V011-C11-DISCUSSION-001. Two suppliers quote different dynamic-range definitions. How should a survey team compare them?

- 01. Moderator, opening proposition: Introduce the exact dispute, “Two suppliers quote different dynamic-range definitions. How should a survey team compare them?” Put this particular dispute to the panel: Two suppliers quote different dynamic-range definitions. How should a survey team compare them. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

- 02. Student A, terminology and scope: Agree the operational meanings of suppliers, quote, dynamic-range and definitions, survey, them in “Two suppliers quote different dynamic-range definitions. How should a survey team compare them”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of Two suppliers quote different dynamic-range definitions; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Dynamic-Range Acceptance Matrix”. Then compare relevant installed configurations with weak references and blockers Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Two suppliers quote different dynamic-range definitions; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your

Copyright 2026, James M. Atkinson

opinion. Source: §11.47 Whole-band loading and dynamic-range penalties in parallel forty-gigahertz capture (p. 6436)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Dynamic-Range Acceptance Matrix”. Then compare relevant installed configurations with weak references and blockers Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. First align lower/upper limits, bandwidth, detector, spacing, signal class, and reference planes Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

- 08. Student D, answer to Student E: Design a discriminating experiment involving Two suppliers quote different dynamic-range definitions: specify the altered receiver state or source condition,

Copyright 2026, James M. Atkinson

predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of Two suppliers quote different dynamic-range definitions; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §11.47 Whole-band loading and dynamic-range penalties in parallel forty-gigahertz capture (p. 6436)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving Two suppliers quote different dynamic-range definitions: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

Copyright 2026, James M. Atkinson

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving Two suppliers quote different dynamic-range definitions, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving Two suppliers quote different dynamic-range definitions: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for Two suppliers quote different dynamic-range definitions. The largest number alone cannot rank capability for the actual task Explain the relevant statistical or calibration

Copyright 2026, James M. Atkinson

uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §11.47 Whole-band loading and dynamic-range penalties in parallel forty-gigahertz capture (p. 6436)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving Two suppliers quote different dynamic-range definitions, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for Two suppliers quote different dynamic-range definitions. The largest number alone cannot rank capability for the actual task Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §11.47 Whole-band loading and dynamic-range penalties in parallel forty-gigahertz capture (p. 6436)

Copyright 2026, James M. Atkinson

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about Two suppliers quote different dynamic-range definitions and How should a survey team compare them; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §11.34 Application 11B.7 Sum blockers only under an explicit cross-power condition (p. 6410)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “Two suppliers quote different dynamic-range definitions”, addressing “How should a survey team compare them”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “Two suppliers quote different dynamic-range definitions. How should a survey team compare them”, specifying

Copyright 2026, James M. Atkinson

the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “Two suppliers quote different dynamic-range definitions. How should a survey team compare them”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion. receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §11.38 Use the model to design discriminating receiver observations (p. 6418)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving An intervention changes both preamplifier and filter and restores a reference, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving An intervention changes both preamplifier and filter and restores a reference: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §11.38 Use the model to design discriminating receiver observations (p. 6418)

Copyright 2026, James M. Atkinson

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for An intervention changes both preamplifier and filter and restores a reference. Preserve both useful capability results without pretending the combined intervention uniquely localized the mechanism Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving An intervention changes both preamplifier and filter and restores a reference, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the conclusion. Source: §11.40 Distinguish strong-signal mechanisms through paired interventions (p. 6421)

Copyright 2026, James M. Atkinson

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for An intervention changes both preamplifier and filter and restores a reference. Preserve both useful capability results without pretending the combined intervention uniquely localized the mechanism Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §11.1 Dynamic Range Is a Family of Conditions (p. 6360)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about An intervention changes both preamplifier and filter and restores a reference and What causal claim is justified immediately; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §11.39 Desensitization Tests in Operational Environments (p. 6420)

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “An intervention changes both preamplifier and filter and restores a reference”, addressing “What causal claim is justified immediately”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and

Copyright 2026, James M. Atkinson

I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §11.38 Use the model to design discriminating receiver observations (p. 6418)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “An intervention changes both preamplifier and filter and restores a reference. What causal claim is justified immediately”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “An intervention changes both preamplifier and filter and restores a reference. What causal claim is justified immediately”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion. V011-C11-DISCUSSION-025. What should a second reviewer find in a complete strong-signal evidence package?

- 01. Moderator, opening proposition: Introduce the exact dispute, “What should a second reviewer find in a complete strong-signal evidence package?” Put this particular dispute to the panel: What should a second reviewer find in a complete strong-signal evidence package. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

- 02. Student A, terminology and scope: Agree the operational meanings of second, reviewer, find and complete, strong-signal, package in “What should a second reviewer find in a complete strong-signal evidence package”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of What

Copyright 2026, James M. Atkinson

should a second reviewer find in a complete strong-signal evidence package; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §11.3 Measure compression without confusing it with control action (p. 6365)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Measure compression without confusing it with control action”. The report should show bounded findings and unresolved alternatives so credibility does not depend on operator recollection Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §11.3 Measure compression without confusing it with control action (p. 6365)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of What should a second reviewer find in a complete strong-signal evidence package; explain what each record can establish State what the existing record

Copyright 2026, James M. Atkinson

establishes, what it does not establish, and which further measurement would change your opinion. Source: §11.21 Blocking and Reciprocal Mixing (p. 6391)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Measure compression without confusing it with control action”. The report should show bounded findings and unresolved alternatives so credibility does not depend on operator recollection Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §11.3 Measure compression without confusing it with control action (p. 6365)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. The weak-reference criterion, parents/blockers, levels/frequencies/modulation, planes, gains, filters, external paths, raw observations, calibration Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §11.41 Dynamic-Range Acceptance Matrix (p. 6425)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving What should a second reviewer find in a complete strong-signal evidence package: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Chapter 11 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C11-ESSAY-001 — Define input/output planes and stimulus interval, retain actual gain/attenuation/filter/detector states, and identify transitions. Use an independent controlled weak probe for sensitivity loss. Measure recovery after a specified pulse/prior state and define observation exclusions. Label fixed-state and closed-loop results separately and avoid relying on one overload flag.

Review: Chapter 11 — Measure compression without confusing it with control action.

V011-C11-ESSAY-002 — State loaded peak-voltage and resistance conventions, fixed coefficients, distinct frequencies, and the absence of even terms. Expand the self and mixed cubic terms to obtain the three-quarters coefficients with unequal amplitude powers. Preserve signs before power conversion and explain coincident-frequency and higher-order limitations.

Review: Chapter 11 — Derive the retained spectral amplitudes.

V011-C11-ESSAY-003 — Equate the equal-tone cubic magnitude with the linear fundamental, convert through R_i and R_o, and obtain the logarithmic separation rules. Distinguish extrapolated intercept from operating point. Show the 3.0103 dB error from total two-tone substitution and the half versus three-halves gain-correction bias.

Review: Chapter 11 — Construct the intercept from the linear asymptote.

Copyright 2026, James M. Atkinson

V011-C11-ESSAY-004 — Predict both product locations and their shifts when one frequency moves. Vary one parent power to distinguish unequal-tone slopes, then vary both under fixed state. Preserve detectability and source purity. Interpret agreement as compatibility with the association, not unique localization, and investigate departures without selecting a cause from slope alone.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-ESSAY-005 — Use the separate amplitude and power laws for the two products and separate fundamental corrections. Explain how the stronger parent can cause a larger fractional correction of the weaker fundamental. Keep individual measured products, reference planes, and correction bounds; show why equal-tone shortcuts erase informative asymmetry.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-ESSAY-006 — Start from delivered peak voltages and cycle-mean cosine power, derive a1 squared $\frac{R_i}{R_o}$, and evaluate the 10, 50-ohm, 200-ohm case. Carry the gain into OIP3 and coefficient recovery. Explain matching assumptions and why power-only product data cannot recover the sign of a_3.

Review: Chapter 11 — Fix the voltage convention and operating domain.

V011-C11-ESSAY-007 — Substitute voltage transmission into linear and cubic coefficients for each location. Track fundamental/product changes, IIP3 and OIP3 reference planes, and equal overall small-signal gain. State the absent noise, mismatch, distortion, and control consequences that prevent claiming universal sensitivity improvement.

Review: Chapter 11 — Ten worked applications of Model 11A.

Copyright 2026, James M. Atkinson

V011-C11-ESSAY-008 — Distinguish one tone from two equal tones and per-tone from total power. Convert one-decibel gain reduction into a voltage ratio, identify the formal powers, and compare the required correction with the five-percent working bound. Explain why omitted terms and actual device behavior prevent treating the extrapolation as a receiver specification.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-ESSAY-009 — Use affine logarithmic formulas and rectangular corner bounds for p, q, and s. Then impose a common additive output error and demonstrate cancellation from IIP3 but one surviving copy in OIP3. Keep hard bounds separate from coverage probabilities and justify the dependency model rather than choosing it for a smaller interval.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-ESSAY-010 — Apply triangle and reverse-triangle magnitude bounds, convert endpoints to power at the same resistance, and propagate through the decreasing dependence of intercept on product level. Discuss loss of a finite upper intercept bound when contamination can cancel the observed magnitude. Specify source/combiner/isolation checks and reject simple incoherent subtraction.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-ESSAY-011 — Define mixer-input blocker power, signed offset, real zero-mean phase process, density convention, and first-order exponential expansion. Show spectrum translation and amplitude scaling, retaining units. Separate direct carrier leakage and other strong-signal mechanisms, and explain why no extra sideband factor is inserted.

Review: Chapter 11 — Translate one blocker through the fluctuating oscillator.

Copyright 2026, James M. Atkinson

V011-C11-ESSAY-012 — Define normalized H and W, equivalent noise bandwidth, signed translated offsets, and overlap factor. Integrate linear density rather than logarithmic labels. State exact flat-spectrum conditions, bounds for varying density, treatment of tails and lines, and the need for frequency-dependent gain when one scalar is insufficient.

Review: Chapter 11 — Integrate the channel that actually produces the reported value.

V011-C11-ESSAY-013 — Preserve signed blocker translation while using the even real-phase density. Identify the different offset intervals sampled by the one-sided channel, integrate the stated local inverse-square law, and explain why a symmetric filter removes this particular asymmetry. Do not infer global finite variance from a local divergent law without continuation.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-ESSAY-014 — Identify blocker transfer into the mixer and divide generated noise by desired transfer for narrow-signal external equivalence. Derive the transfer ratio and 23 dB differential example. Explain broad-waveform weighting and why total sensitivity also requires baseline noise, mismatch, and gain-state accounting.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-ESSAY-015 — State compatible baseline, gain, weighting, plane, and zero cross power. Invert the total-to-baseline logarithm, evaluate the one-decibel fraction, and explain why required blocker reduction differs from excess total rise. Discuss quieter versus noisier baselines and why the metric alone does not give detection probability.

Review: Chapter 11 — Convert added power into a conditional noise-rise limit.

Copyright 2026, James M. Atkinson

V011-C11-ESSAY-016 — State each admitted blocker power, signed offset, and weighted overlap. Require zero admitted cross powers through a justified ensemble or averaging rule. Explain shared-LO dependence, coincident coherent carriers, and differing density offsets. Preserve covariance terms when the power-sum premise fails.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-ESSAY-017 — Convert both compatible output levels to watts, subtract with uncertainty, divide through fixed gain, blocker power, and justified bandwidth. Require unchanged baseline/state and exclude or bound stimulus phase noise, leakage, and other mechanisms. Treat negative or unresolved differences appropriately and describe an aggregate effective density when attribution remains incomplete.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-ESSAY-018 — Define the feasible set and distinguish rectangular freedom from statistical independence. Use monotonic extrema for added power and combine largest added with smallest baseline for maximum rise. Explain how justified dependencies could narrow the interval and why a hard enclosure has no automatic confidence percentage.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-ESSAY-019 — Distinguish pointwise remainder, expected square requiring a fourth moment, retained linear WSS spectrum, and stationary nonlinear filtered bound requiring strict stationarity and carrier-phase assumptions. Retain W no greater than one, unknown cross power, and the Gaussian marginal moment only where invoked. Explain why small global RMS alone need not yield a useful selected-channel error bound.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

Copyright 2026, James M. Atkinson

V011-C11-ESSAY-020 — Choose parent-frequency movement, blocker-power/offset changes, and controlled weak-probe response as distinct tests. Hold or record relevant gain and weighting states, characterize preselector transfer, and examine recovery. Preserve alternative mechanisms where predictions fail rather than force one explanation from a lower floor or apparent slope.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

V011-C11-ESSAY-021 — Include weak reference classes, blocker levels/spacings/modulation, band edges, installed paths, gain/preselection states, and recovery intervals. Test actual deployed configurations and define transitions or limitations. Retain parent/product families and encode band-specific procedural requirements without extrapolating one catalog number.

Review: Chapter 11 — Dynamic-Range Acceptance Matrix.

V011-C11-ESSAY-022 — Refer IIP3 and integrated noise to the same input plane and compatible bandwidth. Set the cubic product level 3p-2I equal to noise N, solve for p, and subtract N. Check the characterized cubic interval and tighter compression, phase-noise, spur, or decision-margin limits. A nonpositive or inapplicable intersection provides no usable claim.

Review: Chapter 11 — Quantitative Model for Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization.

Copyright 2026, James M. Atkinson

V011-C11-ESSAY-023 — Document before/after source, reference, chain, gain, and capability. Explain the demonstrated desensitization of the original configuration while distinguishing which individual change remains causally unresolved if both changed. Require a suitable reference and state limits on environmental absence and transfer to other bands.

Review: Chapter 11 — Hypothetical Case Adjudication: Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization.

V011-C11-ESSAY-024 — Use coherent phasor cancellation and uncertainty about source/combiner/receiver products, retaining reference phase and planes. Contrast a power-only reading with signed or controlled path evidence. Explain the consequence for intercept bounds and why more averaging does not necessarily remove deterministic contamination.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-ESSAY-025 — Tie each finding to signal class, bandwidth, reference planes, gain/filter states, blockers, and recovery. State which local model was tested and what alternatives remain. Preserve raw/reference observations, uncertainty and exclusions, and translate demonstrated limits into procedures for credible weak observations.

Review: Chapter 11 — Dynamic-Range Acceptance Matrix.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-C11-DISCUSSION-001 — First align lower/upper limits, bandwidth, detector, spacing, signal class, and reference planes. Then compare relevant installed configurations with weak references and blockers. The largest number alone cannot rank capability for the actual task.

Review: Chapter 11 — Dynamic Range Is a Family of Conditions.

V011-C11-DISCUSSION-002 — Request desired gain, weak-probe criterion, noise/product response, actual control states, and recovery under the intended stimulus. An icon is one observation and may not mark every relevant error. Keep a bounded conclusion tied to demonstrated capability.

Review: Chapter 11 — Measure compression without confusing it with control action.

V011-C11-DISCUSSION-003 — Separate closed-loop behavior from fixed-state transfer and retain the transition record. Discuss whether the operational question concerns automatic behavior or local stage nonlinearity. Do not fit one polynomial slope across states without evidence.

Review: Chapter 11 — Measure compression without confusing it with control action.

V011-C11-DISCUSSION-004 — Recognize compatibility with the association, then test candidate generating paths under comparable detectability. Receiver, source, combiner, or external nonlinear contacts can share the frequency relation. Preserve alternatives until an intervention discriminates them.

Review: Chapter 11 — Ten worked applications of Model 11A.

Copyright 2026, James M. Atkinson

V011-C11-DISCUSSION-005 — Discuss the unequal product laws and separate low/high results. If an equal-tone metric is desired, establish that test condition explicitly. Avoid using averaged logs or total powers to conceal asymmetry or imply a convention not actually measured.

Review: Chapter 11 — Construct the intercept from the linear asymptote.

V011-C11-DISCUSSION-006 — Explain that coherent contamination can either reinforce or cancel the stage contribution, so a small observed spur need not be conservative. Require phasor bounds or controlled isolation evidence. Report the resulting interval and nonidentifiability rather than the preferred point estimate alone.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-DISCUSSION-007 — Separate nonlinear drive reduction from noise and desired-signal loss. Record state, transfer, and baseline and compare the actual detection criterion. A higher input-referred intercept does not automatically improve all useful dynamic-range measures.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-DISCUSSION-008 — Keep it as the explicitly bounded teaching extrapolation that demonstrates a limitation. Distinguish it from an acceptance test or operating recommendation, and explain the additional terms and measurements needed for actual compression behavior.

Review: Chapter 11 — Ten worked applications of Model 11A.

V011-C11-DISCUSSION-009 — Require evidence of a shared physical/calibration dependency. Similar labels alone do not establish common error. Compare the feasible sets and retain a defensible bound without assigning an unsupported probability or cancellation.

Review: Chapter 11 — Ten worked applications of Model 11A.

Copyright 2026, James M. Atkinson

V011-C11-DISCUSSION-010 — Consider reciprocal mixing, source phase noise, gain/control changes, direct leakage, ADC occupation, and other broadband effects. Use controlled weak probes and blocker offset/level changes. Absence of one product family does not establish one alternative uniquely.

Review: Chapter 11 — Blocking and Reciprocal Mixing.

V011-C11-DISCUSSION-011 — Assess spectral variation over every weighted offset, actual LO path, filter response, and omitted tails or lines. Use an integral or justified envelope. A convenient center value is an exact shortcut only under its flat-density condition.

Review: Chapter 11 — Integrate the channel that actually produces the reported value.

V011-C11-DISCUSSION-012 — Examine signed translation relative to asymmetric weighting before inferring different source powers or instrument faults. Retain desired transfer and gain. The model's even real-phase spectrum does not make every asymmetric observation symmetric.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-DISCUSSION-013 — Measure desired transfer, input-referred baseline, receiver state, and actual weak-reference performance. The same filter may attenuate wanted energy or alter noise/gain. Report the demonstrated improvement in the stated criterion rather than equating display floor with capability.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

Copyright 2026, James M. Atkinson

V011-C11-DISCUSSION-014 — Discuss the ensemble or time average and whether admitted contributions are uncorrelated. Shared phase noise may create dependence, while coincident coherent components require field addition. Retain covariance or declare limits if the sum premise is unproven.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-DISCUSSION-015 — Preserve both original readings, convert to compatible watts, subtract with uncertainty, and refer through fixed gain. Check source noise and other changes before attribution. The dB rise remains a ratio of totals, not the added power itself.

Review: Chapter 11 — Ten worked applications of Model 11B.

V011-C11-DISCUSSION-016 — Compare actual desired signal transfer and absolute noise/detection criterion, not rise alone. The higher baseline can mask a given added wattage in the relative metric. Use the required configuration and target class to make the decision.

Review: Chapter 11 — Convert added power into a conditional noise-rise limit.

V011-C11-DISCUSSION-017 — No probability follows without a distributional or coverage model. Discuss what hard bounds actually cover, dependencies, and their adequacy. Keep an enclosure useful on its own terms rather than adding a numerical confidence label.

Review: Chapter 11 — Ten worked applications of Model 11B.

Copyright 2026, James M. Atkinson

V011-C11-DISCUSSION-018 — The available global bound is insufficient for a precise channel claim, not proof that the actual error is large. Seek information about omitted spectral localization or a stronger direct comparison. Preserve the retained model's limited prediction and explicit uncertainty.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

V011-C11-DISCUSSION-019 — Separate marginal fourth moment from strict stationarity, temporal dependence, carrier-phase assumptions, and filter gain bound. A histogram can support only part of the required evidence. Do not substitute one favorable statistic for the full model premises.

Review: Chapter 11 — Application 11B.10 Bound the omitted phase term in the selected channel.

V011-C11-DISCUSSION-020 — Record the transition, separate states, and remeasure desired transfer and baseline. Fit only a fixed-state comparison appropriate to the proposed mechanism or explicitly report closed-loop behavior. Avoid interpreting a mixed-state slope as a clean nonlinear order.

Review: Chapter 11 — Distinguish strong-signal mechanisms through paired interventions.

V011-C11-DISCUSSION-021 — Describe the tested blockers, chain, state, and failed criterion, then identify corrected or bounded configurations. A specific limitation can guide use without universal condemnation. Acceptance elsewhere needs applicable evidence rather than assuming either universal failure or universal success.

Review: Chapter 11 — Dynamic-Range Acceptance Matrix.

Copyright 2026, James M. Atkinson

V011-C11-DISCUSSION-022 — Translate them into explicit configuration and procedural requirements, including preselection, gain, paths, and recovery exclusions. Retain the supporting matrix and reference observations. A caveat buried behind one dynamic-range number is insufficient for reproducible use.

Review: Chapter 11 — Dynamic-Range Acceptance Matrix.

V011-C11-DISCUSSION-023 — The operational limit must respect the tighter demonstrated mechanism and model domain. Explain the compatible-plane cubic planning calculation while retaining blocking, phase noise, compression, and decision margins. Do not use one model to erase contrary applicable evidence.

Review: Chapter 11 — Quantitative Model for Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization.

V011-C11-DISCUSSION-024 — The original configuration was inadequate and the combined revised configuration restored the criterion under the test. Isolating which change mattered requires further controlled comparison. Preserve both useful capability results without pretending the combined intervention uniquely localized the mechanism.

Review: Chapter 11 — Hypothetical Case Adjudication: Dynamic Range, Compression, Blocking, Intermodulation, and Desensitization.

V011-C11-DISCUSSION-025 — The weak-reference criterion, parents/blockers, levels/frequencies/modulation, planes, gains, filters, external paths, raw observations, calibration and uncertainty, source-purity checks, state transitions, and recovery. The report should show bounded findings and unresolved alternatives so credibility does not depend on operator recollection.

Review: Chapter 11 — Dynamic-Range Acceptance Matrix.

Chapter Glossary

ADMITTED BLOCKER POWER: The power of a specified interfering carrier at the conversion-stage input after preceding gain, loss, and frequency selection, at a declared reference plane.

BLOCKER OFFSET: The signed frequency separation between an admitted interfering carrier and the declared desired-channel center. Model 11B uses it to identify which oscillator phase-noise frequencies enter the weighted channel. An even phase spectrum does not make positive and negative blocker offsets interchangeable when the observation filter is asymmetric.

BLOCKING: Loss of sensitivity or accuracy caused by a strong signal outside or beside the desired channel.

COHERENT CONTAMINATION: An unwanted complex amplitude at the same observed frequency whose phase-dependent addition can raise or lower the magnitude attributed to the modeled source.

COMPRESSION: Reduction of incremental gain as a stage approaches nonlinear or limiting operation.

CROSS POWER: The contribution arising from the joint product of two admitted signal components when their combined mean power is formed. Its sign and magnitude depend on their relationship. Model 11B retains a bound on the cross term between the kept and omitted phase contributions instead of assuming their powers add without interaction.

CUBIC INTERMODULATION MODEL: A bounded memoryless voltage relation retaining linear and third-order terms under explicit amplitude, loading, frequency, and fixed-state assumptions.

Copyright 2026, James M. Atkinson

DESENSITIZATION: Degradation of receiver sensitivity caused by overload, control action, noise elevation, or other strong-signal effects.

DESIRED INPUT EQUIVALENCE: Referral of an internally generated disturbance to the desired-signal input using the declared desired transfer; a center-frequency scalar requires a narrow signal or a justified constant-transfer approximation.

DYNAMIC-RANGE ACCEPTANCE MATRIX: A structured set of receiver tests spanning the weak references, blockers, tone spacings, modulation, gain states, external paths and recovery conditions relevant to the declared use. Its results establish a bounded operating region and known exclusions. One favorable catalog number cannot replace this configuration-dependent evidence.

EFFECTIVE PHASE NOISE: The phase-fluctuation spectrum experienced by a blocker in the actual conversion path, including relevant oscillator and driver contributions under a specified operating state.

FLAT-SPECTRUM APPROXIMATION: Replacement of a varying linear spectral density by one constant over the frequency region carrying significant filter weight. It is exact for the stated constant-density case and requires justification otherwise. A center-frequency phase-noise value alone does not establish the integrated noise when other admitted offsets have different densities.

Copyright 2026, James M. Atkinson

FOURTH MOMENT: The expectation of the fourth power of a stated real random quantity, when finite. Model 11B uses the phase fourth moment to bound omitted nonlinear power. A zero-mean Gaussian marginal supplies a particular moment relation, but that marginal condition alone establishes neither strict stationarity nor a specific phase spectrum.

FUNDAMENTAL CORRECTION: The contribution of retained nonlinear terms to the amplitude at a parent frequency, distinct from a newly generated intermodulation component.

INPUT INTERCEPT LEVEL: The input-referred extrapolated level at which a declared nonlinear-product law meets its associated linear asymptote. Model 11A defines it per tone at the loaded input plane. Its usefulness depends on the local model and measured interval; it is not an attainable operating level or a total multi-tone input power.

INTERCEPT EXTRAPOLATION: The procedure of extending specified low-level fundamental and nonlinear-product laws to their algebraic intersection. In Model 11A it equates the linear fundamental asymptote to a selected cubic-product magnitude, retaining per-tone powers and reference planes. A measured fundamental with finite nonlinear correction requires a fitted asymptote or an explicitly bounded correction.

INTERCEPT POINT: The extrapolated input or output level at which a specified nonlinear product and reference fundamental asymptote have equal power under the declared test convention. It is a parameter of those response laws, not an attainable operating level or a compression threshold. The input and output values differ by the declared power gain expressed in decibels.

Copyright 2026, James M. Atkinson

LOADED VOLTAGE GAIN: The ratio of output voltage across its declared load to input voltage at its declared loaded plane; power gain additionally depends on both resistances.

MEMORYLESS NONLINEARITY: A relation in which the output at an instant depends on the input at that instant without an internal stored state. The fixed cubic law can produce new frequency components even though it has no memory. Thermal history, control-loop dynamics and frequency-selective storage require a different or extended description.

NOISE RISE ALLOWANCE: The additional uncorrelated noise power permitted by a stated rise relative to a fixed baseline measured through the same gain, weighting, and reference plane.

NORMALIZED FILTER POWER RESPONSE: The squared magnitude of the declared observation filter after its reference gain has been specified. It weights the noise admitted at each frequency. Model 11B additionally requires this weighting to remain between zero and one for its remainder bound; center normalization alone would not establish that peak constraint.

ONE-DECIBEL COMPRESSION POINT: A specified stimulus level at which the measured response is one decibel below its declared small-signal linear extrapolation under fixed test conditions. It is a benchmark, not a universal threshold for all measurement error. Automatic gain changes, different stimuli and recovery behavior require separate characterization.

Copyright 2026, James M. Atkinson

OUTPUT INTERCEPT LEVEL: The output-referred extrapolated intersection associated with the declared input intercept and small-signal power gain. The input and output planes and resistance conventions must be compatible. Substituting a compressed measured fundamental for the linear asymptote can bias the extraction, even before ordinary calibration uncertainty is considered.

PER-TONE POWER: The power assigned to one specified sinusoidal component, distinct from the sum of the powers in a multi-tone stimulus.

PHASE REMAINDER BOUND: An enclosure for terms omitted from a declared small-phase expansion, with moment and stationarity requirements stated separately from the retained linear model.

POWER GAIN: The ratio of output power to input power under declared reference-plane, loading and signal conventions. For the chapter’s loaded sinusoidal voltages, both the squared voltage ratio and the input/output resistance ratio enter. A voltage-gain number is therefore insufficient when the reference resistances differ.

PRODUCT COLLISION: Coincidence of two generated or existing spectral components at one frequency, requiring their complex amplitudes to be combined before calculating power.

RECIPROCAL MIXING: Noise produced when local-oscillator phase noise mixes a strong nearby signal into the observation band.

RECIPROCAL MIXING OVERLAP: The dimensionless integral of translated linear single-sideband phase density weighted by the observation channel's normalized power response.

Copyright 2026, James M. Atkinson

RECOVERY EXCLUSION: An interval after a stimulus or state change during which the receiver has not yet met the declared criterion for valid observation.

SINGLE-SIDEBAND PHASE DENSITY: The linear phase-noise quantity equal to one half of the one-sided phase spectral density and, at positive offsets, to the two-sided phase density.

SMALL-SIGNAL ASYMPTOTE: The linear response extrapolated from the declared low-level behavior of a stage. It supplies the fundamental reference for the chapter's intercept construction, rather than the full finite-level fundamental including its cubic correction. Confusing those quantities changes the inferred intercept and can obscure the limits of the approximation.

SOURCE-GENERATED INTERMODULATION: Nonlinear products produced in a stimulus source, combiner, connector or other test-path component before the receiver contribution is isolated. Such products can contaminate an intercept measurement and can combine coherently with receiver-generated amplitudes. Source isolation and harmonic filtering are therefore part of the validity argument, not merely setup details.

SPECTRAL LINE: A discrete-frequency contribution with finite integrated power, distinct from an ordinary continuous spectral density. A carrier or discrete phase-modulation spur must be included through its line contribution and the observation response. Assigning it an arbitrary per-hertz value or treating it as a flat density can misstate admitted power.

Copyright 2026, James M. Atkinson

SPURIOUS-FREE DYNAMIC RANGE: A range defined by specified desired-signal, noise and spur conditions at compatible reference planes and bandwidths. The chapter's third-order planning expression finds where the equal-tone cubic product meets the stated noise floor. Compression, reciprocal mixing, other products or model breakdown can impose a smaller usable range.

STRICT STATIONARITY: Invariance of all finite-dimensional probability distributions under a common shift of time. Model 11B invokes this stronger premise, with a finite fourth moment and its stated blocker-phase convention, when bounding the filtered nonlinear remainder. The weaker covariance premise sufficient for the retained linear spectrum does not automatically provide it.

UNEQUAL-TONE INTERMODULATION: The nonlinear-product behavior produced when the two parent tones have different stated amplitudes or powers. In the retained cubic model, each close-in product weights one parent twice and the other once in power. The two products therefore need separate calculations; symmetry cannot be inferred from their frequency placement alone.

WEAK-PROBE CHALLENGE: A strong-signal test that retains a controlled weaker desired reference to measure changes in useful observation capability.

WIDE-SENSE STATIONARITY: A second-order condition with constant mean and covariance determined by time separation. It supports the chapter's retained linear phase-spectrum treatment when variance is finite. It does not generally make a nonlinear function of the phase stationary, so it cannot silently replace the stronger premise used for the remainder-power bound.

Copyright 2026, James M. Atkinson

ZERO CROSS-POWER CONDITION: A specified ensemble or averaging condition under which the cross terms between admitted contributions vanish and their mean powers may be added.

Chapter 12. Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing

Copyright 2026, James M. Atkinson

12.1 Frequency Reference and Tuning Accuracy

Receiver frequency accuracy depends on its reference oscillator, synthesizer, dividers, numerical tuning, temperature, aging, supply state, and calibration. A displayed center frequency can be numerically exact while the physical tuning is offset. The error may be constant, proportional to frequency, band dependent, or state dependent. Frequency measurements should be checked against traceable references at several points rather than corrected from one tone.[1]

Reference sources include internal crystal oscillators, oven-controlled oscillators, disciplined oscillators, external 10 MHz standards, network time and frequency, and specialized atomic or satellite-referenced systems. Their labels do not establish present performance. Lock status, holdover, antenna condition, phase steps, distribution delay, and cabling must be recorded. A degraded disciplined oscillator can remain close on average while exhibiting short-term noise or excursions.

12.2 Model 12A: connect clock reading, frequency and phase

Clock accuracy is meaningful only relative to a defined time and frequency reference. Model 12A defines the clock reading as ideal time plus a time error. Positive error means that the clock is advanced. Its derivative is fractional frequency error, and multiplying time error by two pi times nominal carrier frequency gives relative unwrapped phase. This convention follows the time-error and fractional-frequency relationship used in the NIST frequency-stability handbook. It is kept explicit because a physical propagation delay has the opposite transfer-phase sign.[2]

Equation 23A. Clock reading and time-error convention

$$c(t)=t+x(t),\ x(t)>0 \text{ means an advanced clock}$$

Equation 23B. Frequency and phase from time error

$$y(t)=\frac{dx}{dt},\ f(t)=f_0[1+y(t)]$$
$$\varphi_{rel}(t)=2\pi f_0 x(t),\ f_0>0$$

The ideal time t, clock reading c and time error x are in seconds. Nominal frequency f_0 is in hertz; fractional frequency y is dimensionless; relative phase is in radians. In the local drift law, d is fractional-frequency change per second. A physical delay τ is in seconds. The nonnegative bounds b_0, b_y and b_d have the units of time error, fractional frequency and fractional-frequency drift, respectively. The tolerance φ_{tol} is a positive phase magnitude in radians, and its equivalent time tolerance follows by division by $2\pi f_0$.

These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

The model is deterministic over a declared interval. An initial epoch error, a constant fractional frequency error, and a local linear frequency drift integrate into a constant, linear, and quadratic time-error term. They answer different questions. A clock can have correct average frequency while its epoch is displaced, or it can begin at the correct epoch and then accumulate substantial error. Neither a frequency-lock indicator nor a plausible timestamp establishes all three terms.

