time covariance using tap energies and channel phase factors. Explain correlated simultaneous channels from unequal energies, time correlation from overlapping frames, and why zero covariance is not independence without a suitable joint distribution. Keep prehistory assumptions explicit and reject counting every frame-channel pair as independent automatically.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-ESSAY-009 — Show how the zero tap removes an entire residue at critical sampling despite unit DC gain and equal aggregate rate. For the stated oversampled bank, retain every affected frame and channel and explain the positive lower energy bound and unequal energy weighting. Do not generalize this repair to every prototype or truncated record.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-ESSAY-010 — State signed formats, total/fractional bits, physical voltage scale, quantized coefficients, product and accumulator widths, conversion locations, tie rule, saturation/wrap policy, transform sign/order/normalization, shifts, and history. Separate code correctness from physical calibration and include stage flags for intermediate overflow.

Review: Chapter 10 — Signed formats and explicit conversion points.

V011-C10-ESSAY-011 — Separate positive and negative coefficient sums, choose endpoint inputs that minimize and maximize the branch, convert to full-product integer codes, and test both asymmetric code endpoints. Explain when the interval protects direct partial sums and why transformed or feedback topologies require another intermediate analysis.

Review: Chapter 10 — Range and error are separate obligations.

Copyright 2026, James M. Atkinson

V011-C10-ESSAY-012 — Use the two-product example to show noncommuting rounding and addition. State the model's conversion schedule and no-overflow premises. Explain that scale restoration magnifies final rounding and does not restore low bits. Distinguish deterministic bounds from assumed white-noise models and account separately for additional twiddle reductions.

Review: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-ESSAY-013 — Use intermediate wrapping or saturation examples and identify stage order and flags. Discuss exact-phase/order mistakes that additional fractional bits cannot fix. Compare to the intended direct reference and test endpoint and nonsymmetric vectors; a coincidentally correct final result does not prove all internal ranges were valid.

Review: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-ESSAY-014 — Identify stored starts, source starts, lengths, clock segment, and anchor. Reorder by declared source identity, resolve global coverage before declaring gaps, compare overlapping payloads, and distinguish repeated values from repeated indices. Preserve unresolved conflicts and show why continuous file offsets or total length do not establish chronology.

Review: Chapter 10 — Source indices, stored offsets, and time anchors.

V011-C10-ESSAY-015 — Use actual nonzero support and unique available source values. For contiguous support, form the gap tail and intersect it with the retained epoch using ceiling/floor bounds. Use set unions for multiple gaps. Explain sparse-support exceptions and the limits of finite recovery for recursive/adaptive state.

Review: Chapter 10 — A continuity condition for finite filtering and decimation.

Copyright 2026, James M. Atkinson

V011-C10-ESSAY-016 — Retain the original grid and validity mask for zero filling, derive the missing-input error, and state a justified amplitude bound if available. Explain deletion's changed neighbors, timestamps, oscillator indices, and retained grid. Distinguish eventual finite-history recovery from restored chronology and preserve both as explicitly derived records.

Review: Chapter 10 — Gap representations, phase, and the limits of timing claims.

V011-C10-ESSAY-017 — Use source deficit three and mixer increment $\frac{\pi}{4}$ to obtain a 135-degree rotation only across constant-deficit support. Explain the four intervals between bounding retained samples, gap-crossing convolution, and changed modulo-four retained source instants. Show why one phase factor cannot repair all consequences.

Review: Chapter 10 — Application 10E.9: absolute phase survives three missing positions.

V011-C10-ESSAY-018 — State what the dependency mask establishes. Add the constant-rate and anchor-error bound for timing, excluding unmodeled wander and resets, and apply the separate no-overflow/rounding contract for numerical values. Explain that valid dependencies are necessary candidates for usable observation but do not certify every signal or calibration property.

Review: Chapter 10 — A continuity condition for finite filtering and decimation.

Copyright 2026, James M. Atkinson

V011-C10-ESSAY-019 — Declare plane, channels, bands, levels, gain/filter/clock states, sample formats, rates, processing, destination, and host conditions. Assign stable criteria with discriminating evidence and predeclared rules. Separate applicability from result, justify exclusions, and require all mandatory applicable criteria satisfied. Preserve contradictions and unresolved associations without scores.

Review: Chapter 10 — Define the case before testing.

V011-C10-ESSAY-020 — Bind each documentary result to its actual subject and trust policy. Distinguish same filename from same bytes, authenticated signing from permitted build expectations, and verified downloaded file from observed loaded image. Identify limits of ordinary readbacks and version strings and retain narrower assurance rather than inventing runtime attestation.

Review: Chapter 10 — Separate signed artifacts from operating configurations.

V011-C10-ESSAY-021 — Use asymmetric signed integer codes, stated byte/IQ/channel order, and a declared boundary. Compare expected vectors from an analytically independent oracle with outputs, trace common libraries, and preserve scaling. Explain why zeros, identical channel values, successful installation, or two programs sharing one map can conceal errors.

Review: Chapter 10 — Ten worked applications of Framework 10F.

V011-C10-ESSAY-022 — Use a justified deterministic interval with explicit inclusive endpoints, classify wholly inside, wholly outside, and overlap cases, and distinguish a coverage interval from a bound. For recording, require the named writer and workload plus source-index checks, not streaming-only success or expected file size. Do not transfer a pass beyond tested scope.

Review: Chapter 10 — Ten worked applications of Framework 10F.

Copyright 2026, James M. Atkinson

V011-C10-ESSAY-023 — Define the admitted analog bands and mixer plan, predict signed/folded mappings at each actual rate, and retain candidates with identical mappings. Use the 10 MHz and 110 MHz two-rate counterexample and the half-rate phase ambiguity. Explain complex sign information and physical I/Q limits, plus why front-end admission evidence remains necessary.

Review: Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation.

V011-C10-ESSAY-024 — Start with code spacing, distinguish half-step bound from uniform centered error, derive mean-square error and the sinusoid amplitude term, then add the white-error density assumption for bandwidth integration. State actual equivalent bandwidth, anti-alias filtering, retained signal gain, endpoint/headroom limits, and why deletion or rescaling alone supplies no gain.

Review: Chapter 10 — Quantization margin and channel bandwidth.

V011-C10-ESSAY-025 — Preserve original samples and logs, establish source-index gaps and processing-state effects, and compare capability and configuration across the destination change. Treat the observations as support for a recording-path mechanism while checking affected records before environmental attribution. Avoid claiming the absence of all environmental bursts or future loss probability zero.

Review: Chapter 10 — Hypothetical Case Adjudication: Software-Defined Radios, Sampling, Quantization, DDC, and Channelization.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-C10-DISCUSSION-001 — Identify protection, filters, gain, clock, and converter as parts of the same measurement chain. Explain information lost before sampling and how digital settings depend on it. Retain a configuration-bound acceptance plan spanning the relevant analog and digital functions.

Review: Chapter 10 — SDR Boundary and Partitioning.

V011-C10-DISCUSSION-002 — Compare mixer sign, NCO state, retained residue, filter delay/history, transform convention, and scaling using complex references. Magnitude agreement does not settle timing or phase meaning. Preserve exact input/output indices before attributing the difference to propagation.

Review: Chapter 10 — Model 10B for digital mixing filtering and decimation.

V011-C10-DISCUSSION-003 — Discuss the admitted blocker bands and actual stage-frequency paths. Require nearby and relevant band tests, range checks, and a declared allowable contribution. A useful single-point result remains bounded and cannot replace rejection-band evidence.

Review: Chapter 10 — Ten worked applications of Model 10B.

V011-C10-DISCUSSION-004 — Distinguish computational efficiency from unchanged exact filter response, then inspect arithmetic, scaling, timing, and actual changed coefficients. Require comparable reference tests. Attribute a measured difference to demonstrated changes rather than the architecture name alone.

Review: Chapter 10 — Ten worked applications of Model 10B.

Copyright 2026, James M. Atkinson

V011-C10-DISCUSSION-005 — Ask for prototype, channel grid, complex response vectors, source records, and center/boundary reference tests. Consider one tone's split response and alias alternatives. Revise source counting only to the multiplicity the complete evidence supports.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-DISCUSSION-006 — Relate selected channels to the intended question, alias distinctions, boundaries, and inversion requirements. Account for actual payload and metadata, and state which distinctions complete-bank retention would preserve. Do not treat reduced rate as proof of independent or complete coverage.

Review: Chapter 10 — Ten worked applications of Model 10C.

V011-C10-DISCUSSION-007 — Discuss redundant samples, prototype filtering, same-frame covariance, and overlapping histories. Rate is a storage/processing count, while information and independence depend on the map and model. Require explicit claims for invertibility or statistical gains.

Review: Chapter 10 — Causal polyphase grouping and the transform convention.

V011-C10-DISCUSSION-008 — Use blind residue, boundary response, transform ordering, and finite history as separate mechanisms. Propose sparse impulses, nonsymmetric vectors, and actual response testing. Preserve the center-tone result without extending it to all inputs or reconstruction.

Review: Chapter 10 — Ten worked applications of Model 10C.

Copyright 2026, James M. Atkinson

V011-C10-DISCUSSION-009 — Use code-center, periodic, and constant-bias counterexamples. Distinguish deterministic half-step bounds, no-overflow assumptions, and statistical models. Require evidence for any noise or independence claim instead of inferring it from the tie rule.

Review: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-DISCUSSION-010 — Compare conversion schedules, output step restoration, intermediate range, coefficient quantization, and state. Lost low bits or saturation cannot be recreated by multiplication. Use exact finite vectors and declared voltage calibration to identify the actual difference.

Review: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-DISCUSSION-011 — Discuss modular cancellation and the intended exact arithmetic contract. Examine intermediate ranges, accumulation order, and boundary cases. A favorable final coincidence may be recorded but does not prove that the implementation meets its no-overflow requirement.

Review: Chapter 10 — Ten worked applications of Model 10D.

V011-C10-DISCUSSION-012 — Separate timestamps, stored offsets, source identity, and payload agreement. Resolve or mark conflicts rather than average them into a third value. Expected length is one consistency check, not a substitute for source-index evidence.

Review: Chapter 10 — Source indices, stored offsets, and time anchors.

Copyright 2026, James M. Atkinson

V011-C10-DISCUSSION-013 — Retain the original data/map, document deletion or filling, carry validity masks, and preserve absolute phase/output epoch. Explain changed convolution and timing. A convenient array can be offered for a defined purpose without presenting it as the original continuous observation.

Review: Chapter 10 — Gap representations, phase, and the limits of timing claims.

V011-C10-DISCUSSION-014 — Apply the actual support mask and distinguish an exact implemented zero from a small coefficient. Retain the declared filter; do not change coefficients merely to clear invalidity. Explain the local dependency result without claiming all intermediate samples are valid generally.

Review: Chapter 10 — Application 10E.7: a zero coefficient changes the validity pattern.

V011-C10-DISCUSSION-015 — Distinguish conditional error magnitude from knowledge of the missing dependency. Retain invalidity and the bound's assumptions while explaining possible limited uses. Do not convert a bounded numerical consequence into a claim that original samples exist.

Review: Chapter 10 — Gap representations, phase, and the limits of timing claims.

V011-C10-DISCUSSION-016 — Examine constant rate error, anchor uncertainty, segment resets, and unmodeled wander separately from loss. Do not insert samples merely to force agreement. Apply a justified timing model and preserve its scope alongside continuity evidence.

Review: Chapter 10 — Application 10E.3: a continuous record with uncertain elapsed time.

Copyright 2026, James M. Atkinson

V011-C10-DISCUSSION-017 — Keep signature integrity and functional behavior as separate criteria. A valid signature cannot compensate for a demonstrated mapping breach. Investigate the implementation without inferring malicious intent solely from the failure and retest the bounded corrected configuration.

Review: Chapter 10 — Separate signed artifacts from operating configurations.

V011-C10-DISCUSSION-018 — Ask which specific criterion is at issue: transmit spectral performance may be outside scope while disabled-transmission evidence may remain required. Unknown applicability is unresolved. Require a defensible scope and rationale rather than relabeling difficult requirements after testing.

Review: Chapter 10 — Define the case before testing.

V011-C10-DISCUSSION-019 — It demonstrates reproducibility under that shared dependency. Discuss what it cannot independently verify and add a discriminating analytical or separately implemented oracle. Avoid either discarding all agreement or overstating its independence.

Review: Chapter 10 — Ten worked applications of Framework 10F.

V011-C10-DISCUSSION-020 — Name the unsupported proposition and retain acceptance-not-demonstrated status under the declared conjunction. Discuss a separately scoped useful case only with explicit requirements and justification. Do not turn a pass fraction or schedule pressure into acceptance of the full case.

Review: Chapter 10 — Define the case before testing.

Copyright 2026, James M. Atkinson

V011-C10-DISCUSSION-021 — Trace dependencies into sample representation, scaling, clipping, channel order, file chronology, and recording workload. Retain unaffected results only with documented applicability. A release-note description is evidence to inspect, not a complete impact proof.

Review: Chapter 10 — Choose evidence that can discriminate the required behavior.

V011-C10-DISCUSSION-022 — Use the established reported configuration consistently while separately measuring clock accuracy as required. Determine whether the actual rate lies inside the acceptance envelope. A successful call cannot make the requested rate the true configuration.

Review: Chapter 10 — Ten worked applications of Framework 10F.

V011-C10-DISCUSSION-023 — Enumerate admitted analog candidates and their mappings, including the chapter's two-rate alias counterexample and automatic retuning. Stability can reject some explanations without selecting a unique origin. Seek independent band and conversion evidence before attribution.

Review: Chapter 10 — Sampling equivalence, admissible bands, and receiver interpretation.

V011-C10-DISCUSSION-024 — Discuss waveform amplitude and crest factor, quantizer distribution, jitter, noise, distortion, clipping, actual filter bandwidth, and full-chain tests. Use the formula as conditional planning arithmetic. Require measured performance in the intended configuration before accepting the system.

Review: Chapter 10 — Quantization margin and channel bandwidth.

Copyright 2026, James M. Atkinson

V011-C10-DISCUSSION-025 — Describe the controlled association, overflow/continuity evidence, and recording-path explanation. Preserve original and revised configurations and assess whether capability changed. State the limits of the environmental inference and avoid converting one corrected run into a guarantee of future loss-free behavior.

Review: Chapter 10 — Hypothetical Case Adjudication: Software-Defined Radios, Sampling, Quantization, DDC, and Channelization.

Copyright 2026, James M. Atkinson

Chapter Glossary

ABSOLUTE SAMPLE INDEX: Integer identity of a sampling event within a declared source segment, distinct from its retained file position.

ACCEPTANCE CASE: A bounded technical argument that a declared configuration satisfies specified applicable requirements using identified evidence and decision rules.

ADMITTED ANALOG BAND: The set of input frequencies allowed by an explicitly justified front-end and signal-class specification before sampling.

ALIASING: Indistinguishable mapping of spectral components caused by sampling without adequate band limitation or by intentional zone translation.

ANALYSIS CHANNELIZER: A bank that filters one sampled input into several indexed output streams with specified frequency translation and sample retention.

APPLICABILITY RATIONALE: The technical explanation establishing whether a criterion belongs to a declared acceptance case; an unknown relationship remains unresolved.

BINARY POINT SCALING: Representation in which an integer code is multiplied by a stated power of two; the fractional-bit count fixes the code step.

CHANNEL GRID: The signed center-frequency list and spacing assigned to a channelizer, distinct from each output stream’s sampling frequency.

CODE-CENTER TEST: A chosen input record exactly aligned with representable quantizer levels; its favorable error is not a distribution-wide guarantee.

Copyright 2026, James M. Atkinson

CONFIGURATION BINDING: The specified association among device, executable artifacts, loaded images, calibration data, and actual settings used by an examination.

CONTINUITY VALIDITY MASK: Binary dependency indicator identifying outputs whose nonzero filter terms all use resolved available samples or justified known prehistory.

CONVERSION SCHEDULE: Ordered locations and rules at which a numerical pipeline changes format, rounds, saturates, or wraps.

CRITICAL SAMPLING: Filter-bank rate condition in which the aggregate output sample rate equals the input rate; it does not by itself establish reconstruction.

DECIMATION PHASE: Retained input-index residue modulo the decimation factor, specifying output time origin and coherent phase.

DIGITAL DOWNCONVERTER: Digital mixer, filter, and decimator that translates and selects a sampled frequency band.

DUPLICATE SAMPLE INDEX: Repeated declaration of one source index in stored data; payload agreement and resolution remain separate questions.

EFFECTIVE NUMBER OF BITS: Converter-performance metric derived from measured noise and distortion relative to an ideal quantizer.

EVIDENCE APPLICABILITY: The demonstrated relationship between an observation or record and the subject, configuration, conditions, and proposition it is used to support.

Copyright 2026, James M. Atkinson

FIR STATE: Stored input history or equivalent realization state required to continue a finite impulse response filter across a processing boundary without changing the declared filter operation. The realization's delay-state coordinates need not be a raw list of prior input samples; transfer the compatible state or reconstruct the equivalent history.

FOLDED FREQUENCY: A representative nonnegative frequency in the first Nyquist interval for real-sample magnitude interpretation, without an implied analog-source identity.

GUARD BIT: Additional representation width retained to accommodate a proved intermediate range; its need depends on the actual operations and input bounds.

I/Q SAMPLES: Paired in-phase and quadrature values representing a complex analytic or translated signal.

MODULAR WRAPAROUND: An overflow rule that discards multiples of a format's code range and returns the corresponding representable signed code. An over-range positive result can therefore become negative. It differs from saturation and from ordinary rounding; restoring a later scale cannot recover the discarded range information or validate an earlier overflowed operation.

NEAREST EVEN ROUNDING: Selection of the nearest representable code, with an exact halfway case assigned to the even integer code.