Equation 23C. Local linear fractional-frequency drift

$$y(t) = y_0 + dt$$
$$x(t) = x_0 + y_0 t + \frac{d}{2} t^2$$

The interval matters because a fitted drift law need not persist through warmup, environmental change, holdover, a power interruption, or reacquisition of a reference. Segment the record at such events. Within a segment, state whether the coefficients are calibrated values, estimates from observed phase, or conservative bounds. A polynomial fit can summarize an observed trend without proving the mechanism that will govern the next interval.

A positive physical delay acts differently from an advanced clock. Delaying a sinusoid produces a negative transfer phase proportional to frequency. A nondispersive delay can therefore be inferred from an unwrapped phase slope, but a single wrapped phase value admits many possible delays. Frequency-dependent filters add phase curvature, in which case one constant delay cannot describe the whole path. The delay calibration must use the frequency range and channel state needed by the later inference.

Copyright 2026, James M. Atkinson

Equation 23D. Physical delay and its transfer-phase sign

$$H(f)=\exp(-j2\pi f\tau)$$
$$\theta(f)=-2\pi f\tau \text{ on the declared unwrapped branch}$$

Equation 23E. Delay from unwrapped phase slope

$$\tau=-\frac{1}{2\pi}\frac{d\theta}{df}$$
$$\tau=-\frac{\theta_2-\theta_1}{2\pi(f_2-f_1)} \text{ for a nondispersive path}$$

Two separated tones can constrain delay, but their wrapped phase difference leaves an ambiguity related to the tone spacing. A prior delay range, an additional frequency pattern, or an independently established unwrap is required to choose among the alternatives. The example below uses a pure delay with compatible absolute phase, making two different delays produce the same wrapped pair. This is a measurement ambiguity, not a numerical precision problem.

Equation 23F. Two-tone delay ambiguity

$$\tau_m=\tau_0+\frac{m}{\Delta f}, m\in\mathbb{Z}, \Delta f>0$$
$$\text{Wrapped difference repeats every } \frac{1}{\Delta \mathrm{f}} \text{ in delay.}$$

Two epoch measurements also provide an average fractional-frequency estimate over their separation. If the endpoint errors are given as deterministic bounds, propagate them as bounds rather than converting them into standard deviations without a distribution. A statistical uncertainty calculation belongs to the measurement model in Chapter 14. Either approach should retain the reference time interval and any correlation between the endpoint measurements.

Copyright 2026, James M. Atkinson

Equation 23G. Average frequency from endpoint time errors

$$y_{avg} = \frac{x_2 - x_1}{t_2 - t_1}$$
$$|\delta y_{avg}| \le \frac{b_1 + b_2}{t_2 - t_1} \, if \; |\delta x_i| \le b_i$$

A reset or retune can insert a phase step. A finite difference that crosses that step includes it, while the continuous derivative on either side may remain unchanged. Do not fit one smooth drift law through a documented discontinuity. Preserve the event time and separate segment phases. Coherent comparison across the event requires a measured deterministic relationship, not merely the fact that both segments use the same nominal sample rate.

Equation 23H. Phase reset as an explicit segment event

$$\varphi(t_r^{+¿}) - \varphi(t_r^{-}) = \Delta\varphi_r ¿ \; cross-reset\ average = continuous-segment\ average + \frac{\Delta\varphi_r}{2\pi\Delta t}$$

The sample clock controls both elapsed-time labels and discrete-frequency labels. If the actual rate differs from the nominal rate by a fractional amount, the elapsed time for a fixed number of actual sample intervals changes inversely. Scaling a normalized discrete frequency with the nominal rate produces a corresponding frequency error. This reuses the sample-index and continuity conventions in Model 10E. Count intervals carefully: a record containing N endpoint samples spans $N-1$ intervals between its first and last sample.

Equation 23I. Actual sample-clock time and frequency scaling

$$f_{s,true} = f_{s,nom}(1+\varepsilon) > 0$$
$$T_{true} = \frac{N}{f_{s,true}}, f_{label} = \frac{f_{true}}{1+\varepsilon}$$
$$N\ sample\ intervals\ have\ N+1\ endpoint\ samples.$$

Copyright 2026, James M. Atkinson

For two channels, subtract their time errors before converting to relative phase. Common contributions can cancel, but unequal distribution paths, resets, aperture delays, or processing offsets remain. The shared reference is only one element of the timing system. A common-signal calibration should traverse the actual analog and digital paths and be repeated after any state change that can alter their relationship.

Equation 23J. Relative channel timing and phase

$$x_{AB} = x_A - x_B$$
$$\varphi_{AB} = 2\pi f_0 x_{AB}$$

A calibration interval can be chosen from justified bounds on initial time error, fractional-frequency error, and drift. Their worst-case accumulated envelope is monotone for nonnegative bounds and nonnegative elapsed time. Compare it with the time error corresponding to the allowed phase error at the stated carrier. If the initial bound already exceeds the limit, no positive waiting interval is feasible. If it equals the limit and a drift bound is nonzero, only the initial instant qualifies. If both frequency and drift bounds vanish, the initial bound alone decides the interval.

Equation 23K. Deterministic accumulated-error envelope

$$|\, x(t) \,| \le b_0 + b_y t + \frac{b_d}{2} t^2$$
$$b_0, b_y, b_d \ge 0, t \ge 0$$

Equation 23L. Finite calibration interval for a positive drift bound

$$B = \frac{\varphi_{tol}}{2\pi f_0} - b_0 > 0$$
$$t_{max} = \frac{2B}{b_y + \sqrt{b_y^2 + 2 b_d B}} \; if \; b_d > 0$$
$$t_{max} = \frac{B}{b_y} \; if \; b_d = 0 \text{ and } b_y > 0$$

12.3 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

12.4 Application 12A.1: Accumulate a constant fractional frequency offset

A clock has constant fractional frequency error +0.2 parts per million and begins with zero time error. Over 86,400 seconds it advances by 0.01728 s, or 17.28 ms. At a nominal 10 MHz, its frequency error is +2 Hz and its relative unwrapped phase accumulates 172,800 cycles. A wrapped phase display cannot retain that cycle count by itself.

The daily result assumes the offset stays constant for the entire day. If the reference is disciplined or its environment changes, use the measured or bounded time-dependent error instead. A small-looking fractional specification can produce a large epoch error over a long interval, while the same offset can be unimportant for a short amplitude-only observation. The acceptable limit follows from the intended timing or coherence decision.

Copyright 2026, James M. Atkinson

12.5 Application 12A.2: Integrate a linear fractional-frequency drift

Start with a +2 μs epoch error, fractional frequency -10^{-8}, and a linear fractional-frequency drift of 2×10^{-12} per second. After 3,600 s, the time error is -21.040000 μs and fractional frequency is -2.8×10^{-9}. At 10 MHz the unwrapped relative phase is -210.400000 cycles.

The positive drift partly offsets the initially negative frequency error, but the accumulated time error remains negative. Reading only the final frequency would miss the history represented by the integral. This constructed polynomial is valid only over its stipulated interval. A holdover claim needs evidence that the coefficient bounds or model remain applicable under the relevant temperature, supply, and prior-lock conditions.

Copyright 2026, James M. Atkinson

12.6 Application 12A.3: Separate an epoch offset from a frequency offset

A clock is advanced by 0.75 μs but has zero fractional frequency error. At 10 MHz, its phase is advanced by 7.5 cycles, represented as −180 degrees in the chosen principal interval from −180 inclusive to +180 exclusive. At 4 million samples per second, the epoch error is three sample intervals. Its frequency error remains zero.

Frequency agreement therefore does not establish aligned samples. A timestamp and a sample index need an explicit relationship to the actual aperture or equivalent sample event. If a transport packet is stamped later, its timestamp may describe a software or interface event instead. Calibrate the required timing point and preserve that definition with the channel record.

Copyright 2026, James M. Atkinson

12.7 Application 12A.4: Keep physical delay and clock-error signs separate

A physical delay of 12.5 ns produces −450 degrees transfer phase at 100 MHz, which wraps to −90 degrees. At 400 MHz it produces −1,800 degrees, which wraps to zero. The second tone can therefore appear phase aligned even though the path delay is unchanged and nonzero.

An acceptance rule that compares only one wrapped phase could pass the delayed channel at 400 MHz and fail it at 100 MHz without explaining why. Use an unwrapped frequency response or a justified delay prior when delay is the measurand. Cable substitution and channel reversal can help distinguish a fixed path delay from a phase-reference offset, provided the changed configuration is itself characterized.

Copyright 2026, James M. Atkinson

12.8 Application 12A.5: Use an unwrapped phase slope while declaring delay ambiguity

Two declared unwrapped phases are −72 degrees at 100 MHz and −86.4 degrees at 120 MHz. Their slope gives a 2 ns delay. The 20 MHz spacing creates a 50 ns wrapped-delay ambiguity period: a pure delay of 52 ns gives the same two wrapped phases. The unwrapped pair, or an independent bound selecting its branch, is therefore essential to the 2 ns conclusion.

Adding decimal places to the two phase readings cannot distinguish those branches. A wider or differently spaced set of calibrated tones can provide additional information, but its ambiguity and constant-phase model must be worked out explicitly. If the path is dispersive, fit or retain its frequency-dependent response instead of forcing a single delay through points that do not support it.

Copyright 2026, James M. Atkinson

12.9 Application 12A.6: Bound a frequency estimate from two epoch measurements

Time-error observations of 1 and 7 μs are separated by 600 s. The central average fractional-frequency estimate is 10^{-8}, corresponding to 0.1 Hz at 10 MHz. If each endpoint has an absolute error bound of 0.1 μs, the difference can range from 5.8 to 6.2 μs. The resulting fractional-frequency interval has approximate endpoints $9.66666667 \times 10^{-9}$ through $1.03333333 \times 10^{-8}$.

This is a worst-case interval because the endpoint errors can take opposite signs. It is not a confidence interval. If the endpoint errors share a common calibration contribution, a statistical analysis may treat their covariance differently, but that requires additional information. The central estimate alone does not show whether a tolerance boundary is resolved.

Copyright 2026, James M. Atkinson

12.10 Application 12A.7: Recognize a phase reset in a finite difference

A phase record has a steady 20 Hz slope and then a 90-degree reset. A 10 μs difference interval crossing the reset reports 20 plus one quarter cycle divided by 10 μs, or 25,020 Hz. Intervals that do not cross the reset continue to report 20 Hz. The large number describes the reset-containing difference, not a persistent oscillator offset.

A derivative is not finite at the idealized phase jump used here. A real instrument may slew rapidly instead, in which case a resolved transient model is needed. In either case, the event must be retained rather than smoothed into a misleading long-term frequency estimate. Splitting the record also prevents a subsequent coherent integration from joining incompatible phase histories without correction.

Copyright 2026, James M. Atkinson

12.11 Application 12A.8: Apply the actual sample clock to elapsed time and frequency labels

A nominal 2 MHz sample clock is actually 25 parts per million high, giving 2000050 samples per second. Two million actual sample intervals occupy 0.999975000625 s, which is -24.999375 μs less than the nominal second. A true 100 kHz tone labeled using the nominal clock appears at 99997.500062 Hz.

The example counts two million intervals, so a record including both endpoints contains two million and one samples. The frequency result also presumes the correct admitted alias class. A wrong clock scale and a wrong alias choice are separate errors and need different challenges. Record the clock estimate and the frequency-axis convention together so that later reprocessing can apply a consistent correction.

Copyright 2026, James M. Atkinson

12.12 Application 12A.9: Form a relative channel phase from two time-error laws

Channel A begins at +100 ns and has fractional frequency $+2\times10^{-9}$. Channel B begins at −50 ns and has fractional frequency -10^{-9}. After 10 s, their relative time error A minus B is 180 ns. At 10 MHz that is 648 degrees unwrapped, or −72 degrees in the principal interval.

These are independently identified channel residuals. A common nominal reference does not make them vanish, because distribution, aperture and processing terms can differ. The appropriate calibration observes a common signal through the paths actually used for the later comparison. If a channel reset or a missing-sample event occurs afterward, the previous relative phase result no longer applies automatically to the successor segment.

Copyright 2026, James M. Atkinson

12.13 Application 12A.10: Choose a calibration interval from deterministic error bounds

At 10 MHz, allow no more than 45 degrees phase error, equivalent to 12.5 ns time error. Suppose justified bounds are 2 ns initially, 10^{-11} in fractional frequency, and 10^{-14} per second in fractional-frequency drift. Solving the quadratic bound gives a maximum interval of approximately 760.681686 s. Substituting the unrounded endpoint returns the 12.5 ns limit.

The result is an engineering interval conditional on those bounds, not a universal recalibration schedule. A changed temperature range, reference source, distribution path, or reset history can invalidate it. Repeat or update the bound when those conditions change. If the initial calibration uncertainty alone exceeds the allowed time error, shortening the interval cannot solve the problem; the initial measurement must improve or the intended claim must change.

Copyright 2026, James M. Atkinson

12.14 Phase Noise and Close-In Observation

Phase noise spreads oscillator energy around a carrier and limits the receiver's ability to see weak signals near strong ones. Contributions arise from the reference, synthesizer, multipliers, local oscillators, clocks, power supplies, and mechanical sensitivity. The analyzer or receiver used to measure phase noise must have lower residual noise or use correlation and reference techniques that separate instrument noise.

Integrated phase noise can be related to timing jitter over a specified offset band, but the integration limits and carrier frequency matter. Close-in flicker, spurs, and far-out white phase noise affect communications, radar, coherent integration, and reciprocal mixing differently. A single jitter number cannot replace the phase-noise spectrum when receiver selectivity is the issue.

Copyright 2026, James M. Atkinson

Figure 65. Multichannel frequency-reference architecture.

Copyright 2026, James M. Atkinson

12.15 Clock Jitter and Sampling Uncertainty

Sampling-clock jitter creates voltage error proportional to signal slope. At high input frequency, a small timing uncertainty can limit effective converter performance even when quantization is excellent. Clock distribution adds skew, additive jitter, duty-cycle distortion, crosstalk, and common-mode coupling. Different digitizers advertised as synchronized may share frequency but not deterministic phase or sample alignment.

Jitter tests use known high-frequency inputs, phase-noise measurements, time-interval instruments, or cross-channel comparison. The measurement distinguishes random and deterministic components where practical. Temperature, cable movement, reference switching, and holdover can change results. For short bursts, trigger and timestamp uncertainty may dominate long-term clock accuracy.

Copyright 2026, James M. Atkinson

$$\sigma_\phi^2 \simeq 2\int_{f_1}^{f_2} 10^{L(f)/10}\, df$$

$\sigma_t = \sigma_\phi/(2\pi f_c)$; example $f_c = 1$ GHz: 0.11 ps

TECHNICAL INTERPRETATION

Integrated jitter depends on the oscillator spectrum AND declared offset integration limits; a single phase-noise point is insufficient.

Figure 66. Phase-noise integration and timing jitter.

12.16 Model 12B: finite-band jitter and coherent signal power

A single RMS jitter value compresses a spectral distribution into one number. That can be useful for a defined timing calculation, but it cannot preserve the offset-dependent receiver consequences of the original phase noise. Model 12B reuses Model 11B's linear single-sideband phase-density convention and states an explicit positive-offset integration band. The corresponding real phase process has equal positive and negative spectral contributions, producing the factor two in its variance. The carrier frequency then converts radians to seconds.

Equation 24A. Linear SSB density and finite-band phase variance

$$\ell(f)=10^{\frac{L_{dBc/Hz}(f)}{10}}$$
$$\sigma_\varphi^2=2\int_F \ell(f)\,df\,,F\subset(0,\infty)\,\textit{is the stated band}$$

Equation 24B. Band-limited phase-to-time conversion

$$\sigma_t=\frac{\sigma_\varphi}{2\pi f_0}\,,f_0>0$$

The phase RMS σ_φ is in radians and timing RMS σ_t is in seconds. Linear SSB density ℓ has reciprocal-hertz units under the adopted radian convention; its logarithmic representation L is reported in dBc/Hz relative to the carrier. The integration set F contains the declared positive offset bands in hertz. Covariance C and increment variance D are in squared radians. In the finite-vector calculation, μ_k is a mean phase and C_{ij} is the covariance of samples i and j; N is their positive integer count.

Integrate linear density, not decibel ordinates. Adjacent bands can be integrated separately and their variance contributions added. A local power-

Copyright 2026, James M. Atkinson

law fit must remain local unless its continuation has been justified and is integrable. A discrete modulation or reference line has a line power rather than a density independent of resolution bandwidth. Analog Devices' MT-008 illustrates linear integration and the phase-to-time conversion; the integration limits in this chapter are chosen explicitly for each constructed case rather than inherited from a generic clock example.[3]

The covariance of the band-limited phase component follows from the cosine transform of its even two-sided spectrum. The phase-difference variance between two instants is twice the variance minus twice their covariance. These are second-order relationships for the stated finite-variance stationary component. They show why two phase-noise distributions with equal integrated variance can affect a given time separation differently: the increment weighting contains one minus the cosine of offset frequency times separation.

Equation 24C. Covariance of the stated phase component

$$C(\tau)=2\int_F \ell(f)\cos(2\pi f\tau)\,df$$

Equation 24D. Phase-increment variance and its spectral weighting

$$D(\tau)=E\left[\left(\varphi(t+\tau)-\varphi(t)\right)^2\right]=2\left[C(0)-C(\tau)\right]$$
$$¿\,4\int_F \ell(f)\left[1-\cos(2\pi f\tau)\right]df$$

Independent timing contributions can have their variances added, but a shared source or coupled path can make them correlated. Retain the

3 Barry N. Taylor and Chris E. Kuyatt, Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results, NIST Technical Note 1297, 1994 edition (September 1994), Appendix A, A.1–A.5, https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. The functional and covariance framework is used within its stated scope; the synthetic ranges, examples and recoverability conclusions are original.

Copyright 2026, James M. Atkinson

covariance or cross-spectral information needed by the calculation. The sign matters: positively correlated errors reinforce when added, while negatively correlated errors can partly cancel. For a difference between channels, the same common contribution can cancel instead of reinforcing. Define the time-error quantity before deciding how to combine its components.

Equation 24E. Two timing contributions with covariance

$$\sigma_{\text{sum}}^2 = \sigma_1^2 + \sigma_2^2 + 2\rho\sigma_1\sigma_2, -1 \le \rho \le 1$$

A PSD alone supplies second-order information. It does not determine every nonlinear phase function. To calculate the exact mean of a complex phase exponential, the next part of the model explicitly assumes a finite jointly Gaussian phase vector with specified mean and covariance. The variance of a phase difference is the sum of the two marginal variances minus twice their covariance. The Gaussian characteristic function then gives the exponential of minus one half that difference variance, multiplied by the deterministic mean-phase factor. This distributional assumption is additional to stationarity or a measured RMS value.

Equation 24F. Finite Gaussian phase-vector differences

$$\varphi \; jointly \; Gaussian : E\varphi = \mu, Cov(\varphi) = C$$
$$D_{ij} = C_{ii} + C_{jj} - 2C_{ij} \ge 0$$

Equation 24G. Gaussian phase-difference characteristic function

$$E\left[\exp\left(j(\varphi_i - \varphi_j)\right)\right] = \exp\left(j(\mu_i - \mu_j)\right)\exp\left(-\frac{D_{ij}}{2}\right)$$

The exponential identity follows by applying the characteristic function of a real normal variable to the phase difference. Integrating its complex exponential against a normal density, or differentiating that Gaussian integral and fixing its value at zero, gives the mean-phase exponential times

Copyright 2026, James M. Atkinson

the exponential of minus one half the variance. A linear combination of a jointly Gaussian vector is normal, so the difference has the required law. Merely knowing the variance of a non-Gaussian difference does not supply this step.

Normalize an equal-weight coherent sum by its positive integer sample count. Expanding its squared magnitude produces every pair of sample phasors, including the diagonal self terms. Taking expectations with the stated Gaussian relation gives mean coherent signal power. Conjugate off-diagonal pairs make the result real. This is not a complete signal-to-noise improvement calculation: additive noise, amplitude variation, and any estimated phase corrections would need their own justified treatment.

Equation 24H. Expected normalized coherent signal power

$$q=\frac{1}{N}\sum_{k=1}^{N}\exp\left(j\varphi_k\right),N\in\mathbb{Z}_{¿0}$$

$$E\left|q\right|^2=\frac{1}{N}+\frac{2}{N^2}\sum_{1\le i<j\le N}\exp\left(-\frac{D_{ij}}{2}\right)\cos\left(\mu_i-\mu_j\right)$$

A common random phase rotates every sample together. It can reduce the magnitude of the ensemble-mean phasor while leaving the coherent power within every record unchanged. Independent sample phases instead create relative rotations and cancellation, with a finite-sample diagonal contribution that remains in the expected power. Equation 24I compares a common Gaussian phase with independent Gaussian phases having the same mean phase and common variance. The shared mean may be taken as zero without changing either power result. Different deterministic mean phases remain in Equations 24H and 24K. These two cases have the same marginal phase variance but different coherence. The Gaussian-vector applications start from stipulated covariance, so they do not rely on

Copyright 2026, James M. Atkinson

interpreting a large measured RF sideband through a small-phase approximation.

Equation 24I. Common Gaussian phase and independent Gaussian phases

$$common\,\varphi : E|q|^2 = 1,\ |\ E\,q\ | = \exp\left(-\frac{\sigma^2}{2}\right)$$
$$independent\ phases : E|q|^2 = \frac{1}{N} + \left(1 - \frac{1}{N}\right)\exp\left(-\sigma^2\right)$$

For a stationary Gaussian vector with equal marginal variance, a specified lag covariance can be substituted directly into the pair sum. It is the increment variance, not the marginal RMS alone, that determines the pair coherence. A proposed covariance matrix must be positive semidefinite to describe a possible joint vector. The geometric lag example below satisfies that condition; an arbitrary table of pairwise correlations might not.

Equation 24J. Equal-variance covariance specified by lag

$$C_{ij} = \sigma^2 \rho^{|i-j|},\ |\ \rho\ | < 1, \mu_k = 0$$
$$D_k = 2\sigma^2[1 - \rho^k]$$
$$E|q|^2 = \frac{1}{N} + \frac{2}{N^2}\sum_{k=1}^{N-1}(N-k)\exp\left(-\sigma^2\left(1-\rho^k\right)\right)$$

Deterministic frequency rotation can be combined with independent Gaussian phase errors by keeping the deterministic phasor sum and the random diagonal contribution separate. Evaluate the finite sum directly at special frequencies where a trigonometric closed form would have a removable zero-over-zero expression. State the actual sample times: N samples separated by a fixed interval have an endpoint span of $N-1$ intervals, even though the geometric-sum numerator involves N times that interval.

Copyright 2026, James M. Atkinson

Equation 24K. Deterministic rotation plus independent phase error

$$\varphi_k = \theta_k + \varepsilon_k, \varepsilon_k \, independent \, N(0, \sigma^2)$$
$$E|q|^2 = \exp(-\sigma^2) \left| \frac{1}{N} \sum_{k=1}^{N} \exp(j\theta_k) \right|^2 + \frac{1 - \exp(-\sigma^2)}{N}$$

Unmeasured phase noise should remain visible as an unmeasured contribution. If a justified upper density bound exists over a finite extra band, integrate it to obtain a variance bound and then convert the interval to timing RMS. Without such a bound, extending a plotted floor is an assumption, not measured evidence. Frequencies outside the declared combined bands remain outside the result, and an RMS number should be labeled accordingly.

Equation 24L. Bound a finite additional offset band

$$0 \le V_{extra} \le 2\ell_{max}(f_H - f_L)$$
$$\frac{\sqrt{V_{meas}}}{2\pi f_0} \le \sigma_{t,combined} \le \frac{\sqrt{V_{meas} + 2\ell_{max}(f_H - f_L)}}{2\pi f_0}$$

Copyright 2026, James M. Atkinson

12.17 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

12.18 Application 12B.1: Integrate a flat SSB density over a declared band

A flat SSB density of −120 dBc/Hz is stipulated from 1 kHz through 1 MHz at a 100 MHz carrier. Its linear density is 10^{-12} per hertz. Multiplying the 999,000 Hz width by twice that density gives $1.998 \times 10^{-6}\ \mathrm{rad}^2$. Phase RMS is 0.001413506 radian, and timing RMS is 2.249665 ps.

The result belongs only to the stated offset band. It does not include a close-in drift or an unmeasured high-offset floor. A comparison with another jitter number is meaningful only after aligning carrier frequency, offset limits, weights and line treatment. Equal numerical picoseconds can otherwise hide very different definitions.

Copyright 2026, James M. Atkinson

12.19 Application 12B.2: Add density bands in linear units

Use −110 dBc/Hz from 1 to 10 kHz and −135 dBc/Hz from 10 kHz to 1 MHz. The two phase-variance contributions are 1.8×10^{-7} and $6.26130977 \times 10^{-8}\ \mathrm{rad}^2$. Their sum is $2.42613098 \times 10^{-7}\ \mathrm{rad}^2$, giving 0.783930 ps at 100 MHz.

The narrower band can contribute strongly because its density is much higher. Averaging the two decibel levels would not integrate either band and would lose their different widths. Keep the contribution table with the result when a design or measurement change affects only one offset region. It then remains clear which part of the noise changed and which part was merely omitted.

Copyright 2026, James M. Atkinson

12.20 Application 12B.3: Keep carrier frequency in the phase-to-time conversion

The same 0.02 radian phase RMS corresponds to 318.309886 ps at 10 MHz and 3.183099 ps at 1 GHz. Conversely, a fixed 1 ps timing RMS corresponds to 0.000062832 and 0.006283185 radian at those two carriers.

Neither comparison shows that one oscillator is better without specifying which physical quantity and observation band are being held fixed. A timing error produces more phase error at a higher carrier. A fixed phase error converts to fewer seconds at that carrier. Preserve the carrier and reference plane whenever phase noise or jitter is transferred between a clock, LO, and sampled-signal calculation.

Copyright 2026, James M. Atkinson

12.21 Application 12B.4: Treat a phase-modulation line as a line, not a density bin

A deterministic 20 kHz phase-modulation line has peak phase 0.01 radian on a 100 MHz carrier. Over complete modulation periods, its phase variance is $5\times10^{-5}\ \mathrm{rad}^2$ and its timing RMS is 11.253954 ps. The first-order RF sideband power is 2.5×10^{-5} on each side, or -46.020600 dBc relative to an unmodulated carrier.

The line power is not a density independent of the analysis bandwidth. A reported dBc/Hz value for the line requires a stated bandwidth convention. Its RMS phase also does not make it a Gaussian phase process. Use its deterministic trajectory when calculating coherence, or state a separate random-phase model if that is the actual experiment. Applying the Gaussian exponential formula solely from this RMS value is unjustified.

Copyright 2026, James M. Atkinson

12.22 Application 12B.5: Include covariance when combining timing contributions

Two additive timing-error contributions have RMS values 2 and 3 ps. Correlation coefficients +0.5, zero, and −0.5 give combined RMS values 4.358899, 3.605551, and 2.645751 ps. The familiar root-sum-square result is only the zero-covariance middle case.

A shared reference can create correlation, but its magnitude and sign still depend on the transfer paths and the defined error quantity. For a relative-channel difference, common-mode timing may cancel instead. Measure or justify the relevant covariance rather than labeling every contribution independent because it has a separate component name. The individual RMS values do not supply that missing information.

Copyright 2026, James M. Atkinson

12.23 Application 12B.6: Distinguish a common random phase from lost coherent power

Eight samples in each record share exactly one zero-mean Gaussian phase with RMS 0.4 radian. The magnitude of the ensemble-mean phasor is 0.92311635, and its square is 0.85214379. Nevertheless, the normalized coherent sum has power one in every record, so its mean power is one.

All eight phasors rotate together and therefore do not cancel within the record. This does not establish their absolute phase relative to an external reference. It establishes that common random rotation and relative phase decorrelation are different effects. The distinction is essential when a measured loss in an ensemble-averaged complex trace is interpreted as a loss of recoverable signal energy.

Copyright 2026, James M. Atkinson

12.24 Application 12B.7: Compute finite-sample coherence for independent Gaussian phases

Now make the eight zero-mean Gaussian phases independent, each still with RMS 0.4 radian. The exact model gives mean normalized coherent power of approximately 0.87062582, or -0.601685 dB relative to unity. Its infinite-sample limit is 0.85214379, but the finite record retains its diagonal self-power contribution.

The marginal RMS is unchanged from Application 12B.6, while the covariance structure is completely different. A single jitter number cannot select between the two results. The independent-phase model may be useful for a stipulated sampled process, but adjacent samples from a narrowband physical phase-noise process are generally not automatically independent. Their actual covariance must support that approximation.

Copyright 2026, James M. Atkinson

12.25 Application 12B.8: Use a specified correlated Gaussian phase vector

Keep eight jointly Gaussian phase samples with 0.4 radian RMS, but specify covariance at lag k as $0.16 \times 0.8^{|k|}$. Substituting those pair differences into Equation 24H gives mean normalized coherent power 0.93937987, or -0.271588 dB. The positive correlation preserves more relative alignment than the independent case.

This covariance is a valid geometric-lag model, not a covariance estimated from an undisclosed instrument record. A measured application would preserve the estimation interval, mean removal, and evidence supporting joint Gaussianity if the exact exponential result were used. Second-order covariance alone can still describe phase differences without establishing that distributional step.

Copyright 2026, James M. Atkinson

12.26 Application 12B.9: Combine deterministic rotation with independent phase errors

Use 100 samples at 100 μs spacing with deterministic residual frequency 50 Hz. Their normalized deterministic coherent power is 0.40531807. Add independent zero-mean Gaussian phase errors with RMS 0.1 radian; expected coherent power becomes 0.40138459, or -3.964393 dB.

Most of the loss here comes from the deterministic rotation, so improving random phase noise alone does not restore coherent integration. The first-to-last sample span is 9.9 ms, while the finite geometric-sum expression uses the 100-sample count. A justified frequency correction can address the rotation, but fitting it to the same weak record introduces an estimation issue that must be evaluated separately.

Copyright 2026, James M. Atkinson

12.27 Application 12B.10: Bound a finite unmeasured high-offset contribution

A measured band contributes $2\times10^{-6}\ \mathrm{rad}^2$. A separate justified upper SSB density bound of 10^{-15} per hertz applies only from 1 to 20 MHz. That finite band can add at most $3.8\times10^{-8}\ \mathrm{rad}^2$. At a 100 MHz carrier, the combined timing-RMS interval has endpoints of approximately 2.250791 and 2.272073 ps.

The upper bound is useful because its domain is explicit. It says nothing about lower offsets excluded from the measured band or offsets above 20 MHz. An unlimited extension of a nonzero white floor would have divergent variance and would contradict the finite-variance premise. A complete timing specification must identify the physical filtering or other evidence that defines its meaningful bandwidth.

Copyright 2026, James M. Atkinson

12.28 Coherent Integration and Phase Preservation

Coherent integration adds complex samples with preserved phase, increasing a stable signal more rapidly than uncorrelated noise. It requires frequency and phase stability over the integration interval. Motion, multipath, modulation, clock error, propagation change, and source instability limit coherence time. Extending integration beyond that time can reduce rather than improve the result.

The practitioner estimates coherence from repeated phase measurements, cross-correlation, or model residuals and validates on a known reference. Phase corrections derived from the signal under test can overfit noise or create artificial coherence. The correction method and degrees of freedom are retained. A weak component revealed only after extensive phase alignment is reported with the processing dependency.

Copyright 2026, James M. Atkinson

12.29 Multichannel Synchronization and Delay Calibration

Copyright 2026, James M. Atkinson

B. Delay produces a phase slope

$\Delta\phi(f) = -360^\circ (f - f_{ref})\Delta\tau$ for f in Hz

$\Delta\tau = 2$ ns gives -0.72°/MHz phase slope.

A common sampling clock does not remove unequal cable, filter, aperture or processing delays. Calibrate phase across the operating bandwidth and document residual frequency-dependent uncertainty.

Figure 67. Phase offset versus broadband delay calibration.

Direction finding, TDOA, phase comparison, and cross-spectral analysis require known channel timing and phase. Shared sampling clocks are not enough if trigger paths, analog filters, cables, ADC apertures, digital pipelines, and packet transport have unequal delays. Calibration uses a common signal injected or radiated into all channels through known

Copyright 2026, James M. Atkinson

geometry and repeated across frequency. The broadband phase-delay distinction is illustrated in Figure 53.

Delay can vary with frequency because of filters and cables. A single time offset may not correct broadband data. Channel swaps and reversal tests help separate sensor geometry from electronics. Missing samples and asynchronous packet timing are monitored. The final uncertainty combines calibration residual, clock stability, location, geometry, interpolation, and signal bandwidth.

Copyright 2026, James M. Atkinson

12.30 Accept coherence at the required boundary and state

Treat reference distribution as a measured network. A common oscillator can feed paths with different cable delays, additive noise, termination sensitivity, power-up behavior, and deterministic phase resets. Identify the clock or LO port, analog aperture, sample index, trigger, and timestamp points used by the intended comparison. A calibration at a convenient reference connector does not automatically establish the relationship at the stored sample boundary.

Use a common injected signal to compare channel amplitude and phase over the required band, then change one element at a time to localize residuals. Channel swaps test whether the error follows a path or a channel. Cable substitution tests delay and sensitivity to installation. Retune, trigger, and restart sequences test whether the phase relation is preserved or must be re-established. Repeat after environmental or configuration changes that can alter the accepted state.

A coherence time should be reported as an interval meeting a specified operation and error criterion. A phase tolerance for beamforming, a coherent tone sum, a cross-spectrum, and a timestamp correlation may lead to different intervals. Model 12B supplies one conditional coherent-power calculation; Model 12A supplies deterministic accumulated-error bounds. Neither replaces actual observation of a system whose reference changes state or whose signal path is not stationary.

Retain the original phase and timing records alongside any correction. A fitted delay, frequency trend, or phase trajectory can improve alignment while concealing the instability being investigated. Verify the correction on a

Copyright 2026, James M. Atkinson

known reference and, where possible, on an interval not used for fitting. If a discontinuity prevents coherent comparison across part of the record, state that boundary and limit the claim to the valid segments instead of forcing a continuous interpretation.

Copyright 2026, James M. Atkinson

12.31 Reference Distribution Acceptance

The reference-distribution system is accepted as a network. Tests include frequency offset, phase noise, additive jitter, channel skew, warmup, holdover, relock, power interruption, cable substitution, and environmental change. Each output is identified and measured at the installed termination, because distribution amplifiers and long cables can dominate performance after the primary reference.

Reference changes during an engagement are logged as configuration events and linked to affected captures. The receiver is not assumed coherent across a retune, trigger reset, firmware restart, or loss of lock unless deterministic phase behavior has been demonstrated. When absolute phase cannot be preserved, the analysis is limited to quantities supported by relative timing or magnitude.

Copyright 2026, James M. Atkinson

12.32 Quantitative Model for Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing

Equation 1. Fractional frequency error

$$\varepsilon_f = \frac{f_{\text{meas}} - f_{\text{ref}}}{f_{\text{ref}}}$$

Fractional frequency error ε_f is the difference between measured and reference frequency divided by reference frequency. It is dimensionless and can be expressed in parts per million or smaller units. The observation interval and reference uncertainty must be stated.

Equation 2. Time jitter from phase noise

$$\sigma_t = \frac{\sigma_\varphi}{2\pi f_c}$$

Root-mean-square time jitter σ_t is related to RMS phase fluctuation σ_φ in radians at carrier frequency f_c when the phase variance has been integrated over a specified offset band. The conversion does not retain the spectral distribution of the noise.

Equations 23 and 24 use the conventions developed in Models 12A and 12B and their respective ten applications. The reference frequency and carrier frequency are positive. Phase-to-time conversion retains the stated offset band and phase convention; it does not establish a broadband physical path delay from one scalar jitter value.

12.33 Hypothetical Applied Calculation: Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing

A 1.000000000 GHz reference is measured 120 Hz high. The fractional error is 1.2×10^{-7}, or 0.12 parts per million. If the measurement receiver's reference uncertainty is 0.2 parts per million, the observed difference is not sufficient to claim that the source is out of tolerance.

Copyright 2026, James M. Atkinson

12.34 Hypothetical Case Adjudication: Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing

Three remote SDR channels share a disciplined 10 MHz source but use independent packet triggers. A TDOA estimate suggests an impossible location until calibration shows packet-alignment variations of several samples. Adding a deterministic trigger and per-channel delay calibration resolves the geometry. Shared frequency alone had not provided synchronized sampling.

Copyright 2026, James M. Atkinson

12.35 Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation

A nominal common frequency reference is not sufficient to claim simultaneous RF observation. Multichannel receivers also require knowledge of sample-aperture phase, clock distribution delay, trigger alignment, counter semantics and periods when a disciplined reference was lost. In a simplified clock model, local time $t_i = a_i t_{ref} + b_i + \epsilon_i(t)$, a_i represents scale or rate error, b_i the epoch offset, and ϵ_i time-dependent deviation. Estimating these parameters from a shared reference pulse can align observed events but must include reference-pulse propagation, antenna geometry, analogue group delay, detector latency and timestamp definition. A host file-creation time need not represent a converter aperture even when the host operating system is synchronised to a trusted time service.

Holdover error grows after loss of discipline according to the underlying oscillator's frequency instability and any applied drift model. If a clock has a constant fractional frequency error $y = 2$ parts per million after the last confirmed reference event, then after 90 seconds its idealised accumulated time offset is y multiplied by 90 s, or 180 microseconds. That is a deterministic illustrative drift, not a bound for every oscillator; temperature and random-walk frequency noise can make the actual deviation vary with elapsed time. An instrument that reports a syntactically precise timestamp to the nearest nanosecond may nevertheless possess hundreds of microseconds of uncertainty under such conditions. Stated time digits, absolute accuracy and phase coherence must be treated as distinct claims.

Copyright 2026, James M. Atkinson

A correct multi-receiver timing uncertainty calculation is covariance aware. If two channel time estimates have variances u_1 squared and u_2 squared and covariance c_12, the variance of their difference is u_1 squared + u_2 squared - 2c_12. A shared reference offset may cancel in a difference, while a common clock-distribution transient may affect all channels and defeat independent corroboration. For a location inference, correlations of arrival-time errors can determine the shape of the feasible spatial region. Assuming zero covariance without evidence may make a calculated error ellipse look implausibly narrow. The acquisition plan should record which inputs are common, which are independently disciplined and where clocks are rederived or resampled.

Copyright 2026, James M. Atkinson

A common reference does not automatically guarantee coherence; path delays and independent timing noise still require calibration.

Figure 68. Common and independent clock jitter.

The integrity record should preserve original sample counters and clock-state events before fitting a common time coordinate. A sample counter can remain continuous through a host writing delay, while a temporary device-buffer overflow can remove samples even if file timestamps are regularly

Copyright 2026, James M. Atkinson

spaced. Partition the record into acquisition epochs separated by resets, loss of lock, counter discontinuities or unvalidated state changes. Timing corrections and interpolation belong to derivative products, with the raw counter sequence still available. Cross-correlation of two received signals is useful only after accounting for their possible shared interference and source content, and is not a substitute for demonstrating that the recorded waveform belonged to the claimed physical event.

12.36 Advanced technical expansion. Shared clocks, holdover uncertainty and coherent-channel covariance

Frequency accuracy and coherent timing involve several quantities that must not be collapsed into one clock specification. A stable reference frequency, short-term phase fluctuations, long-term drift, synchronisation offset, transport asymmetry and sample-aperture timing are connected but different. A converter can have an accurate nominal sample rate while individual aperture times vary enough to damage high-frequency coherent measurement. Conversely, multiple receivers may appear synchronised because they share one reference, yet the same reference fault can affect every channel and create misleadingly consistent results. The measurement record should identify where each timestamp is generated and which event it denotes, rather than assigning all recorded dates the evidential strength of an actual sample-aperture measurement.

For a reference oscillator with nominal frequency f_0 and fractional frequency error y(t), accumulated time error x(t) follows the integral of y(t) over elapsed time under the selected sign convention. A constant fractional error of 1 part in 10^9 causes approximately 1 microsecond of accumulated time error over 1,000 seconds if no correction is applied. A constant error is a simple illustrative model; real holdover includes drift, stochastic noise, temperature sensitivity and retraining after reference acquisition. A user who reports a single 'clock accuracy' value without its averaging interval or holdover duration has not specified the quantity needed for coherent reconstruction. The uncertainty of a time interval may increase substantially

Copyright 2026, James M. Atkinson

when the external reference is lost, even while the receiver continues to emit plausible timestamps.

Short-term stability must be described at a relevant observation interval and with an estimator compatible with the noise process. Allan variance and related stability statistics can help distinguish characteristic oscillator-noise behaviours, but their interpretation depends on sampling, dead time, estimator and the span of available data. A plotted stability curve is not a universal upper bound on future holdover performance. If receiver channels share power supplies, enclosure temperature and common reference distribution, they also share components of the timing error. A multichannel uncertainty budget should therefore include common-mode covariance instead of claiming that averaging the channels creates independently timed evidence. Independence requires a physical argument about fault and noise mechanisms, not just separate channel identifiers.

Relative phase error becomes particularly important as RF frequency rises. For a pure sinusoid of frequency f, a time-offset error delta_t corresponds to phase difference delta_phi = 2 pi f delta_t. A 200-ps relative timing uncertainty at 1 GHz corresponds to approximately 1.257 radians, or 72 degrees. For a phase-coherent array, that is potentially consequential even though the same time error appears negligible on a millisecond-level event log. The error can also be frequency dependent because cable and distribution-network group delays vary across the band. A calibration at one tone therefore does not prove phase agreement for every captured waveform. The installed network, connector state and temperature must be part of the calibration evidence.

Copyright 2026, James M. Atkinson

A distributed receiving system requires separate validation of common time, sample indexing and signal propagation delay. A timestamp assigned when a packet arrives at a computer is not interchangeable with the time of the ADC aperture; network transport, buffering and retransmission can introduce delays uncorrelated with the RF event itself. A hardware trigger may mark one event but not prove that all downstream samples were retained. Record source-clock identity, synchronisation status, reference transitions, per-channel sample counters, measured phase offsets, and the actual delay correction model. On loss of reference lock, partition the record into controlled, transition and holdover intervals; release time-based findings only within the applicable uncertainty of each interval.

An independent challenge should vary reference conditions and use a controlled coherent source of known phase relationship, ideally with separate corroboration of the source path. Inject or observe the reference at multiple frequencies, temperatures and gain states, and measure the residual phase and timing after the exact corrections used in subsequent analysis. Repeat after a reference interruption, because reacquisition may produce a phase discontinuity even when the indicated frequency has returned to nominal. The final assurance can then state what relative coherence was demonstrated, for which duration and bandwidth, and what uncertainty remains. It should not convert agreement of two instruments that shared the same faulty clock into proof of physical source identity or precise arrival-time geometry.

Copyright 2026, James M. Atkinson

12.37 A stochastic and deterministic state description for clocks used in coherent receiving

Frequency accuracy, frequency stability and phase coherence are distinct properties. Accuracy concerns agreement with a stated reference over a declared interval; stability concerns changes in the frequency process as observation time varies; coherence concerns the relative phase behaviour of the quantities actually compared. An oscillator can exhibit excellent short-interval stability while maintaining a substantial fixed frequency offset. Two channels sharing one inaccurate reference can nevertheless retain excellent relative phase coherence, whereas independently accurate oscillators can have poorly controlled relative short-term phase. These distinctions become consequential in RF surveys because the same numerical time stamp may be asked to support carrier-frequency measurement, pulse association, direction finding and an assertion that two receivers observed the same physical event.

Let $x_i(t)$ denote time error of clock i, expressed in seconds relative to the declared reference epoch, and let $y_i(t)=dx_i(t)/dt$ denote instantaneous fractional frequency error where the derivative exists. A useful local deterministic model is $x_i(t)=x_i(0)+y_i(0)t+(1/2)d_i t^2+w_i(t)$, in which $x_i(0)$ is the initial time offset in seconds, $y_i(0)$ is dimensionless fractional-frequency offset, d_i is its local rate of change per second, and $w_i(t)$ represents an explicitly characterised stochastic or unmodelled contribution in seconds. This quadratic model is not a general physical guarantee. A reference reacquisition, cycle slip, counter reset or software correction can introduce discontinuities for which a single differentiable law is

Copyright 2026, James M. Atkinson

inappropriate. Such occurrences require separate state intervals and explicit transition records.

For an RF sinusoid with frequency f_c hertz, the time error x_i produces carrier phase perturbation $\varphi_i(t)=2\pi f_c x_i(t)$ radians under the chosen positive-exponential convention. The phase difference relevant to coherent combination is $\varphi_1-\varphi_2$, not simply the largest individual clock error quoted on a datasheet. Thus uncertainty in the relative time error $\Delta x=x_1-x_2$ must be calculated with its covariance: $\mathrm{Var}(\Delta x)=\mathrm{Var}(x_1)+\mathrm{Var}(x_2)-2\mathrm{Cov}(x_1,x_2)$. Positive common-mode correlation can make relative error much smaller than either absolute uncertainty. Conversely, a shared hidden clock jump can bias every channel and leave relative coherence apparently intact while corrupting absolute event time. A clocking architecture therefore needs independent tests for relative coherence and external time traceability.

Copyright 2026, James M. Atkinson

12.38 Characterising short- and long-term stability without confusing one statistic for another

The ordinary standard deviation of a free-running clock's frequency measurements may depend strongly on record length when drift and low-frequency noise are present. Allan deviation instead characterises differences between adjacent fractional-frequency averages over a specified averaging time τ. For M consecutive non-overlapping averages ybar_k of equal duration τ, define σ_y^2(τ)=[1/(2(M-1))] sum from k=1 to M-1 of (ybar_(k+1)-ybar_k)^2. The definition requires that sampling, gaps and data preprocessing be stated. It is not a prediction of every future time error; that prediction also needs the noise class, deterministic drift, environment, initial state and relevant forecast horizon. Modified Allan deviation and time deviation address related but distinct aspects of noise and timing performance, and the analyst must choose the statistic that answers the instrument's coherence or timestamp requirement.

Noise classes influence extrapolation. White frequency noise can average differently from flicker frequency noise or frequency random walk. Environmental temperature cycles, vibration-induced stress, reference-distribution faults and oscillator ageing may produce deterministic structure not represented adequately by a stationary random process. A log-log plot of a stability statistic can help diagnose a regime, but a short record and an attractive straight line are not proof of a particular power-law noise mechanism. Identify the measurement bandwidth and counter dead time, estimate confidence from the actual number of independent differences, and compare candidate models against held-out data. A stability figure at

Copyright 2026, James M. Atkinson

τ=1 s should not be transferred unqualified to a two-day holdover prediction.

A responsible holdover bound has three layers. First account for the known starting phase and frequency state, including their covariance. Second propagate any supported deterministic frequency slope or temperature response. Third add the random forecast error appropriate to the identified noise process, without assuming samples separated by τ are independent unless the evidence supports that. If the time-scale reference disappears, a receiver can preserve its own sample continuity while losing traceable absolute time. If the internal sampling oscillator also changes or relocks, frequency mapping and sample-aperture spacing may change. These are different failures and should have different flags in the acquisition manifest.

Copyright 2026, James M. Atkinson

12.39 The measurement chain of a distributed reference

A laboratory reference output does not instantaneously become the same phase at every receiver connector. Distribution amplifiers introduce propagation and group delay; coaxial or optical runs respond to temperature and mechanical displacement; connectors, power supplies and multipliers can add their own phase disturbances. Define the actual reference plane at which timing is claimed. For each branch measure fixed delay, its temperature coefficient and any residual stochastic phase difference. A disciplined two-channel test measures a common stable RF source through matched input paths and compares the channels after their separate distribution paths. A subsequent channel swap can help separate receiver-specific effects from fixture or source effects, provided the swap itself is recorded and does not change the physical question.

A 10 MHz reference, a 1-pulse-per-second epoch signal, and an ADC sample clock have different jobs. A locked 10 MHz reference can control long-term frequency without establishing the absolute sample epoch. A 1-PPS edge can mark a nominal epoch without establishing that each sampled edge occurs at the commanded aperture instant. An FPGA packet timestamp may describe a buffer event rather than the first analogue sample. The validation record must link counter states and hardware sample indexes to the epoch mapping. An apparent one-sample disagreement may indicate a dropped sample, an initial alignment error or a genuine propagation-time difference. These mechanisms cannot be identified from nominal reference frequency alone.

Copyright 2026, James M. Atkinson

Timestamp and phase offsets may also be frequency dependent. If a common observation passes through different analogue filters, equal sample-clock epochs need not imply equal group delay of the retained waveform. The appropriate composite delay is the sum of cable propagation, analogue-filter group delay, converter and digital-filter latency, buffering where applicable, and any algorithmic timestamp convention. Some terms are deterministic within a state, others random, and some depend on the signal spectrum. Delay correction must refer to the same feature and observation band as the reported event. A wideband pulse-edge timestamp and a narrowband carrier-phase timestamp need not shift by the same amount.

Copyright 2026, James M. Atkinson

12.40 Reference transitions, cycle slips and false continuity

A receiver that is disciplined to an external reference may encounter a transition to holdover or another reference during collection. The frequency may stay approximately continuous while the phase jumps, or the phase may be steered continuously while the instantaneous frequency deviates during the correction. Both affect a coherent record. Phase unwrapping can conceal a true integer-cycle slip if the tracking algorithm automatically chooses the nearest phase continuation. Conversely, a low-SNR observation may introduce a false slip where the hardware clock never changed. Test for slips with independent counter or status events, a stable reference injection and alternate phase unwrapping parameters. Do not resolve physical ambiguity merely by choosing the smoothest reconstructed phase curve.

A digital resampler can compensate modest sample-rate mismatch and produce a useful common-rate analysis stream, but that is a derived representation. Its interpolation kernel, group delay, edge handling and treatment of gaps must be retained; the result is not evidence that the original converter sampled at a different physical rate. When two receivers are aligned by cross-correlation, the peak can reflect propagation delay, repeated waveform structure or an ambiguous periodic modulation, not necessarily a unique clock offset. Correlation is a measurement of the selected signal and model. A short event with unknown source location cannot generally establish both the emission time and each receiver's absolute clock offset from the same observed arrival times.

Copyright 2026, James M. Atkinson

12.41 Coherence under stochastic phase error

For N equal-amplitude analytic phasors, define the normalised coherent sum $z=(1/N)\sum_{k=1}^{N}\exp(j\varphi_k)$. If the residual phases are independent, zero-mean Gaussian with common variance σ_φ^2, then $E|z|^2=1/N+(1-1/N)\exp(-\sigma_\varphi^2)$. This result depends on the stated distribution and independence. If every φ_k is the same random common phase, $|z|^2=1$ for each realisation and there is no relative coherent-power loss, although an external absolute phase estimate may remain uncertain. A mixed covariance matrix produces a different result. Thus the correct input to multichannel coherence analysis is the pairwise phase-difference structure, not the list of independent oscillator specifications.

Phase-noise spectra must be integrated in linear units over a physically declared Fourier-offset band. A single-sideband level expressed in dBc/Hz is logarithmic and cannot simply be summed across bands as an ordinary power. Discrete spurs require a line-power treatment rather than being treated as a density multiplied by an arbitrary resolution bin. The integrated phase variance depends on high- and low-offset bounds, filters and the definition of the measurement channel. Unmeasured phase-noise regions cannot be assigned zero contribution merely because the displayed plot does not extend to them. At high carrier frequencies even a small time uncertainty may become substantial relative phase, while common-mode cancellation may preserve coherence when both channels share the same disturbance.

Copyright 2026, James M. Atkinson

12.42 Ten numerical applications, each with stipulated assumptions

Application 12C.1. Take a free-running oscillator with a fixed fractional frequency error $y_0=2.0\times10^{-9}$ and no drift or random term during 6 hours. The accumulated time error is $x=y_0\,t=(2.0\times10^{-9})(21{,}600\text{ s})=43.2$ microseconds. This is not the expected error of a disciplined clock; it is a conditional demonstration that an apparently small fractional offset accumulates. At a carrier frequency of 100 MHz, the corresponding raw carrier phase represents 4,320 complete cycles. A phase display confined to $\pm\pi$ cannot recover the number of missed turns from that final sample alone.

Application 12C.2. Let the residual fractional frequency drift rate be $d=4\times10^{-14}\text{ s}^{-1}$ over 4 hours, with zero initial time and frequency error and no stochastic contribution. The quadratic term is $x=(1/2)d\,t^2=0.5\times4\times10^{-14}\times14{,}400^2=4.1472$ microseconds. A straight-line extrapolation from the initial frequency would predict zero and fail. The calculation is a hypothetical model over its declared interval; temperature steps or drift-rate changes require separate segments.

Application 12C.3. Two receiver channels have standard time errors of 2 ns and 3 ns and covariance of +3 ns^2. The differential variance is $4+9-2\times3=7\text{ ns}^2$; the standard deviation is $\sqrt{7}=2.646$ ns. If independence were asserted, the value would be $\sqrt{13}=3.606$ ns. Neither result is automatically an empirical clock specification; covariance must be determined for the actual distribution and shared physical path.

Application 12C.4. A 2 GHz sinusoid observed at two channels has a residual relative delay of 50 ps. The phase is $2\pi\times2\times10^9\times50\times10^{-12}=0.628319$ rad, or

Copyright 2026, James M. Atkinson

36 degrees. An uncorrected 50 ps delay matters greatly at 2 GHz even though it may be negligible for a slow envelope timestamp. The relevant value is the differential delay at the actual RF or coherent baseband phase reference, including analogue and digital path contributions.

Application 12C.5. At 1 GHz input frequency, assume uncorrelated Gaussian sampling-aperture jitter of 1 ps rms and that this source dominates the relevant noise mechanism. The familiar small-jitter sinusoidal bound is $SNR \approx -20\log10(2\pi f \sigma_t) = -20\log10(0.006283) = 44.04$ dB. It is an ideal jitter-limited bound, not a total ADC SINAD or ENOB measurement. Correlated jitter, analogue source phase noise and other converter errors require another model.

Application 12C.6. A hypothetical channel has measured phase standard deviation $\sigma_\varphi = 0.20$ rad, with independent Gaussian phase error across N=8 equal phasors. The expected normalised coherent power is $1/8+(7/8)\exp(-0.04)=0.96569$, corresponding to about -0.152 dB. Replacing those phases with one common random phase of the same marginal variance yields $|z|^2=1$. The example exposes why marginal phase statistics do not determine array coherence.

Application 12C.7. A link of 100 m has propagation velocity 2.0×10^8 m/s under a stipulated effective cable model. Its one-way delay is 500 ns. Two unequal cables differing by 0.40 m contribute an approximate 2.0 ns relative delay. Calibration must determine actual electrical length, dispersion and temperature, not merely tape-measured physical length; the example is an illustration of scale, not a cable-specific certificate.

Copyright 2026, James M. Atkinson

Application 12C.8. A clock-status log shows the last trusted epoch at t=0 and the first detected relock at 1,200 s, while a saved RF segment spans 1,150–1,250 s. Without a trustworthy transition time inside that window, the segment cannot be assigned one uninterrupted clock state. It may be partitioned only if independent evidence supports the boundary; assigning the relock to the log-receipt instant would assume zero telemetry latency and a particular timestamp convention.

Application 12C.9. Four successive fractional-frequency averages in units of 10^-9 are 1, 2, 1 and 3, each lasting 10 s without gap. Their adjacent differences are 1, -1 and 2 in those units. Allan variance at τ=10 s is $(1^2+(-1)^2+2^2)/(2\times3)\times10^{-18}=1\times10^{-18}$ and Allan deviation is 1×10^-9. This is a sample statistic for the stipulated four averages. It provides no justified confidence band without the relevant noise model and estimator treatment.

Application 12C.10. A source is observed at t_A=10.000000150 s and t_B=10.000000390 s. Independently calibrated channel delays are 100 ns and 280 ns. Corrected arrivals are therefore t_A'=10.000000050 s and t_B'=10.000000110 s, differing by 60 ns. That residual could arise from different propagation paths, clock error or event-picking uncertainty. It does not by itself identify a source position. To infer geometry, specify sensor positions, propagation medium, synchronisation errors and the event feature used to assign each timestamp.

Copyright 2026, James M. Atkinson

12.43 Controlled acceptance of a multichannel timing network

A practical acceptance campaign must cover ordinary locked operation, warm start, cold start, source substitution, reference dropout, holdover, relock, thermal excursions, and the loss or corruption of packet metadata. For every condition retain the source configuration, oscillator and synthesiser states, branch delays, sample indexes, time scales and phase observations. Use at least one common injected reference to test relative coherence and a separately traceable epoch test to establish absolute timing. Where the channels share hardware, document the resulting covariance rather than claiming independence. A control programme must also examine the failure path: a receiver may continue writing plausible timestamps during reference loss even if those times have lost their claimed accuracy.

The final timing report should provide explicit validity intervals, an uncertainty budget for absolute epoch and for relative channel delay, stated carrier and observation bandwidths, and the test evidence supporting any correction. It should preserve separate estimates for deterministic drift, stochastic stability, reference-distribution delay and software timestamp latency. Where the data do not determine one of those quantities, retain that limitation instead of absorbing it into a conveniently enlarged generic error bar. The result is a usable coherence assurance: it shows what phase or timing inference is supported, for which channels, over what interval, and under which equipment states.

Copyright 2026, James M. Atkinson

12.44 Clock discipline, common references and why coherent SDR channels require more than simultaneous start commands

A phase-locked or frequency-disciplined oscillator provides a controlled relation between a local oscillator and a reference, but its precision must be described at the timescales on which RF samples are compared. The reference may discipline long-term frequency while a local quartz or microwave oscillator dominates short-term phase noise. A ten-megahertz reference delivered to many receivers is not equivalent to proof that their converter apertures open on the same sample edge, or that their microwave translation oscillators have identical phase. A common one-pulse-per-second event may align counters without determining the fractional sample delay or the initial mixer phase. The three separate requirements are rate accuracy, epoch alignment and relative phase calibration. Only their combination, with uncertainty records, can support strong claims about coherent array processing.

For an RF sinusoid of frequency f, a relative time error δt produces phase error $\delta\varphi=2\pi f\delta t$ in radians when the error is referred to the original RF waveform. At 40 GHz, one picosecond corresponds to 0.2513 rad or 14.4 degrees; keeping this particular phase error under one degree would require $|\delta t|<1/(360f)$, approximately 69.4 femtoseconds. This is an explanatory bound, not a universal converter clock specification. A superheterodyne chain may translate the desired signal to a much lower IF before the ADC, while uncertainty in the LO phase persists as a separate contribution. The phase relationship of the original RF input to each channel

Copyright 2026, James M. Atkinson

must be reconstructed from the complete chain; using the downstream sample rate alone can grossly misstate cross-channel coherence.

A convenient channel model is $z_k[n]=g_k s(t_n-\tau_k)\exp(j\varphi_k[n])+\eta_k[n]$, where g_k is complex gain, τ_k is the calibrated path delay, $\varphi_k[n]$ includes residual LO and sampling-reference phase errors, and η_k comprises channel-specific and shared noise. If several channels share a distributed reference, some errors can be correlated. The variance of the relative phase $\varphi_i-\varphi_j$ equals $\mathrm{Var}(\varphi_i)+\mathrm{Var}(\varphi_j)-2\mathrm{Cov}(\varphi_i,\varphi_j)$; omitting the covariance misstates how much common-reference noise cancels in an interferometric comparison. Conversely, assuming perfect cancellation can be worse when branch-specific PLLs amplify different phase-noise bands or a reference splitter introduces time-varying skew. The covariance needs measurement over the chosen integration time and RF offset, not merely a wiring diagram.

A phase-locked loop changes, rather than eliminates, phase noise. Within a suitable loop bandwidth, output phase may track reference fluctuations plus divider and loop noise; beyond that range the voltage-controlled oscillator and other circuit contributions can dominate. Loop transfer functions, reference multiplication, frequency dividers and mixer stages all alter phase-noise spectral density. The designer should measure integrated phase variance in the bands actually used by coherent processing, as well as Allan deviation or an appropriate frequency-stability statistic over millisecond, second and four-hour timescales. A reference that looks excellent at one-second averaging time might drift badly during a long holdover interval, and the inverse is equally possible. NIST explicitly distinguishes oscillator stability from frequency correctness; both belong in a complete receiver acceptance case.

Copyright 2026, James M. Atkinson

Phase coherence can be validated with a distributed known reference signal injected at a clearly defined electrical or radiated plane. Record complex channel phase against the common reference before and after long acquisitions, while logging clock-lock state, reference-source changes, synthesiser relock, temperature, cable movement and converter lane resets. Detect phase discontinuities with unwrapped phase residuals while guarding against false cycle slips at low amplitude. For a moving antenna or array, geometry can also create real path-dependent phase changes. Report the inferred electronic phase drift separately from actual propagation phase. A single calibration at boot cannot certify every phase relationship for four hours when environmental temperature and system load vary.

The acceptance protocol must include induced clock faults and independent witness timing. Test loss and restoration of the reference, short phase hits, reference switching, deliberate frequency offset, FPGA sample-counter resets, and distributed timestamp jitter. Inject a reference whose timing can be measured by an independent time-interval counter, not solely by the same PLL whose behaviour is in question. If an event falls during an uncertain holdover transition, retain the native samples and mark the interval as phase-uncertain instead of silently phase-rotating it to agree with a preferred hypothesis. Some amplitude or energy conclusions may survive phase uncertainty; source location inferred by interferometry may not.

Copyright 2026, James M. Atkinson

12.45 Selected timing calculations and loss-of-coherence limits for a forty-gigahertz observation system

Application C12.1. A relative delay of 1 ps at 40 GHz yields 360×40×10^9×10^-12=14.4 degrees of RF phase. At 10 GHz the same delay gives 3.6 degrees. Stated in degrees, the answer depends on the original signal frequency to which delay is referred and does not prove that the converter samples directly at that frequency.

Application C12.2. The delay corresponding to one degree at 40 GHz is 1/(360×40×10^9)=69.44 femtoseconds. At 1 GHz it is 2.778 picoseconds. The result is a phase requirement for that particular signal, not a prescription that every individual hardware clock must have such jitter under every measurement purpose.

Application C12.3. With independent random phase-error standard deviations of 0.04 and 0.03 radians for two channels, the relative standard deviation is sqrt(0.04^2+0.03^2)=0.05 radians. If their covariance is +0.0006 radian squared, the relative variance is 0.0016+0.0009−0.0012=0.0013 radian squared, giving about 0.0361 radians. The assumed covariance must be documented rather than inferred from common wiring.

Application C12.4. For sample-clock aperture jitter σ_t=100 femtoseconds and a directly sampled tone at 10 GHz, the sinusoidal jitter-limited SNR is approximately −20 log10(2π×10^10×10^-13)=44.04 dB. At 1 GHz under otherwise identical assumptions it is 64.04 dB. This simplified relation assumes small, uncorrelated timing error and excludes amplitude noise, fixed skew and other distortion.

Copyright 2026, James M. Atkinson

Application C12.5. A common nominal sample rate of 100 MS/s gives 10 ns sample spacing, but synchronising two receive start commands to within 100 ns only locates their epochs within ten sample intervals. A valid coherent comparison requires sample-index alignment, residual fractional-delay calibration and the relevant LO phase relation.

Copyright 2026, James M. Atkinson

Chapter Summary

Frequency and phase integrity are separate from nominal tuning. Reference state, phase noise, jitter, trigger, delay, and coherence determine whether precision spectral and multichannel inferences are valid.

Model 12A distinguishes initial epoch error, fractional-frequency offset and local drift. Integrating them gives time error; a declared carrier converts it to clock phase. Physical delay has the opposite transfer-phase sign. Wrapped observations, phase resets and sample-clock scale errors retain their own ambiguity or segment boundaries. Calibration intervals follow from stated bounds and the required tolerance.

Model 12B integrates phase-noise density in linear units over explicit offset bands and handles lines separately. Carrier frequency controls conversion to timing RMS. Coherent signal power additionally depends on relative phase and covariance. Its exact Gaussian-vector calculation retains finite-sample self terms and deterministic rotation; neither one RMS number nor a spectrum alone establishes all those distributional assumptions.

Accept the installed reference network at the actual acquisition and stored-sample boundaries. Use common signals, channel swaps and state changes to test residual relationships. Preserve original timing records and validate fitted corrections beyond their fitting interval. When phase continuity is not demonstrated, limit comparisons to the supported segments and quantities.

Chapter 12 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C12-MCQ-001. What does positive clock time error mean in Model 12A?

A. The clock frequency must be permanently high

B. A physical propagation path necessarily has positive transfer phase

C. The sample rate must be lower than nominal

D. The clock is advanced relative to ideal reference time

Answer: D. The convention defines clock reading as ideal time plus time error; its derivative determines fractional frequency. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: The clock is advanced relative to ideal reference time.

Distinguishing consideration: compare this with option A, “The clock frequency must be permanently high”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-002. Why can correct frequency coexist with incorrect sample alignment?

A. Zero frequency error implies zero time error at all epochs

B. Frequency agreement fixes every aperture delay

C. A shared rate necessarily aligns every trigger

D. A constant epoch error has zero derivative but shifts timing

Answer: D. Initial epoch and frequency offset are distinct terms in the time-error model. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: A constant epoch error has zero derivative but shifts timing.