Copyright 2026, James M. Atkinson

NONZERO COEFFICIENT SUPPORT: The set of declared filter lags whose implemented coefficients are nonzero. It determines which input samples can affect an output in Model 10E. An exactly zero tap creates no dependency, while a small nonzero tap still does; a justified amplitude bound can limit that dependence without making it absent.

NUMERICALLY CONTROLLED OSCILLATOR: Digital phase accumulator and waveform generator used for frequency translation or synthesis.

OVERSAMPLED CHANNELIZER: An analysis bank whose aggregate output sample rate exceeds its input sample rate under the stated channel count and decimation.

POLYPHASE COMMUTATOR: The sample-routing schedule that assigns input-index residues to coefficient branches; its phase and progression form part of the filter-bank definition.

POLYPHASE COMPONENT: A filter-coefficient subsequence selected by a fixed lag residue modulo an integer rate-change factor.

PROVENANCE VERIFICATION: Examination of an artifact and associated origin or build claims against defined integrity, identity, and policy expectations.

QUANTIZATION ERROR MEAN SQUARE: Average squared difference between a quantizer's output representation and its input; includes squared bias.

REGRESSION COVERAGE: The justified set of requirements reexamined after a change, based on affected subjects and dependencies rather than the change label alone.

Copyright 2026, James M. Atkinson

SAMPLE EPOCH: Fixed source-index reference establishing the retained output grid or oscillator phase convention within a declared segment.

SAMPLING EQUIVALENCE CLASS: Frequencies and phase conventions producing the same ideal uniformly sampled sequence.

SATURATING ARITHMETIC: A numerical operation that clamps an out-of-range code to the permitted endpoint of its declared signed format. Once clamping occurs, the ordinary half-step rounding-error bound no longer applies. Intermediate saturation can alter later results even when the final displayed value lies within range, so the conversion schedule and operation order remain part of the model.

SCALE RESTORATION: Reconstruction of a declared numerical or voltage scale from stored values and the associated exponent, without recovery of discarded precision.

STORED SAMPLE OFFSET: Integer position in the retained sample array, which need not equal the original source index after a gap or overlap.

TIME ANCHOR: An association between a specified source sample index and a time on a declared time scale. Together with a supported sample-rate model it permits other sample times to be calculated. A host-arrival or file-creation timestamp is not interchangeable with this sampling event, and anchor uncertainty remains distinct from continuity of sample indices.

Copyright 2026, James M. Atkinson

UNIFORM QUANTIZATION-ERROR MODEL: The stipulated probability model in which rounding error is uniformly distributed over one code-step interval centered on zero. It gives a mean-square error used in the ideal sine-wave estimate, but the half-step error bound alone does not establish this distribution. Predicting channel noise additionally requires the separate white-error premise.

WHITE-ERROR CHANNEL MODEL: A stipulated uncorrelated error model whose channel power is obtained by integrating its density against squared filter response.

Advanced Micro Devices. Fast Fourier Transform LogiCORE IP Product Guide. PG109, version 9.1, July 17, 2026. Finite word length, rounding implementation, and fixed-point overflow sections. https://docs.amd.com/r/en-US/pg109-xfft/Finite-Word-Length-Considerations.

Annotation. Sections “Finite Word Length Considerations,” “Rounding Implementation,” and “Fixed-Point Data.” These are architecture-specific implementation conventions, not a universal FFT arithmetic specification or evidence that a receiver implements Model 10D. This implementation reference addresses fixed-point FFT scaling, finite word length, rounding choices and overflow behaviour inside a particular programmable logic design. The relevant engineering question is whether every butterfly stage has the width, scaling schedule and saturation policy assumed by the chapter’s worked model. Configuration and test vectors must be retained before the documented core behaviour can be attributed to a particular acquisition system. In this chapter the citation should be read against the local receiver model and the expressly defined quantities, not as a general endorsement of every design choice.

Analog Devices. MT-085, "Fundamentals of Direct Digital Synthesis (DDS)." Rev. 0, October 2008, pp. 2–3. Phase-accumulator tuning relation and truncation distinction. https://www.analog.com/media/en/training-seminars/tutorials/MT-085.pdf.

Annotation. Printed pages 2–3, especially Equation 1 and the distinction between accumulator width and phase truncation. The chapter independently calculates the stated tuning example. The tutorial addresses numerical phase accumulation, frequency tuning and the effects of finite word length in a digital oscillator. The tuning equation, accumulator width, truncation position and reference clock are distinct quantities and must be documented separately. A theoretically possible output frequency or spur location is not proof that a deployed receiver produces it without measurements of clock quality and implementation. Its use here is bounded by the physical reference plane, implementation version and the evidentiary proposition being tested. Forensic use also requires retained acquisition metadata and a documented chain between the observed quantity and the conclusion ultimately reported.

Beavers, Ian. "Missing Half the Signal." Analog Dialogue, RAQ Issue 124. Analog Devices. NCO, FIR, and downsampling architecture; cited in Model 10B. https://www.analog.com/en/resources/analog-dialogue/raqs/raq-issue-124.html.

Annotation. The paragraphs on NCO mixing, FIR filtering and downsampling support the DDC architecture. Model 10B independently fixes its voltage normalization, sign convention and retained-sample rule;

no unstated instrument dBFS convention is adopted. The article documents the constituent operations of digital downconversion: numerically controlled mixing, low-pass filtering and decimation. In-phase and quadrature sign conventions, sample-rate changes and filtering latency are necessary to interpret the retained digital signal. Vendor examples illustrate an architecture but do not certify the bit scaling, numerical precision or channel timing of a particular recorder. The cited work is a methodological reference; the worked examples and the conclusions drawn from them remain separate authorial derivations requiring their own checks.

Cooper, David, et al. Security Considerations for Code Signing. NIST Cybersecurity White Paper. January 26, 2018. Sections 2, 3.4–3.5, and 5. https://nvlpubs.nist.gov/nistpubs/CSWP/NIST.CSWP.01262018.pdf.

Annotation. Sections 2, 3.4–3.5 and 5, printed pages 2, 4 and 7. Supports the bounded distinction between signed-content integrity/authenticity under policy and correct or benign executable behavior. The security guidance is relevant to establishing authenticity, build provenance and integrity of software or firmware used in the measurement chain. A valid signature can support a statement about which artifact was approved under a stated trust policy, but cannot independently demonstrate correct signal processing. Release evidence should connect signer identity, digest, build inputs, installed image and measured instrument configuration. Interpretation requires separating the publication’s stated scope from the chapter’s constructed experimental examples and their necessarily conditional conclusions.

MIT OpenCourseWare. “Lecture 22: Modulated Filter Bank.” 6.341 Discrete-Time Signal Processing. OpenCourseWare 2006 notes for the Fall 2005 course, pp. 1–6. Modulated-bank and polyphase/DFT development; the causal convention in Model 10C is derived explicitly. https://ocw.mit.edu/courses/6-341-discrete-time-signal-processing-fall-2005/9bae63b4a7d9ac6bf534875e13c06ffd_lec22.pdf.

Annotation. Pages 1–6, especially 2–5. The lecture uses an advanced polyphase convention, while Model 10C explicitly derives its own causal lag convention; sign and phase factors are not transferred without that conversion. This lecture or implementation document addresses multirate digital filtering, polyphase decomposition, channelisation and numerical representation. Phase conventions, finite impulse response length, startup state and decimation timing determine whether two computational forms are physically equivalent. Theory-level equivalence must be distinguished from software or FPGA execution whose internal rounding, truncation and control signals differ. The cited work is a methodological reference; the worked examples and the conclusions drawn from them remain separate authorial derivations requiring their own checks.

coordinates are not automatically a raw list of earlier input samples. The software reference provides an executable convention for signal processing calculations and the meaning of their input parameters. Filter initial conditions, complex conjugation, one-sided scaling and array length can change numerical results even when two calls appear mathematically similar. Documenting the exact version and configuration is necessary before treating a library result as reproducible evidence or equivalent to a physical receiver. Interpretation requires separating the publication's stated scope from the chapter's constructed experimental examples and their necessarily conditional conclusions.

Annotation. Version 1.2.6 "Captures Array": sample_start, datetime and global_index. The decoding default for absent global_index does not establish loss-free physical acquisition; verified source-index declarations remain necessary. This interface or metadata specification describes practical mechanisms for configuring, representing or recording software-defined radio streams. Sample index, clock time, overrun indications, selected rates and on-wire representation matter when a forensic examiner reconstructs an acquisition. A software interface declaration alone cannot prove continuity of the resulting samples or correct interpretation by a different reader. In this chapter the citation should be read against the local receiver model and the expressly defined quantities, not as a general endorsement of every design choice.

Chapter 11. Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization

Copyright 2026, James M. Atkinson

11.1 Dynamic Range Is a Family of Conditions

Dynamic range is not one number. A receiver may have noise-limited dynamic range, instantaneous dynamic range, spurious-free dynamic range, blocking dynamic range, intermodulation dynamic range, display range, and digitizer range. Each uses a different lower limit, upper limit, bandwidth, spacing, detector, and test. Quoting the largest catalog value without its definition can overstate survey capability by tens of decibels.[1]

1 United States Navy, Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles, NAVEDTRA 14189 (September 1998), 2-10–2-14, reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388–8392; title and edition at page 8345. These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

Copyright 2026, James M. Atkinson

Figure 61. Two-tone intercept and intermodulation.

The practical question is whether the receiver can detect or measure a signal of interest while specified stronger signals are present. Total input power, individual carrier levels, spacing, modulation, crest factor, preselector state, and gain determine the answer. A receiver that is sensitive

Copyright 2026, James M. Atkinson

on a bench can be blind at a site because its front end, mixer, IF, ADC, or AGC is driven into a different operating state.

Copyright 2026, James M. Atkinson

11.2 Compression and Gain Change

Compression occurs when output no longer follows input with the expected incremental gain. The one-decibel compression point is a common benchmark, but subtle measurement errors can begin well below it. Filters, amplifiers, mixers, detectors, ADCs, and digital scaling can each compress or clip. A strong off-channel signal can reduce the indicated level of a weak on-channel signal without appearing in the displayed span.

Compression testing steps a calibrated input while monitoring desired output, gain state, total power, and overload indicators. For field challenge, input attenuation is changed and corrected traces are compared. If a component fails to change by the expected amount, the receiver may be compressed or the component may originate after the attenuator. Recovery after a pulse or strong carrier is also measured because temporary desensitization can create missed events.

Figure 62. Receiver dynamic range and nonlinear products.

Copyright 2026, James M. Atkinson

11.3 Measure compression without confusing it with control action

A compression test needs a declared input quantity and a fixed receiver state. Step the intended stimulus through a bounded interval while measuring the desired output at the corresponding reference plane. Retain actual attenuation, gain, preselector, and detector states. If an automatic control changes during the sweep, the resulting curve describes the closed-loop receiver behavior, not the fixed-state transfer of one stage. Both may be useful, but they answer different questions and should be labeled separately.

Use an independent weak probe when the question is loss of sensitivity in the presence of a stronger signal. The blocker alone can produce an apparently plausible output while suppressing the probe or changing its estimator. Keep the probe level, frequency, modulation, and detection criterion controlled, then vary blocker level and offset. Observe desired gain, noise, products, and recovery together. A single displayed overload flag cannot establish the onset or absence of every relevant error.

After a strong pulse, measure the interval before the weak probe again meets its criterion. Model 5A supplies a bounded identified one-pole response when its assumptions apply, but limiting, saturation, detector storage, and control holdoff may produce other recovery histories. State the stimulus and prior state used to characterize recovery. The duration becomes an exclusion in the usable acquisition windows of Model 15A when the receiver cannot make valid observations during it.

Copyright 2026, James M. Atkinson

11.4 Intermodulation and Intercept Metrics

Nonlinear stages produce sums and differences of input frequencies. Third-order products are particularly troublesome because they can fall near desired signals and grow rapidly with input level. Input and output intercept points are extrapolated metrics, not actual operating points. They depend on tone spacing, frequency, gain, device state, and measurement range. Two-tone tests should be performed below compression with sources and combiners verified for their own intermodulation.

In a real survey, more than two strong signals may be present, including modulated carriers. Passive contacts, damaged connectors, preamplifiers, mixers, protection devices, and ADCs can all contribute. Changing one parent signal, adding attenuation, inserting preselection, or moving the receiver helps identify the generating path. A product that remains fixed while parent frequencies are changed requires a different explanation.

Copyright 2026, James M. Atkinson

11.5 Model 11A for cubic intermodulation and intercept metrics

A third-order intercept is useful only after the input quantity, output quantity, and extrapolation have been identified. A line on a spectrum display reports power in a selected observation band; it does not identify the nonlinear stage that generated that power. Model 11A derives a deliberately restricted voltage law, then follows its consequences through frequency placement, power conversion, unequal interferers, attenuation, and measurement uncertainty. This development supplies the assumptions behind the chapter's existing Equation 21 without replacing its summary or extending the separate Equation 22 noise-floor approximation.

The starting point is a memoryless third-order expansion around a fixed operating condition. Original circuit lectures distinguish this local description from the input and output filtering that may surround it, and distinguish the extrapolated intercept from large-signal compression. Here the coefficients describe loaded input and output voltages directly. Their numerical examples are constructed teaching cases, not measurements of any receiver. The model does not represent a complete SDR, an automatic-gain-control loop, a sampled-data converter, or an arbitrary frequency-converting mixer.[2]

11.6 Fix the voltage convention and operating domain

Let t denote time in seconds, and let f_1 and f_2 be positive frequencies in hertz with f_1 below f_2. Let A_1 and A_2 be positive peak voltages measured at the declared input reference plane, not open-circuit generator voltages. The two cosines have zero initial phase for this derivation. The input $x\backslash(t\backslash)$ and output $y\backslash(t\backslash)$ are real instantaneous voltages. Their variation with time is dynamic, although the model has no stored state: the output at a given instant depends only on the input at that instant. A fixed propagation delay could be accounted for separately without changing the power calculations.

Equation 21A Two tone voltage at the loaded input plane

$$x(t)=A_1\cos(2\pi f_1 t)+A_2\cos(2\pi f_2 t)$$

Equation 21B Declared odd cubic voltage law

$$y(t)=a_1 x(t)+a_3 x^3(t)$$

The constant a_1 is strictly positive and is a dimensionless voltage gain. The nonzero real constant a_3 has units of inverse square volts. A negative a_3 initially reduces a fundamental component; a positive a_3 initially increases it. Constant offset and even-order terms are set to zero as restrictions of this model, not because actual receiver hardware must have those properties. Bias, temperature, supply, loading, gain state, and fixture condition remain fixed during a comparison. A thermally drifting gain or a contact whose mechanical condition changes is outside this time-invariant coefficient description.

Let R_i and R_o be positive, real, frequency-independent input and output resistances in ohms. The output voltage is taken across R_o. The source is matched to R_i when available source power is identified with delivered input

Copyright 2026, James M. Atkinson

power; without that condition, record the delivered voltage and impedance rather than substituting a generator setting. For a cosine, mean-square voltage is half the squared peak amplitude. Thus the input power P_k of tone k is in watts, and the dimensionless small-signal power gain G_p includes both reference resistances.

Equation 21C Per tone power and small signal power gain

$$P_k = \frac{A_k^{\ 2}}{2 R_i}, G_p = \frac{a_1^{\ 2} R_i}{R_o}$$

Use distinct, nearby frequencies whose retained spectral products do not coincide. In particular, the two parent tones, their third harmonics, the mixed sum products, and the two close-in products must be separately identifiable, with both close-in frequencies positive. Degenerate frequency choices require the coincident complex amplitudes to be added before computing power. A frequency-independent polynomial also cannot predict how a real filter, matching network, or mixer weights those components. The present analysis refers all amplitudes to the same specified planes before introducing any separately declared attenuation.

Copyright 2026, James M. Atkinson

11.7 Derive the retained spectral amplitudes

Cubing the sum in Equation 21A yields two self-cubic terms and two mixed terms. The mixed term containing the square of the first tone occurs three times in the expansion, as does the mixed term containing the square of the second. The following identities expose the corresponding fundamental, harmonic, sum, and difference components. Here u and v are arbitrary dimensionless phase angles. Their substitution by the two time-dependent tone phases establishes the frequency locations; the factor of three from the polynomial expansion must still be retained.

Equation 21D Self cubic trigonometric identity

$$4\cos^3 u = 3\cos u + \cos 3u$$

Equation 21E Mixed cubic trigonometric identity

$$4\cos^2 u \cos v = 2\cos v + \cos(2u+v) + \cos(2u-v)$$

Write B_1 and B_2 for the signed peak coefficients at the two fundamental frequencies. Write C_{21} for the signed peak coefficient at twice f_1 minus f_2, and C_{12} for the coefficient at twice f_2 minus f_1. The mixed square term contributes both a component at the other fundamental and two intermodulation components. The self-cubic term contributes three quarters of its coefficient to its own fundamental and one quarter to its third harmonic. Collecting the coefficients gives the following results; the

Copyright 2026, James M. Atkinson

fractional coefficient agrees with the independent multinomial development of third-order mixing.[3]

Equation 21F First fundamental coefficient

$$B_1 = A_1\left[a_1 + \frac{3a_3}{4}\left(A_1^{\,2} + 2A_2^{\,2}\right)\right]$$

Equation 21G Second fundamental coefficient

$$B_2 = A_2\left[a_1 + \frac{3a_3}{4}\left(A_2^{\,2} + 2A_1^{\,2}\right)\right]$$

Equation 21H Close in third order coefficients

$$C_{21} = \frac{3a_3}{4}A_1^{\,2}A_2, C_{12} = \frac{3a_3}{4}A_1A_2^{\,2}$$

The signs of C_{21} and C_{12} preserve phase information relative to the specified cosines. Power measurement squares their magnitudes and discards that sign. Their associated sum-frequency coefficients have the same magnitudes in this memoryless model. The two third-harmonic coefficients are one quarter of a_3 times the cube of the corresponding peak input. Consequently, a clean third-harmonic observation is not interchangeable with a close-in two-tone measurement, even though both arise from the retained cubic term.