Distinguishing consideration: compare this with option A, “Zero frequency error implies zero time error at all epochs”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-003. How does positive physical delay differ from positive clock advance in the stated conventions?

A. Delay changes only amplitude, not phase

B. Delay gives negative transfer phase; advance gives positive relative clock phase

C. Both always give the same positive phase

D. Both always give negative phase independent of definition

Answer: B. The transfer exponential and clock-error convention have opposite signs and must not be conflated. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: Delay gives negative transfer phase; advance gives positive relative clock phase.

Distinguishing consideration: compare this with option A, “Delay changes only amplitude, not phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-004. What can resolve the two-tone wrapped-delay ambiguity?

A. The fact that both tones are detected

B. More decimal places in the same wrapped readings alone

C. A justified unwrap, compatible delay prior, or additional calibrated frequency information

D. A common nominal frequency label alone

Answer: C. Branch selection requires additional information, not numerical precision alone. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: A justified unwrap, compatible delay prior, or additional calibrated frequency information.

Distinguishing consideration: compare this with option A, “The fact that both tones are detected”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-005. Why are bounded endpoint time errors not automatically standard uncertainties?

A. Their signs are always independent Gaussian variables

B. Bounds specify permitted values without a probability distribution

C. A sufficiently long interval makes all error models equivalent

D. Every bound is exactly one standard deviation

Answer: B. Statistical uncertainty needs justified distribution and dependency information beyond the bounds. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: Bounds specify permitted values without a probability distribution.

Distinguishing consideration: compare this with option A, “Their signs are always independent Gaussian variables”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-006. How many endpoint samples are required to span N actual sample intervals?

A. N plus one

B. N minus one

C. N

D. Two N

Answer: A. A count of samples differs by one from the count of intervals between first and last endpoints. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: N plus one.

Distinguishing consideration: compare this with option B, “N minus one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-007. If the true sample clock is high and software labels a valid alias-class tone using the lower nominal rate, what happens?

A. The label is true frequency divided by one plus fractional rate error

B. The label always equals the true frequency

C. The alias class becomes uniquely known from the clock correction

D. The label is necessarily higher by exactly the rate error in hertz

Answer: A. Frequency-axis scaling and alias identification are separate requirements. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: The label is true frequency divided by one plus fractional rate error.

Distinguishing consideration: compare this with option B, “The label always equals the true frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-008. When is a positive waiting interval infeasible under the deterministic calibration envelope?

A. The frequency and drift bounds are small but positive with available margin

B. The time tolerance is expressed in nanoseconds rather than seconds

C. The initial error bound already exceeds the tolerance

D. The initial bound is below tolerance and both growth bounds are zero

Answer: C. Shortening the interval cannot repair an initial uncertainty already outside the allowed region. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: The initial error bound already exceeds the tolerance.

Distinguishing consideration: compare this with option A, “The frequency and drift bounds are small but positive with available margin”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-009. What derivative connects time error to fractional-frequency error?

A. The derivative of displayed amplitude

B. The second derivative of phase divided by sample count

C. The time error itself without a derivative

D. The first derivative of time error with respect to ideal time

Answer: D. The model defines fractional frequency as dx/dt; local drift is its derivative. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: The first derivative of time error with respect to ideal time.

Distinguishing consideration: compare this with option A, “The derivative of displayed amplitude”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-010. A constant positive fractional-frequency error starts from zero epoch error. How does time error evolve?

A. Linearly upward with elapsed time

B. It remains zero because the initial epoch was correct

C. It changes only at trigger edges

D. It decreases quadratically for every positive error

Answer: A. Integrating a constant frequency offset produces a linear time-error accumulation. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: Linearly upward with elapsed time.

Distinguishing consideration: compare this with option B, “It remains zero because the initial epoch was correct”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-011. A local fractional-frequency drift is constant. Which time-error term does it produce?

A. A linear term equal to drift without time units

B. A quadratic term with one-half the drift coefficient

C. Only a constant epoch offset

D. A logarithmic term independent of initial state

Answer: B. Integrating a linear fractional-frequency law yields the stated quadratic time term. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: A quadratic term with one-half the drift coefficient.

Distinguishing consideration: compare this with option A, “A linear term equal to drift without time units”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-012. What units belong to fractional-frequency drift d in Model 12A?

A. Hertz squared for every carrier

B. Radians alone

C. Seconds

D. Per second

Answer: D. Fractional frequency is dimensionless, so its time derivative has inverse-time units. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: Per second.

Distinguishing consideration: compare this with option A, “Hertz squared for every carrier”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-013. Which event can invalidate extrapolating a fitted drift law through the next interval?

A. Warmup, holdover, reference reacquisition, or a power interruption

B. A stated unchanged reference plane

C. An additional copy of the same calibration file

D. A consistent unit conversion

Answer: A. The polynomial is local to a declared segment and operating conditions.

Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: Warmup, holdover, reference reacquisition, or a power interruption.

Distinguishing consideration: compare this with option B, “A stated unchanged reference plane”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-014. What does a lock indicator fail to establish by itself?

A. That a lock status was reported

B. The nominal reference label

C. Epoch alignment, short-term purity, and all drift behavior

D. The presence of a recorded status field

Answer: C. Status is evidence of a reported condition, not a full timing or noise characterization. Source: §12.1 Frequency Reference and Tuning Accuracy (p. 6950)

Why the selected alternative fits: Epoch alignment, short-term purity, and all drift behavior.

Distinguishing consideration: compare this with option A, “That a lock status was reported”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Frequency Reference and Tuning Accuracy.

V011-C12-MCQ-015. Why measure frequency response at several reference points?

A. A numerically exact tuning command guarantees physical accuracy

B. One tone mathematically fixes every synthesizer error

C. Errors can be constant, proportional, band-dependent, or state-dependent

D. Every oscillator error is a single constant offset

Answer: C. A multi-point, state-aware check distinguishes error forms that one correction cannot cover. Source: §12.1 Frequency Reference and Tuning Accuracy (p. 6950)

Why the selected alternative fits: Errors can be constant, proportional, band-dependent, or state-dependent.

Distinguishing consideration: compare this with option A, “A numerically exact tuning command guarantees physical accuracy”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Frequency Reference and Tuning Accuracy.

V011-C12-MCQ-016. A clock at nominal 10 MHz has constant fractional error plus 0.2 ppm. What is frequency error?

A. Minus 2 Hz

B. Plus 20 Hz

C. Plus 2 Hz

D. Plus 0.2 Hz

Answer: C. Multiplying 10 million hertz by 0.2 millionths gives 2 Hz. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: Plus 2 Hz.

Distinguishing consideration: compare this with option A, “Minus 2 Hz”; that competing statement does not meet the question’s stated requirement.

V011-C12-MCQ-017. Under that constant offset for 86400 seconds from zero time error, what epoch advance accumulates?

A. 17.28 microseconds

B. 172.8 seconds

C. 17.28 ms

D. 0.2 ms

Answer: C. Time error is fractional error times elapsed time; constancy over the full interval is essential. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: 17.28 ms.

Distinguishing consideration: compare this with option A, “17.28 microseconds”; that competing statement does not meet the question’s stated requirement.

V011-C12-MCQ-018. A constant epoch advance of 0.75 microseconds with zero frequency error represents how many 10 MHz cycles?

A. 0.75 cycles

B. 7.5 cycles

C. 75 cycles

D. Zero cycles

Answer: B. Phase advance in cycles is nominal frequency times time error, independent of its zero derivative. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: 7.5 cycles.

Distinguishing consideration: compare this with option A, “0.75 cycles”; that competing statement does not meet the question’s stated requirement.

V011-C12-MCQ-019. Why can a nonzero physical delay appear phase aligned at one frequency?

A. Its phase can wrap by an integer number of cycles

B. The receiver's amplitude calibration cancels all delay

C. Zero wrapped phase proves zero delay

D. Delay disappears when frequency increases

Answer: A. Wrapped phase retains no unique cycle count without additional evidence. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: Its phase can wrap by an integer number of cycles.

Distinguishing consideration: compare this with option B, “The receiver's amplitude calibration cancels all delay”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Worked applications with hypothetical inputs.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-MCQ-020. For a nondispersive path, how is delay obtained from unwrapped phase slope?

A. Minus the slope divided by two pi

B. The slope multiplied by carrier amplitude

C. The inverse of one wrapped phase reading

D. Plus the slope divided by two pi under the declared delay convention

Answer: A. The negative transfer-phase convention fixes the slope sign; dispersion requires a richer response. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: Minus the slope divided by two pi.

Distinguishing consideration: compare this with option B, “The slope multiplied by carrier amplitude”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-021. Two tones separated by 20 MHz produce a wrapped-delay ambiguity period of what?

A. 500 ns

B. 50 ns

C. 5 ns

D. 20 ns

Answer: B. The difference-phase ambiguity repeats after one divided by tone spacing. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: 50 ns.

Distinguishing consideration: compare this with option A, “500 ns”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Worked applications with hypothetical inputs.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-MCQ-022. What does phase curvature across frequency suggest for delay correction?

A. Only epoch error can create any frequency dependence

B. A perfect frequency-independent time shift is proven

C. All phase measurements must be invalid

D. One constant nondispersive delay may be insufficient

Answer: D. Frequency-dependent filters can require retaining or fitting their actual response. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: One constant nondispersive delay may be insufficient.

Distinguishing consideration: compare this with option A, “Only epoch error can create any frequency dependence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-023. Time-error observations increase from 1 to 7 microseconds over 600 seconds. What average fractional-frequency estimate follows?

A. Six times ten to the minus six

B. One times ten to the minus six

C. One times ten to the minus ten

D. One times ten to the minus eight

Answer: D. The six-microsecond difference divided by 600 seconds gives 10^{-8}.

Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: One times ten to the minus eight.

Distinguishing consideration: compare this with option A, “Six times ten to the minus six”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Worked applications with hypothetical inputs.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-MCQ-024. If each endpoint has a freely signed hard error bound 0.1 microsecond, what is the difference-error bound?

A. 0.2 microsecond

B. Zero because both bounds have the same size

C. 0.1 microsecond

D. About 0.1414 microsecond as a deterministic maximum

Answer: A. Opposite endpoint errors can add in the difference; RSS would need a different model. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: 0.2 microsecond.

Distinguishing consideration: compare this with option B, “Zero because both bounds have the same size”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-MCQ-025. A 90-degree phase reset lies inside a 10-microsecond difference interval with continuous 20 Hz phase slope. What apparent average frequency results?

A. 9020 Hz

B. 20 Hz

C. 25020 Hz

D. 2500 Hz

Answer: C. One quarter cycle over 10 microseconds adds 25000 Hz to the continuous slope. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: 25020 Hz.

Distinguishing consideration: compare this with option A, “9020 Hz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Worked applications with hypothetical inputs.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-MCQ-026. Why not fit one smooth drift through a documented phase reset?

A. The derivative remains finite at an ideal instantaneous jump

B. A reset is always Gaussian phase noise

C. The finite difference includes a discontinuity absent from either continuous segment

D. Equal nominal rates prove the phases join continuously

Answer: C. Retain event time and separate phase segments; a real slew needs its own resolved model. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: The finite difference includes a discontinuity absent from either continuous segment.

Distinguishing consideration: compare this with option A, “The derivative remains finite at an ideal instantaneous jump”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-MCQ-027. Two million sample intervals at actual rate 2000050 per second occupy what time approximately?

A. 1.000025 seconds

B. 0.999950 seconds

C. 0.999975 seconds

D. Exactly one second

Answer: C. Elapsed time varies inversely with actual clock rate; the nominal second is too long here. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: 0.999975 seconds.

Distinguishing consideration: compare this with option A, “1.000025 seconds”; that competing statement does not meet the question’s stated requirement.

V011-C12-MCQ-029. How should relative timing of channels A and B be computed before phase conversion?

A. Assume zero difference because they share a reference label

B. Convert only the larger channel error

C. Subtract their time errors, then multiply by the stated carrier's two pi frequency

D. Add their absolute time errors regardless of the target quantity

Answer: C. The defined relative quantity determines which common terms cancel and which unequal paths remain. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: Subtract their time errors, then multiply by the stated carrier's two pi frequency.

Distinguishing consideration: compare this with option A, “Assume zero difference because they share a reference label”; that competing statement does not meet the question’s stated requirement.

V011-C12-MCQ-033. If initial error is within tolerance and both frequency/drift bounds vanish, what determines the calibration interval under this model?

A. The number of displayed digits

B. A universal one-day interval

C. The nominal carrier period alone

D. The initial bound alone, with no finite growth-imposed limit

Answer: D. Without growth terms the envelope is constant, subject to continued applicability of the assumptions. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why the selected alternative fits: The initial bound alone, with no finite growth-imposed limit.

Distinguishing consideration: compare this with option A, “The number of displayed digits”; that competing statement does not meet the question’s stated requirement.

V011-C12-MCQ-034. Why is the derived maximum calibration interval not a universal schedule?

A. A tighter initial bound cannot affect the interval

B. Only the model's chapter number determines the schedule

C. It depends on justified bounds, carrier, tolerance, and operating conditions

D. Every oscillator requires the same 760.68-second interval

Answer: C. Changing environment, path, or reference state can invalidate the conditional envelope. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: It depends on justified bounds, carrier, tolerance, and operating conditions.

Distinguishing consideration: compare this with option A, “A tighter initial bound cannot affect the interval”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Worked applications with hypothetical inputs.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-MCQ-035. What is distinct about an aperture timestamp versus a packet-arrival timestamp?

A. A shared frequency automatically calibrates transport latency

B. Packet delivery always occurs at the sampling instant

C. They are interchangeable when their units are seconds

D. They describe different events unless a relationship is established

Answer: D. The timing boundary must match the measurand and source-index mapping. Source: §12.3 Worked applications with hypothetical inputs (p. 6956)

Why the selected alternative fits: They describe different events unless a relationship is established.

Distinguishing consideration: compare this with option A, “A shared frequency automatically calibrates transport latency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Worked applications with hypothetical inputs.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-MCQ-036. Why is the single-sideband density integrated with factor two for real-phase variance?

A. Every phase-noise line is Gaussian

B. The carrier frequency is counted twice

C. The symmetric negative-offset phase band contributes equal variance

D. Every jitter calculation must double an already integrated RMS

Answer: C. The positive-offset SSB density equals the two-sided phase density under the adopted convention. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why the selected alternative fits: The symmetric negative-offset phase band contributes equal variance.

Distinguishing consideration: compare this with option A, “Every phase-noise line is Gaussian”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-037. Why state the jitter integration band?

A. A jitter RMS automatically includes every unmeasured offset

B. Changing limits leaves RMS unchanged

C. All clocks have the same universal integration limits

D. The result includes only the declared phase component and separately treated lines

Answer: D. Unmeasured regions remain outside the claim unless characterized or bounded. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why the selected alternative fits: The result includes only the declared phase component and separately treated lines.

Distinguishing consideration: compare this with option A, “A jitter RMS automatically includes every unmeasured offset”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-C12-MCQ-038. Do the phase covariance and increment-variance identities require Gaussianity?

A. No; they are second-order relations under the stated spectral/covariance assumptions

B. Yes; all covariance arithmetic requires a Gaussian vector

C. Only when the carrier is exactly 100 MHz

D. No; no finite variance or stationarity is needed for the stated spectral identities

Answer: A. The exact nonlinear exponential result later requires a separate distributional assumption. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why the selected alternative fits: No; they are second-order relations under the stated spectral/covariance assumptions.

Distinguishing consideration: compare this with option B, “Yes; all covariance arithmetic requires a Gaussian vector”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-C12-MCQ-039. Why can a common random phase leave normalized coherent power unchanged within each record?

A. All sample phasors rotate together without relative cancellation

B. Random phase is always equivalent to no absolute phase uncertainty

C. Its ensemble-mean complex phasor must retain unit magnitude

D. Each sample acquires an independent compensating rotation

Answer: A. Common rotation and relative decorrelation have different effects on record power. Source: §12.23 Application 12B.6: Distinguish a common random phase from lost coherent power (p. 6983)

Why the selected alternative fits: All sample phasors rotate together without relative cancellation.

Distinguishing consideration: compare this with option B, “Random phase is always equivalent to no absolute phase uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power.

Review: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power.

V011-C12-MCQ-040. Can one marginal RMS phase or jitter value determine finite-record coherent power?

A. Yes; every vector with that RMS has the same sum power

B. Only when the RMS is expressed in radians rather than seconds

C. Yes; only sample count supplies the missing distribution

D. No; covariance and deterministic phase differences also matter

Answer: D. Common, independent, and correlated vectors can have equal marginal RMS but different coherence. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why the selected alternative fits: No; covariance and deterministic phase differences also matter.

Distinguishing consideration: compare this with option A, “Yes; every vector with that RMS has the same sum power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-C12-MCQ-042. May a deterministic PM line use the Gaussian coherent-power formula solely because its RMS is known?

A. Only if its frequency is an integer number of kilohertz

B. No; use its trajectory or justify a separate random model

C. Yes; the RMS fixes its entire characteristic function

D. Yes; every sinusoid is jointly Gaussian

Answer: B. A line's deterministic phase law does not establish the Gaussian-vector premise. Source: §12.21 Application 12B.4: Treat a phase-modulation line as a line, not a density bin (p. 6981)

Why the selected alternative fits: No; use its trajectory or justify a separate random model.

Distinguishing consideration: compare this with option A, “Only if its frequency is an integer number of kilohertz”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.4: Treat a phase-modulation line as a line, not a density bin.

V011-C12-MCQ-066. Why can the squared magnitude of an ensemble-mean phasor differ from mean record power?

A. A phase histogram uniquely gives the complete time record

B. Random common phase changes only sample rate

C. Expectation and squared magnitude do not generally commute

D. Every expectation is equal to one

Answer: C. The common-phase example has diminished mean complex phasor but unit power in each record. Source: §12.23 Application 12B.6: Distinguish a common random phase from lost coherent power (p. 6983)

Why the selected alternative fits: Expectation and squared magnitude do not generally commute.

Distinguishing consideration: compare this with option A, “A phase histogram uniquely gives the complete time record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power.

Review: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power.

V011-C12-MCQ-067. In the stated positive geometric-correlation example, why is coherent power greater than in the independent case with equal RMS?

A. The marginal phase variance is secretly zero

B. The record has acquired additional samples

C. Relative phase increments are smaller on average

D. Positive correlation always doubles physical signal power

Answer: C. Coherence depends on differences and their covariance, not marginal RMS alone. Source: §12.25 Application 12B.8: Use a specified correlated Gaussian phase vector (p. 6985)

Why the selected alternative fits: Relative phase increments are smaller on average.

Distinguishing consideration: compare this with option A, “The marginal phase variance is secretly zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.8: Use a specified correlated Gaussian phase vector.

Review: Chapter 12 — Application 12B.8: Use a specified correlated Gaussian phase vector.

V011-C12-MCQ-068. What must be justified before applying an independent-phase model to adjacent samples of physical narrowband phase noise?

A. A smooth average spectrum alone

B. A large sample count alone

C. Their actual covariance supports that approximation

D. The fact that all samples are stored separately

Answer: C. Narrowband processes can correlate nearby phases; the independence assumption is not automatic. Source: §12.24 Application 12B.7: Compute finite-sample coherence for independent Gaussian phases (p. 6984)

Why the selected alternative fits: Their actual covariance supports that approximation.

Distinguishing consideration: compare this with option A, “A smooth average spectrum alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.7: Compute finite-sample coherence for independent Gaussian phases.

Review: Chapter 12 — Application 12B.7: Compute finite-sample coherence for independent Gaussian phases.

V011-C12-MCQ-069. A deterministic residual frequency produces substantial coherent-sum loss. What does reducing random phase noise alone fail to do?

A. Preserve the original deterministic phase record

B. Reduce the random contribution under its model

C. Remove the deterministic rotation

D. Change the stated marginal random variance

Answer: C. The mean-phase trajectory remains unless a justified correction addresses it. Source: §12.26 Application 12B.9: Combine deterministic rotation with independent phase errors (p. 6986)

Why the selected alternative fits: Remove the deterministic rotation.

Distinguishing consideration: compare this with option A, “Preserve the original deterministic phase record”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.9: Combine deterministic rotation with independent phase errors.

Review: Chapter 12 — Application 12B.9: Combine deterministic rotation with independent phase errors.

V011-C12-MCQ-070. For 100 samples separated by 100 microseconds, what is first-to-last span?

A. 10 ms

B. 0.1 ms

C. 100 ms

D. 9.9 ms

Answer: D. There are 99 intervals between 100 endpoint samples, even when a geometric sum contains N. Source: §12.26 Application 12B.9: Combine deterministic rotation with independent phase errors (p. 6986)

Why the selected alternative fits: 9.9 ms.

Distinguishing consideration: compare this with option A, “10 ms”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.9: Combine deterministic rotation with independent phase errors.

Review: Chapter 12 — Application 12B.9: Combine deterministic rotation with independent phase errors.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-071. Why assess a frequency correction fitted to the same weak record separately?

A. A deterministic correction can never improve alignment

B. Fitting can overfit noise or create artificial coherence

C. A larger number of fit parameters guarantees external source truth

D. All fitted corrections are necessarily invalid

Answer: B. The method, degrees of freedom, and validation outside the fit matter to interpretation. Source: §12.28 Coherent Integration and Phase Preservation (p. 6988)

Why the selected alternative fits: Fitting can overfit noise or create artificial coherence.

Distinguishing consideration: compare this with option A, “A deterministic correction can never improve alignment”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Coherent Integration and Phase Preservation.

Review: Chapter 12 — Coherent Integration and Phase Preservation.

V011-C12-MCQ-073. What is the effect of extending a nonzero flat phase-noise floor to infinite offset without a physical limit?

A. A finite universal jitter independent of bandwidth

B. Automatic conversion of lines into Gaussian noise

C. A guaranteed upper bound on every oscillator

D. Divergent variance, contrary to the finite-variance premise

Answer: D. The domain of an assumed spectrum matters; finite measured or bounded bands must remain explicit. Source: §12.27 Application 12B.10: Bound a finite unmeasured high-offset contribution (p. 6987)

Why the selected alternative fits: Divergent variance, contrary to the finite-variance premise.

Distinguishing consideration: compare this with option A, “A finite universal jitter independent of bandwidth”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Application 12B.10: Bound a finite unmeasured high-offset contribution.

Review: Chapter 12 — Application 12B.10: Bound a finite unmeasured high-offset contribution.

V011-C12-MCQ-078. Why is shared sampling frequency insufficient for multichannel alignment?

A. Triggers, apertures, filters, cables, pipelines, and transport can have unequal delays

B. Equal frequency makes every sample simultaneous

C. Calibration at any connector automatically reaches stored samples

D. Only antenna geometry can cause relative phase

Answer: A. The relevant boundary is the actual measured path and sample relationship. Source: §12.29 Multichannel Synchronization and Delay Calibration (p. 6989)

Why the selected alternative fits: Triggers, apertures, filters, cables, pipelines, and transport can have unequal delays.

Distinguishing consideration: compare this with option B, “Equal frequency makes every sample simultaneous”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Multichannel Synchronization and Delay Calibration.

V011-C12-MCQ-081. Why test retune, restart, and trigger sequences explicitly?

A. They may preserve, reset, or change the phase relation

B. Only long-term frequency aging matters

C. A shared clock makes resets irrelevant

D. Every device preserves deterministic phase across all such events

Answer: A. Coherence across state changes requires demonstrated deterministic behavior, not assumption. Source: §12.31 Reference Distribution Acceptance (p. 6994)

Why the selected alternative fits: They may preserve, reset, or change the phase relation.

Distinguishing consideration: compare this with option B, “Only long-term frequency aging matters”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Reference Distribution Acceptance.

Review: Chapter 12 — Reference Distribution Acceptance.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-082. At what termination should distribution outputs be tested for installed acceptance?

A. Any convenient unloaded connector without qualification

B. A nominal 50-ohm label regardless of deployed load

C. Only the primary oscillator before distribution

D. The actual installed termination

Answer: D. Distribution amplifiers and cables can dominate performance after the primary reference. Source: §12.31 Reference Distribution Acceptance (p. 6994)

Why the selected alternative fits: The actual installed termination.

Distinguishing consideration: compare this with option A, “Any convenient unloaded connector without qualification”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Reference Distribution Acceptance.

Review: Chapter 12 — Reference Distribution Acceptance.

V011-C12-MCQ-086. A measured 1 GHz reference is 120 Hz high while measurement-reference uncertainty is 0.2 ppm. What is justified from that difference alone?

A. The measurement reference must be exact because its label is 1 GHz

B. The source frequency is necessarily correct

C. It is insufficient to claim the source is out of tolerance

D. The source is proven 0.12 ppm out of every possible tolerance

Answer: C. The observed 0.12 ppm difference must be interpreted with reference uncertainty and a stated tolerance rule. Source: §12.32 Quantitative Model for Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing (p. 6995)

Why the selected alternative fits: It is insufficient to claim the source is out of tolerance.

Distinguishing consideration: compare this with option A, "The measurement reference must be exact because its label is 1 GHz"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 12 — Quantitative Model for Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing.

Review: Chapter 12 — Quantitative Model for Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Copyright 2026, James M. Atkinson

V011-C12-MCQ-100. Two equal-weight unit phasors have deterministic phases zero and pi, with no random phase error. What is their normalized coherent power?

A. Zero

B. One half

C. One

D. Two

Answer: A. Their opposite deterministic phases cancel exactly. Zero random jitter alone does not establish a coherently aligned sum. Source: §12.16 Model 12B: finite-band jitter and coherent signal power (p. 6971)

Why the selected alternative fits: Zero.

Distinguishing consideration: compare this with option B, “One half”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Fill-in-the-Blank Questions

V011-C12-FIB-001. The clock model writes its reading as ideal time plus time _____.

Answer: error. The sign convention defines positive error as an advanced clock.

Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “error” completes the stated technical proposition.

Question context: The clock model writes its reading as ideal time plus time _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-002. Fractional-frequency error is the first time _____ of clock time error.

Answer: derivative. A constant epoch offset therefore has zero fractional-frequency error. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)
Why this term is required: “derivative” completes the stated technical proposition.
Question context: Fractional-frequency error is the first time _____ of clock time error
Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.
Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-003. A constant fractional-frequency offset integrates to a _____ time-error term.

Answer: linear. The initial epoch is a separate constant term. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “linear” completes the stated technical proposition.

Question context: A constant fractional-frequency offset integrates to a _____ time-error term

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-004. A local linear fractional-frequency drift contributes a _____ time-error term.

Answer: quadratic. Integration introduces one half of drift times elapsed time squared. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “quadratic” completes the stated technical proposition.

Question context: A local linear fractional-frequency drift contributes a _____ time-error term

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-005. The fractional-frequency quantity is

_____.

Answer: dimensionless. It may be reported in ppm while retaining its reference and observation interval. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “dimensionless” completes the stated technical proposition.

Question context: The fractional-frequency quantity is _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-006. The local drift coefficient has units per

_____.

Answer: second. It is the rate of change of dimensionless fractional-frequency error. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “second” completes the stated technical proposition.

Question context: The local drift coefficient has units per _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-007. Clock advance is converted to relative unwrapped phase using two pi times nominal carrier _____.

Answer: frequency. The carrier must be positive and the time-error convention retained. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “frequency” completes the stated technical proposition.

Question context: Clock advance is converted to relative unwrapped phase using two pi times nominal carrier _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-FIB-010. For a nondispersive path, delay is minus unwrapped phase slope divided by two _____.

Answer: pi. The slope is with respect to frequency, with phase in radians. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “pi” completes the stated technical proposition.

Question context: For a nondispersive path, delay is minus unwrapped phase slope divided by two _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-011. The two-tone wrapped-delay ambiguity period is one divided by tone _____.

Answer: spacing. Additional calibrated information or a prior selects among branches. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “spacing” completes the stated technical proposition.

Question context: The two-tone wrapped-delay ambiguity period is one divided by tone _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-012. At a 10 MHz tone spacing, that ambiguity period is _____ ns.

Answer: 100. One divided by ten million hertz is 100 nanoseconds. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “100” completes the stated technical proposition.

Question context: At a 10 MHz tone spacing, that ambiguity period is _____ ns

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-013. A phase curve with frequency-dependent curvature may require a _____ path model rather than one constant delay.

Answer: dispersive. Filters can have a frequency-dependent group delay. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “dispersive” completes the stated technical proposition.

Question context: A phase curve with frequency-dependent curvature may require a _____ path model rather than one constant delay

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-FIB-015. Freely signed deterministic endpoint bounds add in the worst-case difference rather than combine by root-sum-_____.

Answer: square. RSS would require an appropriate statistical model and dependencies. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “square” completes the stated technical proposition.

Question context: Freely signed deterministic endpoint bounds add in the worst-case difference rather than combine by root-sum-_____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-016. A phase reset must be retained as a segment _____.

Answer: event. A smooth drift fit should not conceal a documented discontinuity.

Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “event” completes the stated technical proposition.

Question context: A phase reset must be retained as a segment _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-017. A finite difference across a reset includes the phase jump divided by two pi times interval _____.

Answer: duration. That term is not necessarily a persistent oscillator-frequency offset. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)
Why this term is required: “duration” completes the stated technical proposition.
Question context: A finite difference across a reset includes the phase jump divided by two pi times interval _____
Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.
Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-018. N endpoint samples span N minus _____ sample intervals.

Answer: one. Careful interval counting is needed for elapsed time and phase calculations. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “one” completes the stated technical proposition.

Question context: N endpoint samples span N minus _____ sample intervals

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-FIB-019. At fixed sample-interval count, elapsed time is inversely proportional to actual sample _____.

Answer: rate. A faster true clock produces a shorter physical interval. Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

Why this term is required: “rate” completes the stated technical proposition.

Question context: At fixed sample-interval count, elapsed time is inversely proportional to actual sample _____

Basis and qualification: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C12-ESSAY-001. Derive the relation among clock reading, time error, fractional frequency, and unwrapped phase.

- Opening: Present a thesis that answers this precise question: Derive the relation among clock reading, time error, fractional frequency, and unwrapped phase. Identify which evidence would falsify the proposed conclusion Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)
- Core terminology and scope: Define relation, clock, reading in the question's particular technical setting; explain how error, fractional, unwrapped differ if that distinction would change the analysis of "Derive the relation among clock reading, time error, fractional frequency, and unwrapped phase" Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define positive time error as advance, differentiate to obtain fractional frequency, and multiply by the positive nominal carrier for phase Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting the relation among clock reading, time error, fractional frequency, and unwrapped phase to the claimed result, following "Application 12A.2: Integrate a linear fractional-frequency drift"; name the intermediate states and measurable outputs Source: §12.5 Application 12A.2: Integrate a linear fractional-frequency drift (p. 6958)

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for the relation among clock reading, time error, fractional frequency, and unwrapped phase. Integrate a constant offset and local linear drift with separate initial epoch Source: §12.5 Application 12A.2: Integrate a linear fractional-frequency drift (p. 6958)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 12A.1: Accumulate a constant fractional frequency offset” that resolves the question about the relation among clock reading, time error, fractional frequency, and unwrapped phase; derive the relevant result with units and stated validity conditions Source: §12.4 Application 12A.1: Accumulate a constant fractional frequency offset (p. 6957)
- Evidence and method: Specify the native observations, control records and calculations that would resolve the relation among clock reading, time error, fractional frequency, and unwrapped phase. State units and interval boundaries, and explain why correct frequency need not imply aligned sample epochs Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)
- Worked application or illustrative case: Build a worked example of “the relation among clock reading, time error, fractional frequency, and unwrapped phase”, addressing this associated condition: Define positive time error as advance, differentiate to obtain fractional frequency, and multiply by the.... Define positive time error as advance, differentiate to obtain fractional frequency, and multiply by

the positive nominal carrier for phase Source: §12.5 Application 12A.2: Integrate a linear fractional-frequency drift (p. 6958)

- Alternative explanations and failure modes: Construct two plausible technical explanations for “the relation among clock reading, time error, fractional frequency, and unwrapped phase”. Using “Application 12A.1: Accumulate a constant fractional frequency offset”, specify a discriminator and the result expected under each explanation Source: §12.4 Application 12A.1: Accumulate a constant fractional frequency offset (p. 6957)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to the relation among clock reading, time error, fractional frequency, and unwrapped phase, including the effect of missing measurements and inconsistent operating conditions Source: §12.12 Application 12A.9: Form a relative channel phase from two time-error laws (p. 6965)
- Scholarly synthesis and implications: Explain what the result about the relation among clock reading, time error, fractional frequency, and unwrapped phase authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)
- Closing: Conclude by answering “Derive the relation among clock reading, time error, fractional frequency, and unwrapped phase” using only the demonstrated evidence; state the remaining decisive verification step Source: §12.2 Model 12A: connect clock reading, frequency and phase (p. 6951)

V011-C12-ESSAY-004. Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds.