Define η_k as the magnitude of the cubic correction to fundamental k divided by its linear coefficient, with j denoting the other tone. Unless a later application is expressly an extrapolation exercise, use the declared working

---

3 Barry N. Taylor and Chris E. Kuyatt, Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results, NIST Technical Note 1297, 1994 edition (September 1994), Appendix A, A.1–A.5, https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. Copyright 2026, James M. Atkinson

condition η_1 and η_2 no greater than 0.05. This bounds each retained fundamental correction to five percent and keeps both signed fundamentals on the positive-gain branch. It does not bound omitted fifth-order terms, validate a physical receiver, or establish that temperature and state remained fixed. Those questions require evidence beyond the smallness of one retained coefficient.

Equation 21I Declared relative fundamental correction

$$\eta_k = \frac{3|a_3|}{4a_1}\left(A_k^{\,2} + 2A_j^{\,2}\right),\ j \neq k$$

Copyright 2026, James M. Atkinson

11.8 Construct the intercept from the linear asymptote

For equal peak amplitudes A, either close-in coefficient has magnitude three quarters of the magnitude of a_3 times A cubed. The intercept construction equates that magnitude to the linear fundamental a_1 times A, not to the full coefficient B_1. Define A_I as the positive peak input amplitude at this algebraic intersection, and P_I as the corresponding input power of one tone. Both are extrapolated parameters. A nonzero a_3 gives a finite value; as its magnitude tends to zero, the cubic intercept tends to infinity without establishing the absence of other distortion mechanisms.

Equation 21J Extrapolated input intercept in voltage and power

$$A_I^2 = \frac{4a_1}{3|a_3|}, P_I = \frac{A_I^2}{2R_i}$$

Substitution eliminates the unknown magnitude of a_3 from the intermodulation powers. Let P_{21} and P_{12} be the powers of the individual close-in products across R_o. These equations are exact for the declared polynomial and resistance conventions. They demonstrate why unequal interferers require separate calculations: one product contains the square of the first parent power, while the other contains the square of the second. A symmetric pair of product powers is predicted only when the parent powers are equal under these restrictions.

Equation 21K Unequal tone intermodulation powers

$$P_{21} = \frac{G_p P_1^2 P_2}{P_I^2}, P_{12} = \frac{G_p P_1 P_2^2}{P_I^2}$$

For logarithmic calculations, lower-case p_1, p_2, q, and s denote powers in dBm, defined as ten times the base-ten logarithm of watts divided by one

Copyright 2026, James M. Atkinson

milliwatt. Let g be ten times the base-ten logarithm of G_p, in decibels. Let I_3 and O_3 denote the input and output intercept levels in dBm. In an equal-tone case, p is the input level of one tone, q is its linear-asymptote output level, and s is one product level. A power gain is added as a difference in decibels, not as a power in dBm.

Equation 21L Equal tone logarithmic power law

$$q=p+g, s=3p+g-2I_3, O_3=I_3+g$$

Equation 21M Input and output intercept extraction

$$I_3=p+\frac{q-s}{2}, O_3=\frac{3q-s}{2}$$

The usual separation rule therefore uses one fundamental and one associated intermodulation product. Summing the two parent powers first introduces an inappropriate three-decibel change for equal tones. Instrument documentation also distinguishes low-side, high-side, and averaged tone results; an average of logarithmic levels is not the total power of their sum. Preserve the individual measurements and state the selected convention rather than allowing a display label to decide which quantity entered Equation 21M.[4]

If the measured fundamental includes a finite cubic correction, its level differs from q by a gain change δg. Using that measured value in the input extraction formula introduces half that gain change into the intercept

4 Analog Devices, “System Noise-Figure Analysis for Modern Radio Receivers” (June 14, 2013), “Baseline Case: Cascade of Linear Circuit Blocks” and “Noise Temperature,” https://www.analog.com/en/resources/technical-articles/system-noisefigure-analysis-for-modern-radio-receivers.html; James P. Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. These sources distinguish receiver noise from source and path contributions; the scalar assumptions and synthetic cases are stated in Model 2B.

Copyright 2026, James M. Atkinson

estimate; using it in both occurrences of the output extraction formula introduces three halves. These are algebraic biases within this model, separate from calibration uncertainty. A fitted low-level linear asymptote or an explicitly bounded correction is needed when the requested precision makes those differences material.

Copyright 2026, James M. Atkinson

11.9 Ten worked applications of Model 11A

Applications 11A.1 through 11A.10 use synthetic values and the same bounded polynomial argument. They vary the inference, not merely the numerical setting. Where logarithmic straight-line examples are used, q denotes the linear asymptote as defined above. No example authorizes a stimulus level, establishes instrument safety, or substitutes for the applicable measurement configuration. The formal compression calculation is explicitly distinguished from the working domain.

Copyright 2026, James M. Atkinson

11.10 Application 11A.1 Locate the products before measuring their powers

Choose f_1 equal to 100 MHz and f_2 equal to 101 MHz, with frequency spacing of 1 MHz. Twice the first frequency minus the second is 99 MHz; twice the second minus the first is 102 MHz. The mixed sum frequencies are 301 and 302 MHz, and the self-cubic harmonics are 300 and 303 MHz. These six generated positive frequencies are distinct from both fundamentals, so no coefficient addition caused by frequency coincidence is needed. A receiver examining a narrow band around 99 MHz could therefore encounter a polynomial product even though neither parent lies in that narrow observation band.

Now increase only the first parent by 0.20 MHz while retaining the second. The lower product moves from 99 to 99.40 MHz, and the upper product moves from 102 to 101.80 MHz. The two-to-one and opposite one-to-one shifts follow from their respective frequency expressions. This intervention supplies a discriminating prediction, provided the observation path follows the appropriate frequencies and does not change state. A matching movement is compatible with the model, but does not locate the generating component. A fixed feature contradicts this particular parent-product association only if frequency accuracy, detectability, and stable configuration are adequate.

Copyright 2026, James M. Atkinson

11.11 Application 11A.2 Evaluate the cubic amplitudes and extraction bias

Set a_1 to 10, a_3 to minus 100 inverse square volts, both resistances to 50 ohms, and both input peak amplitudes to 0.020 V. Each input power is 0.000004 W, or minus 23.979400 dBm. The linear output coefficient is 0.200 V peak. The equal-tone cubic correction subtracts 0.001800 V, leaving B_1 and B_2 at 0.198200 V. Each close-in signed coefficient is minus 0.000600 V peak. The relative fundamental correction is 0.009, within the stated 0.05 limit.

Squaring 0.198200 V and dividing by 100 ohms gives a fundamental power of 0.0003928324 W, or minus 4.057927 dBm. The corresponding product power is 0.0000000036 W, or minus 54.436975 dBm. Equation 21J gives an input intercept of 1.249387 dBm; the small-signal gain is 20 dB, giving an output intercept of 21.249387 dBm. The actual fundamental gain change is minus 0.078527 dB. If its finite-power level is used instead of the linear asymptote, the input estimate becomes 1.210124 dBm and the output estimate becomes 21.131597 dBm. Neither discrepancy is a calibration defect; both are caused by applying an asymptotic extraction to a corrected fundamental.

Copyright 2026, James M. Atkinson

11.12 Application 11A.3 Resolve unequal parent amplitudes

Retain the same coefficients and resistances, but set A_1 to 0.040 V and A_2 to 0.010 V. Their powers are minus 17.958800 and minus 30.000000 dBm. Equation 21H gives C_{21} equal to minus 0.001200 V peak and C_{12} equal to minus 0.000300 V peak. Their magnitude ratio is four, so their power ratio is sixteen and their logarithmic separation is 12.041200 dB. Direct conversion gives minus 48.416375 and minus 60.457575 dBm. Replacing both parents by their average would erase the very asymmetry the calculation predicts.

The fundamentals also differ in their relative correction. Equations 21F and 21G give 0.394600 and 0.097525 V peak. Relative to the respective linear coefficients of 0.400 and 0.100 V, the gain changes are minus 0.118058 and minus 0.217681 dB. The weak second tone experiences the larger fractional correction because its gain contains the squared amplitude of the stronger first tone. Both correction magnitudes remain below five percent. If only the first parent power is increased by one decibel within the model domain, the lower product rises two decibels and the upper product rises one, rather than both following the equal-tone three-decibel rule.

Copyright 2026, James M. Atkinson

11.13 Application 11A.4 Keep each tone separate in the intercept calculation

Consider an equal-tone low-level asymptote with input p equal to minus 25 dBm, linear output q equal to minus 5 dBm, and one product s equal to minus 65 dBm. The separation is 60 dB. Half that separation is 30 dB, producing I_3 equal to 5 dBm and O_3 equal to 25 dBm. Increasing each input by 2 dB makes the linear fundamental minus 3 dBm and the cubic product minus 59 dBm. The new separation is 56 dB; adding half to the new input level of minus 23 dBm again gives 5 dBm.

The total input power of the two original equal tones is minus 21.989700 dBm. Substituting this total for p while retaining the single-tone separation gives the wrong input intercept, 8.010300 dBm. The error is exactly the logarithm of two expressed in decibels. Adding the two fundamental powers creates the analogous problem at the output. A record should therefore identify the per-tone level, chosen product, frequencies, reference planes, and gain state. The numerical constancy of two intercept estimates tests a necessary slope relationship here; it does not demonstrate that the source, combiner, and measurement receiver contributed no product.

Copyright 2026, James M. Atkinson

11.14 Application 11A.5 Recover a coefficient without confusing voltage and power gain

Let R_i be 50 ohms, R_o be 200 ohms, and a_1 be 10. Equation 21C gives G_p equal to 25, or 13.979400 dB, rather than 20 dB. Suppose the inferred input intercept is 5 dBm. Its power is 0.003162278 W, and twice R_i times that power is 0.316227766 square volts. Rearranging Equation 21J gives the magnitude of a_3 as 42.163702 inverse square volts. The output intercept is 18.979400 dBm. Omitting the resistance ratio would overstate it by 6.020600 dB.

Power-only intermodulation data do not choose the sign of this coefficient. To see the consequence, apply equal peaks of 0.050 V. With a negative coefficient, each fundamental is 0.488141459 V peak; with a positive coefficient, it is 0.511858541 V peak. Their gain changes are minus 0.208486 and plus 0.203599 dB relative to the 0.500 V linear coefficient. The product magnitudes are identical in both cases. Both have a correction magnitude of approximately 0.023717, within the declared bound. A signed or gain-sensitive observation supplies information that the two product powers alone have discarded.

Copyright 2026, James M. Atkinson

11.15 Application 11A.6 Test the slope over a declared power interval

Use the asymptotic case from Application 11A.4. Reduce each input from minus 25 to minus 31 dBm without changing any coefficient or reference plane. The linear output falls from minus 5 to minus 11 dBm, whereas the product falls from minus 65 to minus 83 dBm. Thus a 6 dB parent-power reduction produces an 18 dB product-power reduction and improves the fundamental-to-product separation from 60 to 72 dB. Applying Equation 21M at the new point still gives the same 5 dBm input intercept.

Suppose a constructed comparison instead places the product at minus 77 dBm while the linear fundamental remains minus 11 dBm. That product moved only 12 dB, giving an apparent input intercept of 2 dBm. The two values cannot both describe the same exact fixed-coefficient cubic-only case under the stated measurements. Plausible departures include another coherent contribution, a noise-limited reading, a state change, frequency-dependent response, or higher-order behavior. The slope mismatch identifies the failure of the proposed description; it does not select one departure uniquely. An observed floor also prevents extrapolating indefinitely to weaker products merely because the formula continues to produce a number.

Copyright 2026, James M. Atkinson

11.16 Application 11A.7 Compare attenuation before and after the nonlinear stage

Place an ideal, matched, frequency-flat attenuator with power loss L equal to 10 dB either before or after the modeled stage. Its voltage transmission k is ten raised to minus L divided by twenty. Before the stage, substitution replaces the effective first coefficient by k times a_1 and the cubic coefficient by k cubed times a_3. After the stage, both coefficients are multiplied by k. The physical location therefore changes the input-referred nonlinearity even when the overall small-signal gain is the same.[5]

Equation 21N Input attenuation coefficient transformation

$$a_{1,pre} = k\,a_1,\; a_{3,pre} = k^3 a_3$$

Equation 21O Output attenuation coefficient transformation

$$a_{1,post} = k\,a_1,\; a_{3,post} = k\,a_3$$

Take an input intercept of 0 dBm, gain of 20 dB, and equal inputs of minus 20 dBm per tone at the original plane. The linear fundamentals are 0 dBm and the products are minus 40 dBm. Pre-attenuation yields fundamentals of minus 10 dBm and products of minus 70 dBm. Post-attenuation also yields fundamentals of minus 10 dBm, but products of minus 50 dBm. Referenced to the new external input plane, pre-attenuation raises I_3 to 10 dBm and leaves O_3 at 20 dBm; post-attenuation leaves I_3 at 0 dBm and lowers O_3 to 10 dBm. Noise, mismatch, attenuator distortion, and sensitivity are absent from

5 H. T. Friis, “Noise Figures of Radio Receivers,” Proceedings of the IRE 32, no. 7 (July 1944): 419–22, https://doi.org/10.1109/JRPROC.1944.232049. The publisher’s abstract was read for the historical network, component, mismatch, and measurement framing. 11.17 Application 11A.8 Separate formal compression from the working domain

This application deliberately examines the extrapolation boundary of the truncated polynomial. Assume a negative a_3 and remain on the positive fundamental branch. A one-decibel power-gain reduction corresponds to a voltage ratio r equal to ten raised to minus one twentieth, approximately 0.891250938. With one input tone, the cubic fundamental correction is three quarters of a_3 times its peak cubed. With two equal tones, it is nine quarters. Let P_{c1} be the single-tone input power at the formal reduction, and P_{c2} the per-tone input power for two equal tones.

Equation 21P Formal cubic compression powers

$$P_{c1}=P_I(1-r), P_{c2}=\frac{P_I(1-r)}{3}$$

The resulting ratios are 0.108749062 and 0.036249687 times P_I. Their logarithmic offsets below I_3 are 9.635745 dB and 14.406957 dB, respectively. For an input intercept of 5 dBm, the formal levels are minus 4.635745 dBm for one tone and minus 9.406957 dBm per tone for two. The second result cannot be substituted for the first or interpreted as total two-tone power. Both require a 10.874906 percent fundamental correction and therefore exceed this treatment's five-percent working bound. Higher-order terms can alter actual compression, as the original circuit treatment explicitly warns. These numbers demonstrate a model-specific algebraic relation, not a receiver compression specification.[6]

11.18 Application 11A.9 Propagate calibration bounds with their dependencies

Return to p equal to minus 25 dBm, q equal to minus 5 dBm, and s equal to minus 65 dBm. Suppose independent bounded-error coordinates permit departures of at most u_p equal to 0.2 dB, u_q equal to 0.3 dB, and u_s equal to 0.5 dB in either direction. Independent here means the admissible set is the full rectangular set of error values; no probability distribution or confidence level is assigned. Let u_I and u_O denote the maximum absolute errors in the input and output intercept levels, respectively, in decibels. Because the intercept expressions are affine in these logarithmic coordinates, their extrema occur at the appropriate corners.

Equation 21Q Worst case intercept error bounds

$$u_I = u_p + \frac{u_q + u_s}{2}, u_O = \frac{3u_q + u_s}{2}$$

The input bound is 0.2 plus half the sum of 0.3 and 0.5, which is 0.6 dB. Thus I_3 lies from 4.4 to 5.6 dBm. The output bound is one and a half times 0.3 plus half of 0.5, or 0.7 dB, giving 24.3 to 25.7 dBm. Now change the error model: suppose the only output error is a common additive offset b bounded by 0.3 dB, while p is exact. Adding b to both q and s cancels it from their difference. The input intercept remains exactly 5 dBm under that restricted error model, whereas the output intercept becomes 25 dBm plus b. Treating the

11.19 Application 11A.10 Bound a coherent contaminating product

Add a declared observation model at one product frequency. Let U_{m} be the measured root-mean-square phasor magnitude, U_{c} the magnitude attributable to the modeled stage, and E a nonnegative bound on an additive coherent contaminating phasor at the same reference plane. The contaminant phase is unknown. The triangle and reverse-triangle inequalities, rather than subtraction of powers, give the permitted interval for U_{c}. This extension describes uncertainty in observing the polynomial product; it introduces no additional receiver dynamics.

Equation 21R Magnitude enclosure for coherent contamination

$$max\left(0, U_m - E\right) \leq U_c \leq U_m + E$$

Choose U_{m} equal to 1.000 mV rms, E equal to 0.100 mV rms, and R_o equal to 50 ohms. The permitted stage magnitude is 0.900 through 1.100 mV rms. Squaring those endpoints and dividing by 50 gives product powers from minus 47.904850 to minus 46.161846 dBm. With p equal to minus 20 dBm and q equal to 0 dBm, Equation 21M reverses the interval order and gives I_3 from 3.080923 to 3.952425 dBm. Ignoring the contamination would give 3.494850 dBm. If E reaches U_{m}, the observation enclosure includes zero. The stipulated nonzero cubic coefficient excludes an exactly zero stage product, but permits arbitrarily small positive magnitudes, so no finite upper intercept bound follows. Source isolation, source-harmonic suppression,

Copyright 2026, James M. Atkinson

and measurement-receiver checks are therefore substantive parts of a defensible test, not decorations around a computed intercept.[7]

11.20 Carry the conditions into receiver interpretation

A power sweep can support the local cubic description only over the observed interval and declared operating state. Repeat the relevant frequency and level conditions when the interpretation depends on them, preserve the separate low and high products, and characterize the complete path to the chosen reference planes. Frequency-selective memory, automatic gain, thermal history, mismatch, modulation envelopes, and higher orders can defeat a single real coefficient. The sign and phase of a contaminating contribution can also make a small displayed spur compatible with a larger stage-generated product.

Do not transfer this analog intercept construction automatically to a digitizer or entire SDR chain. The manufacturer tutorial on converter intermodulation distinguishes the usual analog power-law extrapolation from converter distortion and clipping behavior. For the complete receiver, the data and acceptance case must establish which portion of the path supports a local model and which behavior requires direct characterization. Chapter 10 retains responsibility for sampling, numerical representation, continuity, and configuration identity; this section supplies a conditional analog-stage calculation without closing those separate requirements.[8]

11.21 Blocking and Reciprocal Mixing

Blocking is the reduction of sensitivity or accuracy caused by a strong signal separated from the desired channel. It can arise from front-end compression, AGC, filter leakage, mixer or IF overload, ADC range occupation, or control-state changes. The blocker may be outside the instrument's selected span. Testing requires a calibrated desired signal and one or more blockers at defined offsets and modulation.

Reciprocal mixing occurs when local-oscillator phase noise around a strong signal raises the apparent noise near the tuned frequency. The result can resemble environmental broadband noise or a cluster of weak signals. Better preselection may not help if the blocker is within the admitted band, while a lower-phase-noise LO or different tuning plan can. The receiver noise floor should be measured as a function of blocker level and offset.

Copyright 2026, James M. Atkinson

TECHNICAL INTERPRETATION

An external blocker can alter effective gain and internal noise without becoming the apparent weak signal under examination.

Figure 63. Strong-signal blocking and desensitisation.

Copyright 2026, James M. Atkinson

11.22 Model 11B for reciprocal mixing and admitted noise

A strong carrier can degrade a weak-signal measurement without producing the discrete intermodulation products developed in Model 11A. Phase fluctuations in the receiving local oscillator spread a translated copy of the blocker around its nominal intermediate frequency. Part of that spread can enter the desired observation channel even when the blocker carrier lies outside it. A displayed noise increase is consequently compatible with an internally generated contribution. Its magnitude depends on the admitted blocker power, the oscillator spectrum at the relevant offsets, and the weighting of the observation channel. None of those three quantities can be replaced safely by an unspecified catalog number.

Model 11B develops that mechanism under fixed conversion gain and a small-phase expansion. It makes the phase-noise convention explicit, derives the weighted integration, and carries the result through reference-plane changes, noise-rise limits, several blockers, measurement subtraction, and a bound on the omitted term. Equations 22A through 22T belong to this local development. The chapter's existing standalone Equation 22 remains the separate spurious-free-dynamic-range approximation. Every numerical case below is synthetic; no displayed result is an observation of a particular receiver, oscillator, site, or emitter.

Copyright 2026, James M. Atkinson

11.23 Define the phase spectrum before converting decibels

Let t denote time in seconds and $\varphi(t)$ the real oscillator phase fluctuation in radians after removal of the nominal carrier phase. For the retained linear calculation, assume a zero-mean, wide-sense stationary process with finite variance. Its two-sided power spectral density is $S_{\varphi,2}(f)$, in square radians per hertz, with signed Fourier frequency f in hertz. Real phase makes that spectrum even. Assume an ordinary density over the offsets being integrated; a discrete phase spur instead contributes a spectral line that must be integrated as such. A close-in asymptote cannot be extended to zero or infinity if doing so gives infinite total phase variance.

NIST defines the single-sideband phase-noise quantity as one half of the one-sided phase spectral density. Accordingly, for a positive offset f, define $\ell(f)$ as the linear single-sideband density and $L(f)$ as its logarithmic value in dBc/Hz. The two-sided phase density has the same numerical value as ℓ at that positive offset. The factor of two is already included in this convention.[9]

Equation 22A Single sideband and phase spectrum convention

$$\ell(f)=S_{\varphi,2}(f)=\frac{S_{\varphi,1}(f)}{2}=10^{\frac{L(f)}{10}}\ Hz^{-1}, f>0$$

Here $S_{\varphi,1}$ denotes the one-sided phase spectral density. Radians are dimensionless in the power conversion, so ℓ has units of inverse hertz. The

9 James P. Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. Its historical radiometer thresholds are not adopted as acceptance limits for the present constructed receiver.

Copyright 2026, James M. Atkinson

logarithm in Equation 22A applies to the density expressed relative to one inverse hertz. The later formulas use ℓ, not the logarithmic number L, inside an integral. Adding dBc/Hz samples or averaging them arithmetically does not perform a power-density integration. The distinction matters whenever one portion of the admitted offset interval carries substantially more noise than another.

Copyright 2026, James M. Atkinson

11.24 Translate one blocker through the fluctuating oscillator

Let the desired channel center be v equal to zero in a complex intermediate-frequency representation, with signed frequency v measured in hertz. Let Δ be the blocker's signed offset from that center. P_{B} is its positive power in watts at the mixer input after all preceding frequency-selective gain or loss. It is not automatically the generator setting or the power at an antenna connector. Normalize the complex envelope so that its squared magnitude represents power; the known conversion gain is removed at this stage. The unmodulated blocker envelope is the first two factors in Equation 22B.

The phase Θ_{B} is uniform over one full cycle and independent of φ. This ensemble convention leaves the blocker power unchanged and permits stationary power calculations for its modulated remainder. It is not a claim that an actual carrier randomly resets on each observation. A deterministic phase gives the same retained single-blocker spectrum because φ has zero mean and stationary covariance. The uniform-phase convention becomes useful when stronger stationarity assumptions are imposed for the nonlinear error bound.

Equation 22B Power normalized translated blocker envelope

$$z_B(t)=\sqrt{P_B}e^{j(2\pi\Delta t+\Theta_B)}e^{-j\varphi(t)}$$

Expand only the oscillator phase factor. The complex number j is the square root of minus one, and $r\backslash(t\backslash)$ is defined by the exact identity in Equation 22C. The retained perturbation $u_1\backslash(t\backslash)$ is minus j times $\varphi\backslash(t\backslash)$ times the unmodulated blocker envelope. It has units of square root watts. Multiplication by the carrier exponential translates the phase spectrum by Δ, while multiplication by the blocker amplitude scales its density by P_{B}. Thus

Copyright 2026, James M. Atkinson

no independent phase-noise source needs to be invented at the desired frequency.

Equation 22C Retained phase term and exact remainder

$$e^{-j\varphi(t)}=1-j\varphi(t)+r(t)$$

Equation 22D Spectrum of the retained blocker perturbation

$$S_{u1}(v)=P_B S_{\varphi,2}(v-\Delta)=P_B \ell(\,|\,\Delta-v\,|\,)$$

Equation 22D has units of watts per hertz. The use of an absolute offset inside ℓ follows from the even spectrum of a real phase process; it does not make a signed blocker offset interchangeable when the observation filter is asymmetric. The nominal blocker carrier is a separate spectral line. Require that its direct leakage through the observation path be negligible or independently characterized. The reciprocal-mixing calculation alone neither predicts that leakage nor excludes gain compression, an automatic-gain-control response, digitizer clipping, or a contribution from the blocker source itself.

Copyright 2026, James M. Atkinson

11.25 Integrate the channel that actually produces the reported value

Let $H(v)$ be the dimensionless complex response of the fixed observation filter, normalized at the desired center so that $H(0)$ equals one. Set $W(v)$ equal to its squared magnitude. For this treatment, require zero through unity power weighting and finite integral. This peak-normalized condition is also used later in the remainder bound; a filter with gain above unity after this normalization requires a revised bound. B_{eff} is the equivalent noise bandwidth in hertz. The mathematical filter may represent a declared digital channel as well as an analog response, provided its power weighting and normalization are established.

Equation 22E Power weighting and equivalent noise bandwidth

$$W(v)=|H(v)|^2, B_{eff}=\int_{-\infty}^{\infty} W(v)\,dv$$

An instrument's resolution-bandwidth label does not by itself specify this integral. Keysight's 89600 VSA help defines its RBW as equivalent noise bandwidth and distinguishes that convention from the 3 dB width generally used by swept analyzers. The relevant specification must therefore be checked for the actual instrument and processing path. A detector, averaging rule, window correction, or logarithmic display transformation must not be silently substituted for a linear power integral.[10]

Copyright 2026, James M. Atkinson

Define the dimensionless overlap factor K_Δ by weighting the translated single-sideband spectrum over the entire channel. This notation separates three questions: which blocker power reached the mixer, which oscillator offsets intersect the channel, and how the observation path weights them. The frequencies with nonzero W are assumed to stay away from the blocker carrier and any excluded zero-offset singularity. Where the response has small tails, their omitted contribution needs a bound rather than an unrecorded truncation.

Equation 22F Weighted oscillator and channel overlap

$$K_\Delta = \int_{-\infty}^{\infty} W(v)\,\ell(\,|\,\Delta - v\,|\,)\,dv$$

Equation 22G Input equivalent and output reciprocal mixing powers

$$N_{RM} = P_B K_\Delta, N_{out} = G\,N_{RM}$$

N_{RM} is the retained reciprocal-mixing power referred to the mixer input, in watts. G is the fixed positive dimensionless power gain from that plane to the reported output, after accounting for the normalized channel response. N_{out} is the corresponding output contribution. Both quantities describe the same added component at different planes. If conversion gain varies appreciably across the admitted noise spectrum, incorporate that frequency dependence into the weighting and revise the normalization; a single G is then insufficient. For a real mixer with another admitted image or conversion path, that path also requires explicit treatment.

When ℓ is constant over every offset carrying significant weight, K_Δ equals that constant times B_{eff}. Replacing it by the value at the center offset is an approximation when the spectrum varies. If lower and upper linear densities bound the entire weighted region, multiplying each bound by B_{eff} encloses

Copyright 2026, James M. Atkinson

K_{Δ}. A single tabulated center value supplies no such enclosure without information about the shape. This is particularly important on a sloping spectrum, near a phase spur, or when the desired channel occupies a substantial fraction of the blocker separation.

Equation 22H Flat spectrum special case

$$N_{RM} = P_B \ell(|\Delta|) B_{eff}(flat\ \ell)$$

Equation 22I Logarithmic form of the flat spectrum result

$$n_{RM} = p_B + L(|\Delta|) + 10\log_{10}\left(\frac{B_{eff}}{1\,Hz}\right)$$

In Equation 22I, p_{B} and n_{RM} are the blocker and added-noise levels in dBm, each defined relative to one milliwatt. L is in dBc/Hz, and the bandwidth ratio is dimensionless. The manufacturer mixer treatment gives the same blocker-power, phase-density, and bandwidth product under a flat-spectrum assumption. Its oscillator-driver discussion also shows why an external oscillator specification need not describe all phase noise present inside the conversion path. The relevant quantity is the effective phase spectrum seen by the admitted blocker.[11]

---

11 Rohde & Schwarz, R&S ESW EMI Test Receiver User Manual, 1177.6298.02, version 18 (2025), §§9.7.1.2–9.7.1.3, 193–94, https://scdn.rohde-schwarz.com/ur/pws/dl_downloads/pdm/cl_manuals/user_manual/1177_6298_01/ESW_UserManual_en_18.pdf. The manual identifies firmware 3.20 and higher; the cited architecture is a specific instrument example.

Copyright 2026, James M. Atkinson

11.26 Convert added power into a conditional noise-rise limit

Let N_0 be the positive baseline noise power referred to the same mixer-input plane, integrated by the same W, with the same conversion gain and processing. Assume its cross power with the retained reciprocal-mixing contribution is zero, so their powers add. Define R as the rise in total noise level in decibels. A finite permissible rise $R_{\max}$, also in decibels and nonnegative, then bounds the allowed added power. This compares noise powers; it does not directly establish detection probability for an unknown waveform or a particular decision rule.

Equation 22J Noise rise from an added uncorrelated contribution

$$R = 10\log_{10}\left(1 + \frac{N_{RM}}{N_0}\right)$$

Equation 22K Reciprocal mixing allowance for a specified rise

$$N_{RM} \le N_0\left(10^{\frac{R_{max}}{10}} - 1\right)$$

The allowance tends to zero as the permissible rise tends to zero. It depends on the baseline: the same added watts produce a larger rise in a quieter receiver. A high initial noise floor can consequently make a blocker appear less damaging by this metric without making weak signals easier to detect. If a blocker changes gain, bandwidth, or baseline noise, the observed on/off ratio no longer isolates Equation 22J. Signal transfer and receiver state must then be measured alongside the apparent floor.

Copyright 2026, James M. Atkinson

11.27 Ten worked applications of Model 11B

Applications 11B.1 through 11B.10 use constructed data and the stated conventions. They test distinct decisions: an ordinary estimate, inversion of an allowance, bandwidth normalization, nonuniform spectral integration, signed offsets, reference-plane translation, multiple blockers, linear subtraction, bounded uncertainty, and the validity of the retained expansion. Except where a failure is expressly examined, gain and filter remain fixed, the blocker carrier is excluded, and baseline and added-noise cross powers vanish. Values are rounded only for presentation; the calculation records retain unrounded quantities.

Copyright 2026, James M. Atkinson

11.28 Application 11B.1 Compute the added noise and its consequence

Take a mixer-input blocker level of minus 30 dBm, equal to 0.000001 W. Let the relevant oscillator density be flat at minus 140 dBc/Hz, so ℓ equals 10 to the minus fourteenth per hertz, across a channel with B_{eff} equal to 200,000 Hz. Multiplication gives K_{Δ} equal to 0.000000002 and N_{RM} equal to 2.000000 times 10 to the minus fifteenth W. The corresponding level is minus 116.989700 dBm. Equivalently, adding minus 30, minus 140, and 53.010300 dB gives the same result.

A baseline of minus 114 dBm is 3.981072 times 10 to the minus fifteenth W. The added-to-baseline ratio is 0.502377, giving a rise of 1.767790 dB. The weaker numerical level of the added component does not make it negligible: it adds approximately half the original noise power. If a fixed output gain of 20 dB were used, both baseline and added powers would rise by that gain and their ratio would remain unchanged. Comparing an output noise level directly with the input-equivalent baseline would instead introduce a false gain factor.

Copyright 2026, James M. Atkinson

11.29 Application 11B.2 Invert a one decibel allowance

Retain the minus 114 dBm baseline and 200,000 Hz bandwidth, but require a noise rise no greater than 1 dB. Ten to the power 0.1 minus one is 0.258925. The allowed added power is therefore 1.030801 times 10 to the minus fifteenth W, or minus 119.868253 dBm. For a minus 30 dBm blocker and the flat-spectrum model, subtracting the blocker level and the 53.010300 dB bandwidth term gives a maximum density of minus 142.878553 dBc/Hz. A more positive density would exceed the allowance.

Alternatively, hold the density at minus 140 dBc/Hz and solve for blocker level. The maximum is minus 32.878553 dBm at the mixer input. This is 2.878553 dB below the original blocker, whereas the original noise rise exceeded the target by only 0.767790 dB. The two differences are not equal because the requirement is on total noise, including N_0. The algebra supplies a conditional allocation. It does not establish that adding an attenuator will achieve it, because an attenuator may also alter desired-signal transfer, input-referred baseline noise, mismatch, or receiver state.

Copyright 2026, James M. Atkinson

11.30 Application 11B.3 Distinguish filter width from noise bandwidth

Construct a finite channel with W equal to one between minus 50 and plus 50 kHz, equal to 0.1 in the two adjoining intervals out to minus and plus 100 kHz, and zero elsewhere. The width of the region at or above half the peak power response is 100 kHz. Its equivalent noise bandwidth is instead 100 kHz plus 0.1 times the combined 100 kHz in the skirts, giving 110 kHz. The abrupt steps are an idealized integration exercise, not a proposed realizable filter shape.

With the minus 30 dBm blocker and flat minus 140 dBc/Hz density over the relevant finite offsets, N_{RM} is 1.100000 times 10 to the minus fifteenth W, or minus 119.586073 dBm. Using 100 kHz would predict minus 120 dBm, an underestimate of 0.413927 dB. No globally white phase process is assumed: the density is declared flat only where this finite filter samples it, with a finite-variance continuation elsewhere. The example isolates the area error. It does not infer the skirts of an unknown filter from a single reported width.

Copyright 2026, James M. Atkinson

11.31 Application 11B.4 Integrate a nonuniform oscillator spectrum

Place a minus 30 dBm blocker at Δ equal to plus 1 MHz and use unit weighting over ν from minus 100 to plus 100 kHz. The oscillator offsets sampled are 900 through 1,100 kHz. Define the density as minus 130 dBc/Hz from 900 to 950 kHz, minus 140 from 950 to 1,050 kHz, and minus 150 from 1,050 to 1,100 kHz. The three linear overlap contributions are respectively 0.000000005, 0.000000001, and 0.00000000005. Their sum is K_{Δ} equal to 0.00000000605.

The resulting added power is 6.050000 times 10 to the minus fifteenth W, or minus 112.182446 dBm. Using only the minus 140 dBc/Hz value at the center offset with the full 200 kHz bandwidth would give minus 116.989700 dBm, underestimating the contribution by 4.807254 dB. Against the minus 114 dBm baseline, the correctly integrated noise rise is 4.013473 dB. The noisiest 50 kHz portion dominates despite occupying only one quarter of the bandwidth. Averaging the three logarithmic density labels would assign a different and unjustified weighting.

Copyright 2026, James M. Atkinson

11.32 Application 11B.5 Preserve the sign of the blocker offset

Use an asymmetric unit-weight channel from v equal to zero through 100 kHz, with zero weight elsewhere. On the offset ranges encountered, let ℓ\(f\) equal C divided by f squared, where C equals 0.01 Hz. This local law has units of inverse hertz; a finite-variance continuation is assumed outside those ranges. Keep P_{B} at minus 30 dBm. For Δ equal to plus 1 MHz, integration gives C times the difference between the reciprocal of 900,000 Hz and the reciprocal of 1,000,000 Hz. Thus K_{Δ} is 1.111111 times 10 to the minus ninth.