- Opening: Present a thesis that answers this precise question: Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds. Identify which evidence would falsify the proposed conclusion Source: §12.9 Application 12A.6: Bound a frequency estimate from two epoch measurements (p. 6962)
- Core terminology and scope: Define fractional, epoch, propagate in the question's particular technical setting; explain how hard, endpoint, bounds differ if that distinction would change the analysis of "Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds" Source: §12.9 Application 12A.6: Bound a frequency estimate from two epoch measurements (p. 6962)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define the ideal-time separation and difference of epoch errors, compute the central ratio, and use the sum of freely signed endpoint bounds for the maximum departure Source: §12.9 Application 12A.6: Bound a frequency estimate from two epoch measurements (p. 6962)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds to the claimed result, following "Application 12A.10: Choose a calibration interval from deterministic error bounds"; name the intermediate states and measurable outputs Source: §12.13 Application 12A.10: Choose a calibration interval from deterministic error bounds (p. 6966)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds. Distinguish shared calibration dependencies and statistical covariance from rectangular hard bounds Source: §12.13 Application 12A.10: Choose a calibration interval from deterministic error bounds (p. 6966)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Application 12A.2: Integrate a linear fractional-frequency drift” that resolves the question about Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds; derive the relevant result with units and stated validity conditions Source: §12.5 Application 12A.2: Integrate a linear fractional-frequency drift (p. 6958)
- Evidence and method: Specify the native observations, control records and calculations that would resolve Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds. State that the estimate does not reveal all within-interval behavior Source: §12.9 Application 12A.6: Bound a frequency estimate from two epoch measurements (p. 6962)
- Worked application or illustrative case: Build a worked example of “Estimate average fractional frequency from two epoch errors and propagate hard endpoint bounds”, addressing this associated condition: Define the ideal-time separation and difference of epoch errors, compute the central ratio, and use the sum.... V011-C12-DISCUSSION-001. A system shows the correct average frequency but channels are several samples apart. How should the discrepancy be approached?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A system shows the correct average frequency but channels are several samples apart. How should the discrepancy be approached?” Put this particular dispute to the panel: A system shows the correct average frequency but channels are several samples apart. How should the discrepancy be approached. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

- 02. Student A, terminology and scope: Agree the operational meanings of shows, average, frequency and channels, samples, discrepancy in “A system shows the correct average frequency but channels are several samples apart. How should the discrepancy be approached”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A system shows the correct average frequency but channels are several samples apart; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §12.35 Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation (p. 6999)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation”. Use common-signal calibration at the actual stored-sample boundary Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §12.35 Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation (p. 6999)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original

Copyright 2026, James M. Atkinson

trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A system shows the correct average frequency but channels are several samples apart; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §12.29 Multichannel Synchronization and Delay Calibration (p. 6989)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation”. Use common-signal calibration at the actual stored-sample boundary Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §12.35 Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation (p. 6999)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Separate epoch, aperture, trigger, distribution, and processing delays from frequency offset Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them

Copyright 2026, James M. Atkinson

without changing the measurand. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A system shows the correct average frequency but channels are several samples apart: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A system shows the correct average frequency but channels are several samples apart; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §12.29 Multichannel Synchronization and Delay Calibration (p. 6989)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A system shows the correct average frequency but channels are several samples apart: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A system shows the correct average frequency but channels are several samples apart, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §12.35 Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation (p. 6999)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A system shows the correct average frequency but channels are

Copyright 2026, James M. Atkinson

several samples apart: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A system shows the correct average frequency but channels are several samples apart. Equal frequency is useful evidence but cannot establish alignment by itself Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §12.29 Multichannel Synchronization and Delay Calibration (p. 6989)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A system shows the correct average frequency but channels are several samples apart, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the

Copyright 2026, James M. Atkinson

conclusion. Source: §12.35 Clock holdover, phase-reference lineage and covariance-aware receiver synchronisation (p. 6999)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A system shows the correct average frequency but channels are several samples apart. Equal frequency is useful evidence but cannot establish alignment by itself Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §12.29 Multichannel Synchronization and Delay Calibration (p. 6989)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A system shows the correct average frequency but channels are several samples apart and How should the discrepancy be approached; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §12.4 Application 12A.1: Accumulate a constant fractional frequency offset (p. 6957)

Copyright 2026, James M. Atkinson

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A system shows the correct average frequency but channels are several samples apart”, addressing “How should the discrepancy be approached”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A system shows the correct average frequency but channels are several samples apart. How should the discrepancy be approached”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “A system shows the correct average frequency but channels are several samples apart. How should the discrepancy be approached”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion. Source: §12.6 Application 12A.3: Separate an epoch offset from a frequency offset (p. 6959)

V011-C12-DISCUSSION-020. One constant delay correction fixes a narrowband test but not broadband data. What should be done?

- 01. Moderator, opening proposition: Introduce the exact dispute, “One constant delay correction fixes a narrowband test but not broadband data. What should be done?” Put this particular dispute to the panel: One constant delay correction fixes a narrowband test but not broadband data. What should be done. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §12.8 Application 12A.5: Use an unwrapped phase slope while declaring delay ambiguity (p. 6961)

- 02. Student A, terminology and scope: Agree the operational meanings of constant, delay, fixes and narrowband, broadband, data in “One constant delay correction fixes a narrowband test but not broadband data. What should be done”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §12.8 Application 12A.5: Use an unwrapped phase slope while declaring delay ambiguity (p. 6961)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of One constant delay correction fixes a narrowband test but not broadband data; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §12.30 Accept coherence at the required boundary and state (p. 6992)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “Accept coherence at the required boundary and state”. Use the required band and state, retain residuals, and avoid forcing a single offset through inconsistent points Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §12.30 Accept coherence at the required boundary and state (p. 6992)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of One constant delay correction

Chapter 12 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C12-ESSAY-001 — Define positive time error as advance, differentiate to obtain fractional frequency, and multiply by the positive nominal carrier for phase. Integrate a constant offset and local linear drift with separate initial epoch. State units and interval boundaries, and explain why correct frequency need not imply aligned sample epochs.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-ESSAY-002 — Write the negative transfer exponential and derive delay from unwrapped frequency slope. Contrast positive clock-error phase, account for wrapping, and show how a nonzero delay can appear aligned at a selected frequency. Require calibrated path state and treat dispersion separately from constant delay.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-ESSAY-003 — Derive the ambiguity period from tone spacing and identify compatible branches. Explain the 2 ns versus 52 ns example and why added numerical precision cannot select one. State what a prior, extra calibrated frequencies, or established unwrap contributes and retain any constant-phase/dispersion assumptions.

Review: Chapter 12 — Worked applications with hypothetical inputs.

Copyright 2026, James M. Atkinson

V011-C12-ESSAY-004 — Define the ideal-time separation and difference of epoch errors, compute the central ratio, and use the sum of freely signed endpoint bounds for the maximum departure. Distinguish shared calibration dependencies and statistical covariance from rectangular hard bounds. State that the estimate does not reveal all within-interval behavior.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-ESSAY-005 — Separate continuous slope and reset contribution, evaluate the 90-degree/10-microsecond case, and distinguish an ideal jump from a resolved real slew. Preserve the event and segment phases. Do not fit one drift law or coherently join segments without a measured relationship.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-ESSAY-006 — Count actual sample intervals and endpoint samples, use inverse actual rate for elapsed time, and derive nominal frequency labeling for the selected alias class. Apply the 25 ppm example with clear sign. Separate clock correction from analog alias identification and preserve source-index and anchor definitions.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-ESSAY-007 — Subtract epoch and frequency/drift terms before multiplying by the carrier. Use the chapter's 180 ns/10 MHz example, distinguish wrapped and unwrapped phase, and identify common terms that cancel. Require calibration through actual paths and new applicability review after reset, missing samples, or configuration change.

Review: Chapter 12 — Worked applications with hypothetical inputs.

Copyright 2026, James M. Atkinson

V011-C12-ESSAY-008 — Construct the monotone accumulated-error envelope, convert phase tolerance to time tolerance, and solve the positive-root or zero-drift case. Address initial bound above/equal/below tolerance and zero growth. State the environmental and state assumptions and avoid presenting the computed interval as a universal schedule.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-ESSAY-009 — Use traceable references at several points and relevant gain/tuning states, retain reference uncertainty, lock/holdover, temperature, aging, and conversion settings. Explain why one tone or a numerically exact command cannot characterize all errors. Tie the result to the intended observation interval and installed chain.

Review: Chapter 12 — Frequency Reference and Tuning Accuracy.

V011-C12-ESSAY-010 — State the real-phase side convention, positive offset set, linear density conversion, factor two, variance integration, square root, and carrier division. Treat disjoint bands and discrete lines separately. Preserve unmeasured offsets and avoid extending local laws beyond an integrable justified domain.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-C12-ESSAY-011 — Identify which phase or timing quantity is held fixed, align offset limits, weighting, line handling, and reference planes, and show the inverse carrier conversion. Explain why a scalar RMS can conceal noise location and cannot rank oscillators or predict close-in receiver performance without the definitions.

Review: Chapter 12 — Application 12B.3: Keep carrier frequency in the phase-to-time conversion.

Copyright 2026, James M. Atkinson

V011-C12-ESSAY-012 — Use the even spectrum's cosine transform, then expand the variance of a phase difference. Identify the one-minus-cosine weighting and demonstrate why equal integrated variance need not imply equal increments. State second-order stationarity and finite-variance conditions without introducing unnecessary Gaussian assumptions.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-C12-ESSAY-013 — Retain covariance and its sign, calculate the 2 ps/3 ps cases, and explain the zero-covariance RSS condition. Discuss a common reference's possible cancellation in a difference and its reinforcement in a sum. Require evidence for the relevant transfer and correlation rather than infer independence from component names.

Review: Chapter 12 — Application 12B.5: Include covariance when combining timing contributions.

V011-C12-ESSAY-014 — State joint Gaussian mean/covariance, form each difference variance, apply the Gaussian characteristic function, and retain deterministic mean differences. Expand the normalized squared sum including diagonal terms and conjugate pairs. Require a positive-semidefinite covariance matrix and distinguish this signal-power result from a complete SNR calculation.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Copyright 2026, James M. Atkinson

V011-C12-ESSAY-015 — Compare within-record phasor alignment, ensemble-mean phasor, and mean record power. Use the eight-sample 0.4-radian cases to show unit common-phase power versus the finite independent result. Explain why marginal RMS alone cannot choose the appropriate covariance model or establish absolute phase.

Review: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power.

V011-C12-ESSAY-016 — Define the valid covariance and lag increment variance, substitute the finite multiplicities into the pair sum, and compare the stated correlated and independent outcomes. Distinguish a stipulated teaching covariance from an estimated physical one and preserve evidence for joint Gaussianity if the exact exponential result is claimed.

Review: Chapter 12 — Application 12B.8: Use a specified correlated Gaussian phase vector.

V011-C12-ESSAY-017 — Keep the deterministic finite phasor sum and random diagonal contribution separate. State actual sample times and endpoint span, evaluate special-frequency limits correctly, and explain why reducing random phase noise does not remove deterministic cancellation. Assess separately a correction estimated from the same weak data.

Review: Chapter 12 — Application 12B.9: Combine deterministic rotation with independent phase errors.

Copyright 2026, James M. Atkinson

V011-C12-ESSAY-018 — Use complete-period sinusoidal phase variance and the small-modulation sideband convention, state line power and any bandwidth representation, and retain the deterministic trajectory for coherence. Explain why RMS equivalence does not establish a Gaussian process or resolution-independent density.

Review: Chapter 12 — Application 12B.4: Treat a phase-modulation line as a line, not a density bin.

V011-C12-ESSAY-019 — Integrate a justified upper SSB density over only the stated extra band with the factor two, add to measured variance, and convert lower/upper totals through square root and carrier. Identify excluded offsets and physical bandwidth assumptions. Do not describe extrapolated floors as measurements or extend a nonzero density to infinity.

Review: Chapter 12 — Application 12B.10: Bound a finite unmeasured high-offset contribution.

V011-C12-ESSAY-020 — Use a common signal through the actual analog, aperture, trigger, digital, and stored-sample paths across frequency. Retain geometry, skew, frequency-dependent delay, missing samples, and interpolation residuals. Use swaps and cable changes to localize error, and demonstrate phase behavior after retune/restart rather than assuming shared frequency is enough.

Review: Chapter 12 — Multichannel Synchronization and Delay Calibration.

Copyright 2026, James M. Atkinson

V011-C12-ESSAY-021 — Choose the operation and allowed phase/timing or coherent-power error, identify deterministic drift and stochastic covariance contributions, and validate with a known reference. Include motion, propagation, source instability, and state changes where relevant. Report an interval under those conditions rather than one universal coherence number.

Review: Chapter 12 — Accept coherence at the required boundary and state.

V011-C12-ESSAY-022 — Retain raw timing/phase records, correction model, degrees of freedom, fitting interval, and uncertainty. Challenge on known and held-out signals, assess overfitting and artificial coherence, and state the processing dependency. Do not treat a fitted trajectory as proof of the physical mechanism that produced the original data.

Review: Chapter 12 — Coherent Integration and Phase Preservation.

V011-C12-ESSAY-023 — Identify outputs, termination, cabling, reference identity, frequency/phase noise, additive jitter, skew, warmup, holdover, relock, interruption, and environmental conditions. Measure at the required boundary and log changes to affected captures. Separate absolute phase claims from supported relative or magnitude quantities.

Review: Chapter 12 — Reference Distribution Acceptance.

V011-C12-ESSAY-024 — Explain how common frequency differs from deterministic trigger and sample alignment. Use per-channel common-signal delay calibration and packet/source timing evidence to test the discrepancy. Preserve original records and revised configuration, and avoid assigning the impossible location to a physical source before timing validity is established.

Review: Chapter 12 — Hypothetical Case Adjudication: Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing.

Copyright 2026, James M. Atkinson

V011-C12-ESSAY-025 — Calculate fractional difference with units and ppm conversion, identify reference uncertainty and tolerance rule, and state observation interval and operating state. Use the 120 Hz at 1 GHz example to distinguish an observed difference from a proven out-of-tolerance source. Preserve the calibration chain and avoid extending one measurement to all conditions.

Review: Chapter 12 — Quantitative Model for Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing.

Discussion Guidance

V011-C12-DISCUSSION-001 — Separate epoch, aperture, trigger, distribution, and processing delays from frequency offset. Use common-signal calibration at the actual stored-sample boundary. Equal frequency is useful evidence but cannot establish alignment by itself.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-DISCUSSION-002 — Ask for unwrap, delay prior, additional calibrated frequencies, phase convention, and dispersion model. Precision within one branch does not select among branches. Report unresolved ambiguity rather than manufacture a unique delay.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-DISCUSSION-003 — Examine the changed segment, environment, prior lock, and coefficient bounds. A local fit describes observations without proving future mechanism. Establish new applicability or retain an explicit unresolved holdover limitation.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-DISCUSSION-004 — Write the signal and clock conventions explicitly, identify conjugation/transfer definitions and reference direction, then compare physical quantities. Opposite signs can be consistent conventions, while an undocumented sign can reverse a delay inference.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

Copyright 2026, James M. Atkinson

V011-C12-DISCUSSION-005 — Require a justified distribution and dependency model for that conversion. Preserve the hard bound if no such evidence exists. Distinguish maximum-error acceptance from a probabilistic statement rather than relabeling numbers for convenience.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-DISCUSSION-006 — Improve the initial measurement/path, change justified operating conditions, or narrow the intended claim. A shorter recalibration interval cannot solve an initial violation. Explain the conditional requirement without inventing a universal schedule.

Review: Chapter 12 — Model 12A: connect clock reading, frequency and phase.

V011-C12-DISCUSSION-007 — Retain the event, distinguish a true phase step or slew from continuous frequency behavior, and segment the analysis. The spike may be a valid finite-difference description while misleading as persistent offset. Coherent joining needs an established cross-event relationship.

Review: Chapter 12 — Worked applications with hypothetical inputs.

V011-C12-DISCUSSION-008 — Align carrier, integration bands, spectral weighting, line treatment, and reference plane first. Discuss offset-dependent receiver consequences and the physical quantity held fixed. Equal or smaller scalar values can describe different questions.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

Copyright 2026, James M. Atkinson

V011-C12-DISCUSSION-009 — Keep unmeasured frequencies explicit and seek justified finite bandwidth or bounds. An infinite nonzero floor gives divergent variance. A conditional extrapolation must remain labeled as an assumption within its stated domain.

Review: Chapter 12 — Application 12B.10: Bound a finite unmeasured high-offset contribution.

V011-C12-DISCUSSION-010 — Use their actual trajectory or joint law and covariance. RMS alone does not determine nonlinear phasor expectations. Treat line power and continuous density separately and reject a Gaussian formula justified only by matching RMS.

Review: Chapter 12 — Application 12B.4: Treat a phase-modulation line as a line, not a density bin.

V011-C12-DISCUSSION-011 — Define whether the relevant quantity is a sum or difference, investigate shared sources and transfer paths, and retain uncertainty about covariance. RSS is a conditional model rather than an automatic consequence of different component names.

Review: Chapter 12 — Application 12B.5: Include covariance when combining timing contributions.

V011-C12-DISCUSSION-012 — Compare magnitude of the mean with mean magnitude squared and inspect relative phases. Common rotation can preserve record power while losing absolute reference alignment. State which quantity was measured before interpreting a loss.

Review: Chapter 12 — Application 12B.6: Distinguish a common random phase from lost coherent power.

Copyright 2026, James M. Atkinson

V011-C12-DISCUSSION-013 — Compare covariance, mean trajectories, sample count, and joint distribution. The common, independent, and correlated examples intentionally differ. Require model applicability rather than force one scalar RMS to determine all outcomes.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-C12-DISCUSSION-014 — Check symmetry, variances, and positive-semidefinite joint feasibility, then assess empirical support. Individually plausible pair values may be inconsistent together. Keep the exact Gaussian calculation conditional on a valid justified joint model.

Review: Chapter 12 — Model 12B: finite-band jitter and coherent signal power.

V011-C12-DISCUSSION-015 — Quantify the finite-N difference relative to the required accuracy and label any approximation. At small N the self term can matter substantially, and N=1 must retain unit phasor power. Simplicity does not justify changing an exact finite claim silently.

Review: Chapter 12 — Application 12B.7: Compute finite-sample coherence for independent Gaussian phases.

V011-C12-DISCUSSION-016 — Inspect deterministic residual frequency, mean phase trajectory, motion/propagation, modulation, and source instability. A random-noise improvement does not remove deterministic cancellation. Validate any correction separately from its fitted record.

Review: Chapter 12 — Application 12B.9: Combine deterministic rotation with independent phase errors.

Copyright 2026, James M. Atkinson

V011-C12-DISCUSSION-017 — Retain degrees of freedom, raw phase, fitting/held-out intervals, known-reference tests, and uncertainty. Examine whether noise was fitted or selection manufactured coherence. Report the transformation-dependent result rather than an unsupported stable-source claim.

Review: Chapter 12 — Coherent Integration and Phase Preservation.

V011-C12-DISCUSSION-018 — Trace distribution, aperture, trigger, pipelines, packet alignment, and source-index association. Calibrate through actual paths and states. Connector performance is one boundary result, not automatic end-to-end timing evidence.

Review: Chapter 12 — Accept coherence at the required boundary and state.

V011-C12-DISCUSSION-019 — Test deterministic behavior with common references through the relevant retune sequence, retain resets and states, and establish any repeatable correction. If continuity is unresolved, restrict phase comparison to valid segments and use supported magnitude or timing quantities elsewhere.

Review: Chapter 12 — Reference Distribution Acceptance.

V011-C12-DISCUSSION-020 — Measure frequency-dependent response and distinguish dispersion from an epoch shift. Use the required band and state, retain residuals, and avoid forcing a single offset through inconsistent points. Revalidate corrections outside the fitting interval.

Review: Chapter 12 — Multichannel Synchronization and Delay Calibration.

Copyright 2026, James M. Atkinson

V011-C12-DISCUSSION-021 — Assess delay, termination sensitivity, additive noise, and channel relationships affected by that path. Repeat appropriate common-signal and state tests. Retain unaffected evidence only when its applicability is demonstrated.

Review: Chapter 12 — Reference Distribution Acceptance.

V011-C12-DISCUSSION-022 — Define each operation's error criterion and relevant boundary first. Different deterministic and stochastic requirements can produce different valid intervals. A single universal number conceals those distinctions.

Review: Chapter 12 — Accept coherence at the required boundary and state.

V011-C12-DISCUSSION-023 — Explain the prior alignment defect and the calibrated successor result while preserving evidence and configuration. The shared clock did not alone synchronize sampling. Avoid attributing the original impossible geometry to a physical source without valid timing.

Review: Chapter 12 — Hypothetical Case Adjudication: Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing.

V011-C12-DISCUSSION-024 — State the observed difference, reference uncertainty, interval, and decision rule. Do not declare the source out of tolerance from the difference alone. Additional reference evidence or a better measurement may resolve the required comparison.

Review: Chapter 12 — Quantitative Model for Frequency Accuracy, Phase Noise, Clocks, Coherence, and Multichannel Timing.

Copyright 2026, James M. Atkinson

V011-C12-DISCUSSION-025 — The defined time/phase convention, actual rates and sample intervals, reference identity/state, calibration paths, raw records, corrections, integration bands, covariance/distribution assumptions, resets, and valid segments. Each precision claim should remain tied to its operation and error criterion.

Review: Chapter 12 — Accept coherence at the required boundary and state.

Copyright 2026, James M. Atkinson

Chapter Glossary

APERTURE DELAY: The timing displacement associated with when a converter actually samples its input relative to the declared timing reference. Unequal channel apertures contribute to relative timing alongside analog paths and digital processing. A calibration of a convenient clock connector does not automatically measure this acquisition-boundary contribution.

BAND-LIMITED PHASE VARIANCE: The phase variance contributed by a stated finite set of offset bands and line measures under an explicit spectral normalization.

CALIBRATION ERROR ENVELOPE: A justified deterministic bound on accumulated time or phase error over a declared interval after calibration.

CALIBRATION INTERVAL: The elapsed interval over which a declared error criterion remains satisfied under justified initial-error, frequency-error and drift bounds. Model 12A compares their accumulated envelope with a carrier-dependent phase tolerance. The admissible interval can be zero, finite or unrestricted within the assumed model; a schedule alone does not establish those bounds.

CHANNEL-SWAP TEST: A controlled interchange of channels or paths used to test whether an observed timing or phase residual follows the electronics, the path or the measurement geometry. Its interpretation requires preserving the other relevant conditions and recording the swap. It supports localization without making one successful comparison a universal calibration.

Copyright 2026, James M. Atkinson

CHARACTERISTIC FUNCTION: The expected complex exponential of a real random quantity at a specified argument. Model 12B evaluates it for a Gaussian phase difference to obtain a mean-phase factor and a variance-dependent attenuation factor. Applying that identity to a non-Gaussian difference requires its actual distribution, not merely a matching variance.

CLOCK TIME ERROR: The difference between a clock's reading and ideal reference time, positive for an advanced clock in the adopted convention.

COHERENCE TIME: Interval over which relative phase remains sufficiently stable for a specified coherent operation.

COHERENT PHASOR SUM: A complex sum that preserves the relative phases of its declared contributions. Its squared magnitude contains self and cross terms, so common rotation and relative rotation have different consequences. The chapter's normalized signal-power result does not by itself include additive noise, amplitude variation or uncertainty introduced by estimated phase corrections.

COMMON PHASE ROTATION: A phase contribution shared by every sample in a record, which can alter ensemble complex phase without causing relative cancellation within that record.

COVARIANCE MATRIX VALIDITY: The requirement that a proposed covariance matrix describe a possible joint random vector, including symmetry and positive semidefiniteness. Individually plausible pairwise correlations do not guarantee that the complete matrix meets this condition. Model 12B uses a specified valid geometric lag structure before evaluating the coherent-power sum.

Copyright 2026, James M. Atkinson

DETERMINISTIC PHASE ROTATION: A specified progression of mean phase across the actual sample times, such as that produced by a frequency offset. Model 12B keeps its finite phasor sum separate from independent random phase errors. Special frequencies are evaluated by the finite sum instead of an indeterminate trigonometric quotient.

ENDPOINT TIME COMPARISON: An estimate of average fractional-frequency error obtained from two time-error observations divided by their reference-time separation. Deterministic endpoint-error limits propagate as a bound on that average. They do not become standard deviations without an additional statistical model, and the interval must not conceal an unmodeled reset.

EPOCH OFFSET: The time-reading error at a declared reference instant. It is the initial condition in Model 12A and is distinct from subsequent fractional-frequency error or drift. Correct average frequency does not remove an existing epoch offset, while a correct initial epoch does not prevent later accumulated error.

FINITE-SAMPLE SELF TERM: The diagonal contribution obtained when the squared magnitude of a finite coherent phasor sum is expanded. Each unit-magnitude phasor contributes its own power before cross terms are considered. This produces the finite-count contribution in Model 12B and prevents replacing expected coherent power by the squared ensemble-mean phasor.

FRACTIONAL FREQUENCY ERROR: Frequency difference normalized to a reference frequency.

Copyright 2026, James M. Atkinson

FREQUENCY DRIFT: A change of fractional frequency with elapsed time under a declared local model. A constant drift coefficient gives a quadratic contribution to accumulated time error. Its fitted value and validity interval must remain explicit; the same law need not survive warmup, reference loss, restart or environmental change.

FREQUENCY SYNCHRONIZATION: Agreement of specified frequency rates or their controlled relationship over a declared interval. It can coexist with unknown epoch, trigger or channel-phase offsets. Sharing a reference oscillator therefore does not establish the sample alignment or deterministic phase relationship required for every multichannel inference.

HOLDOVER: Operation of a disciplined clock after loss of its external reference using its internal oscillator and stored model.

JOINT GAUSSIAN PHASE MODEL: An explicit distributional model in which every linear combination of the finite phase vector is normally distributed, allowing degenerate cases. The declared mean and covariance then determine the characteristic function used in Model 12B. Stationarity, marginal RMS values or a measured power spectrum alone do not establish this additional assumption.

MEAN COHERENT SIGNAL POWER: The expectation of the squared magnitude of a declared coherent signal sum, distinct from the squared ensemble-mean phasor and from a complete SNR calculation.

Copyright 2026, James M. Atkinson

NONDISPERSIVE DELAY: A delay that is constant over the frequency region used in the model, producing a linear unwrapped transfer-phase dependence on frequency. A slope estimate can identify it within the selected branch. Phase curvature from filters or other path behavior means that one constant delay may be inadequate for broadband correction.

OFFSET INTEGRATION BAND: The specified set of positive frequency offsets included in a phase-noise variance calculation. Its limits and any separately included lines form part of the result. Noise outside the set is not measured by the resulting RMS value, and extrapolating a displayed floor requires an additional justified assumption or bound.

OUT-OF-FIT VALIDATION: Evaluation of a fitted timing, phase or delay correction on observations not used to select that correction. It helps reveal overfitting and retained instability that an apparently aligned fitting record can conceal. The original records and correction method remain available so that processing-dependent conclusions can be examined.

PHASE COVARIANCE: The second-order relationship between phase deviations at two specified times or sample positions. Together with the marginal variances, it determines the variance of their difference. Equal marginal RMS values can therefore produce different coherent behavior when the covariance differs; the required relationship cannot be inferred from a scalar jitter number alone.

PHASE-INCREMENT VARIANCE: The variance of the difference between two phase samples, determined by their individual variances and covariance.

PHASE NOISE: Random phase fluctuation represented as spectral density around a carrier or reference.

Copyright 2026, James M. Atkinson

PHASE RESET: A discrete change in phase associated with an identified event such as retuning, triggering or restarting. A finite difference crossing the event includes the step even if the continuous frequency behavior is unchanged on either side. Segment boundaries and any measured cross-event relationship must therefore be preserved.

REFERENCE DISTRIBUTION NETWORK: The installed paths carrying a reference to the devices and boundaries that depend on it. Distribution amplifiers, cables, terminations and state changes can add delay or noise after the primary source. Acceptance therefore identifies and tests the actual outputs rather than relying only on the source's nominal accuracy or lock indication.

RELATIVE CHANNEL PHASE: The phase relationship between specified channels at a stated frequency and observation boundary. Model 12A obtains it from the difference of their time errors. A common contribution can cancel, but unequal analog paths, apertures, resets and processing delays remain unless measured or otherwise accounted for.

RMS TIMING JITTER: The root-mean-square timing fluctuation associated with a declared phase component and positive carrier frequency. Model 12B obtains it from that component's RMS phase by the stated phase-to-time conversion. The scalar retains neither the detailed offset distribution nor a complete account of deterministic delay, trigger error or sample alignment.

SAMPLE ALIGNMENT: The established relationship between sample indices and the corresponding acquisition instants across channels. Trigger paths, aperture times, digital pipelines and missing data can affect it even when the channels share frequency. The required relationship must be verified at the stored-data boundary used by the analysis.

Copyright 2026, James M. Atkinson

SAMPLE-CLOCK SCALE ERROR: A discrepancy between the actual and nominal sample rates that changes both elapsed-time labels and the frequency scale attached to normalized discrete data. For a fixed interval count, true elapsed time depends inversely on actual rate. Correcting one displayed frequency does not by itself establish correct timestamps or continuity.

SAMPLE-INTERVAL COUNT: The number of elapsed intervals between sample endpoints; a span of N intervals contains N plus one endpoint samples.

SINGLE-SIDEBAND PHASE-NOISE DENSITY: The carrier-referred noise-density convention used for one positive offset side of the phase spectrum, expressed linearly per hertz or logarithmically in dBc/Hz. Model 12B states the small-phase convention explicitly and includes both symmetric contributions when obtaining real-phase variance. A discrete spur requires a separate line treatment.

TIMING SKEW: Relative delay between nominally simultaneous channels, triggers, or signal paths.

TRANSFER PHASE: The phase difference imposed by a specified input-to-output path at a stated frequency. With the chapter's sinusoidal convention, a positive physical delay gives negative transfer phase. This sign must not be interchanged with the positive relative phase assigned to an advanced clock in Model 12A.

Copyright 2026, James M. Atkinson

UNMEASURED SPECTRAL CONTRIBUTION: A phase-noise contribution outside the directly evaluated spectral region. Model 12B bounds a specified finite extra band only when a justified upper density limit is supplied. Without that information, extending a plot or quoting the measured-band RMS as a complete jitter value would add unsupported evidence.

UNWRAPPED PHASE: A phase trajectory represented on a declared continuous branch rather than reduced at each observation to a principal angular interval. Its slope can support frequency or delay calculations when the model applies. Choosing the branch requires evidence; numerical precision alone cannot resolve an integer-cycle ambiguity.

WRAPPED-DELAY AMBIGUITY: The family of delays compatible with specified wrapped phase observations until additional phase, frequency or prior-range information selects a branch.

Annotation. Printed page 5, “Definitions and Terminology,” and section 3.1, “Noise Model,” equations (1)–(4), support the stated time-error, fractional-frequency and phase conventions. The deterministic drift envelope, interval selection, sample-clock examples and multistate acceptance procedure are the chapter’s original applications under declared premises. The reference supplies a technical framework for interpreting oscillator stability or correlated phase-noise measurements. Observation interval, averaging statistic, timebase origin and common-clock correlation should be specified before translating a frequency statistic into arrival-time or phase evidence. A nominally stable source can still have an offset or transient recovery event, and averaging may suppress or distort correlated components. Its use here is bounded by the physical reference plane, implementation version and the evidentiary proposition being tested.

Analog Devices. MT-085, "Fundamentals of Direct Digital Synthesis (DDS)." Rev. 0, October 2008, pp. 2–3. Phase-accumulator tuning relation and truncation distinction. https://www.analog.com/media/en/training-seminars/tutorials/MT-085.pdf.

Annotation. Printed pages 2–3 explain numerical tuning relative to a clock. This bounded citation does not establish the actual accuracy,

Copyright 2026, James M. Atkinson

phase continuity or trigger behavior of an unspecified receiver or reference network. The tutorial addresses numerical phase accumulation, frequency tuning and the effects of finite word length in a digital oscillator. The tuning equation, accumulator width, truncation position and reference clock are distinct quantities and must be documented separately. A theoretically possible output frequency or spur location is not proof that a deployed receiver produces it without measurements of clock quality and implementation. The cited work is a methodological reference; the worked examples and the conclusions drawn from them remain separate authorial derivations requiring their own checks.

Kester, Walt. MT-008, Converting Oscillator Phase Noise to Time Jitter. Rev. A. Analog Devices, October 2008. https://www.analog.com/media/en/training-seminars/tutorials/MT-008.pdf.