For Δ equal to minus 1 MHz, the same observation channel samples offsets from 1,000,000 to 1,100,000 Hz. The integral is C times the difference between their reciprocals, giving 9.090909 times 10 to the minus tenth. The corresponding noise levels are minus 119.542425 and minus 120.413927 dBm. Their 0.871502 dB separation comes from channel asymmetry, although the underlying real-phase spectrum is even. Replacing both signed offsets by a positive number before applying W would erase this distinction. A symmetric filter would remove this particular difference for the stated even spectrum.

Copyright 2026, James M. Atkinson

11.33 Application 11B.6 Move both blocker and desired reference planes

Let $P_{\mathrm{B,ext}}$ be blocker power at an external connector, and let A_B be the positive power transfer from that connector to the mixer at the blocker frequency. Let A_D be the corresponding power transfer for a narrow desired signal at the desired center. Both are dimensionless and can include gain or loss. The desired-external-input-equivalent reciprocal noise is the mixer-input-equivalent noise divided by A_D. Consequently, the blocker rejection relevant to desired-signal comparison is the ratio A_B to A_D.

Equation 22L Blocker transfer and desired input reference

$$P_B = A_B P_{B,ext}$$
$$N_{ext} = \frac{N_{RM}}{A_D} = P_{B,ext} \frac{A_B}{A_D} K_\Delta$$

Take an external blocker of minus 5 dBm, blocker transfer of minus 25 dB, and desired-center transfer of minus 2 dB. The mixer sees minus 30 dBm. With the density and bandwidth of Application 11B.1, its reciprocal contribution remains minus 116.989700 dBm at the mixer-input-equivalent plane. Dividing by the desired power transfer raises the externally referred value to minus 114.989700 dBm. The differential rejection is 23 dB, not the 25 dB blocker loss alone.

This scalar reference conversion applies to the declared narrow desired signal or an adequate constant-transfer approximation across its spectrum. A broad desired waveform requires the frequency-dependent desired transfer and its signal weighting; A_D at one center frequency is not sufficient to refer the entire waveform. Nor does the 23 dB differential figure establish the change in total sensitivity. Noise generated ahead of and behind the

Copyright 2026, James M. Atkinson

selective element and any change in mismatch or gain must be included in the baseline comparison. The example establishes the reference transformation of this one generated contribution.

Copyright 2026, James M. Atkinson

11.34 Application 11B.7 Sum blockers only under an explicit cross-power condition

Let m be a positive integer number of blockers, with index k running from one through m. Each $P_{\mathrm{B},k}$ is a mixer-input blocker power and each Δ_k its signed offset. Sum their reciprocal contributions only if the admitted cross powers vanish under the declared ensemble or averaging procedure. Independent uniform carrier phases, independent also of the phase-noise process, are one sufficient ensemble condition. A shared local oscillator alone does not imply independent contributions. Distinct deterministic carriers can produce cyclostationary cross terms before a justified time average; coincident coherent carriers require field addition.

Equation 22M Multiple blocker power sum under zero cross powers

$$N_{\Sigma}=\sum_{k=1}^{m} P_{B,k} K_{\Delta k}$$

For an explicitly uncorrelated three-contribution case, use 200 kHz effective bandwidth and flat densities over each relevant region. The respective pairs of blocker level and density are minus 30 dBm with minus 140 dBc/Hz, minus 40 dBm with minus 130 dBc/Hz, and minus 35 dBm with minus 145 dBc/Hz. The resulting powers are 2.000000, 2.000000, and 0.200000 times 10 to the minus fifteenth W. Their sum is 4.200000 times 10 to the minus fifteenth W, or minus 113.767507 dBm.

Against the minus 114 dBm baseline, the noise rise is 3.128102 dB. The second blocker is ten decibels weaker than the first, but its phase-noise density is ten decibels higher at the applicable offset; their contributions are equal. The third contributes only one tenth as much. Summing blocker

Copyright 2026, James M. Atkinson

powers before selecting an oscillator offset would hide these differences. If the three admitted contributions have nonzero cross powers, their complex covariance terms must be retained and the numerical sum above is not the applicable model.

Copyright 2026, James M. Atkinson

11.35 Application 11B.8 Infer an effective density from linear subtraction

Suppose the output noise is minus 112 dBm with a blocker absent and minus 107 dBm with it present. Let fixed power gain G be 100, or 20 dB, and B_{eff} be 100 kHz. The mixer-input blocker is minus 20 dBm. Define N_{off} and N_{on} as the two output noise powers in watts. Under unchanged baseline, filter, and gain, and after excluding or bounding other added contributions, their difference is the output reciprocal-mixing power. A negative or unresolved difference cannot support a positive density estimate.

Equation 22N Conditional on and off power subtraction

$$N_{RM} = \frac{N_{on} - N_{off}}{G}$$

Equation 22O Flat effective density inferred from the added power

$$\hat{\ell} = \frac{N_{on} - N_{off}}{G\, P_B B_{eff}}$$

The two output powers are 6.309573 times 10 to the minus fifteenth W and 1.995262 times 10 to the minus fourteenth W. Subtracting in watts gives 1.364305 times 10 to the minus fourteenth W. Dividing by G gives 1.364305 times 10 to the minus sixteenth W, or minus 128.650885 dBm, at the mixer-input-equivalent plane. Division by the blocker power and bandwidth gives an inferred density of minus 158.650885 dBc/Hz. The observed 5 dB rise is a ratio of totals; it is not the added power in either dBm or dBc/Hz.

This inference is attributable to receiver reciprocal mixing only when the other conditions are supported. Analog Devices' single-tone desensitization discussion explicitly includes phase noise from the jammer generator as

Copyright 2026, James M. Atkinson

another route into the measurement. Qualify the stimulus spectrum at the relevant offset, including its path to the receiver, and characterize changes in gain and baseline. Otherwise the inferred number is an effective aggregate under the assumed subtraction model. A quiet source specification at a different offset or reference plane does not resolve the attribution.[12]

11.36 Application 11B.9 Carry hard bounds through the nonlinear noise rise

Suppose the flat-spectrum inputs are known only within a full rectangular set of deterministic bounds: blocker level from minus 30.5 to minus 29.5 dBm, density from minus 142 to minus 138 dBc/Hz, bandwidth from 190 to 210 kHz, and baseline from minus 114.3 to minus 113.7 dBm. A rectangular set means every combination within these limits is admitted. It does not assign statistical independence, a probability distribution, or a coverage probability. Denote the lower and upper blocker levels by p_{minus} and p_{plus}, density limits by L_{minus} and L_{plus}, and bandwidth limits by B_{minus} and B_{plus}.

Equation 22P Monotone bounds for the flat added noise level

$$n_{minus} = p_{minus} + L_{minus} + 10\log_{10}\left(\frac{B_{minus}}{1\,Hz}\right)$$
$$n_{plus} = p_{plus} + L_{plus} + 10\log_{10}\left(\frac{B_{plus}}{1\,Hz}\right)$$

Equation 22P gives added-noise levels from minus 119.712464 to minus 114.277807 dBm, equivalent to 1.068449 through 3.734387 times 10 to the minus fifteenth W. The smallest rise combines the smallest added power with the largest baseline, producing 0.970729 dB. The largest combines the largest added power with the smallest baseline, producing 3.021411 dB. These extrema follow from monotonicity, not from adding logarithmic rise uncertainties. Correlated calibration errors or a restricted feasible set could narrow the interval, but that requires a justified dependency model. Calling this deterministic enclosure a 95 percent interval would add information the premises do not contain.

Copyright 2026, James M. Atkinson

11.37 Application 11B.10 Bound the omitted phase term in the selected channel

A small phase variance motivates the retained approximation but does not alone quantify its error in a narrow selected channel. For any real value of φ, the integral form of the exponential remainder gives the pointwise inequality in Equation 22Q. Squaring and taking expectation gives the second inequality at each time for which the fourth moment exists. Neither inequality requires stationarity. The NIST treatment supplies the small-phase interpretation of single-sideband power and a sinusoidal-modulation benchmark; the bounds here are a separate derivation for the declared stochastic model.[13]

Equation 22Q Pointwise remainder and fourth moment enclosure

$$\left|r(t)\right| \le \frac{\varphi^2(t)}{2}$$
$$E\left[\left|r(t)\right|^2\right] \le \frac{E\left[\varphi^4(t)\right]}{4}$$

To apply a stationary filtered-power bound to the nonlinear remainder, now strengthen the assumptions: φ must be strictly stationary with a finite fourth moment, and Θ_{B} retains its independent uniform distribution. Wide-sense stationarity alone is sufficient for the earlier retained linear spectrum, but does not generally make a nonlinear function of φ stationary. Let P_r be the mean power after filtering the omitted envelope term, and let N_{exact} be the

13 Analog Devices, ADL8201: DC to 30 GHz, RF Limiter, data sheet, rev. 0 (January 2026), tables 1–6, 3–5, https://www.analog.com/media/en/technical-documentation/data-sheets/adl8201.pdf. Device performance, survivability, and absolute maximum ratings have separate conditions; no numerical device rating is transferred to the synthetic front-end cases.

Copyright 2026, James M. Atkinson

filtered power of the full perturbation obtained by subtracting the unmodulated blocker envelope from Equation 22B. These definitions keep direct carrier leakage outside the comparison.

Equation 22R Filtered omitted power under stronger stationarity

$$P_r \leq \frac{P_B E\left[\varphi^4(t)\right]}{4}$$

The filter cannot increase this stationary remainder power because its power weighting is everywhere at most one. The exact perturbation is the sum of retained and omitted envelopes, which need not be uncorrelated. Applying the Cauchy-Schwarz inequality to their filtered cross power yields Equation 22S. Dropping that cross term would give an unjustifiably optimistic error bound. This is an absolute bound on the selected perturbation power, not a claim about the actual sign of the correction.

Equation 22S Selected power error including the cross term

$$\left|N_{exact} - N_{RM}\right| \leq 2\sqrt{N_{RM} P_r} + P_r$$

For a numerical evaluation, additionally give the strictly stationary process a zero-mean Gaussian marginal with standard deviation σ_φ in radians. The fourth moment then has the value in Equation 22T. This marginal condition supplies the moment, not the required stationarity or a particular oscillator spectrum. Retain a minus 30 dBm blocker and a selected first-order power N_{RM} of 2.000000 times 10 to the minus fifteenth W. These values are compatible with many different out-of-channel phase spectra.

Equation 22T Fourth moment of the declared Gaussian marginal

$$E\left[\varphi^4(t)\right] = 3\sigma_\varphi^{\ 4}$$

Copyright 2026, James M. Atkinson

With σ_φ equal to 0.001 rad, the fourth moment is 3.000000 times 10 to the minus twelfth. Equation 22R bounds P_r by 7.500000 times 10 to the minus nineteenth W. Equation 22S then bounds the selected absolute power error by 7.820967 times 10 to the minus seventeenth W, or 3.910483 percent of the retained result. The corresponding upper change in level is 0.166594 dB. This enclosure includes an unknown cross-term sign; the upper logarithmic change is not a symmetric uncertainty interval in decibels.

Increase σ_φ to 0.03 rad while keeping the same selected first-order power by allowing more phase variance elsewhere. The omitted-power bound becomes 6.075000 times 10 to the minus thirteenth W, and the selected absolute-error bound becomes 6.772137 times 10 to the minus thirteenth W. That is 338.606850 times the retained result, permitting an upper level change of 25.309764 dB. The bound is now uninformative for precise channel prediction, although 0.03 rad still appears small as a total rms phase. A loose global bound does not prove a large actual error. It shows that total variance and a fourth moment alone do not localize the omitted spectrum sufficiently.

Copyright 2026, James M. Atkinson

11.38 Use the model to design discriminating receiver observations

The mechanism predicts a retained noise contribution proportional to blocker power while the effective phase spectrum and observation path remain fixed. A one-decibel blocker change therefore changes that contribution by one decibel, but generally changes the total displayed noise by less because baseline power remains. Offset variation probes the weighted oscillator spectrum; bandwidth variation probes its integral. Those interventions provide distinct checks. A fitted line obtained while automatic gain, filter selection, or numerical scaling changes does not test the fixed-state prediction. Record the state and input/output planes alongside each power, not after the fit has been interpreted.

A useful normalization check comes from a small sinusoidal phase modulation of peak β radians. Each first-order sideband has power relative to the carrier of β squared divided by four. Their combined power is β squared divided by two, equal to the phase variance. Thus a single selected sideband uses the single-sideband convention without an additional doubling. This constructed benchmark checks a calculation or implementation; a measured discrete spur still needs its own line-power treatment.[14]

For a survey receiver, the practical result is a conditional operating envelope. Preselection changes admitted blocker power; retuning changes

The ideal product identities are developed in Model 4A; its candidate spur locations do not establish the amplitudes of real mixer products.

Copyright 2026, James M. Atkinson

the oscillator offsets sampled by a fixed channel; another oscillator or conversion path can change the effective phase spectrum. Each intervention must also preserve or remeasure desired-signal transfer and baseline noise. A reduced apparent floor alone cannot establish improved weak-signal detectability if the desired response has fallen as well. The following field-desensitization section therefore requires known references and controlled receiver configurations. Model 11B explains one contribution that such observations can separate, while leaving the full detection and state-response problem open.

Copyright 2026, James M. Atkinson

11.39 Desensitization Tests in Operational Environments

Field desensitization is assessed with known references placed near the search frequency while the site's strong emitters remain present. The reference can be radiated under controlled conditions or injected through a coupler. Its level is stepped, and detection probability or measured amplitude is recorded across receiver settings. Preselection, attenuation, antenna orientation, and location are varied to find a configuration that restores reliable observation.

These tests must not interfere with authorized services or create an unaccounted signal. Coupling, shielding, power, frequency, and timing are controlled. The reference is clearly marked in data and removed before final searches where appropriate. A sensitivity claim without strong-signal context is inadequate for a TSCM survey conducted in a dense RF environment.

Copyright 2026, James M. Atkinson

11.40 Distinguish strong-signal mechanisms through paired interventions

Cubic intermodulation and reciprocal mixing can both obscure a weak component, but their developed models predict different dependencies. Model 11A connects specified parent tones to discrete products under a fixed memoryless cubic law. Model 11B connects admitted blocker power and effective phase-noise density to weighted added noise. Neither model alone covers every desensitization mechanism. Compression, AGC, switching transients, and broadband interference remain alternatives to examine when the observations do not follow the proposed dependence.

Choose an intervention that changes one modeled cause while keeping the observation channel interpretable. Moving a parent frequency tests a product location. Changing admitted blocker power tests a noise contribution. Inserting a preselector changes blocker admission but may also alter desired loss and noise, so preserve its measured transfer and use the appropriate reference-plane correction. A smaller displayed floor after filtering is not automatically an improvement in input-referred sensitivity unless the desired transfer and baseline noise are also accounted for.

An attenuation challenge has a location. Attenuation before a nonlinear stage changes its drive; attenuation after that stage scales an already generated product together with other downstream signals. Model 11A develops this distinction explicitly. Input attenuation can also change a control loop or cause the receiver to choose another gain range. Record those effects and compare the corrected desired reference, not only the

Copyright 2026, James M. Atkinson

unexplained component. An apparent slope that mixes several state transitions is not a clean estimate of nonlinear order.

Copyright 2026, James M. Atkinson

Interpretation is conditional: predicted slopes assume nonlinearity follows the input attenuator and no AGC or noise-floor limitation.

Figure 64. Attenuation challenge for signal origin.

Use off-state and on-state measurements through the same gain and weighting when estimating added noise. Subtract powers in linear units and retain the uncertainty of both measurements. Model 11B shows why a small difference can be poorly determined and why a coherent contaminant

Copyright 2026, James M. Atkinson

cannot be removed by an uncorrelated-power subtraction. If the two states alter the desired transfer, correct that change or redesign the experiment before interpreting the difference as one new noise mechanism.

The synthetic calculations in this chapter provide predictions that can be challenged, not substitute acceptance data. Build the actual receiver matrix around the bands, external paths, blocker environments, signal classes, and recovery intervals expected in use. Include boundary conditions where a procedure must switch configuration or declare insufficient capability. A documented limitation can guide a successful survey; an unqualified dynamic-range number cannot tell the operator which weak observations remain trustworthy.

Copyright 2026, James M. Atkinson

11.41 Dynamic-Range Acceptance Matrix

An operational receiver is accepted against a matrix of weak references, blockers, tone spacings, modulation types, preselector states, gain settings, and recovery intervals. The objective is not to reproduce one catalog number but to establish the safe and useful region for the complete field configuration. Tests extend to band edges, automatic-state changes, and the external preamplifier or splitter paths actually deployed.

Known limitations are encoded in the survey procedure. An instrument may be approved for occupancy search in one band while requiring external preselection or reduced gain in another. Acceptance records include parent signals and products so that field observations can be screened against known residual families.

Copyright 2026, James M. Atkinson

11.42 Quantitative Model for Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization

Equation 1. Third-order input intercept estimate

$$\mathrm{IIP3}_{\mathrm{dBm}} = P_{\mathrm{in,dBm}} + \frac{P_{\mathrm{fund,dBm}} - P_{\mathrm{IM3,dBm}}}{2}$$

For a two-tone test in the linear small-signal region, input third-order intercept is estimated from tone input power and the output separation between fundamentals and third-order products. The sources, combiner, and measurement receiver must contribute negligible products.