Annotation. Printed pages 3–4, especially “Converting Phase Noise to Jitter” and equations (2)–(3), support linear phase-noise integration and the carrier-dependent phase-to-time conversion. The chapter selects its own finite bands and independently develops the covariance and Gaussian-vector coherent-power results; it does not adopt illustrative integration limits as universal requirements. This source informs the distinction between deterministic sampling-time displacement and random timing uncertainty. The effect of timing uncertainty depends on input frequency, the integration limits for phase noise and correlation between parallel sampling paths. Ideal jitter-limited SNR formulae are bounds under specified models, not measured effective number of bits

Copyright 2026, James M. Atkinson

or evidence that parallel ADCs create a wider word. Interpretation requires separating the publication's stated scope from the chapter's constructed experimental examples and their necessarily conditional conclusions.

Chapter 13. Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration

Copyright 2026, James M. Atkinson

13.1 Measurement Chain Ownership

A receiver measurement is only as interpretable as the components ahead of its declared input plane. Antennas convert fields to terminal quantities according to pattern, polarization, impedance, effective aperture, and installation. Cables, adapters, splitters, filters, attenuators, bias networks, preamplifiers, and switches then alter amplitude, phase, noise, mode content, and dynamic range. These elements are not accessories outside the receiver problem; they are part of the measured transfer function.[1]

Ownership is divided deliberately across the series. V010 and V093 govern antenna and probe theory, V087 governs cables and connectors, V016 governs EMC and common-mode paths, and V011 governs how those elements are integrated and corrected in the receiver chain. The local treatment is sufficient to define reference planes, gain and loss, switching state, and measurement uncertainty without duplicating the full design theory of each component.

13.2 Define a complete path at named planes

An external receiving path should be specified as an ordered assembly. Name the antenna terminal plane, the remote-amplifier input and output if present, the ends of each cable, the switching or filtering planes, and the receiver connector. This turns an informal list of accessories into a measurement model. It also determines ownership of corrections. If the antenna calibration already includes a particular adapter, that adapter must not be corrected a second time; if the receiver calibration stops at its front connector, a field cable remains outside that calibration.

Keep three related records. The assembly record identifies physical components and their order. The state record identifies switch positions, gain, attenuation, bias, temperature, and receiver configuration during an observation. The correction record identifies the measured transfers, their reference planes, frequency grids, interpolation, uncertainty, and serial applicability. A photograph can help reconstruct the assembly, but it cannot replace the state or correction record. Conversely, a list of calibration certificates cannot prove that the listed components were connected in the intended order.

The two orders in Application 2B.2 are an instructive example. Their total desired-signal gain is identical, but their input noise temperatures differ greatly. A record containing only total gain would allow an analyst to miss the difference. For the remote-amplifier order, moving the reported plane from the antenna terminal to the receiver connector also removes the amplifier and cable from the reported receiver contribution. Both results

Copyright 2026, James M. Atkinson

may be useful, provided the plane is explicit. A comparison must return them to the same physical question before declaring an improvement.

Copyright 2026, James M. Atkinson

13.3 Antennas and Field-to-Terminal Conversion

An antenna terminal voltage or power depends on incident field, polarization, direction, near- or far-field condition, impedance, loading, and surrounding structure. Antenna factor, effective height, and effective aperture provide different conversion relationships under defined assumptions. Indoors, multipath and reactive coupling can make a nominal free-space calibration an incomplete description. A field-strength result should therefore identify the antenna, geometry, calibration basis, cable, and uncertainty.

Orientation changes are an analytical control as well as a search technique. A genuine polarized field should respond consistently with antenna pattern and geometry, while common-mode cable pickup or receiver enclosure leakage may respond differently. Antenna substitution can reveal frequency-dependent calibration errors or local near-field coupling. Measurements made with unknown active antennas or built-in automatic gain should not be converted to field strength without characterization.

Copyright 2026, James M. Atkinson

Ideal matched linear polarisations; real antenna cross-polar discrimination, multipath and orientation may prevent a perfect null.

Figure 70. Antenna polarisation mismatch.

Copyright 2026, James M. Atkinson

Figure 71. Integrated antenna-to-receiver measurement path.

Copyright 2026, James M. Atkinson

13.4 Keep field conversion separate from terminal power

An antenna-terminal measurement and a field estimate are different measurands. The terminal result can be supported by a calibrated conducted injection at that terminal plane. A field estimate additionally depends on the antenna response, polarization, direction, environment, and geometry. Equation 25 gives the ideal available-power relation for its stated aperture assumptions. It should not be used to convert an arbitrary near-field probe reading into a plane-wave power density. When only a comparative survey indication is supported, retain that interpretation instead of adding a field-strength unit that suggests a broader calibration.

Antenna factor is usually applied to a specified terminal voltage and load condition. A receiver that reports power requires a consistent voltage-power conversion at that impedance before the field conversion is applied. Available power, delivered power, open-circuit voltage, and loaded voltage are not interchangeable. A factor calibrated for a loaded 50-ohm voltage should not be applied directly to an open-circuit voltage estimate. Keeping the quantities and units in the correction record prevents an apparently constant offset from concealing a factor-of-two voltage error.

NPL's antenna guide distinguishes the uncertainty of an antenna calibration from additional uncertainty when the antenna is used in an emission measurement. It discusses mutual coupling, pattern, phase center, mounting, and feed-cable effects, and gives a rod-antenna example in which cable common-mode current makes layout consequential. These passages support a bounded conclusion: a certificate for the antenna does not, by itself, characterize every installed arrangement. The guide's historical EMC

Copyright 2026, James M. Atkinson

geometries and numerical examples are not adopted here as general limits for an indoor survey.[2]

For an installed comparison, hold antenna position, orientation, and nearby conductors as stable as the purpose requires. If the aim is to map spatial variation, movement is intentional and belongs in the record. If the aim is to compare two receiver states, unintended movement is a confounding variable. A small antenna rotation can change polarization coupling while an altered cable route changes the installed response. The resulting level change may be real at the receiver terminal without representing a change in the external source. Record the controlled question before interpreting the change.

2 Joint Committee for Guides in Metrology, International vocabulary of metrology: Basic and general concepts and associated terms, VIM3 online edition, entries 2.48, 2.49 and 2.53, https://jcgm.bipm.org/vim/en/2.48.html, https://jcgm.bipm.org/vim/en/2.49.html and https://jcgm.bipm.org/vim/en/2.53.html, read November 2, 2026. These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

13.5 External Preamplifiers, Bias, and Stability

External preamplifiers are placed near the antenna to overcome cable loss and receiver noise. Their gain, noise figure, compression, intercept, reverse isolation, input protection, bias state, and stability determine whether they improve the system. Bias tees and remote power introduce conducted paths that can carry switching noise, oscillation, or common-mode current. A preamplifier can also reradiate local-oscillator leakage from the receiver through inadequate reverse isolation.

Stability tests include terminated input, output loading, supply variation, cable-length variation, temperature, strong-signal exposure, and spectrum observation over the amplifier's full response. Gain should be measured rather than assumed from a label. If the amplifier is switched or remote-controlled, its state and transition time are logged. Field recordings with different amplifier states are corrected and kept distinct.

Copyright 2026, James M. Atkinson

13.6 Remote amplification requires electrical and installed checks

A remote preamplifier can overcome the noise penalty of a long cable, as Application 2B.2 shows. Its input is also where the external spectrum first meets an active device. A narrow downstream receiver channel does not protect it from signals elsewhere in its own passband. Establish the desired and blocker transfers up to the remote input, then apply the front-end analysis of Chapter 3. If preselection is added ahead of the remote amplifier, repeat the noise calculation with its actual loss and physical temperature. The improved rejection and the increased input-equivalent noise are both consequences of the new assembly.

Bias delivery is part of the state. Record the power source, bias tee or separate feed, nominal operating conditions, and any monitoring available at the remote unit. A voltage measured at the supply does not establish the voltage at the amplifier after a resistive cable or protection element. A battery substitution can be a useful comparison, but it can change both supply noise and the conductive path to other equipment. If the observation changes, those alternatives remain until a more selective test separates them.

Stability should be checked in the configurations that the assembly can actually encounter. A remote amplifier may behave differently with an antenna, a matched termination, an open switch branch, or a long cable. A narrow unexpected line, a raised baseline, or a gain change can indicate oscillation or another instability, but those observations are not unique to it. Terminated-input and alternate-load comparisons, bias monitoring, and an

Copyright 2026, James M. Atkinson

independent observation of the amplifier output can constrain the explanation. Perform such tests within the component's documented operating conditions.

A stable bench assembly can still be a poor installed measurement system if its temperature, supply, or mechanical state drifts during use. Retain a reference before and after the observation and after consequential changes such as reconnection, relocation, or a gain-state change. If a reference fails, investigate the affected time interval rather than silently applying a single correction to all earlier records. A measured drift may support a bounded correction when its evolution is understood; an intermittent or unexplained change generally requires a more limited interpretation.

Copyright 2026, James M. Atkinson

13.7 Attenuators, Filters, Splitters, and Switches

Attenuators provide level control, impedance improvement, and linearity challenge. Filters restrict admitted energy. Splitters and couplers distribute signals while introducing loss, isolation limits, amplitude or phase imbalance, and unused-port requirements. Switches add path-dependent loss, repeatability, leakage, and switching transients. These components can enable controlled multichannel comparison, but they also create hidden differences if their paths are assumed identical.

Acceptance measurements use a network analyzer or calibrated source and receiver across the relevant frequency range and power level. High-power, pulsed, or nonlinear behavior may require separate tests. Unused ports are terminated as specified. Mechanical torque, connector condition, path labels, and temperature are controlled. A correction file is linked to the exact serialized path rather than to a generic component model.

Copyright 2026, James M. Atkinson

13.8 Treat connections and unused branches as part of the network

A switch selects a path but does not make every other path disappear. Finite isolation can admit a strong signal from an unused branch, and an unterminated branch can alter the impedance presented through the switch. A splitter likewise changes delivered power and can couple its output loads. The matched scalar cascade is appropriate only when the effective transfer and added-noise behavior of the selected assembly satisfy its assumptions. If changing an unused termination changes the observed result, the system needs a multiport or empirical description that includes that branch.

Insertion loss measured with a network analyzer is valuable, but the result is tied to its calibration planes, source and load conditions, frequency, and signal level. A connector that is reassembled after calibration can introduce a different reflection or loss. Mechanical strain can make that difference intermittent. Retain the identity of adapters and cables, use the relevant connector practices, and verify the complete selected path after assembly. A nominal cable type is not a substitute for a measured transfer when the required accuracy makes individual variation consequential.

Mismatch can affect a noise measurement in two ways: it changes delivered source power and can change the receiver's own gain and noise response to the source impedance. Weatherspoon and colleagues explicitly separate these effects in their vector-corrected noise-temperature work. Their method uses receiver noise parameters and measured reflection coefficients. This is why a generic scalar mismatch allowance or a single

Copyright 2026, James M. Atkinson

insertion-loss correction cannot always repair a high-accuracy hot/cold measurement. Model 2B deliberately assumes matching; moving outside that boundary requires the additional characterization.[3]

An attenuator can reduce the influence of reflections while adding thermal noise and lowering signal level. Its usefulness depends on which uncertainty or failure dominates. For a strong reference calibration, the improved match may be valuable. For a weak field observation, the same pad may make the signal undetectable. The correct comparison uses the complete uncertainty and sensitivity at the selected plane, with the pad's loss and temperature included. Do not treat improved return loss as a free improvement in every other measurement property.

3 Barry N. Taylor and Chris E. Kuyatt, Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results, NIST Technical Note 1297, 1994 edition (September 1994), Appendix A, A.1–A.5, https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. The functional and covariance framework is used within its stated scope; the synthetic ranges, examples and recoverability conclusions are original.

13.9 Common-Mode Current and Installed-Path Effects

Coaxial and shielded paths can carry external common-mode current on their outer surfaces even when the internal transmission mode is well matched. Cable routing, shield termination, grounding, ferrites, equipment bonding, and nearby structures affect pickup and radiation. A receiver connected through a long cable can detect the cable as an antenna, making the nominal sensing element less important than the installed path.

Common-mode challenges include changing cable route, adding or moving ferrites, bonding the enclosure, using optical isolation, operating from battery, and comparing a short local cable. These changes must be interpreted carefully because they also alter impedance and environment. The report identifies whether the observation is referred to the intended antenna terminals or to the complete installed receiving structure.

Copyright 2026, James M. Atkinson

13.10 Separate the intended coaxial path from installed coupling

The intended coaxial signal is associated with the field between the center conductor and the inside of the shield. Current on the outside of the shield can participate in a different coupling path involving the antenna, enclosure, ground, and nearby conductors. A matched two-port measurement of the intended path does not fully describe that installed path. This distinction explains why an excellent conducted insertion-loss result can coexist with a receiver indication that changes when a cable is moved.

A useful installed comparison preserves the desired observation geometry while deliberately changing one coupling opportunity. Examples include rerouting a defined cable segment, changing a permitted bonding arrangement, or introducing a characterized common-mode treatment. Record the exact change and remeasure the intended-path transfer when it could be affected. A ferrite comparison is evidence of sensitivity to that intervention; it is not, by itself, proof of a unique current distribution or external source. The treatment may also move the cable or alter its impedance.

A battery-powered optical link can remove a conductive cable path, but it introduces its own gain, noise, bandwidth, timing, and power-state behavior. Its result becomes an independent comparison only after those properties are understood well enough for the question. If the optical configuration has much less sensitivity, the disappearance of a weak feature is inconclusive. If it preserves the desired reference while an anomalous

Copyright 2026, James M. Atkinson

feature changes, the comparison is stronger. Preserve both observations and the reference evidence that makes them comparable.

Copyright 2026, James M. Atkinson

Model curves are conceptual; measure current and coupling with the actual cable, grounding, termination and choke impedance.

Figure 72. Coaxial common-mode coupling.

13.11 Integrated Path Acceptance

The full path is accepted as a serialized assembly with measured response, configuration control, torque, labels, cable route, bias state, and environmental range. Calibration is repeated after any accessory substitution or relocation that changes loss, phase, balance, or common-mode behavior. Reference sweeps include the active antennas and remote preamplifiers under the same power and control state used during deployment.

Field checks compare a stable reference through short and installed paths, alternate antennas, and battery or isolated operation. Disagreement is resolved before environmental data is interpreted. The path record provides both corrections and limitations, including frequencies where gain, match, common-mode rejection, or dynamic range do not support quantitative conclusions.

13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration

Equation 1. Available power from effective aperture

$$P_r = S_{\text{inc}} A_e$$

For a matched receiving antenna in the far field with polarization accounted for, available received power P_r equals incident power density S_{inc} times effective aperture A_e. Near-field coupling, mismatch, loss, and multipath require additional treatment.

Equation 2. Cascaded corrected level

$$P_{\text{ref,dBm}} = P_{\text{ind,dBm}} + \sum_i L_{\text{i,dB}} - \sum_j G_{\text{j,dB}}$$

Equation 25 is the bounded antenna-to-terminal interface stated for this chapter; antenna pattern, polarization, field region, and matching remain part of its conditions. Equation 26 reuses the scalar path correction from Model 2B. The full signed correction chain and its uncertainty are worked in Chapter 14 rather than inferred from a catalog sum.

Power at a chosen upstream reference plane equals indicated power plus downstream passive losses and minus downstream gains, using signed frequency- and state-dependent corrections. Mismatch and uncertainty are separate terms.

Copyright 2026, James M. Atkinson

Table 1. Chapter 13 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Antenna conversion	Pattern, polarization, geometry, calibration, impedance, and field region	Supports field or terminal interpretation	Indoor and near-field conditions can invalidate free-space assumptions
External preamplifier	Gain, noise figure, intercept, compression, bias, stability, and reverse isolation	Can overcome cable and receiver noise	Can oscillate, overload, or reradiate receiver leakage
Passive path	Loss, return loss, isolation, imbalance, power rating, and serialized correction	Provides controlled level and routing	Generic model data may not describe the installed path
Installed common mode	Cable route, shield termination, bonds, ferrites, enclosure, and battery comparison	Separates intended antenna response from cable pickup	Changing the route can also change the environmental field

Copyright 2026, James M. Atkinson

13.13 Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration

A calibrated antenna delivers -92.0 dBm at its terminals. The path contains 6.4 dB cable and switch loss and a preamplifier with 20.1 dB gain. The receiver should indicate about -78.3 dBm before mismatch and calibration uncertainty. An actual -70 dBm indication is inconsistent by 8.3 dB and requires checking gain state, correction file, overload, and common-mode pickup.

Copyright 2026, James M. Atkinson

13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration

A weak component disappears when the remote preamplifier is replaced by a passive through path, but it also remains when the antenna input is terminated. Changing the bias cable length shifts the component. These observations implicate the installed active and bias path. Self-oscillation is one hypothesis, alongside conducted or radiated pickup, reference leakage, and other network-dependent responses. Separately observing the amplifier output and controlling the bias and load conditions would help discriminate those mechanisms while checking that the comparison retains the required detection capability.

Copyright 2026, James M. Atkinson

13.15 A constructed acceptance case for the assembled chain

Consider the remote-amplifier order in Application 2B.2, operated in its declared linear state. Its desired-signal gain from the antenna terminal to the receiver output is 44 dB. A conducted reference of −112 dBm at that terminal should therefore produce −68 dBm at the stated output. This prediction is a transfer check, separate from the noise calculation. A reference injected only at the receiver connector bypasses the remote amplifier and cable, so it cannot verify their contribution even if the final displayed level is correct.

Build the acceptance record around that distinction. First verify the receiver alone at its own connector. Then verify the assembled conducted path at the antenna-terminal plane, retaining the raw output and all corrections. Finally perform an installed reference observation with the antenna in its documented geometry if a field-based conclusion is required. Each step extends the tested scope. Passing the first step cannot be described as passing the third, and a failure in the third does not immediately identify the receiver as the cause.

Table 13A. Minimum information for the constructed integrated path

Record	Required content	Reason
Assembly	Serial components, order, connectors, unused ports	Reconstructs the actual network
State	Gain, attenuation, filter, bias, temperature, time	Identifies the valid transfer and noise law
Desired transfer	Frequency, reference planes, gain, uncertainty	Supports terminal-level correction
Blocker transfer	Blocker frequencies and admitted levels	Tests loading before vulnerable stages

Copyright 2026, James M. Atkinson

Record	Required content	Reason
Installed geometry	Antenna orientation, mounting, cable route	Bounds field and common-mode interpretation
Closure	Before/after references and changes	Bounds the interval of demonstrated validity

Now introduce the declared blocker through a controlled path and retain the desired reference. If desired gain remains consistent while the noise rises, inspect the source spectrum and the reciprocal-mixing prediction. If desired gain changes, test gain control or compression before trusting the quiet-state noise budget. If an apparent product changes with cable routing while the conducted reference remains stable, examine installed coupling. These outcomes route the investigation toward different mechanisms; they do not require an invented single score for overall receiver quality.

The closing report should state which plane and configuration were accepted, the frequencies and signal conditions actually challenged, the reference uncertainty, and any interval in which state was unknown. Component certificates belong in the supporting record, while the acceptance conclusion belongs to the assembled measurement that was performed. This distinction allows the same hardware to support a strong conclusion for a bounded conducted measurement and a more cautious conclusion for an installation whose field coupling was only partially characterized.

Copyright 2026, James M. Atkinson

13.16 Integrated reference-plane analysis and system-level acceptance

An antenna, a feeder, a filter, an attenuator, a protective device and a receiver should be treated as a single measurement chain only after each relevant reference plane has been declared. The incident field at the antenna location is an electromagnetic quantity whose connection to terminal power depends upon antenna factor, effective aperture, polarisation, orientation, impedance and environmental coupling. The available power at an antenna port is not necessarily the power delivered to a particular load through a real transmission line. Every claim of received power therefore identifies whether it refers to the antenna's nominal available power, the conducted power at a connector, the receiver input after a passive network, or a detector output reconstructed through a calibrated transfer function. Without this declaration, two perfectly reproducible measurements can appear to disagree while describing different measurands.

The system's linear response can be described locally through a frequency-dependent transducer gain, but the validity of that response must be established for the source and load impedances under which it is used. The commonly employed decibel correction is useful for matched, small-signal comparisons where reflections are negligible or included in the calibration. If the antenna has a complex source impedance and the cable or preselector has substantial reflections, a scalar loss measured against a matched laboratory source may not reproduce the in-situ transfer. A rigorous approach retains complex scattering parameters, cable length, temperature, connector condition and uncertainty associated with the actual source/load

Copyright 2026, James M. Atkinson

match. The decision to use a simpler model is itself an engineering judgement, and its possible error should be bounded rather than concealed.

The measurement chain also has a spatial boundary. In a room with near-field coupling or significant reflections, antenna factor derived from a far-field plane-wave calibration may not faithfully convert a detected voltage into local electric-field strength. An antenna orientation change may alter its coupling to the source, the building's conducting surfaces and the cable's common-mode path. The investigator should distinguish a change in the incident environment from a change in effective antenna transfer. Repositioning an antenna or retorquing a connector may be useful as a challenge test, but the altered geometry means that a subsequent signal-level difference cannot automatically be attributed to source variability. Where the aim is to compare observations, record a repeatable geometry and an independent reference whenever practicable.

A dedicated preamplifier close to the antenna may improve the sensitivity of a long-cable arrangement, yet it shifts the vulnerability to out-of-band blockers nearer the antenna. The operator must evaluate both the input noise budget and the absolute power arriving at that amplifier. A downstream attenuator cannot protect an earlier amplifier from overload. Conversely a high-isolation preselector placed before a low-noise amplifier may suppress powerful interferers but incur enough insertion loss to harm sensitivity to a legitimate low-level test signal. An effective design balances these constraints at the actual antenna location. Catalogued noise figure, gain and compression values are starting hypotheses for validation, not final statements of system performance after installation.

Copyright 2026, James M. Atkinson

13.17 Electromagnetic return paths, cables and the risk of false spatial inference

Coaxial systems are often represented as a clean TEM transmission line with current on the inner conductor and the interior surface of the screen. Real installations can also carry common-mode current on the exterior conductor. That current may be excited by nearby fields, grounding differences, power-supply noise or conductive structures connected to the cable. Consequently the cable itself can become part of the receiving structure. A spectrum feature that changes when a cable is moved or rerouted may reflect such a coupling path, rather than a change in the true field at the intended antenna. This should be tested using appropriate isolation and common-mode suppression arrangements, not inferred from the colour or direction of a waterfall trace.

A connector defect can be both a linear and a nonlinear problem. Loose contacts and corroded junctions alter return loss and insertion loss; under powerful excitations, a nonlinear contact may mix frequencies and create a new component that appears to originate at another location. Mechanical strain can make that component intermittent. The investigator should preserve a baseline transfer measurement of the assembled cable, use consistent connector cleaning and torque procedures appropriate to the hardware, and repeat controlled tests after suspected mechanical movement. Avoid defeating protective bonding or altering safety arrangements merely to pursue a lower-noise measurement; any diagnostic configuration change must remain within electrical-safety and lawful operational limits.

Copyright 2026, James M. Atkinson

The route of a cable changes more than its nominal attenuation. Temperature and bending can alter phase delay, particularly when a receiver network depends upon coherence. A cable showing acceptable magnitude response may have drifted enough in phase or group delay to invalidate a timing or direction-finding conclusion. For ordinary occupancy surveys this may be immaterial, but for coherent arrays it becomes a direct source of uncertainty. Accordingly the chapter's reference-plane register should distinguish amplitude corrections from phase and timing corrections. It should also specify whether calibration was performed with the actual in-situ assembled path or a nominally similar replacement. Substituting accessories without updating their records can destroy traceability even when the displayed spectrum appears stable.

13.18 Ten worked examples in integrated antenna-to-receiver measurements

Copyright 2026, James M. Atkinson

13.18.1 Example 13.X1. Conducted power transferred across a measured feeder

Suppose an antenna-terminal reference signal has available power -67.0 dBm under matched conditions. The selected feeder has measured loss 4.2 dB and a protective filter adds 1.3 dB at the frequency of interest. Ignoring mismatch and nonlinearity, the receiver input power is -67.0-4.2-1.3=-72.5 dBm. If a preamplifier with 16.0 dB calibrated gain is installed ahead of the feeder, the receiver input would nominally be -56.5 dBm, provided the amplifier remains linear and the filter position is unchanged. These figures are not field-strength estimates. They refer to power conventions at defined conducted planes. A frequency-dependent antenna factor or effective-aperture model and a suitable propagation assumption would be required to relate a free-space field to the original available power. The gain intervention can improve a noise budget without validating a claim of additional information about the outside emitter.

Copyright 2026, James M. Atkinson

13.18.2 Example 13.X2. Converting measured return loss to reflection magnitude

A connectorised system is measured to have return loss 14.0 dB at one test frequency. On the conventional definition, $|\Gamma|=10^{(-RL/20)}=10^{(-14/20)}=0.1995$. Its reflected-power fraction is $|\Gamma|^2=0.0398$, approximately 4 percent. The mismatch-only power reduction in a simplified one-interface model is $-10 \log_{10}(1-0.0398)=0.176$ dB. That is not a universally valid end-to-end power correction. If source and load are both mismatched, their complex reflection coefficients and phase interactions contribute to mismatch uncertainty. Thus the 0.176 dB estimate is a diagnostic scale, not a replacement for a proper transducer-gain assessment. At frequencies where the cable becomes electrically longer, small mechanical changes can alter those phase relationships and require recalibration.

Copyright 2026, James M. Atkinson

13.18.3 Example 13.X3. Antenna effective aperture in an ideal far-field model

For a receiving antenna with linear gain G=2.0 at a free-space wavelength lambda=0.30 m, the ideal effective aperture is A_e = G lambda^2/(4 pi) = 2(0.09)/12.566=0.01432 square metres. If an assumed incident plane-wave power flux density is 1.0 microwatt per square metre and polarisation is perfectly matched, the ideal available antenna power is 1.432 times 10^(-8) W, approximately -48.44 dBm. This calculation assumes far-field illumination, a suitable gain convention, correct matching and a plane-wave relation between the incident flux and antenna response. Near metalwork or a local source, those assumptions may be false. The number should therefore be labelled an ideal reference computation rather than a measured field or an attribution to any particular emitter.

Copyright 2026, James M. Atkinson

13.18.4 Example 13.X4. Polarisation mismatch of orthogonal linearly polarised antennas

For two ideal linearly polarised antennas with polarisation axes separated by theta degrees, the received power ratio from polarisation alone is cos^2(theta). At theta=60 degrees the fraction is 0.25, corresponding to 10 log10(0.25)=-6.02 dB. At 90 degrees the ideal model predicts zero coupling, but real antennas have finite cross-polar response, environmental depolarisation and near-field effects. A negative result from one antenna orientation does not establish that no RF energy was present. The operator should report the orientation, antenna characteristics and uncertainty, and test other polarisations where the survey question requires adequate coverage. This computation concerns one polarisation mechanism and cannot explain the entire amplitude variation in a complex room.

Copyright 2026, James M. Atkinson

13.18.5 Example 13.X5. Selecting a remote preamplifier with a long feeder

A receiver has a nominal noise figure of 6 dB, and a matched 8 dB cable precedes it. Under reference-temperature assumptions, the cable has a linear loss of 6.31, so the system's input noise figure referred ahead of the cable is roughly 14 dB when no other elements are present. Introduce a near-antenna amplifier with 20 dB available gain and 2 dB noise figure. The combined noise factor is approximately $F_{amp}+(F_{cableReceiver}-1)/G_{amp}$, where $F_{amp}=1.585$, $G_{amp}=100$, and $F_{cableReceiver}=10^{(14/10)}=25.12$. Thus $F_{total}\approx1.585+0.2412=1.826$, giving $NF_{total}\approx2.61$ dB. This idealised improvement is substantial, but the amplifier now confronts the full antenna environment. A blocker or lightning-protection requirement may make the seemingly better sensitivity configuration inappropriate without additional filtering and safe installation measures.

Copyright 2026, James M. Atkinson

13.18.6 Example 13.X6. Coherence loss from uncorrected cable delay

A phase-coherent receiver pair has an unmodelled relative time-delay change of 0.5 ns between calibration and measurement. At a 1 GHz carrier, the corresponding phase shift is phi=360 degrees times frequency times delay, giving phi=360(10^9)(0.5 x 10^(-9))=180 degrees. A naive coherent combination could therefore subtract what should add. The exact effect depends on the algorithm, signal frequency and whether differential delay was estimated during acquisition, but the scale demonstrates why an amplitude-only cable calibration is insufficient for array processing. For a broadband waveform, group-delay variation and sample timing must also be considered. The example does not imply that the installation physically moved by a fixed distance; dielectric and temperature changes can create differential electrical delay without an equivalent visible movement.

Copyright 2026, James M. Atkinson

13.18.7 Example 13.X7. Loss and system noise from a protective filter

A protective input filter adds 1.8 dB passband insertion loss and rejects a stipulated off-band blocker by 35 dB. In a matched reference-temperature cascade, placing it before a sufficiently good first amplifier will ordinarily worsen the intrinsic input noise figure by approximately its insertion loss. Nevertheless the filter may be essential if it prevents an otherwise saturating blocker from reaching the amplifier. Suppose a blocker arrives at -4 dBm. After 35 dB rejection it reaches the vulnerable amplifier at approximately -39 dBm, an enormous reduction compared with the unfiltered -4 dBm condition. The passband noise penalty and blocker suppression should both be reported. It would be erroneous to describe the 35 dB rejection as a 35 dB improvement in sensitivity. Instead the result is increased validity in the specified strong-signal environment, subject to testing the filter's finite transition band and power handling.

Copyright 2026, James M. Atkinson

13.18.8 Example 13.X8. Converting a correction uncertainty into a confidence statement

A receiver reports -82.0 dBm at its input plane. A calibrated feeder loss of 3.2 dB and filter loss of 1.5 dB are added to refer the result back to the antenna port, giving -77.3 dBm under the adopted sign convention. If the independent standard uncertainties of displayed level, feeder loss and filter loss are 0.4, 0.2 and 0.3 dB respectively, the root-sum-square uncertainty is sqrt(0.4^2+0.2^2+0.3^2)=0.5385 dB. A nominal expansion factor of two yields about 1.08 dB under the approximation, but whether a formal coverage interval is justified depends on distribution assumptions, degrees of freedom and correlation. If the losses were established against the same calibration source, treating them as independent may not be defensible. A report should list the contributing terms, their correlations and the exact reference plane.

Copyright 2026, James M. Atkinson

13.18.9 Example 13.X9. Intermittent common-mode cable response

A controlled laboratory source at fixed level is monitored by an antenna and cable assembly. With the cable on its normal route the apparent component is -75 dBm; after a deliberate safe rerouting with the antenna position unchanged it becomes -64 dBm. The 11 dB difference demonstrates a configuration dependence of the measured system, not by itself a change in the laboratory source. A common-mode current path on the feeder is one hypothesis; changes in connector impedance, cable microphonics or the electromagnetic geometry are alternatives. The proper follow-up uses a second calibrated and physically distinct receiving arrangement, measured common-mode suppression where appropriate and a configuration ledger. One must not apply an unexplained 11 dB correction to the original evidence or describe the rerouted state as necessarily closer to the truth. Both are observed states whose physical causes still need resolution.

Copyright 2026, James M. Atkinson

13.18.10 Example 13.X10. Why field strength cannot be inferred from connector power alone

Suppose a receiver input indicates -90 dBm of conducted power. A direct conversion to incident electric-field strength is impossible without an antenna transfer model and valid environmental assumptions. If the associated antenna has a calibrated antenna factor AF=20 dB per metre in a suitable far-field arrangement and a measurement at its terminal corresponds to 20 dB microvolts, the ideal indicated electric-field strength would be 40 dB microvolts per metre by E_dBuV/m = V_dBuV + AF_dB/m. Yet the original -90 dBm is not automatically equal to 20 dB microvolts at a mismatched port. Voltage and power conversion require the reference impedance and appropriate delivered-power convention. The numerical field-strength result is therefore conditional on measured voltage at the antenna terminal, calibration geometry and proper polarisation correction. This distinction prevents an attractive number from disguising a missing physical premise.

Copyright 2026, James M. Atkinson

13.19 Verification, records and the interpretation of negative observations

An installation acceptance record should identify the antenna type and serial identifier, orientation, fixture position, cable path, connector condition, filter and preamplifier state, protection components, instrument input state, calibration interval, temperature and relevant frequency span. Each important transfer correction should have a provenance link to the test equipment, procedure and reference standard used to determine it. The record distinguishes a component datasheet value from an actual system calibration. A nominal gain figure measured at room temperature cannot automatically be transferred to a sunlit roof installation or a concealed cable routed through a fluctuating thermal environment. The technical burden is proportional to the intended inference. Simple occupancy screening may need less detailed phase calibration than coherent source localisation, but it still needs truthful documentation of its uncertainty.