Equation 21 is the small-signal, per-tone intercept relation derived in Model 11A and Applications 11A.1–11A.10. A fitted intercept extrapolates the local cubic trend. It is not an operating input power and does not establish source purity, compression behavior, or immunity to a different blocker mechanism.

Equation 2. Spurious-free dynamic range approximation

$$\mathrm{SFDR}_{\mathrm{dB}} \approx \frac{2}{3}\left(\mathrm{IIP3}_{\mathrm{dBm}} - N_{\mathrm{floor,dBm}}\right)$$

For a third-order-limited system with compatible bandwidth and input-referred quantities, spurious-free dynamic range is approximately two thirds of the difference between IIP3 and noise floor. The relation is a simplified planning model and excludes blockers, higher-order effects, compression, and nonwhite noise.

Equation 22 follows directly from the local equal-tone cubic law rather than introducing a separate receiver mechanism. Let p be the numerical input power of either tone in dBm, I the numerical IIP3 at that same plane, and N the input-equivalent noise power in dBm integrated over the declared

Copyright 2026, James M. Atkinson

observation bandwidth. The input-equivalent third-order product level is $3p-2I$. Set that level equal to N and solve for the permitted per-tone level; subtracting N then gives the stated planning range.

Derived form of Equation 22. Equal-tone cubic intersection with the declared noise floor

$$p_{\mathrm{IM3}}=3p-2I,\ p_{\max}=\frac{N+2I}{3},\ p_{\max}-N=\frac{2}{3}(I-N)$$

For the hypothetical values $I=-20\ \mathrm{dBm}$ and $N=-125\ \mathrm{dBm}$, the intersection is $p=-55\ \mathrm{dBm}$ per tone and the difference is 70 dB. The calculation is useful only if the cubic law remains adequate up to that level, the required signal and product bandwidths and planes agree, and compression, phase noise, other spurs, and the desired decision margin do not impose a tighter limit. A nonpositive range, or an intersection outside the characterized cubic interval, supplies no usable operating claim.

Table 1. Chapter 11 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Compression	Input level, gain, output, total power, attenuation state, and recovery	Identifies departure from linear response	Errors can begin before the nominal 1 dB point
Intermodulation	Parent frequencies, levels, spacing, source purity, products, and level slope	Tests nonlinear product generation	The test source or combiner can create the same products

Copyright 2026, James M. Atkinson

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Blocking	Desired reference, blocker level and offset, modulation, sensitivity change, and AGC state	Measures strong-signal desensitization	The blocker may be outside the displayed span
Reciprocal mixing	LO phase noise, blocker offset, floor rise, tuning plan, and preselection	Explains close-in noise elevation	Can resemble environmental noise or dense weak signals

11.43 Hypothetical Applied Calculation: Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization

Two equal input tones at -45 dBm each produce fundamentals at -20 dBm and third-order products at -70 dBm. The 50 dB output separation gives an estimated IIP3 of -20 dBm. If the input-referred noise floor is -125 dBm in the measurement bandwidth, the simplified third-order SFDR estimate is about 70 dB.

Copyright 2026, James M. Atkinson

11.44 Hypothetical Case Adjudication: Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization

A receiver appears unable to detect a calibrated -110 dBm reference near 450 MHz at a city site. A 100 kW broadcast transmitter at a much lower frequency is outside the displayed span but drives the broadband preamplifier. Removing the preamplifier and inserting a high-pass filter restores detection. The failed search configuration is documented as desensitized.

Copyright 2026, James M. Atkinson

11.45 Memory-dependent intermodulation and the limits of static intercept-point inference

A familiar two-tone third-order-intercept model describes a bounded small-signal region of a nonlinear device. It should not be converted into a universal prediction for an antenna-connected receiver whose gain control, bias conditions and protection network have memory. A memoryless cubic relation $y(t) = a_1 x(t) + a_3 x(t)^3$ can explain third-order products near $2f_1 - f_2$ and $2f_2 - f_1$ for two inputs, but the coefficients may depend on drive level, frequency, temperature and history. More elaborate models require convolution or state variables because a carrier arriving immediately after a strong blocker may experience different gain than the same carrier arriving in a settled state. A high intercept figure measured on a static two-tone laboratory fixture cannot certify transient detection performance under arbitrary pulsed interferers.

For a hypothetical two-tone equal-level test, suppose the fundamental output increases by 1 dB when each input rises by 1 dB, while a third-order product rises by 3 dB over the demonstrated local region. If the measured fundamental exceeds its extrapolated third-order product by 42 dB at a given input level, then a straight-line output intercept estimate lies 21 dB above that input level in the same coordinate convention. This is an extrapolation of two local slopes, not proof that hardware can physically accept that much power without compression or damage. If a bias loop changes between steps, the slope is not the one stipulated by the elementary construction. The report should retain the input levels,

Copyright 2026, James M. Atkinson

measured slopes, uncertainties and conditions that justify using that straight-line model.

A more discriminating experiment varies tone separation and stimulus order. Certain bias and thermal effects become apparent when the tones are moved or the duty factor changes while their total mean power is kept nominally fixed. Record whether the product appears at the external reference plane, within a combiner, after a gain stage or only after downstream sampling and processing. A simple input attenuation test can offer evidence about location but is not conclusive when the attenuator simultaneously changes automatic gain state. A suitable reference measurement independently bounds source harmonics and combiner intermodulation. Without that control the receiver may be blamed for products already generated in the test apparatus, thereby producing a reproducible but incorrect system diagnosis.

Report compression, blocking, desensitisation, reciprocal mixing and discrete intermodulation as different outcomes. Compression concerns changed transfer for the desired signal; blocking can reduce gain or operation even without a new spectral line; reciprocal mixing can raise local noise; intermodulation can produce discrete frequencies. One event may induce several concurrently. A forensic record should include the affected weak-reference response and its recovery interval, rather than merely counting visible products. This is especially important when the questioned phenomenon is intermittent and the system's recovery behaviour determines whether the next emission could have been observed at all.

Copyright 2026, James M. Atkinson

11.46 Advanced technical expansion. Memory-dependent nonlinearities and multicarrier stress

A receiver's large-signal response cannot always be described by a single third-order intercept point. Input intercept and output intercept are useful approximations for a bounded two-tone test conducted in a small enough region that the corresponding polynomial terms dominate. Under operational multicarrier exposure, amplifier bias, thermal feedback, automatic control and memory in filters or protection elements may change the response dynamically. An architecture can pass a continuous-wave two-tone test yet produce transient desensitisation or spectral regrowth when subjected to a high-crest-factor waveform. The appropriate model begins by defining the waveforms, their instantaneous amplitude distribution and the operating states of all vulnerable elements. It is not enough to add average powers and assume that the sum defines the worst instantaneous condition.

A memoryless polynomial model $y = a_1x + a_3x^3$ can identify the frequencies of some third-order products, but a Volterra-type representation allows output at one time to depend on combinations of earlier inputs. Such models are powerful precisely because they distinguish instantaneous amplitude from waveform history. Their coefficients cannot be inferred from a single intercept figure, and their use must be limited by the experiments that identify them. If a device under test has a gain-control loop, bias network or thermal time constant, a long burst and a short burst with equal peak level can have different distortion and recovery behaviour. The examiner must therefore preserve burst duration and duty factor as

Copyright 2026, James M. Atkinson

independent test dimensions. Results obtained at one temperature or repetition rate are conditional, not blanket device ratings.

The crest factor of a waveform is the ratio of its peak magnitude to its RMS magnitude under an explicitly stated averaging interval. A 12-dB peak-to-average power ratio corresponds to a peak power approximately 15.85 times the average. Thus a multicarrier signal with mean power -20 dBm can, under that stipulated ratio, reach a peak power near -8 dBm even before gain changes are considered. These values do not prove compression in a particular amplifier. They demonstrate why the stage-level peak must be compared with an experimentally supported input envelope rather than an attractive average-power budget. A limiter may respond to peaks, while a slowly adapting AGC responds to a different statistic and timescale. Their combined behaviour can create a weak-event blind interval extending beyond the duration of the principal blocker.

Reciprocal mixing adds another dependency. Phase noise around an oscillator can mix the energy of a strong blocker into the weak desired channel, even though a narrow final display excludes the blocker itself. A prediction based on phase-noise density requires the blocker power at the relevant conversion plane, oscillator spectrum under the actual state, and the filter weighting of the desired channel. Integrating phase-noise density over an offset band yields different results from using its value at one representative offset. A broad blocker whose own modulation creates in-band sidebands requires an additional source-path noise measurement, or a reciprocal-mixing conclusion may be confounded by the blocker source's actual spectrum. Changing LO conditions while maintaining comparable wanted-signal sensitivity is a useful discriminating experiment.

Copyright 2026, James M. Atkinson

The most informative acceptance protocol combines a calibrated weak reference with one or more controlled blockers. It first measures the quiet weak-reference response and noise; it then introduces blockers one at a time, followed by combined conditions, while retaining raw IF or complex samples and all gain states. Measure compression, intermodulation, noise-floor displacement, recovery duration and false detections as separate outputs. Repeat with the front-end attenuation and preselection changes that the competing hypotheses predict should matter. If the weak reference vanishes because a changed filter rejected it, the trial does not demonstrate improved blocking immunity. If a nonlinear line disappears only after a generator combiner is changed, the observed mechanism may not be in the receiver at all. A valid operating envelope must follow the physical paths and actual experimental controls, not merely the most favourable trace.

A resulting survey report should distinguish a measured blocker response from an extrapolation to unknown environmental signals. State the source levels, modulation, crest factor, temperature, reference plane, receiver path and tested duration range. Explain which waveform families were challenged and which remain outside the accepted envelope. A gain-corrected display that returns to its initial level does not establish that all intermediate samples were valid. Preserve bad intervals, overload indicators and subsequent closing checks. This produces a useful technical conclusion even when a receiver architecture is found to be unsuitable for a particular strong-signal environment: the constraint is established, bounded and reproducible rather than hidden inside a nominal dynamic-range specification.

Copyright 2026, James M. Atkinson

11.47 Whole-band loading and dynamic-range penalties in parallel forty-gigahertz capture

Simultaneous wideband acquisition exposes a receiver to an unusually large set of possible blockers. The required input protection depends on the power which reaches each vulnerable stage, not on the amplitude of a narrow detected line after GPU channelisation. Forty gigahertz of nominal coverage can be partitioned into many independently preselected slices, but each slice must have measured rejection outside its intended passband and sufficient headroom for the local electromagnetic environment. A high-gain front end chosen only to reach minus-170-dBm/Hz noise density may be driven into compression by an unrelated broadcast or radar signal. Once a mixer, amplifier or ADC clips, no subsequent fine-resolution FFT can restore the lost weak signal, even though the resulting software spectrum may look remarkably clean.

The aggregate spectral display also has a correlated-error problem. A common clock harmonic may create apparent emissions in many slices. A spur from an FPGA lane or power supply may repeat at regular frequency offsets. Frequency translation can mirror an unwanted tone into a nominally empty band. When two independent antennas reveal the same feature, the conclusion is stronger only if they also change relevant system-error paths. A useful acceptance test injects a deliberately placed weak reference near a strong blocker and verifies its recovery while varying input attenuation, preselection and conversion state. The experiment should measure not only recovered tone amplitude but also spectral products, noise-floor elevation, missed bursts and recovery time.

Copyright 2026, James M. Atkinson

The fundamental objective is a map of valid operating conditions. At every frequency slice and gain state, document the maximum admitted signal envelope, noise density, measured spurious-free dynamic range, conversion image rejection, timing coherence and frequency-dependent calibration uncertainty. A low-level signal that is measurable in a quiet terminated-input test may be unmeasurable during a strong event. The valid finding should therefore specify frequency, observation time, event class and interference envelope instead of expressing dynamic range as a single catalogue number. That approach makes the forty-gigahertz design technically testable and enables engineering decisions about front-end allocation, isolation, attenuator placement and whether additional analogue preselection is needed.

Copyright 2026, James M. Atkinson

Chapter Summary

Receiver capability is determined by noise and strong-signal behavior together. Compression, intermodulation, blocking, reciprocal mixing, and recovery tests define whether a weak observation is credible in the actual environment.

Model 11A starts from loaded voltages and a fixed memoryless cubic law. It distinguishes per-tone powers, unequal products, reference resistances and linear-asymptote intercepts. Measured fundamentals can carry a finite correction, and a small observed product can hide coherent contamination. The resulting spurious-free-range estimate remains conditional on the same local model and noise definition.

Model 11B instead integrates translated oscillator phase noise through the actual observation-channel weighting. Admitted blocker power, signed offset, gain and baseline remain explicit. Power subtraction, deterministic bounds and omitted-term analysis preserve their different assumptions. A flat-density shortcut or a small total phase variance does not automatically justify a precise narrow-channel result.

Useful challenges retain a controlled weak reference while changing a predicted cause. Recheck desired transfer and receiver state when adding attenuation, preselection or retuning. Characterize recovery as an observation exclusion where needed. The acceptance matrix records the tested configurations and limitations, allowing later findings to remain within demonstrated capability rather than a generic dynamic-range label.

Chapter 11 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C11-MCQ-001. Why cannot one catalog dynamic-range number establish survey capability?

A. Display range always equals usable weak-signal range

B. Digitizer range automatically determines analog blocking

C. Different definitions use different limits, bandwidths, spacings, detectors, and tests

D. The largest quoted number includes every strong-signal mechanism

Answer: C. The relevant capability is configuration- and signal-condition-specific.

Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

Why the selected alternative fits: Different definitions use different limits, bandwidths, spacings, detectors, and tests.

Distinguishing consideration: compare this with option A, “Display range always equals usable weak-signal range”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Dynamic Range Is a Family of Conditions.

Review: Chapter 11 — Dynamic Range Is a Family of Conditions.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-002. What is the practical strong-signal question for a receiver?

A. Whether the display can draw a large amplitude interval

B. Whether a catalog intercept exceeds the nominal input level

C. Whether a specified weak signal can be detected or measured with stated stronger signals present

D. Whether one bench sensitivity value is numerically small

Answer: C. The required weak observation, environment, and receiver state define the useful test. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

Why the selected alternative fits: Whether a specified weak signal can be detected or measured with stated stronger signals present.

Distinguishing consideration: compare this with option A, “Whether the display can draw a large amplitude interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Dynamic Range Is a Family of Conditions.

Review: Chapter 11 — Dynamic Range Is a Family of Conditions.

V011-C11-MCQ-003. Why retain an independent weak probe while varying a blocker?

A. The probe makes all receiver stages linear

B. The blocker alone uniquely measures every detection threshold

C. A weak probe guarantees unchanged AGC state

D. The blocker output can remain plausible while weak-signal capability degrades

Answer: D. Controlled desired-signal response reveals loss of the capability the blocker can obscure. Source: §11.3 Measure compression without confusing it with control action (p. 6365)

Why the selected alternative fits: The blocker output can remain plausible while weak-signal capability degrades.

Distinguishing consideration: compare this with option A, “The probe makes all receiver stages linear”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Measure compression without confusing it with control action.

Review: Chapter 11 — Measure compression without confusing it with control action.

V011-C11-MCQ-004. An AGC state changes during an input sweep. What does the resulting curve describe?

A. Only the calibrated source output

B. A pure fixed-coefficient compression curve by definition

C. Closed-loop receiver behavior rather than a fixed-state stage transfer alone

D. A universal intercept independent of control state

Answer: C. State changes can alter gain separately from fixed-stage compression and must be labeled. Source: §11.3 Measure compression without confusing it with control action (p. 6365)

Why the selected alternative fits: Closed-loop receiver behavior rather than a fixed-state stage transfer alone.

Distinguishing consideration: compare this with option A, “Only the calibrated source output”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Measure compression without confusing it with control action.

Review: Chapter 11 — Measure compression without confusing it with control action.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-005. After a strong pulse, what determines the recovery exclusion for a weak observation?

A. A universal one-pole constant for every receiver

B. When the controlled weak probe again meets its stated criterion under the tested prior state

C. The time at which the strong pulse's screen trace disappears alone

D. The nominal sweep duration regardless of gain recovery

Answer: B. Recovery is mechanism- and state-dependent; invalid intervals bound usable observation. Source: §11.3 Measure compression without confusing it with control action (p. 6365)

Why the selected alternative fits: When the controlled weak probe again meets its stated criterion under the tested prior state.

Distinguishing consideration: compare this with option A, “A universal one-pole constant for every receiver”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Measure compression without confusing it with control action.

Review: Chapter 11 — Measure compression without confusing it with control action.

V011-C11-MCQ-006. Can a blocker outside the displayed span reduce weak in-span sensitivity?

A. Yes, it can stress earlier stages or control behavior

B. No, the final display span physically rejects it at the antenna

C. Only when the receiver has no preamplifier

D. Only if its carrier appears in the final RBW

Answer: A. Final span does not define all energy admitted to earlier stages. Source: §11.21 Blocking and Reciprocal Mixing (p. 6391)

Why the selected alternative fits: Yes, it can stress earlier stages or control behavior.

Distinguishing consideration: compare this with option B, “No, the final display span physically rejects it at the antenna”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Blocking and Reciprocal Mixing.

Review: Chapter 11 — Blocking and Reciprocal Mixing.

V011-C11-MCQ-007. Why define the model's input amplitudes at the loaded reference plane?

A. Peak voltage can be used as RMS without conversion

B. A generator's open-circuit voltage always equals the load voltage

C. Loaded and available powers agree for every mismatch

D. Delivered voltage and resistance determine power; open-circuit settings need not equal them

Answer: D. The matched condition permits available and delivered powers to coincide; otherwise establish the actual loaded quantity. Source: §11.6 Fix the voltage convention and operating domain (p. 6368)

Why the selected alternative fits: Delivered voltage and resistance determine power; open-circuit settings need not equal them.

Distinguishing consideration: compare this with option A, “Peak voltage can be used as RMS without conversion”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Fix the voltage convention and operating domain.

Review: Chapter 11 — Fix the voltage convention and operating domain.

V011-C11-MCQ-008. Does the declared odd cubic law predict second-order sum and difference products?

A. Only if the two input powers are equal

B. Yes; every cubic coefficient automatically includes a square term

C. No; those require an omitted term or another mechanism

D. Yes; every observed product validates the odd-only restriction

Answer: C. The restriction is mathematical, not a claim that actual hardware lacks even-order behavior. Source: §11.6 Fix the voltage convention and operating domain (p. 6368)

Why the selected alternative fits: No; those require an omitted term or another mechanism.

Distinguishing consideration: compare this with option A, “Only if the two input powers are equal”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Fix the voltage convention and operating domain.

Review: Chapter 11 — Fix the voltage convention and operating domain.

V011-C11-MCQ-009. What are the units of the cubic voltage coefficient a_3?

A. Watts

B. Inverse square volts

C. Dimensionless power gain

D. Volts squared

Answer: B. Multiplying a_3 by voltage cubed must yield output voltage. Source: §11.6 Fix the voltage convention and operating domain (p. 6368)

Why the selected alternative fits: Inverse square volts.

Distinguishing consideration: compare this with option A, “Watts”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Fix the voltage convention and operating domain.

Review: Chapter 11 — Fix the voltage convention and operating domain.

V011-C11-MCQ-010. For voltage gain a1, what is the small-signal power gain with loaded resistances R_i and R_o?

A. a1 squared for all impedance choices

B. a1 divided by two

C. a1 times R_o divided by R_i

D. a1 squared times R_i divided by R_o

Answer: D. Power conversion includes both reference resistances; equal-resistance simplification is conditional. Source: §11.6 Fix the voltage convention and operating domain (p. 6368)

Why the selected alternative fits: a1 squared times divided by.

Distinguishing consideration: compare this with option A, “a1 squared for all impedance choices”; that competing statement does not meet the question’s stated requirement.

V011-C11-MCQ-013. Which input combination governs the lower close-in product's voltage magnitude in the model?

A. First-tone peak squared times second-tone peak

B. The average of the two tone powers only

C. The sum of the two peak voltages only

D. First-tone peak times second-tone peak squared

Answer: A. The coefficient at twice f1 minus f2 contains A1 squared times A2.

Source: §11.7 Derive the retained spectral amplitudes (p. 6370)

Why the selected alternative fits: First-tone peak squared times second-tone peak.

Distinguishing consideration: compare this with option B, “The average of the two tone powers only”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Derive the retained spectral amplitudes.

V011-C11-MCQ-014. Increasing only the first parent power by 2 dB produces what product-power changes in the valid fixed cubic model?

A. Lower product plus 2 dB and upper product plus 4 dB

B. Both products plus 2 dB

C. Lower product plus 4 dB and upper product plus 2 dB

D. Both products plus 6 dB

Answer: C. The unequal-tone laws contain P1 squared P2 and P1 P2 squared, respectively. Source: §11.8 Construct the intercept from the linear asymptote (p. 6373)

Why the selected alternative fits: Lower product plus 4 dB and upper product plus 2 dB.

Distinguishing consideration: compare this with option A, “Lower product plus 2 dB and upper product plus 4 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Construct the intercept from the linear asymptote.

V011-C11-MCQ-015. Can equal observed product powers determine the sign of a_3?

A. Yes; equal powers require negative a_3

B. No; power discards the signed coefficient

C. Only if input powers are equal, regardless of phase evidence

D. Yes; equal powers require positive a_3

Answer: B. Fundamental gain change or appropriately referenced phase is needed to distinguish the constructed signs. Source: §11.9 Ten worked applications of Model 11A (p. 6376)

Why the selected alternative fits: No; power discards the signed coefficient.

Distinguishing consideration: compare this with option A, "Yes; equal powers require negative"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-MCQ-018. If the measured fundamental differs from its linear asymptote by delta g dB, what bias enters the input-intercept estimate using that one value?

A. Twice delta g

B. All of delta g

C. One half of delta g

D. Three halves of delta g

Answer: C. Input extraction contains one half of the fundamental-to-product level difference. Source: §11.8 Construct the intercept from the linear asymptote (p. 6373)

Why the selected alternative fits: One half of delta g.

Distinguishing consideration: compare this with option A, “Twice delta g”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Construct the intercept from the linear asymptote.

Review: Chapter 11 — Construct the intercept from the linear asymptote.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-019. If that measured value is used in the output-intercept formula, what is the resulting gain-change bias?

A. Zero for every gain change

B. Three halves of delta g

C. Minus all of delta g

D. One half of delta g

Answer: B. The output formula gives the fundamental level coefficient three halves.

Source: §11.8 Construct the intercept from the linear asymptote (p. 6373)

Why the selected alternative fits: Three halves of delta g.

Distinguishing consideration: compare this with option A, “Zero for every gain change”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Construct the intercept from the linear asymptote.

Review: Chapter 11 — Construct the intercept from the linear asymptote.

V011-C11-MCQ-035. A coherent contaminant bound equals the measured spur magnitude. What happens to an upper intercept bound under this observation model?

A. The contaminant power may simply be subtracted as independent noise

B. No finite upper bound follows because arbitrarily small positive stage products remain possible

C. The intercept is exactly zero dBm

D. The measured spur becomes an exact stage-power estimate

Answer: B. The phasor enclosure reaches zero; the nonzero cubic coefficient does not provide a positive measured lower magnitude. Source: §11.9 Ten worked applications of Model 11A (p. 6376)

Why the selected alternative fits: No finite upper bound follows because arbitrarily small positive stage products remain possible.

Distinguishing consideration: compare this with option A, “The contaminant power may simply be subtracted as independent noise”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11A.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-MCQ-036. Which mechanism can raise apparent channel noise around a strong blocker without discrete cubic products?

A. Only the ideal quantizer bit count

B. Only a wider display amplitude range

C. Only third-harmonic generation

D. Reciprocal mixing through oscillator phase noise

Answer: D. The blocker translates oscillator phase fluctuations into the observation channel. Source: §11.21 Blocking and Reciprocal Mixing (p. 6391)

Why the selected alternative fits: Reciprocal mixing through oscillator phase noise.

Distinguishing consideration: compare this with option A, “Only the ideal quantizer bit count”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Blocking and Reciprocal Mixing.

Review: Chapter 11 — Blocking and Reciprocal Mixing.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-037. What does blocker power in Model 11B refer to?

A. The final displayed carrier level regardless of gain

B. Power at the mixer input after preceding gain and selection

C. Always the signal generator's setting

D. Always the antenna-connector power without correction

Answer: B. The admitted power and its plane are essential to the generated-noise prediction. Source: §11.24 Translate one blocker through the fluctuating oscillator (p. 6396)

Why the selected alternative fits: Power at the mixer input after preceding gain and selection.

Distinguishing consideration: compare this with option A, “The final displayed carrier level regardless of gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Translate one blocker through the fluctuating oscillator.

Review: Chapter 11 — Translate one blocker through the fluctuating oscillator.

V011-C11-MCQ-038. Why is the two-sided phase density not doubled again in the reciprocal-mixing integral?

A. The phase process is complex rather than real

B. The observation filter automatically halves all powers

C. Every two-sided density contains no negative frequencies

D. At positive offset it already equals the declared single-sideband density

Answer: D. The one-sided phase density is twice this value; another factor of two would double-count under the defined convention. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why the selected alternative fits: At positive offset it already equals the declared single-sideband density.

Distinguishing consideration: compare this with option A, “The phase process is complex rather than real”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-039. What stationarity suffices for the retained linear phase-noise spectrum?

A. No second-order stationarity or finite variance

B. Zero-mean wide-sense stationarity with finite variance

C. Only a deterministic sinusoid with no noise

D. Strict stationarity with Gaussian marginals is always necessary at this first step

Answer: B. The stronger nonlinear-remainder conditions are separate from the retained second-order spectrum. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why the selected alternative fits: Zero-mean wide-sense stationarity with finite variance.

Distinguishing consideration: compare this with option A, “No second-order stationarity or finite variance”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

V011-C11-MCQ-040. How should dBc/Hz values enter a weighted power-density integral?

A. Average the logarithmic labels without bandwidth weights

B. Convert each to its linear inverse-hertz density first

C. Add the dBc/Hz numbers directly across frequency

D. Treat each dBc/Hz label as a discrete line power

Answer: B. The integral sums linear density times bandwidth weighting; logarithmic labels cannot be integrated as powers directly. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why the selected alternative fits: Convert each to its linear inverse-hertz density first.

Distinguishing consideration: compare this with option A, “Average the logarithmic labels without bandwidth weights”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-041. How should a discrete oscillator phase spur be handled?

A. As a density value multiplied by arbitrary one-hertz bins

B. As zero because the ordinary-density model excludes it

C. By averaging its dBc label with the continuous floor

D. As a spectral line with its own integrated power contribution

Answer: D. A line and an ordinary density have different representations; the defined density assumption does not erase spurs. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why the selected alternative fits: As a spectral line with its own integrated power contribution.

Distinguishing consideration: compare this with option A, “As a density value multiplied by arbitrary one-hertz bins”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

V011-C11-MCQ-042. Which phase-spectrum extension is inadmissible in the stated finite-variance model?

A. Extending a divergent close-in law to zero or infinity without a valid continuation

B. Using an even real-phase density over the specified offsets

C. Integrating a finite admitted offset band

D. Bounding omitted filter-tail contributions

Answer: A. A density whose integral diverges contradicts the assumed finite phase variance. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why the selected alternative fits: Extending a divergent close-in law to zero or infinity without a valid continuation.

Distinguishing consideration: compare this with option B, “Using an even real-phase density over the specified offsets”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

V011-C11-MCQ-043. What translates the oscillator phase spectrum to a blocker's neighborhood?

A. The logarithmic display axis

B. Multiplication by the blocker carrier exponential

C. The nominal RBW label alone

D. A universal additive broadband source independent of blocker power

Answer: B. Frequency translation and blocker amplitude scaling produce the retained perturbation spectrum. Source: §11.24 Translate one blocker through the fluctuating oscillator (p. 6396)

Why the selected alternative fits: Multiplication by the blocker carrier exponential.

Distinguishing consideration: compare this with option A, “The logarithmic display axis”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Translate one blocker through the fluctuating oscillator.

Review: Chapter 11 — Translate one blocker through the fluctuating oscillator.

V011-C11-MCQ-044. Which contribution remains separate from the reciprocal-mixing calculation?

A. The retained phase-noise sidebands

B. Direct leakage of the nominal blocker carrier

C. The admitted blocker level used in the model

D. The specified observation-channel weighting

Answer: B. Carrier leakage must be negligible or independently characterized; the perturbation model does not predict it. Source: §11.24 Translate one blocker through the fluctuating oscillator (p. 6396)

Why the selected alternative fits: Direct leakage of the nominal blocker carrier.

Distinguishing consideration: compare this with option A, “The retained phase-noise sidebands”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Translate one blocker through the fluctuating oscillator.

Review: Chapter 11 — Translate one blocker through the fluctuating oscillator.

V011-C11-MCQ-045. What is the observation filter's power weighting W?

A. Its nominal bandwidth label

B. Its complex phase alone

C. Squared magnitude of its complex response

D. Its voltage response without squaring

Answer: C. The integrated power uses the actual squared response and the stated normalization. Source: §11.25 Integrate the channel that actually produces the reported value (p. 6398)

Why the selected alternative fits: Squared magnitude of its complex response.

Distinguishing consideration: compare this with option A, “Its nominal bandwidth label”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Integrate the channel that actually produces the reported value.

Review: Chapter 11 — Integrate the channel that actually produces the reported value.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-046. Why require the center response to equal one in this model?

A. To make every filter's bandwidth one hertz

B. To force all phase noise to be white

C. To guarantee the blocker carrier is removed

D. To define gain and input-equivalent power consistently

Answer: D. The desired-center normalization separates a fixed gain from channel weighting. Source: §11.25 Integrate the channel that actually produces the reported value (p. 6398)

Why the selected alternative fits: To define gain and input-equivalent power consistently.

Distinguishing consideration: compare this with option A, “To make every filter's bandwidth one hertz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Integrate the channel that actually produces the reported value.

Review: Chapter 11 — Integrate the channel that actually produces the reported value.

V011-C11-MCQ-047. When is using only center-offset phase-noise density exact?

A. Whenever the RBW label is available

B. When the density is flat over all significantly weighted offsets

C. Whenever the blocker is one megahertz away

D. Whenever a log plot looks smooth

Answer: B. Otherwise the shortcut needs a justified approximation or spectral bounds over the weighted region. Source: §11.25 Integrate the channel that actually produces the reported value (p. 6398)

Why the selected alternative fits: When the density is flat over all significantly weighted offsets.

Distinguishing consideration: compare this with option A, “Whenever the RBW label is available”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Integrate the channel that actually produces the reported value.

Review: Chapter 11 — Integrate the channel that actually produces the reported value.

V011-C11-MCQ-048. Does equal blocker separation above and below the center guarantee equal added noise?

A. No, an asymmetric observation filter can weight different offsets

B. Only the sign of the receiver gain determines the answer

C. Yes, even phase density makes every signed translation identical

D. Yes, because only absolute blocker frequency matters

Answer: A. Even phase spectrum does not remove signed-offset effects relative to asymmetric W. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: No, an asymmetric observation filter can weight different offsets.

Distinguishing consideration: compare this with option B, “Only the sign of the receiver gain determines the answer”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11B.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-MCQ-049. What filter quantity replaces a nominal width in the flat-density added-noise expression?

A. Equivalent noise bandwidth from the integral of W

B. Only the 3 dB width for every implementation

C. The number of output channels

D. The entire RF tuning range

Answer: A. Actual area under the power weighting determines admitted flat-density noise. Source: §11.25 Integrate the channel that actually produces the reported value (p. 6398)

Why the selected alternative fits: Equivalent noise bandwidth from the integral of W.

Distinguishing consideration: compare this with option B, “Only the 3 dB width for every implementation”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Integrate the channel that actually produces the reported value.

Review: Chapter 11 — Integrate the channel that actually produces the reported value.

V011-C11-MCQ-050. A filter has unit power weight over 100 kHz and weight 0.1 over another total 100 kHz. What is its equivalent noise bandwidth?

A. 110 kHz

B. 200 kHz

C. 10 kHz

D. 100 kHz

Answer: A. The weighted area is 100 plus 0.1 times 100 kHz. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: 110 kHz.

Distinguishing consideration: compare this with option B, “200 kHz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11B.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-MCQ-051. Under the flat-density model, blocker level is minus 30 dBm, density minus 140 dBc/Hz, and bandwidth 200 kHz. What added level follows?

A. Minus 170 dBm

B. Minus 110 dBm

C. About minus 116.99 dBm

D. About minus 113.98 dBm

Answer: C. Add the blocker, density, and 53.0103 dB bandwidth term without an extra sideband factor. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: About minus 116.99 dBm.

Distinguishing consideration: compare this with option A, “Minus 170 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-MCQ-052. Which ratio controls externally referred reciprocal noise relative to a narrow desired signal?

A. Blocker transfer divided by desired transfer

B. Desired transfer divided by blocker transfer

C. The product of the two transfers without referral

D. Blocker transfer alone

Answer: A. The mixer contribution must be divided by desired transfer to refer it to the external desired-input plane. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: Blocker transfer divided by desired transfer.

Distinguishing consideration: compare this with option B, “Desired transfer divided by blocker transfer”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-MCQ-053. Blocker loss is 25 dB and desired loss is 2 dB. What differential rejection enters that reference comparison?

A. 2 dB

B. 27 dB

C. 25 dB

D. 23 dB

Answer: D. The blocker-to-desired power-transfer ratio contains the difference of losses. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: 23 dB.

Distinguishing consideration: compare this with option A, “2 dB”; that competing statement does not meet the question’s stated requirement.

V011-C11-MCQ-054. Why is one center-frequency desired transfer insufficient for a broad waveform?

A. Broad signals have no input reference plane

B. The desired loss is always frequency-independent

C. A broad waveform automatically removes phase-noise contributions

D. Its frequency-dependent signal weighting may matter

Answer: D. The scalar referral is valid for a narrow signal or a justified constant-transfer approximation. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: Its frequency-dependent signal weighting may matter.

Distinguishing consideration: compare this with option A, “Broad signals have no input reference plane”; that competing statement does not meet the question’s stated requirement.

V011-C11-MCQ-055. May several blocker contributions be power-summed merely because they share one LO?

A. Only if all blockers have equal power, regardless of phase

B. Yes; distinct carriers never have cross terms

C. No; admitted cross powers must vanish under a justified ensemble or averaging

D. Yes; a common LO ensures independence

Answer: C. Shared phase processes do not establish uncorrelated contributions; coherent cases can require field addition. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: No; admitted cross powers must vanish under a justified ensemble or averaging.

Distinguishing consideration: compare this with option A, “Only if all blockers have equal power, regardless of phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-MCQ-056. What condition allows baseline and added reciprocal-noise powers to add in the rise formula?

A. The blocker is outside the displayed span

B. Zero cross power with unchanged gain and weighting

C. The baseline is expressed in dBm

D. The total noise image is visually smooth

Answer: B. The formula is conditional on compatible quantities and an uncorrelated-power decomposition. Source: §11.26 Convert added power into a conditional noise-rise limit (p. 6401)

Why the selected alternative fits: Zero cross power with unchanged gain and weighting.

Distinguishing consideration: compare this with option A, “The blocker is outside the displayed span”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Convert added power into a conditional noise-rise limit.

Review: Chapter 11 — Convert added power into a conditional noise-rise limit.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-057. If added power equals half the positive baseline, what is total noise rise?