The survey report should specify how the receiving chain could have missed a relevant signal. Blind intervals, antenna pattern nulls, polarisation mismatch, preselector rejection, weak-signal sensitivity, overload recovery and operator-selected frequency coverage all limit negative claims. Multiple receiver chains provide stronger corroboration only when their failure modes are sufficiently independent. Two instruments sharing the same compromised antenna splitter or reference clock do not become independent simply because their displays resemble one another. The final assessment must account for the installation's actual physical pathways and not merely the nominal specifications of its individual modules. The strongest defensible negative statement describes the tested frequencies,

Copyright 2026, James M. Atkinson

observation intervals, configurations and decision thresholds under which no qualifying event was detected.

The governing documentation should permit a second examiner to reconstruct the measurement corrections and understand why the selected geometry, reference planes and component states were appropriate. It should separate raw conducted measurements from derived field values, and measured timing from inferred location. Any disputed result should remain traceable to the relevant recording, calibration record and instrument state. Worked computations in this section are hypothetical demonstrations of method rather than measurements of a real installation. Their accuracy under the stated assumptions must still be confirmed for the user's actual instruments and source geometry before they are used as evidential findings.

Copyright 2026, James M. Atkinson

13.20 Transducer gain, mismatch and antenna calibration at the installed measurement plane

An antenna and receiver connected by a cable form an interacting network, not a succession of ideal scalar decibel corrections. The available power from an antenna depends on its Thevenin equivalent and source impedance, while delivered power depends on the receiving input impedance and the intervening network. When an antenna is reactive or the receiver's input match changes with gain state, a calibrated insertion loss between nominally matched ports is insufficient to predict the installed transducer gain. The complete relation requires reflection coefficients, transmission coefficients and a declared plane. A scalar path correction remains useful where mismatch effects have been measured, bounded or shown negligible, but the engineer should not confuse the convenience of dBm arithmetic with universal applicability of the model.

Let reflection coefficient Gamma = (Z - Z0)/(Z + Z0), where Z is the complex port impedance and Z0 is the real positive reference impedance. The reflected-power fraction is |Gamma| squared for the corresponding power-wave convention. A source with |Gamma| = 0.3 has reflected fraction 0.09, or nine percent, under the stated reference, whereas a second state with magnitude 0.1 reflects one percent. These figures do not by themselves establish the network's net transducer gain, because phase, multiple reflections and cable electrical length can change the result. A reported change in power after cable substitution may arise from the new mismatch geometry even if the cable's matched-port insertion loss appears

Copyright 2026, James M. Atkinson

unchanged. Measuring only one cable loss number would leave an ambiguity that cannot be removed by a later scalar correction.

Antenna factor introduces a second conversion: an electric field strength in volts per metre is related to the voltage at a specifically defined antenna port under specified frequency, polarisation, geometry and loading. Applying an antenna factor without checking those conditions can turn a receiver input-voltage reading into an unsupported environmental field claim. For a simple hypothetical calibration, suppose a port voltage of 10 microvolts is related to a plane-wave field through an applicable antenna factor of 20 per metre. The field magnitude is then 200 microvolts per metre before other stated corrections. This result assumes the chosen calibration definition and the same installed orientation and reference plane. If the antenna is used in a reactive near field rather than the calibration geometry, the same factor may not apply and the true vector field cannot be inferred from one scalar reading.

The appropriate acceptance record uses actual cable routing, connector identity, torque or installation method, bias tees, protective elements and preselector states. Each substitution should be accompanied by a closing reference test at the new configuration. Calibration of the antenna alone and calibration of the receiver alone do not automatically compose into a traceable installed-system result. The uncertainty budget must distinguish repeated connection variation, systematic antenna-factor uncertainty, mismatch, environmental coupling and the applicability of the far-field model. A signal disappearing after a probe has been moved is useful evidence of changed coupling; it is not necessarily the physical position of a particular transmitting apparatus.

$$\Gamma = (Z_L - Z_0)/(Z_L + Z_0) = 0.20$$

TECHNICAL INTERPRETATION

A mismatched receiver input reflects RF power; return loss, VSWR and mismatch loss are distinct metrics with explicit assumptions.

Figure 73. Transmission-line impedance mismatch.

Copyright 2026, James M. Atkinson

13.21 Vector reference-plane transport and installed-path uncertainty at antennas and cables

An antenna, cable and receiver comprise a coupled network rather than a list of independent scalar attenuation labels. If a generator measures a nominal cable insertion loss using matched reference impedances, that result does not automatically describe the power accepted when the cable is attached to a reactive antenna or a receiver whose input return loss changes with attenuator state. Reflection coefficients at both ends affect delivered power, and standing-wave patterns can change with cable length, bending, temperature and connector condition. A rigorous measurement record distinguishes available source power, incident travelling-wave power and delivered load power. Treating all of them as dBm at an unspecified plane can give an arithmetically smooth but physically incorrect correction.

For a single transmission line with propagation constant gamma = alpha + j beta and length ell, the forward travelling-wave coefficient is exp(-gamma ell) under the chosen normalisation. An additional reflection term depends on the source and load reflection coefficients and the phase accumulated along the path. If the product of reflection magnitudes is small, scalar insertion loss may be an acceptable approximation with a bounded mismatch allowance. If the product is appreciable, the delivered transfer changes with electrical length, and replacing the path by a single loss value conceals frequency-dependent ripple. A vector network analyser can characterise the ports when its calibration planes and connector repeatability are controlled, but a VNA calibration alone does not establish

Copyright 2026, James M. Atkinson

the antenna's environmental effective aperture or the geometry of a later field installation.

Mismatch uncertainty has a physically interpretable range. Suppose the magnitudes of effective source and load reflection coefficients are 0.2 and 0.3 under a simplified two-reflection model. Their product is 0.06. The factor in delivered transfer arising from the denominator |1 - Gamma_s Gamma_l exp(-j phi)| squared lies between 1/(1.06)^2 and 1/(0.94)^2 as unknown relative phase phi varies. The corresponding gain difference between these extremes is 20 log10(1.06/0.94), approximately 1.04 dB. This is a bounded variation within the stated model, not a normally distributed uncertainty or an empirical calibration certificate. Any correction using a measured complex reflection state can reduce the range, but its own frequency, temperature and connector repeatability conditions must then be recorded.

Antenna factor and effective aperture require careful treatment of polarisation and field region. A calibrated receiving antenna used in a known plane-wave far field can support a relation between incident field and terminal voltage with a stipulated orientation and load. Indoors, the spatial distribution may include reflections, near fields and strongly varying polarisation, so a single manufacturer's far-field antenna factor can be inappropriate for precise source-field inference. An antenna's gain pattern measured in an anechoic chamber also need not describe its installed response near metallic furniture, cable supports or shielded structures. The useful defensive measurement may remain terminal power or a comparative signal level without claiming absolute field strength at the unknown emitter.

Copyright 2026, James M. Atkinson

Common-mode currents along coaxial shields can create a reception path that is distinct from the nominal antenna terminals. The cable itself may participate in the effective receiving structure and alter apparent direction, polarisation and spatial response. A diagnostic can compare ferrite treatment, shield routing, balun or choke configuration, and physically different cable paths while maintaining a calibrated desired reference. These are interventions with their own transfer consequences; a reduction in a suspect signal after a choke is added does not alone prove where it originated. Examine whether the choke also changed the desired signal and whether an alternative RF input path remained available.

Vector calibration and uncertainty can be organised around a chain of measured complex ratios. State each reference plane, frequency grid, calibration standard, connector sequence, temperature range and processing convention. Keep a covariance-aware model for shared calibration terms; when several measurement paths rely upon the same calibration kit or power reference, their uncertainties cannot be treated as independent merely because files were exported separately. For a distributed receiving array, phase and timing errors must also be linked to the actual clock state. The final report should distinguish a locally valid relative comparison from an absolute field or source-power inference that the experiment did not establish.

13.22 Additional study: vector reference planes, mismatch and multiport calibration in an installed receiving path

The phrase cable loss frequently disguises an extensive chain of electromagnetic assumptions. A measurement made at a receiver connector may be related to an antenna terminal through a set of adapters, a mechanically stressed feeder, a preselector, a switch, a limiter and an external amplifier. The forward transfer can depend on the source impedance, frequency, input power, temperature, cable configuration and the state of every unterminated or imperfectly terminated branch. In general, the transducer power gain of an assembled two-port is not obtained by adding individually measured matched insertion-loss values in decibels. That scalar approximation is useful within a declared mismatch allowance, but it omits coherent multiple reflections and any common-mode coupling that bypasses the intended differential or coaxial route. A vector treatment makes the limitations of a simple correction explicit.

For a linear two-port network referenced to a real impedance Z_0, let a_1 and a_2 denote incident power waves and b_1 and b_2 the corresponding outgoing waves. The scattering relation is $[b_1, b_2]^T = S[a_1, a_2]^T$, where S is a 2-by-2 complex matrix with entries S_{11}, S_{12}, S_{21} and S_{22}. The numerical magnitudes are defined under a stated power-wave convention and common reference impedance, and the squared magnitude $|S_{21}|^2$ is the forward delivered-power ratio only under the specified matched-port conditions. For a passive reciprocal device within its linear range, S_{21} and S_{12} may be equal under consistent normalisation, but reciprocity does not establish zero reflection, unchanging temperature or the absence of

Copyright 2026, James M. Atkinson

installation-specific common-mode effects. An amplifier can be nonreciprocal and can add noise and distortion even where its small-signal scattering matrix is correctly calibrated.

The receiving source and load are usually not ideal matches. Introduce source and load reflection coefficients Γ_S and Γ_L, both complex and dimensionless, at their declared reference planes. The corresponding transducer power gain is $G_T = [(1-|\Gamma_S|^2)|S_{21}|^2(1-|\Gamma_L|^2)] / |(1-S_{11}\Gamma_S)(1-S_{22}\Gamma_L)-S_{12}S_{21}\Gamma_S\Gamma_L|^2$ for a general linear two-port under the conventional source-available-to-load-delivered power definition. This relation requires a passive or active stable operating state in which the adopted small-signal S parameters apply. It is not a proof that an amplifier stays linear under a strong adjacent transmitter. The denominator shows why a product of matched scalar losses can misrepresent the assembled transfer when reflections interact coherently. The phase of each reflection coefficient matters; two networks with the same individual return-loss magnitudes can produce different composite transfer functions.

An antenna referenced to environmental field strength demands further care. For a plane wave incident in the antenna's characterised far-field regime, an effective-height or antenna-factor model can relate a specified field component to a terminal quantity. That relation depends on polarisation, direction, receiving pattern, loading and frequency. It does not automatically apply in the reactive near field of a device hidden within building materials or in strong coupling with a cable sheath. The antenna may be electrically small, spatially nonuniformly illuminated or oriented so that the field direction changes materially across its aperture. A single antenna factor measured in one laboratory geometry cannot guarantee

Copyright 2026, James M. Atkinson

absolute field measurement accuracy under arbitrary installed conditions. For a TSCM survey it may still support useful relative observations, provided those conclusions are explicitly bounded by the tested geometry and transfer paths.

Mismatch uncertainty should be distinguished from unknown connection state. If all component reflection coefficients are characterised vectorially, the corresponding transducer gain can be calculated within the adopted calibration model. If only magnitudes of return losses are known, the unknown phases can cause a range of possible gains. The conservative task is then to bound the transfer over the permitted phase combinations instead of assuming random, independent reflections without evidence. If a cable or switch changes during the survey, even the earlier bounded model may no longer describe the new configuration. Its significance should be established by a new measurement or a demonstrated state-invariance argument, not by retaining the previous correction file because the connector types are unchanged.

Multiport devices reveal a different error. A splitter's unused output may appear irrelevant to the main connection, but its termination can alter input match and isolation. In a switching matrix, imperfect isolation can admit another antenna, a calibration generator or a locally generated source into the monitored path. A terminated reference-plane measurement may therefore fail to reproduce a survey condition in which another port was connected to an active device. An advanced acceptance protocol should characterise not only the selected signal route but also the influence of plausible states at other ports. A complete description can use a larger scattering matrix, or measured state-dependent transfer coefficients where

Copyright 2026, James M. Atkinson

a full multiport model is impractical. Whichever representation is chosen, the evidential claim must identify which configurations were actually examined.

Common-mode currents are especially consequential when observing weak RF signals in buildings. The intended measurement may involve a differential signal between a coaxial inner conductor and the inside of its shield, yet the outside of that shield can carry current excited by nearby electronics or building wiring. That current can couple into the receiver through connectors, chassis structures or imperfect balance. A cable movement may change the observed trace by changing the antenna pattern of the entire installation rather than the apparent free-space source. An attenuation or termination test inside the nominal signal route may not suppress this separate path in the predicted way. The useful response is a controlled physical perturbation and an independent observation of the common-mode route, with attention to safety and the applicable connection geometry.

A hypothetical matched-reference example uses an installed passive chain whose measured forward coefficient has magnitude 0.50 at one frequency. Under matched source and load, $|S_{21}|^2 = 0.25$, equivalent to a -6.0206 dB power transfer. If the reflection conditions change, that number is not automatically the delivered-power ratio at the receiver. As an elementary one-interface illustration, let the source voltage reflection coefficient have magnitude 0.20 and the load magnitude 0.30. Their product magnitude is 0.06; depending on relative phase, a simple single-reflection correction denominator $|1-\Gamma_S \Gamma_L|^2$ ranges between $(1-0.06)^2$ and $(1+0.06)^2$. The corresponding gain multiplier can lie between approximately 0.890 and

Copyright 2026, James M. Atkinson

1.132. This ±-like range is illustrative and does not replace the full network relation above. It shows how a small-looking reflection product can create a consequential calibration difference without a change in the nominal cable attenuation.

A second constructed example concerns a known 50-ohm passive termination at the far end of a line with return-loss magnitude 20 dB. The corresponding reflection magnitude is $|\Gamma| = 10^{(-20/20)} = 0.1$, and the reflected fraction of incident power is $|\Gamma|^2 = 0.01$, or one percent. Reporting a 20 dB return loss as though twenty percent of power were reflected confuses logarithmic amplitude and power. It also obscures where the measurement was made: the reflection coefficient referred to a different plane acquires phase through the connecting line. That phase is useful for location and mismatch analysis, but it cannot be treated as a property of the remote termination alone without accounting for the line.

A third constructed example uses a line velocity factor of 0.66 relative to the speed of light and physical length ten metres. With speed of light c = 299,792,458 metres per second, propagation velocity is approximately 1.97863×10^8 metres per second, and one-way delay is about 50.54 ns. A phase-sensitive multichannel comparison that ignores this delay can accumulate a phase difference of $2\pi f \tau$ at frequency f. At 10 MHz the phase is approximately 181.94 degrees, modulo a full cycle. A calibration valid for amplitude alone cannot eliminate that timing error. If the coaxial dielectric temperature changes the velocity factor or length sufficiently, phase drift may require repeated calibration even though the measured insertion loss remains nearly unchanged.

Copyright 2026, James M. Atkinson

13.23 Controlled qualification of the installed network

The acceptance procedure starts by declaring the source and destination planes, the electrical reference impedance, the installed topology and the permitted operating states. First, characterise individual components with calibrated fixtures and recorded connector condition. Secondly, measure the assembled path without assuming that the separate measurements multiply exactly. Thirdly, vary plausible antenna loading, switch states, bias conditions and temperatures to identify the actual transfer envelope. The observed deviations should be compared with an uncertainty model containing source match, load match, connection repeatability, instrument calibration, common references and the possible influence of other ports. A single vector-network-analyser pass is not complete assurance of the arrangement after transport or reconnection.

For a field observation, retain both native receiver quantities and the corrections that refer them to the chosen plane. A terminal-power result is not a free-space field-strength result without an applicable antenna model, nor is it the emitted power of an alleged source. A movement experiment may support a spatial inference only after the antenna pattern, coupling and receiver states changed by the movement have been considered. In particular, moving a long cable can alter common-mode coupling while the antenna tip remains at the same physical location. An observation that depends on cable route is a reason to examine installation effects, not automatic proof of a concealed transmitter hidden along the route.

A fourth synthetic case illustrates a cable-reconnection effect. Two independent passes show the same installed source and receiver but a

Copyright 2026, James M. Atkinson

corrected component level changes by 0.8 dB after the cable and adapter are reconnected. If the repeatability budget for that connection is only 0.2 dB standard uncertainty, the difference merits investigation. It is not legitimate to dismiss the 0.8 dB solely because each individual instrument calibration certificate remains current. Conversely, the level difference does not establish the external source changed; load mismatch, cable bending, connector contact and common-mode current are plausible alternatives. The appropriate controlled test restores the connection geometry, measures vector match and repeats the source reference without cherry-picking a favourable trace.

A fifth example involves multiport isolation. Suppose an unselected antenna path leaks into the selected receiver route at −45 dB relative to its input, while the unselected path carries a −10 dBm local signal. In the small-signal scalar approximation, that leakage can produce a −55 dBm contribution at the selected output reference plane before any other gain or loss. A desired weak component at −105 dBm may be completely obscured, despite the switch being marked as selecting the proper antenna. The calculation is a warning about the need to know the actual isolation and loading. It is not a claim that every switch behaves this way. An end-to-end test with the unselected port deliberately and safely driven can reveal the path, but the test must not inject unauthorised interference into the environment.

The scientific output is an installed-path transfer dossier. It should identify the frequency-specific complex transfer where supported, mismatch and thermal limits, calibration data, state changes, branch isolation, common-mode observations and all circumstances in which the scalar correction is known to be inadequate. The dossier supports calibrated receiver readings

Copyright 2026, James M. Atkinson

but does not expand the legitimate inference beyond what the network and antenna measurements establish. Its strength is that a later reviewer can reconstruct why a measured component was assigned to the environment, the measurement system or an unresolved mixture of the two.

Copyright 2026, James M. Atkinson

13.24 Advanced technical expansion. Vector reference-plane transfer in a mismatched installed path

An installed RF path cannot always be corrected by adding cable insertion loss and subtracting amplifier gain. Such scalar treatment assumes a particular relationship among source, load and calibration impedances, usually under conditions sufficiently close to the matched reference model. An antenna may present a complex impedance that varies strongly with frequency and position, while a receiver input changes its reflection coefficient with attenuation or preselector state. Multiple reflections then modify the voltage and power actually delivered to the first active device. A quoted matched-port insertion loss may remain a valid component specification while being an incomplete description of the installed transfer. The analyst should distinguish available source power, incident travelling-wave power, accepted power and any estimated field quantity rather than using one unqualified dBm label for all four.

Scattering parameters offer a systematic language for this problem. In a two-port network, complex incident travelling-wave amplitudes a_1 and a_2 and reflected amplitudes b_1 and b_2 are related by $[b_1,b_2]^T = S[a_1,a_2]^T$ in an explicitly normalised wave convention. The parameters S_{11} and S_{22} describe reflection at the defined ports; S_{21} describes forward transfer under the specified reference conditions; S_{12} describes reverse coupling. Their values are complex functions of frequency and usually of configuration and temperature. Converting an S_{21} magnitude alone into a universal field-strength correction is unjustified when antenna mismatch, loading and polarisation remain uncharacterised. A useful receiver system model treats

Copyright 2026, James M. Atkinson

each calibrated network section as a multiport and connects them using a consistent wave or impedance representation, retaining the source and load states.

Consider a hypothetical antenna with reflection coefficient magnitude 0.3 at a 50-ohm reference, and a receiver input with coefficient magnitude 0.2. Even before propagation through a cable is considered, the product of the reflection magnitudes is 0.06, so a simple geometric series of round-trip voltage contributions can be sensitive to relative reflection phase. The exact transmitted power depends on the complex coefficients, electrical length and the power-wave convention. It is inappropriate to convert 0.06 directly into an exact loss or uncertainty without the full network relation. The example shows why a system using nominally 50-ohm connectors can still exhibit consequential mismatch uncertainty: connector labels provide the chosen reference impedance, not proof of matching under the installed operating condition.

Vector calibration and de-embedding are necessary when phase or coherent timing is part of the measurand. A cable may have acceptable insertion loss but substantial temperature-dependent electrical length. The phase of its transfer depends on frequency, path length and environmental conditions; a mechanically flexed lead can also couple an unwanted common-mode signal through its shield or nearby structures. For a one-metre illustrative change in electrical path length and propagation velocity 2.0×10^8 m/s, the corresponding pure propagation delay change is 5 ns. At 100 MHz that delay represents half a cycle of phase. Such a large change is intentionally illustrative, not a likely small thermal perturbation. It demonstrates that a calibration expressed solely in decibels does not supply a coherent phase

Copyright 2026, James M. Atkinson

correction. Smaller physical changes can be consequential at sufficiently high carrier frequency.

Antenna factors introduce another measurement boundary. Converting terminal voltage to electric-field strength requires the antenna's applicable factor, polarisation, environment, geometry and reference convention. A field calibration performed in an appropriate radiating arrangement may not apply unaltered to the reactive near field of an unknown installation. For a source close to metallic structures or cable routing, local current distribution can change the measured coupling in ways not captured by a free-space far-field approximation. The examiner should not infer transmitter power from a received level without a justified propagation model. A useful report can preserve calibrated terminal or receiver-input power when source-power inference remains underdetermined. Precision in the receiver readout cannot restore the missing field geometry.

The laboratory procedure must separately characterise small-signal multiport transfer, source and load reflections, path switching, noise contribution, nonlinear overload and temperature drift. Record reference-plane identities, calibration kit and its validity interval, instrument correction data, accessory serial numbers, installed cable route and antenna orientation. Conduct a repeat measurement after reconnecting the path to estimate connection repeatability, and perform a controlled common-mode challenge when shield currents could explain an unexpected component. A vector network analyser test alone does not establish large-signal behaviour of an active preamplifier or limiter, and a later connector continuity test does not prove that a field signal used the assumed path. Release each

correction within its measured frequency, temperature and physical-configuration domain.

Copyright 2026, James M. Atkinson

Chapter Summary

The antenna-to-receiver path is one calibrated structure. Field conversion, external gain, passive corrections, switching state, and common-mode behavior must remain traceable to serialized components and installed geometry.

The assembly, state and correction records answer different questions. Name every relevant plane and assign each correction once. Antenna-terminal power and field strength remain distinct measurands: field conversion adds polarization, pattern, loading, geometry and installation conditions. A conducted reference verifies only the path it traverses; an antenna certificate does not establish every installed arrangement.

Remote gain can overcome cable and receiver noise while increasing exposure to blockers, bias coupling or instability. Passive networks add loss, reflection and branch interactions. Their selected and unused ports belong to the model. When source impedance changes the receiver’s own response, a matched scalar cascade may require additional vector or empirical characterization.

Use controlled comparisons to separate intended transfer from installed coupling. Recheck desired response when changing cables, terminations, bias or isolation, and retain the observations that establish comparable sensitivity. Accept the serialized arrangement at named planes and states, with tested conditions and unknown intervals stated. A changed indication directs further discrimination; it does not uniquely identify an external source or fault.

Chapter 13 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C13-MCQ-001. An assembly record lists all component serial numbers but omits their order. What remains unreconstructable even if total desired gain is known?

A. The sum of the listed component gains alone

B. Placement-dependent noise and loading exposure

C. The nominal model number of each component

D. Whether the total gain file contains the stated sum

Answer: B. Equal total gain does not establish equal input-equivalent noise or the level reaching each vulnerable stage. Source: §13.2 Define a complete path at named planes (p. 7537)

Why the selected alternative fits: Placement-dependent noise and loading exposure.

Distinguishing consideration: compare this with option A, “The sum of the listed component gains alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Define a complete path at named planes.

Review: Chapter 13 — Define a complete path at named planes.

V011-C13-MCQ-002. What is established by a conducted reference injected only at the receiver connector?

A. The cable's terminal-to-connector correction

B. The complete antenna field-conversion chain

C. The remote amplifier's installed stability

D. The downstream response from that named plane

Answer: D. Upstream components and field conversion are bypassed by the injection. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: The downstream response from that named plane.

Distinguishing consideration: compare this with option A, “The cable's terminal-to-connector correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-003. Why can an antenna factor certificate fail to establish an installed field estimate?

A. A terminal measurement eliminates polarization dependence

B. The factor is valid only when expressed in linear units

C. The installed geometry and coupling may differ from the calibration conditions

D. The receiver calibration necessarily includes all cable effects

Answer: C. Applicability depends on loading, geometry, polarization and installed coupling, not merely possession of a certificate. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: The installed geometry and coupling may differ from the calibration conditions.

Distinguishing consideration: compare this with option A, “A terminal measurement eliminates polarization dependence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power.

Review: Chapter 13 — Keep field conversion separate from terminal power.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-004. A battery substitution removes a line from a remote amplifier measurement. Which conclusion is justified?

A. Supply ripple has uniquely been identified

B. The receiver's conducted amplitude calibration has been disproved

C. The antenna must have stopped receiving the external source

D. The line is sensitive to that intervention, which changed possible supply and conductive paths

Answer: D. Battery operation can alter grounding and conductive coupling as well as supply noise; a selective follow-up is needed. Source: §13.6 Remote amplification requires electrical and installed checks (p. 7545)

Why the selected alternative fits: The line is sensitive to that intervention, which changed possible supply and conductive paths.

Distinguishing consideration: compare this with option A, “Supply ripple has uniquely been identified”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Remote amplification requires electrical and installed checks.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-005. Why can a nominally unused switch port change the selected-path measurement?

A. Finite isolation and impedance coupling make its termination consequential

B. Unused ports contribute only a fixed temperature-independent loss

C. A selected switch path is always an isolated two-port

D. Only the selected port's connector torque matters

Answer: A. The unused branch can admit energy or change impedance; its state belongs in the assembly model. Source: §13.8 Treat connections and unused branches as part of the network (p. 7548)

Why the selected alternative fits: Finite isolation and impedance coupling make its termination consequential.

Distinguishing consideration: compare this with option B, “Unused ports contribute only a fixed temperature-independent loss”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Treat connections and unused branches as part of the network.

Review: Chapter 13 — Treat connections and unused branches as part of the network.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-006. Which pair of effects makes source mismatch important in receiver noise measurements?

A. Changed delivered source noise and changed receiver gain or added noise

B. Changed displayed units and changed reference impedance label only

C. Changed receiver gain only, with delivered source noise necessarily fixed

D. Changed source noise only, with receiver response necessarily fixed

Answer: A. A scalar insertion-loss correction need not capture the receiver's impedance-dependent noise response. Source: §13.8 Treat connections and unused branches as part of the network (p. 7548)

Why the selected alternative fits: Changed delivered source noise and changed receiver gain or added noise.

Distinguishing consideration: compare this with option B, “Changed displayed units and changed reference impedance label only”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Treat connections and unused branches as part of the network.

Review: Chapter 13 — Treat connections and unused branches as part of the network.

V011-C13-MCQ-007. A cable reroute changes an anomalous indication while the conducted desired transfer stays stable. What is the appropriate next hypothesis to test?

A. A uniquely identified external transmitter moving in frequency

B. Installed coupling involving the exterior shield and surrounding structure

C. A required error in the receiver frequency reference

D. A necessary change in the calibrated internal coaxial loss

Answer: B. Stable conducted transfer narrows one explanation but does not uniquely identify the installed coupling mechanism. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Why the selected alternative fits: Installed coupling involving the exterior shield and surrounding structure.

Distinguishing consideration: compare this with option A, “A uniquely identified external transmitter moving in frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Separate the intended coaxial path from installed coupling.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-MCQ-016. Which set is needed before converting antenna-terminal power to field strength?

A. Receiver attenuation setting and display units alone

B. Antenna conversion convention, geometry, polarization, loading and field region

C. Cable loss and room temperature alone

D. Antenna serial number and nominal frequency alone

Answer: B. The field-to-terminal relation has conditions beyond the receiver's conducted calibration. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: Antenna conversion convention, geometry, polarization, loading and field region.

Distinguishing consideration: compare this with option A, “Receiver attenuation setting and display units alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power.

Review: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-MCQ-017. Why should a near-field probe reading not automatically be reported as plane-wave power density?

A. The receiver gain becomes irrelevant in the near field

B. The probe output cannot be expressed as voltage

C. Any near-field measurement has exactly zero uncertainty

D. The plane-wave field relation may not describe the local field

Answer: D. The conversion must use a model appropriate to the field region and probe response. Source: §13.3 Antennas and Field-to-Terminal Conversion (p. 7539)

Why the selected alternative fits: The plane-wave field relation may not describe the local field.

Distinguishing consideration: compare this with option A, “The receiver gain becomes irrelevant in the near field”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Antennas and Field-to-Terminal Conversion.

Review: Chapter 13 — Antennas and Field-to-Terminal Conversion.

V011-C13-MCQ-018. A factor calibrated for voltage across a 50 ohm load is applied to an open-circuit voltage estimate. What must be checked first?

A. Whether the indicated and correction levels use the same logarithmic reference

B. Whether the calibration uncertainty is reported as standard or expanded

C. Whether the downstream frequency response is adequately sampled

D. Whether the voltage convention and loading match the factor definition

Answer: D. Loaded and open-circuit voltages are different measurands; an ideal matched-source case can differ by a factor of two. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: Whether the voltage convention and loading match the factor definition.

Distinguishing consideration: compare this with option A, “Whether the indicated and correction levels use the same logarithmic reference”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power.

Review: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-MCQ-019. Which distinction is essential when applying an antenna conversion?

A. Peak voltage versus RMS voltage only

B. Available power versus delivered power at the actual load

C. Mean power versus the number of report pages

D. Absolute frequency versus carrier offset only

Answer: B. Mismatch and loading determine whether available and delivered quantities coincide. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: Available power versus delivered power at the actual load.

Distinguishing consideration: compare this with option A, “Peak voltage versus RMS voltage only”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power.

Review: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-MCQ-020. Antenna rotation changes terminal power during a receiver-setting comparison. What has been confounded?

A. Receiver-state response with an unavoidable frequency-unit conversion

B. Only the antenna certificate date

C. Receiver-state response with polarization and geometry changes

D. Only the receiver's output impedance

Answer: C. Geometry must be held or documented when the purpose is to compare receiver states. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: Receiver-state response with polarization and geometry changes.

Distinguishing consideration: compare this with option A, “Receiver-state response with an unavoidable frequency-unit conversion”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power.

Review: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-MCQ-021. For an intentional spatial field map, what is the appropriate treatment of antenna movement?

A. Treat every movement as an invalid experiment

B. Apply one undocumented orientation correction afterward

C. Record the position and orientation as part of each observation

D. Discard geometry once terminal power is known

Answer: C. Movement can be the experimental variable, but its state must remain traceable. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: Record the position and orientation as part of each observation.

Distinguishing consideration: compare this with option A, “Treat every movement as an invalid experiment”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-MCQ-022. Why may placing a preamplifier near the antenna improve sensitivity through a long cable?

A. Its gain can reduce the input-equivalent influence of subsequent cable and receiver noise

B. It makes antenna mismatch irrelevant

C. It removes the cable's physical loss entirely

D. It prevents every blocker from entering the first active stage

Answer: A. Remote gain changes the downstream noise weighting but does not erase loss or loading limits. Source: §13.5 External Preamplifiers, Bias, and Stability (p. 7544)

Why the selected alternative fits: Its gain can reduce the input-equivalent influence of subsequent cable and receiver noise.

Distinguishing consideration: compare this with option B, “It makes antenna mismatch irrelevant”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — External Preamplifiers, Bias, and Stability.

Review: Chapter 13 — External Preamplifiers, Bias, and Stability.

V011-C13-MCQ-023. A narrow channel filter is located after a broadband remote amplifier. Which risk remains?

A. The amplifier can respond only within the final channel bandwidth

B. The amplifier sees only the displayed in-channel power

C. The filter necessarily protects every upstream stage

D. Out-of-channel signals can overload the remote amplifier before filtering

Answer: D. The first active element sees signals admitted before the downstream filter. Source: §13.5 External Preamplifiers, Bias, and Stability (p. 7544)

Why the selected alternative fits: Out-of-channel signals can overload the remote amplifier before filtering.

Distinguishing consideration: compare this with option A, “The amplifier can respond only within the final channel bandwidth”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — External Preamplifiers, Bias, and Stability.

V011-C13-MCQ-024. Which amplifier property matters when receiver local-oscillator leakage could reach the antenna?

A. Forward gain alone

B. Reverse isolation

C. The amplifier's forward small-signal gain

D. Output display resolution alone

Answer: B. Limited reverse isolation can allow leakage to propagate backward and reradiate. Source: §13.5 External Preamplifiers, Bias, and Stability (p. 7544)

Why the selected alternative fits: Reverse isolation.

Distinguishing consideration: compare this with option A, “Forward gain alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — External Preamplifiers, Bias, and Stability.

Review: Chapter 13 — External Preamplifiers, Bias, and Stability.

V011-C13-MCQ-026. Why is the supply voltage measured at a base unit insufficient to establish amplifier bias?