A. Minus 3.010 dB

B. 0.5 dB

C. About 1.761 dB

D. 3.010 dB

Answer: C. The total-to-baseline ratio is 1.5, whose ten-times logarithm is about 1.761 dB. Source: §11.26 Convert added power into a conditional noise-rise limit (p. 6401)

Why the selected alternative fits: About 1.761 dB.

Distinguishing consideration: compare this with option A, “Minus 3.010 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Convert added power into a conditional noise-rise limit.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-058. For a one-decibel rise limit, the permitted added power is approximately what fraction of baseline?

A. 0.1

B. 1

C. 0.2589

D. 1.2589

Answer: C. The allowance is ten to 0.1 minus one, not the total ratio itself. Source: §11.26 Convert added power into a conditional noise-rise limit (p. 6401)

Why the selected alternative fits: 0.2589.

Distinguishing consideration: compare this with option A, “0.1”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Convert added power into a conditional noise-rise limit.

Review: Chapter 11 — Convert added power into a conditional noise-rise limit.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-059. Why can the same added watts give a smaller rise in a noisier receiver?

A. The added-to-baseline ratio is smaller

B. The noise-rise formula ignores baseline

C. Added power becomes negative in a noisy receiver

D. The higher baseline improves weak-signal detectability automatically

Answer: A. A smaller relative rise need not mean better absolute sensitivity. Source: §11.26 Convert added power into a conditional noise-rise limit (p. 6401)

Why the selected alternative fits: The added-to-baseline ratio is smaller.

Distinguishing consideration: compare this with option B, “The noise-rise formula ignores baseline”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Convert added power into a conditional noise-rise limit.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-060. Why is a five-decibel on/off increase not five dBm of added noise?

A. The on value alone is the added component

B. The off value should be subtracted from blocker frequency

C. It is a ratio of totals; subtract compatible linear powers first

D. Decibel differences always equal added watts

Answer: C. Refer the positive difference through fixed gain and exclude other changed contributions before inferring a density. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: It is a ratio of totals; subtract compatible linear powers first.

Distinguishing consideration: compare this with option A, “The on value alone is the added component”; that competing statement does not meet the question’s stated requirement.

V011-C11-MCQ-061. What does the deterministic rise interval from a full rectangular set of input bounds establish?

A. Statistical independence of calibration errors

B. An automatic 95 percent confidence interval

C. An enclosure for all admitted combinations, with no coverage probability

D. A probability distribution inferred from endpoint counts

Answer: C. Hard bounds and stochastic uncertainty claims require different premises. Source: §11.27 Ten worked applications of Model 11B (p. 6402)

Why the selected alternative fits: An enclosure for all admitted combinations, with no coverage probability.

Distinguishing consideration: compare this with option A, “Statistical independence of calibration errors”; that competing statement does not meet the question’s stated requirement.

V011-C11-MCQ-063. A one-decibel blocker change in a fixed model changes which level by one decibel?

A. The retained reciprocal contribution, not generally the total noise

B. The baseline alone

C. The desired signal automatically

D. The total floor by exactly one decibel under every baseline

Answer: A. The contribution is proportional to blocker power, while unchanged baseline dilutes the total-level change. Source: §11.38 Use the model to design discriminating receiver observations (p. 6418)

Why the selected alternative fits: The retained reciprocal contribution, not generally the total noise.

Distinguishing consideration: compare this with option B, “The baseline alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Use the model to design discriminating receiver observations.

V011-C11-MCQ-064. What happens if a blocker changes AGC or filter state during an on/off comparison?

A. The state change cancels because both readings use dBm

B. The ratio no longer isolates the fixed-state noise-rise model

C. The comparison still proves reciprocal mixing uniquely

D. Only the reported clock time is affected

Answer: B. Desired transfer, weighting, and baseline must remain compatible or be recharacterized. Source: §11.26 Convert added power into a conditional noise-rise limit (p. 6401)

Why the selected alternative fits: The ratio no longer isolates the fixed-state noise-rise model.

Distinguishing consideration: compare this with option A, “The state change cancels because both readings use dBm”; that competing statement does not meet the question’s stated requirement.

V011-C11-MCQ-066. What is the pointwise bound on the omitted exponential phase term r for real phase phi?

A. Magnitude of r no greater than phi squared divided by two

B. Magnitude of r no greater than phi cubed for all signs

C. Magnitude of r always equals phase variance

D. r is exactly zero whenever RMS phase is below one radian

Answer: A. The remainder identity supplies a pointwise bound independently of stationarity. Source: §11.37 Application 11B.10 Bound the omitted phase term in the selected channel (p. 6415)

Why the selected alternative fits: Magnitude of r no greater than phi squared divided by two.

Distinguishing consideration: compare this with option B, “Magnitude of r no greater than phi cubed for all signs”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

V011-C11-MCQ-067. Which assumptions support the stationary filtered nonlinear-remainder bound beyond the retained linear model?

A. A Gaussian marginal alone without stationarity

B. Wide-sense stationarity alone for every nonlinear function

C. Only a small displayed noise rise

D. Strict stationarity, finite fourth moment, and the declared independent uniform carrier phase

Answer: D. A nonlinear function need not be stationary from wide-sense stationarity alone; moment and carrier assumptions remain distinct. Source: §11.37 Application 11B.10 Bound the omitted phase term in the selected channel (p. 6415)

Why the selected alternative fits: Strict stationarity, finite fourth moment, and the declared independent uniform carrier phase.

Distinguishing consideration: compare this with option A, “A Gaussian marginal alone without stationarity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

V011-C11-MCQ-068. What does a zero-mean Gaussian marginal supply for the fourth moment?

A. Strict stationarity automatically

B. The full oscillator spectrum at every offset

C. A proof of independent phase samples

D. Three times the fourth power of phase standard deviation

Answer: D. The marginal moment does not determine time dependence or replace other assumptions. Source: §11.37 Application 11B.10 Bound the omitted phase term in the selected channel (p. 6415)

Why the selected alternative fits: Three times the fourth power of phase standard deviation.

Distinguishing consideration: compare this with option A, “Strict stationarity automatically”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-069. Why must the retained and omitted filtered terms' cross power be bounded?

A. The carrier phase makes every nonlinear term independent

B. They need not be uncorrelated

C. All cross powers are always zero by construction

D. The omitted term has no amplitude units

Answer: B. Dropping an unknown cross term understates the possible selected-power error. Source: §11.37 Application 11B.10 Bound the omitted phase term in the selected channel (p. 6415)

Why the selected alternative fits: They need not be uncorrelated.

Distinguishing consideration: compare this with option A, “The carrier phase makes every nonlinear term independent”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

V011-C11-MCQ-070. For retained power N and omitted power bound P, what error enclosure is used?

A. P alone in every case

B. Two times N plus P as an exact error

C. Two times sqrt(NP) plus P

D. N minus P regardless of phase

Answer: C. Cauchy–Schwarz bounds the cross term and the omitted power adds separately. Source: §11.37 Application 11B.10 Bound the omitted phase term in the selected channel (p. 6415)

Why the selected alternative fits: Two times sqrt(NP) plus P.

Distinguishing consideration: compare this with option A, “P alone in every case”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

V011-C11-MCQ-071. Why can a small total phase RMS fail to justify a precise narrow-channel prediction?

A. Every narrow filter makes the omitted term vanish

B. Small RMS necessarily implies large actual selected error

C. The global omitted-power bound may be large relative to the selected first-order power

D. The fourth moment uniquely locates its spectrum

Answer: C. A loose bound is uninformative, not proof of a large error; localization needs more evidence. Source: §11.37 Application 11B.10 Bound the omitted phase term in the selected channel (p. 6415)

Why the selected alternative fits: The global omitted-power bound may be large relative to the selected first-order power.

Distinguishing consideration: compare this with option A, “Every narrow filter makes the omitted term vanish”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

V011-C11-MCQ-072. What does peak-normalized W no greater than one permit in the remainder argument?

A. The filter cannot increase stationary omitted power under the model

B. The filter must have zero delay

C. The filter guarantees zero direct carrier leakage

D. The filter makes the remainder independent of the retained term

Answer: A. The power gain bound is a distinct premise used to carry global remainder power into the selected channel. Source: §11.37 Application 11B.10 Bound the omitted phase term in the selected channel (p. 6415)

Why the selected alternative fits: The filter cannot increase stationary omitted power under the model.

Distinguishing consideration: compare this with option B, “The filter must have zero delay”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-073. For small sinusoidal phase modulation of peak beta, what is each first-order sideband's carrier-relative power?

A. Beta squared divided by two

B. Two beta squared

C. Beta squared

D. Beta squared divided by four

Answer: D. The two sidebands together have beta squared divided by two, matching phase variance under this benchmark. Source: §11.38 Use the model to design discriminating receiver observations (p. 6418)

Why the selected alternative fits: Beta squared divided by four.

Distinguishing consideration: compare this with option A, “Beta squared divided by two”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Use the model to design discriminating receiver observations.

Review: Chapter 11 — Use the model to design discriminating receiver observations.

V011-C11-MCQ-074. What distinguishes the predictions of Models 11A and 11B?

A. The cubic model covers every AGC transient while reciprocal mixing covers all clipping

B. Both predict only fixed noise independent of blocker level

C. Both provide the same universal detector-probability formula

D. Discrete parent-dependent cubic products versus weighted blocker-induced phase-noise contribution

Answer: D. Each conditional mechanism leaves other strong-signal failures open.

Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

Why the selected alternative fits: Discrete parent-dependent cubic products versus weighted blocker-induced phase-noise contribution.

Distinguishing consideration: compare this with option A, “The cubic model covers every AGC transient while reciprocal mixing covers all clipping”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Copyright 2026, James M. Atkinson

V011-C11-MCQ-075. When can off/on subtraction be interpreted as one added uncorrelated contribution?

A. Whenever the blocker carrier is not visible

B. Compatible transfer, weighting, planes, justified cross-power condition, and retained uncertainty

C. Whenever two dBm numbers can be subtracted

D. Whenever the on trace is higher, regardless of state

Answer: B. Subtract linear powers; a valid difference requires the measurement and decomposition assumptions. Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

Why the selected alternative fits: Compatible transfer, weighting, planes, justified cross-power condition, and retained uncertainty.

Distinguishing consideration: compare this with option A, “Whenever the blocker carrier is not visible”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

V011-C11-MCQ-076. What is a useful intervention for testing a proposed cubic parent-product frequency association?

A. Move one parent frequency while preserving detectable output and receiver state

B. Only lower the screen's trace reference without changing the input

C. Only increase the display averaging count

D. Change every gain and filter simultaneously

Answer: A. The model predicts specific product-frequency movements that a controlled test can challenge. Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

Why the selected alternative fits: Move one parent frequency while preserving detectable output and receiver state.

Distinguishing consideration: compare this with option B, “Only lower the screen's trace reference without changing the input”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

V011-C11-MCQ-077. What must be rechecked after inserting preselection to reduce a displayed noise floor?

A. Only the number of visible peaks

B. Desired transfer, baseline noise, and actual receiver state

C. Only the nominal filter name

D. Nothing if the floor decreased

Answer: B. The filter can also attenuate the desired signal or change the chain, so floor alone is not input-referred sensitivity. Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

Why the selected alternative fits: Desired transfer, baseline noise, and actual receiver state.

Distinguishing consideration: compare this with option A, “Only the number of visible peaks”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

V011-C11-MCQ-078. Why record the physical location of an attenuation challenge?

A. Only the attenuator's label affects the outcome

B. A matched attenuator cannot change stage drive

C. All attenuation locations are equivalent after display correction

D. Attenuation before and after generation has different effects

Answer: D. A pre-stage loss alters nonlinear drive; a post-stage loss scales already generated signals. Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

Why the selected alternative fits: Attenuation before and after generation has different effects.

Distinguishing consideration: compare this with option A, “Only the attenuator's label affects the outcome”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

V011-C11-MCQ-085. For a measured spur phasor contaminated by an unknown-phase phasor of RMS magnitude at most E, what bounds the uncontaminated stage-spur RMS magnitude?

A. From max(0, measured minus E) to measured plus E

B. Exactly measured minus E for every phase

C. Only the upper value, with no possible lower ambiguity

D. Measured power minus E power only

Answer: A. Triangle and reverse-triangle inequalities apply to phasors, not incoherent power subtraction. Source: §11.9 Ten worked applications of Model 11A (p. 6376)

Why the selected alternative fits: From max(0, measured minus E) to measured plus E.

Distinguishing consideration: compare this with option B, “Exactly measured minus E for every phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Ten worked applications of Model 11A.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-MCQ-090. Under the compatible equal-tone cubic planning model, how is SFDR obtained?

A. Equate total input power to the noise floor

B. Use OIP3 minus output display range with any bandwidth

C. Subtract the two parent powers directly

D. Find the per-tone level where input-equivalent IM3 reaches the stated noise floor, then subtract that floor

Answer: D. The resulting two-thirds relation depends on common planes, bandwidths, and a valid cubic interval. Source: §11.42 Quantitative Model for Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization (p. 6426)

Why the selected alternative fits: Find the per-tone level where input-equivalent IM3 reaches the stated noise floor, then subtract that floor.

Distinguishing consideration: compare this with option A, “Equate total input power to the noise floor”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 11 — Quantitative Model for Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization.

Review: Chapter 11 — Quantitative Model for Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization.

V011-C11-FIB-054. A real phase process has an _____ two-sided phase spectrum.

Answer: even. This does not remove signed-offset effects with an asymmetric observation filter. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why this term is required: “even” completes the stated technical proposition.

Question context: A real phase process has an _____ two-sided phase spectrum

Basis and qualification: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

Copyright 2026, James M. Atkinson

V011-C11-FIB-055. The linear single-sideband density equals _____ of the one-sided phase spectral density.

Answer: half. At positive offset it also equals the two-sided phase density numerically. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why this term is required: “half” completes the stated technical proposition.

Question context: The linear single-sideband density equals _____ of the one-sided phase spectral density

Basis and qualification: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

Copyright 2026, James M. Atkinson

V011-C11-FIB-056. The logarithmic phase-noise density unit used in this model is dBc per _____.

Answer: hertz. It must be converted to linear inverse-hertz density before power integration. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why this term is required: “hertz” completes the stated technical proposition.

Question context: The logarithmic phase-noise density unit used in this model is dBc per _____

Basis and qualification: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

Copyright 2026, James M. Atkinson

V011-C11-FIB-057. To convert L dBc/Hz to linear density, raise ten to L divided by _____.

Answer: 10. The logarithmic quantity represents a power-density ratio. Source: §11.23 Define the phase spectrum before converting decibels (p. 6394)

Why this term is required: “10” completes the stated technical proposition.

Question context: To convert L dBc/Hz to linear density, raise ten to L divided by _____

Basis and qualification: Chapter 11 — Define the phase spectrum before converting decibels.

Review: Chapter 11 — Define the phase spectrum before converting decibels.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C11-ESSAY-001. Develop a compression test that distinguishes fixed-stage transfer from automatic receiver control action.

- Opening: Present a thesis that answers this precise question: Develop a compression test that distinguishes fixed-stage transfer from automatic receiver control action. Identify which evidence would falsify the proposed conclusion Source: §11.3 Measure compression without confusing it with control action (p. 6365)
- Core terminology and scope: Define compression, distinguishes, transfer in the question's particular technical setting; explain how automatic, control, action differ if that distinction would change the analysis of "Develop a compression test that distinguishes fixed-stage transfer from automatic receiver control action" Source: §11.3 Measure compression without confusing it with control action (p. 6365)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define input/output planes and stimulus interval, retain actual gain/attenuation/filter/detector states, and identify transitions Source: §11.3 Measure compression without confusing it with control action (p. 6365)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a compression test that distinguishes fixed-stage transfer from automatic receiver control action to the claimed result, following "Compression and Gain Change"; name the intermediate states and measurable outputs Source: §11.2 Compression and Gain Change (p. 6363)
- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a

compression test that distinguishes fixed-stage transfer from automatic receiver control action. Use an independent controlled weak probe for sensitivity loss Source: §11.2 Compression and Gain Change (p. 6363)

- Analytical framework: Identify the equation, calibration or evidential decision test in “Model 11A for cubic intermodulation and intercept metrics” that resolves the question about a compression test that distinguishes fixed-stage transfer from automatic receiver control action; derive the relevant result with units and stated validity conditions Source: §11.5 Model 11A for cubic intermodulation and intercept metrics (p. 6367)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a compression test that distinguishes fixed-stage transfer from automatic receiver control action. Measure recovery after a specified pulse/prior state and define observation exclusions Source: §11.3 Measure compression without confusing it with control action (p. 6365)
- Worked application or illustrative case: Build a worked example of “a compression test that distinguishes fixed-stage transfer from automatic receiver control action”, addressing this associated condition: Define input/output planes and stimulus interval, retain actual gain/attenuation/filter/detector states, and.... Define input/output planes and stimulus interval, retain actual gain/attenuation/filter/detector states, and identify transitions Source: §11.2 Compression and Gain Change (p. 6363)

Copyright 2026, James M. Atkinson

- Alternative explanations and failure modes: Construct two plausible technical explanations for “a compression test that distinguishes fixed-stage transfer from automatic receiver control action”. Using “Model 11A for cubic intermodulation and intercept metrics”, specify a discriminator and the result expected under each explanation Source: §11.5 Model 11A for cubic intermodulation and intercept metrics (p. 6367)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to a compression test that distinguishes fixed-stage transfer from automatic receiver control action, including the effect of missing measurements and inconsistent operating conditions Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)
- Scholarly synthesis and implications: Explain what the result about a compression test that distinguishes fixed-stage transfer from automatic receiver control action authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §11.3 Measure compression without confusing it with control action (p. 6365)
- Closing: Conclude by answering “Develop a compression test that distinguishes fixed-stage transfer from automatic receiver control action” using only the demonstrated evidence; state the remaining decisive verification step Source: §11.3 Measure compression without confusing it with control action (p. 6365)