A. Cable resistance and protection elements can change the voltage at the remote device

B. The nominal supply voltage already includes every cable drop

C. A correct receiver supply guarantees the remote device voltage

D. RF gain uniquely determines the device's DC voltage

Answer: A. The device's actual electrical state must be verified at the relevant location. Source: §13.6 Remote amplification requires electrical and installed checks (p. 7545)

Why the selected alternative fits: Cable resistance and protection elements can change the voltage at the remote device.

Distinguishing consideration: compare this with option B, “The nominal supply voltage already includes every cable drop”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Remote amplification requires electrical and installed checks.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-MCQ-028. A line appears after a remote amplifier is installed. Which observation alone proves self-oscillation?

A. A change in gain alone

B. The presence of a narrow line alone

C. None; alternate-load, bias and output observations are needed to discriminate causes

D. A changed baseline alone

Answer: C. Pickup, leakage and network-dependent responses can produce similar observations. Source: §13.6 Remote amplification requires electrical and installed checks (p. 7545)

Why the selected alternative fits: None; alternate-load, bias and output observations are needed to discriminate causes.

Distinguishing consideration: compare this with option A, “A change in gain alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Remote amplification requires electrical and installed checks.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-MCQ-029. Why retain a reference before and after a consequential assembly change?

A. To ensure every intervening defect can be corrected with one constant

B. To establish the external source identity

C. To bound demonstrated validity and detect changes affecting the observation interval

D. To eliminate the need for configuration records

Answer: C. Reference closure tests stability of the measurement path, not all possible mechanisms. Source: §13.6 Remote amplification requires electrical and installed checks (p. 7545)

Why the selected alternative fits: To bound demonstrated validity and detect changes affecting the observation interval.

Distinguishing consideration: compare this with option A, “To ensure every intervening defect can be corrected with one constant”; that competing statement does not meet the question’s stated requirement.

V011-C13-MCQ-031. When may a drift correction across an interval be defensible?

A. Only when the receiver has no external components

B. Whenever two endpoints have different readings

C. When its evolution is understood and the correction is bounded with uncertainty

D. Whenever the operator expects slow drift

Answer: C. A model of the evolution is needed; endpoints alone do not establish arbitrary intervening behavior. Source: §13.6 Remote amplification requires electrical and installed checks (p. 7545)

Why the selected alternative fits: When its evolution is understood and the correction is bounded with uncertainty.

Distinguishing consideration: compare this with option A, “Only when the receiver has no external components”; that competing statement does not meet the question’s stated requirement.

V011-C13-MCQ-051. Short-path and installed-path reference measurements disagree beyond their supported bounds. What comes first?

A. Attribute the difference immediately to a new external source

B. Average the two values and assign the mean as truth

C. Delete the short-path result

D. Resolve the path discrepancy before interpreting environmental observations

Answer: D. Unresolved measurement-path validity undermines the environmental inference. Source: §13.11 Integrated Path Acceptance (p. 7554)

Why the selected alternative fits: Resolve the path discrepancy before interpreting environmental observations.

Distinguishing consideration: compare this with option A, “Attribute the difference immediately to a new external source”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Integrated Path Acceptance.

Review: Chapter 13 — Integrated Path Acceptance.

V011-C13-MCQ-052. At frequencies where installed match or dynamic range is inadequate, what belongs in the path record?

A. A statement that the instrument model guarantees validity

B. Explicit limitations on quantitative conclusions

C. Only the favorable parts of the frequency sweep

D. A uniform correction asserted without evidence

Answer: B. Acceptance must identify the frequency and condition boundaries.

Source: §13.11 Integrated Path Acceptance (p. 7554)

Why the selected alternative fits: Explicit limitations on quantitative conclusions.

Distinguishing consideration: compare this with option A, “A statement that the instrument model guarantees validity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Integrated Path Acceptance.

Review: Chapter 13 — Integrated Path Acceptance.

V011-C13-MCQ-053. Under Equation 25's matched far-field assumptions, what is available received power for 2 $\frac{mW}{m^2}$ incident density and 0.05 m^2 effective aperture?

A. 40 mW

B. 0.1 W

C. 10 mW

D. 0.1 mW

Answer: D. Multiplication gives 0.002 $\frac{W}{m^2}$ times 0.05 m^2 = 0.0001 W. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why the selected alternative fits: 0.1 mW.

Distinguishing consideration: compare this with option A, “40 mW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-054. Which condition is explicitly required when using received power equals incident density times effective aperture as stated?

A. Unknown antenna loading with no mismatch allowance

B. Arbitrary near-field geometry without a probe model

C. Far-field matching with polarization accounted for

D. Any indoor multipath arrangement with a single scalar guarantee

Answer: C. The simple aperture relation is bounded by the stated antenna and field conditions. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why the selected alternative fits: Far-field matching with polarization accounted for.

Distinguishing consideration: compare this with option A, “Unknown antenna loading with no mismatch allowance”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-055. An indication is −80 dBm, downstream losses total 7 dB and downstream gains total 18 dB. What is the upstream corrected level?

A. −69 dBm

B. −91 dBm

C. −55 dBm

D. −105 dBm

Answer: B. The upstream level is indicated power plus loss minus gain: −80 + 7 − 18. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why the selected alternative fits: −91 dBm.

Distinguishing consideration: compare this with option A, "−69 dBm"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-056. Why are upstream correction terms frequency dependent?

A. Serialized identity alone establishes the response at unmeasured frequencies

B. A single-frequency calibration necessarily represents every nearby filter transition

C. The receiver's internal correction includes every external response

D. Path loss and gain can vary across frequency and state

Answer: D. The correction must describe the response at the measurement frequency and state. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why the selected alternative fits: Path loss and gain can vary across frequency and state.

Distinguishing consideration: compare this with option A, “Serialized identity alone establishes the response at unmeasured frequencies”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-057. Which term is not automatically removed by the scalar signed gain-and-loss correction?

A. The included calibrated amplifier gain

B. The included calibrated switch loss

C. Mismatch and its uncertainty

D. The included calibrated cable loss

Answer: C. Equation 26 does not silently solve all mismatch effects. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why the selected alternative fits: Mismatch and its uncertainty.

Distinguishing consideration: compare this with option A, “The included calibrated amplifier gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-MCQ-058. The chapter's antenna terminal is −92.0 dBm, loss is 6.4 dB and gain is 20.1 dB. What receiver indication is predicted?

A. −78.3 dBm

B. −65.5 dBm

C. −105.7 dBm

D. −118.5 dBm

Answer: A. Forward propagation subtracts loss and adds gain: −92.0 − 6.4 + 20.1.

Source: §13.13 Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7557)

Why the selected alternative fits: −78.3 dBm.

Distinguishing consideration: compare this with option B, "−65.5 dBm"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-059. For a predicted −78.3 dBm indication and observed −70.0 dBm, what is the signed observed-minus-predicted discrepancy?

A. −8.3 dB

B. +8.3 dB

C. −13.7 dB

D. +13.7 dB

Answer: B. The observed reading is 8.3 dB higher, prompting investigation of the path and state. Source: §13.13 Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7557)

Why the selected alternative fits: +8.3 dB.

Distinguishing consideration: compare this with option A, "−8.3 dB"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-MCQ-060. Which response best follows an unexplained 8.3 dB excess over the modeled indication?

A. Assign the full excess immediately to antenna gain

B. Check state, correction, overload and installed coupling

C. Report it as proof of a stronger external source

D. Subtract it permanently as a known calibration offset

Answer: B. The discrepancy identifies a validation problem, not a unique cause.

Source: §13.13 Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7557)

Why the selected alternative fits: Check state, correction, overload and installed coupling.

Distinguishing consideration: compare this with option A, “Assign the full excess immediately to antenna gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-MCQ-061. A line remains with the antenna input terminated and shifts when bias-cable length changes. Which scope is first implicated?

A. A uniquely established self-oscillation mode

B. The installed active and bias path

C. Only the calibrated antenna field factor

D. Only the intended antenna's far-field reception

Answer: B. The controls implicate the path but leave multiple mechanisms to discriminate. Source: §13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7558)

Why the selected alternative fits: The installed active and bias path.

Distinguishing consideration: compare this with option A, “A uniquely established self-oscillation mode”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-062. Which follow-up is most useful for the chapter's bias-cable case?

A. Observe amplifier output separately while controlling load and bias

B. Apply a free-space antenna factor to the terminated input

C. Assume termination excludes all radiated pickup

D. Change the report's reference plane without new measurements

Answer: A. Independent output and selective electrical controls can separate competing mechanisms. Source: §13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7558)

Why the selected alternative fits: Observe amplifier output separately while controlling load and bias.

Distinguishing consideration: compare this with option B, “Apply a free-space antenna factor to the terminated input”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-MCQ-063. What is the first stage of the constructed acceptance sequence?

A. Accept the complete path from total catalog gain

B. Verify the receiver at its own connector

C. Challenge common mode without checking desired response

D. Declare field calibration from component certificates

Answer: B. The sequence builds scope from receiver to assembled conducted path to installed field observation. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Verify the receiver at its own connector.

Distinguishing consideration: compare this with option A, “Accept the complete path from total catalog gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-064. After receiver-only verification, which test extends coverage to the remote amplifier and cable?

A. A second injection at the receiver connector

B. A conducted reference at the antenna-terminal plane

C. A software correction applied without a reference

D. A photograph of the active antenna

Answer: B. The reference must traverse the components being verified. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: A conducted reference at the antenna-terminal plane.

Distinguishing consideration: compare this with option A, “A second injection at the receiver connector”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-066. A receiver-only reference passes but an installed field comparison fails. What follows?

A. The receiver pass does not isolate the failure to the receiver

B. The receiver must be the sole cause

C. The entire installed chain is accepted

D. The antenna certificate must be fraudulent

Answer: A. Each test covers a different scope; the failure requires localization.

Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: The receiver pass does not isolate the failure to the receiver.

Distinguishing consideration: compare this with option B, “The receiver must be the sole cause”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-067. What does the constructed record's blocker-transfer entry establish?

A. Only total integrated display noise

B. Only the gain at the desired signal frequency

C. Admitted levels at blocker frequencies before vulnerable stages

D. The identity of every blocker transmitter

Answer: C. Loading depends on the blocker path, which may differ from desired transfer. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Admitted levels at blocker frequencies before vulnerable stages.

Distinguishing consideration: compare this with option A, “Only total integrated display noise”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-068. A blocker raises measured noise while desired gain remains consistent. Which investigation is supported?

A. Inspect source spectrum and the reciprocal-mixing prediction

B. Treat all added noise as externally radiated at the desired frequency

C. Discard the unchanged gain reference

D. Assume gain compression has been uniquely proved

Answer: A. Stable gain and increased noise favor a different test route from gain-change cases. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Inspect source spectrum and the reciprocal-mixing prediction.

Distinguishing consideration: compare this with option B, “Treat all added noise as externally radiated at the desired frequency”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-069. A blocker changes desired gain. What should be checked before trusting a quiet-state noise budget?

A. Gain control or compression

B. Only antenna polarization

C. The antenna's loaded-voltage convention

D. Only the passive cable's catalog temperature coefficient

Answer: A. The chain may no longer be in the linear state assumed by the noise budget. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Gain control or compression.

Distinguishing consideration: compare this with option B, “Only antenna polarization”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-070. Why retain raw output as well as applied corrections during assembly acceptance?

A. Because raw output and corrected input necessarily have equal numerical values

B. Because a corrected result cannot have a defined reference plane

C. To replace every independent input reference with a correction file

D. To allow the transfer calculation and correction ownership to be reconstructed

Answer: D. Both raw measurement and transformation are needed for an auditable result. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: To allow the transfer calculation and correction ownership to be reconstructed.

Distinguishing consideration: compare this with option A, “Because raw output and corrected input necessarily have equal numerical values”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-072. An installed configuration was unknown for one observation interval. How should the report treat it?

A. Identify the interval and limit claims depending on that state

B. Erase the interval from the configuration history

C. Assign the nearest known state without evidence

D. Treat unknown state as zero uncertainty

Answer: A. State uncertainty can prevent a quantitative claim even when later references pass. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Identify the interval and limit claims depending on that state.

Distinguishing consideration: compare this with option B, “Erase the interval from the configuration history”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-073. Why should a catalog sum not be treated as an assembled acceptance measurement?

A. Decibel arithmetic cannot represent cascade gain

B. Catalog data always overestimate every loss

C. A measurement is valid only when no components are passive

D. It does not test actual connections, states, loading or installed coupling

Answer: D. The numerical sum is a model whose applicability needs evidence.

Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: It does not test actual connections, states, loading or installed coupling.

Distinguishing consideration: compare this with option A, “Decibel arithmetic cannot represent cascade gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-079. For a matched 50 ohm antenna convention, why could an open-circuit voltage substitution cause a 6.02 dB voltage-level discrepancy?

A. A factor-of-two voltage difference corresponds to 20 log10(2)

B. Open-circuit voltage is necessarily zero

C. The decibel convention changes from logarithmic to linear

D. A factor-of-two voltage difference is always 3.01 dB

Answer: A. This illustrates why voltage loading conventions must match; it is not a universal correction for unknown impedance. Source: §13.4 Keep field conversion separate from terminal power (p. 7542)

Why the selected alternative fits: A factor-of-two voltage difference corresponds to 20 log10(2).

Distinguishing consideration: compare this with option B, “Open-circuit voltage is necessarily zero”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-MCQ-084. Why can replacing a preamplifier with a passive through path be an ambiguous challenge?

A. It tests only the antenna's polarization

B. It changes desired gain and sensitivity as well as removing the active element

C. It necessarily leaves all noise and bandwidth unchanged

D. It proves all terminated-input lines are amplifier oscillations

Answer: B. A comparison must account for multiple properties changed by the substitution. Source: §13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7558)

Why the selected alternative fits: It changes desired gain and sensitivity as well as removing the active element.

Distinguishing consideration: compare this with option A, “It tests only the antenna's polarization”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-MCQ-085. Why distinguish desired transfer from blocker transfer in the assembly record?

A. Every chain has identical gain at all frequencies

B. Desired gain alone specifies every upstream loading condition

C. Frequency-selective elements can pass the desired signal and blocker very differently

D. Blocker level matters only after the final channel filter

Answer: C. The levels reaching vulnerable stages require their own frequency-specific path analysis. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Frequency-selective elements can pass the desired signal and blocker very differently.

Distinguishing consideration: compare this with option A, “Every chain has identical gain at all frequencies”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-086. What makes a conducted reference suitable for an acceptance test?

A. Known input at a named plane with uncertainty and applicable state control

B. A calibration file applied twice to obtain agreement

C. A signal whose level is guessed from the final indication

D. Any detectable environmental carrier with unknown variation

Answer: A. A reference must support the particular transfer claim independently of the measured output. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Known input at a named plane with uncertainty and applicable state control.

Distinguishing consideration: compare this with option B, “A calibration file applied twice to obtain agreement”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-087. Which result can the same hardware legitimately support with different confidence?

A. A field conclusion stronger than all supporting geometry evidence

B. An unconditional universal receiver-quality score

C. A well-bounded conducted level and a more limited installed field estimate

D. Identical confidence for every measurand by hardware identity alone

Answer: C. The evidence and model applicability differ by measurand and tested scope. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: A well-bounded conducted level and a more limited installed field estimate.

Distinguishing consideration: compare this with option A, “A field conclusion stronger than all supporting geometry evidence”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-088. If an accessory relocation changes common-mode behavior while nominal coaxial loss is unchanged, what follows?

A. The old installed acceptance necessarily remains complete

B. No field-based claim can ever be made again

C. Only the passive two-port correction needs review

D. The installed acceptance may need renewal despite similar conducted loss

Answer: D. Installed coupling is a separate relevant property of the configuration.

Source: §13.11 Integrated Path Acceptance (p. 7554)

Why the selected alternative fits: The installed acceptance may need renewal despite similar conducted loss.

Distinguishing consideration: compare this with option A, “The old installed acceptance necessarily remains complete”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Integrated Path Acceptance.

Review: Chapter 13 — Integrated Path Acceptance.

V011-C13-MCQ-089. Why preserve both untreated and treated observations in a common-mode comparison?

A. The untreated measurement can be reconstructed exactly from memory

B. Only the treated result is ever scientifically relevant

C. They document the actual intervention effect and support later alternative explanations

D. Keeping both automatically proves a unique source

Answer: C. The evidence is the bounded comparison, including its references and limitations. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Why the selected alternative fits: They document the actual intervention effect and support later alternative explanations.

Distinguishing consideration: compare this with option A, “The untreated measurement can be reconstructed exactly from memory”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Separate the intended coaxial path from installed coupling.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-MCQ-090. In a field-based acceptance report, which missing record most directly prevents reconstruction of the receiving geometry?

A. Antenna orientation, mounting and cable route

B. The receiver-connector correction uncertainty

C. The total number of calibration files

D. The remote amplifier's nominal output impedance

Answer: A. These geometric states affect field conversion and installed coupling.

Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Antenna orientation, mounting and cable route.

Distinguishing consideration: compare this with option B, “The receiver-connector correction uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-091. What separates a component certificate from an assembled acceptance conclusion?

A. The certificate supports a component's stated conditions; acceptance follows the tested arrangement

B. The acceptance conclusion can ignore component applicability

C. The certificate automatically validates every connected component

D. A component certificate is always irrelevant to uncertainty

Answer: A. Certificates contribute evidence but do not replace the assembled test.

Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: The certificate supports a component's stated conditions; acceptance follows the tested arrangement.

Distinguishing consideration: compare this with option B, “The acceptance conclusion can ignore component applicability”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

V011-C13-MCQ-092. Which response is appropriate when an acceptance challenge changes desired gain and an anomalous feature simultaneously?

A. Ignore the reference because only the anomaly matters

B. Assume equal detection capability from equal receiver model numbers

C. First account for the changed transfer and loading before interpreting the anomaly's disappearance

D. Conclude that the original anomaly was definitely an external signal

Answer: C. A changed reference exposes a confound in the challenge. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: First account for the changed transfer and loading before interpreting the anomaly's disappearance.

Distinguishing consideration: compare this with option A, “Ignore the reference because only the anomaly matters”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-093. What does a controlled cable-route intervention ideally preserve?

A. The desired observation geometry and a verified intended-path response

B. Every possible coupling path unchanged

C. An unrecorded position and unknown antenna orientation

D. Only the receiver's display scale

Answer: A. A useful selective comparison changes a defined opportunity while controlling the relevant response. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Why the selected alternative fits: The desired observation geometry and a verified intended-path response.

Distinguishing consideration: compare this with option B, “Every possible coupling path unchanged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Separate the intended coaxial path from installed coupling.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-MCQ-094. Why is a single overall receiver-quality score not required by the constructed acceptance case?

A. All measured outcomes are interchangeable

B. One gain measurement determines every receiver property

C. Different reference outcomes direct mechanism-specific investigations with explicit scope

D. The chapter excludes numerical measurements

Answer: C. Desired gain, noise and route sensitivity answer different questions and should retain that distinction. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: Different reference outcomes direct mechanism-specific investigations with explicit scope.

Distinguishing consideration: compare this with option A, “All measured outcomes are interchangeable”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-095. An accepted arrangement is later used outside its tested environmental range. What is the appropriate conclusion?

A. Serialization alone guarantees identical response

B. All previous measurements become automatically invalid

C. The prior acceptance does not by itself establish validity in the new range

D. The original correction becomes exactly zero

Answer: C. The boundary of tested conditions must be respected and extended by evidence. Source: §13.11 Integrated Path Acceptance (p. 7554)

Why the selected alternative fits: The prior acceptance does not by itself establish validity in the new range.

Distinguishing consideration: compare this with option A, “Serialization alone guarantees identical response”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Integrated Path Acceptance.

Review: Chapter 13 — Integrated Path Acceptance.

V011-C13-MCQ-096. Why include a before-and-after reference closure entry alongside an assembly inventory?

A. Reference timing is irrelevant once serial numbers are known

B. Inventory and closure are interchangeable records

C. A closure entry proves all external signals were stationary

D. It bounds when demonstrated transfer validity held, whereas inventory identifies what was connected

Answer: D. Hardware identity and temporal validity answer different reconstruction questions. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: It bounds when demonstrated transfer validity held, whereas inventory identifies what was connected.

Distinguishing consideration: compare this with option A, “Reference timing is irrelevant once serial numbers are known”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-097. In a linear scalar path, the receiver indicates −60 dBm and the net downstream gain is 44 dB. What is the upstream level?

A. −104 dBm

B. −44 dBm

C. −16 dBm

D. +104 dBm

Answer: A. Referring upstream subtracts the net downstream gain from the indication. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why the selected alternative fits: −104 dBm.

Distinguishing consideration: compare this with option B, "−44 dBm"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-MCQ-098. What must be retained when a path is accepted only for a bounded conducted measurement?

A. A universal zero-mismatch assumption

B. A claim that every field conversion is also accepted

C. The named plane, tested state, reference uncertainty and stated limitations

D. Only the nominal receiver bandwidth

Answer: C. A bounded conducted claim can be strong without implying untested installed behavior. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why the selected alternative fits: The named plane, tested state, reference uncertainty and stated limitations.

Distinguishing consideration: compare this with option A, “A universal zero-mismatch assumption”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-MCQ-099. Which evidence would strengthen a claim that an optical comparison preserved the relevant weak-signal capability?

A. An unchanged cable label

B. The optical link's advertised maximum data rate alone

C. A strong saturated reference visible in both paths

D. A known weak reference measured with compatible bandwidth, gain and noise in both paths

Answer: D. The reference should test the capability pertinent to the feature, not merely gross connectivity. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Why the selected alternative fits: A known weak reference measured with compatible bandwidth, gain and noise in both paths.

Distinguishing consideration: compare this with option A, “An unchanged cable label”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Separate the intended coaxial path from installed coupling.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-MCQ-100. What is the role of the chapter's antenna and path equations in acceptance?

A. They establish unique causes for every discrepancy

B. They replace all state and uncertainty records

C. They make installed geometry irrelevant

D. They provide bounded predictions to test against configured measurements

Answer: D. Model predictions aid acceptance only with the declared assumptions and supporting tests. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why the selected alternative fits: They provide bounded predictions to test against configured measurements.

Distinguishing consideration: compare this with option A, “They establish unique causes for every discrepancy”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Fill-in-the-Blank Questions

V011-C13-FIB-001. The record of serialized components and their order is the _____ record.

Answer: assembly. It reconstructs the actual connected network, distinct from state and numerical correction records. Source: §13.2 Define a complete path at named planes (p. 7537)

Why this term is required: “assembly” completes the stated technical proposition.

Question context: The record of serialized components and their order is the _____ record

Basis and qualification: Chapter 13 — Define a complete path at named planes.

Review: Chapter 13 — Define a complete path at named planes.

Copyright 2026, James M. Atkinson

V011-C13-FIB-002. Gain, attenuation, filter and bias settings belong to the _____ record.

Answer: state. The transfer and noise law can depend on these operating conditions. Source: §13.2 Define a complete path at named planes (p. 7537)

Why this term is required: “state” completes the stated technical proposition.

Question context: Gain, attenuation, filter and bias settings belong to the _____ record

Basis and qualification: Chapter 13 — Define a complete path at named planes.

Review: Chapter 13 — Define a complete path at named planes.

Copyright 2026, James M. Atkinson

V011-C13-FIB-003. The correction record must name the upstream and downstream reference _____.

Answer: planes. A correction's scope is defined by the physical boundaries it spans.

Source: §13.2 Define a complete path at named planes (p. 7537)

Why this term is required: “planes” completes the stated technical proposition.

Question context: The correction record must name the upstream and downstream reference _____

Basis and qualification: Chapter 13 — Define a complete path at named planes.

Review: Chapter 13 — Define a complete path at named planes.

Copyright 2026, James M. Atkinson

V011-C13-FIB-004. An adapter already included in an assembly calibration must not be corrected a _____ time.

Answer: second. Duplicating a correction assigns the same physical contribution twice. Source: §13.2 Define a complete path at named planes (p. 7537)

Why this term is required: “second” completes the stated technical proposition.

Question context: An adapter already included in an assembly calibration must not be corrected a _____ time

Basis and qualification: Chapter 13 — Define a complete path at named planes.

Review: Chapter 13 — Define a complete path at named planes.

Copyright 2026, James M. Atkinson

V011-C13-FIB-005. Equal total desired gain does not guarantee equal input-equivalent _____ when component order changes.

Answer: noise. Gain order changes the weighting of subsequent noise contributions. Source: §13.2 Define a complete path at named planes (p. 7537)

Why this term is required: “noise” completes the stated technical proposition.

Question context: Equal total desired gain does not guarantee equal input-equivalent _____ when component order changes

Basis and qualification: Chapter 13 — Define a complete path at named planes.

Review: Chapter 13 — Define a complete path at named planes.

Copyright 2026, James M. Atkinson

V011-C13-FIB-006. A calibration ending at the receiver connector does not include the external _____ path.

Answer: antenna-to-receiver. The upstream cables, accessories and remote active stages need their own applicable evidence. Source: §13.1 Measurement Chain Ownership (p. 7536)

Why this term is required: “antenna-to-receiver” completes the stated technical proposition.

Question context: A calibration ending at the receiver connector does not include the external _____ path

Basis and qualification: Chapter 13 — Measurement Chain Ownership.

Review: Chapter 13 — Measurement Chain Ownership.

V011-C13-FIB-031. Attenuation can improve match while reducing wanted signal and adding _____ noise.

Answer: thermal. The sensitivity cost accompanies the matching benefit. Source: §13.7 Attenuators, Filters, Splitters, and Switches (p. 7547)

Why this term is required: “thermal” completes the stated technical proposition.

Question context: Attenuation can improve match while reducing wanted signal and adding _____ noise

Basis and qualification: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

Review: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

Copyright 2026, James M. Atkinson

V011-C13-FIB-032. A splitter's finite interport _____ allows branch interactions.

Answer: isolation. One output's load or energy can affect another output. Source: §13.7 Attenuators, Filters, Splitters, and Switches (p. 7547)

Why this term is required: “isolation” completes the stated technical proposition.

Question context: A splitter's finite interport _____ allows branch interactions

Basis and qualification: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

Review: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

Copyright 2026, James M. Atkinson

V011-C13-FIB-033. For a switch, path changes may require time for transients to _____.

Answer: settle. The measurement must be taken in the valid operating state. Source: §13.7 Attenuators, Filters, Splitters, and Switches (p. 7547)

Why this term is required: “settle” completes the stated technical proposition.

Question context: For a switch, path changes may require time for transients to _____

Basis and qualification: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

Review: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

V011-C13-FIB-055. An indication of −72 dBm with 4 dB loss and 15 dB gain refers upstream to _____ dBm.

Answer: −83. Compute −72 + 4 − 15. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why this term is required: "−83" completes the stated technical proposition.

Question context: An indication of −72 dBm with 4 dB loss and 15 dB gain refers upstream to _____ dBm

Basis and qualification: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-FIB-056. A −90 dBm input with 3 dB loss and 18 dB gain produces _____ dBm in the linear scalar model.

Answer: −75. Forward propagation gives −90 − 3 + 18. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why this term is required: "−75" completes the stated technical proposition.

Question context: A −90 dBm input with 3 dB loss and 18 dB gain produces _____ dBm in the linear scalar model

Basis and qualification: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-FIB-057. The chapter's −92.0 dBm terminal, 6.4 dB loss and 20.1 dB gain predict _____ dBm.

Answer: −78.3. This is the stated hypothetical forward-transfer calculation. Source: §13.13 Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7557)

Why this term is required: "−78.3" completes the stated technical proposition.

Question context: The chapter's −92.0 dBm terminal, 6.4 dB loss and 20.1 dB gain predict _____ dBm

Basis and qualification: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-FIB-058. Observed −70.0 dBm minus predicted −78.3 dBm equals a discrepancy of _____ dB.

Answer: 8.3. The observed value is higher than the prediction. Source: §13.13 Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7557)

Why this term is required: “8.3” completes the stated technical proposition.

Question context: Observed −70.0 dBm minus predicted −78.3 dBm equals a discrepancy of _____ dB

Basis and qualification: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-FIB-073. Component certificates support the record, but acceptance belongs to the assembled _____ performed.

Answer: measurement. A component certificate is not an automatic assembled-path conclusion. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why this term is required: “measurement” completes the stated technical proposition.

Question context: Component certificates support the record, but acceptance belongs to the assembled _____ performed

Basis and qualification: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-FIB-074. In the bias-cable case, antenna-input termination still leaves the anomalous component _____.

Answer: present. That observation implicates alternatives to normal antenna-terminal reception. Source: §13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7558)

Why this term is required: “present” completes the stated technical proposition.

Question context: In the bias-cable case, antenna-input termination still leaves the anomalous component _____

Basis and qualification: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-FIB-075. Changing bias cable length shifts the component, implicating the active and _____ path.

Answer: bias. Multiple network-dependent mechanisms remain possible. Source: §13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7558)

Why this term is required: “bias” completes the stated technical proposition.

Question context: Changing bias cable length shifts the component, implicating the active and _____ path

Basis and qualification: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-FIB-076. Separate observation of the amplifier _____ can help discriminate the case's mechanisms.

Answer: output. It adds evidence outside the original receiver indication. Source: §13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7558)

Why this term is required: “output” completes the stated technical proposition.

Question context: Separate observation of the amplifier _____ can help discriminate the case's mechanisms

Basis and qualification: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-FIB-077. Removing a preamplifier changes sensitivity, so an anomaly's disappearance alone may be _____.

Answer: inconclusive. A reduction in detection capability can produce the same observation. Source: §13.14 Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7558)

Why this term is required: “inconclusive” completes the stated technical proposition.

Question context: Removing a preamplifier changes sensitivity, so an anomaly's disappearance alone may be _____

Basis and qualification: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-FIB-078. For a field-based result, an installed reference must retain documented antenna _____.

Answer: geometry. Orientation, mounting and surrounding conductors affect the conversion. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why this term is required: “geometry” completes the stated technical proposition.

Question context: For a field-based result, an installed reference must retain documented antenna _____

Basis and qualification: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

V011-C13-FIB-079. The Table 13A record of before-and-after references is the _____ entry.

Answer: closure. It bounds the interval of demonstrated transfer validity. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why this term is required: “closure” completes the stated technical proposition.

Question context: The Table 13A record of before-and-after references is the _____ entry

Basis and qualification: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-FIB-080. A switched-path correction must identify the selected switch _____.

Answer: position. Different paths can have different loss, phase and isolation.

Source: §13.7 Attenuators, Filters, Splitters, and Switches (p. 7547)

Why this term is required: “position” completes the stated technical proposition.

Question context: A switched-path correction must identify the selected switch _____

Basis and qualification: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

Review: Chapter 13 — Attenuators, Filters, Splitters, and Switches.

Copyright 2026, James M. Atkinson

V011-C13-FIB-081. If a splitter branch termination changes, the corresponding network _____ has changed.

Answer: state. The selected path can depend on the consequential unused branches. Source: §13.8 Treat connections and unused branches as part of the network (p. 7548)

Why this term is required: “state” completes the stated technical proposition.

Question context: If a splitter branch termination changes, the corresponding network _____ has changed

Basis and qualification: Chapter 13 — Treat connections and unused branches as part of the network.

Review: Chapter 13 — Treat connections and unused branches as part of the network.

V011-C13-FIB-083. With 0.5 mW available received power and 0.1 m^2 effective aperture, the stated aperture model implies _____ $\frac{mW}{m^2}$ incident density.

Answer: 5. Divide available received power by aperture under the model conditions.

Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why this term is required: "5" completes the stated technical proposition.

Question context: With 0.5 mW available received power and 0.1 effective aperture, the stated aperture model implies _____ incident density

Basis and qualification: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-FIB-084. At fixed aperture, a threefold incident power density produces a _____ increase in available received power.

Answer: threefold. Equation 25 is linear in density for unchanged conditions. Source: §13.12 Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration (p. 7555)

Why this term is required: “threefold” completes the stated technical proposition.

Question context: At fixed aperture, a threefold incident power density produces a _____ increase in available received power

Basis and qualification: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-FIB-091. For a useful cable-route comparison, the changed cable segment should be explicitly _____.

Answer: defined. Selective intervention requires a reconstructable physical change.

Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Why this term is required: “defined” completes the stated technical proposition.

Question context: For a useful cable-route comparison, the changed cable segment should be explicitly _____

Basis and qualification: Chapter 13 — Separate the intended coaxial path from installed coupling.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

Copyright 2026, James M. Atkinson

V011-C13-FIB-092. An optical path's advertised bandwidth alone does not establish its weak-signal _____.

Answer: sensitivity. Noise and gain also determine capability. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Why this term is required: “sensitivity” completes the stated technical proposition.

Question context: An optical path's advertised bandwidth alone does not establish its weak-signal _____

Basis and qualification: Chapter 13 — Separate the intended coaxial path from installed coupling.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

Copyright 2026, James M. Atkinson

V011-C13-FIB-093. Where the installed match or dynamic range is inadequate, the correction record should state quantitative _____.

Answer: limitations. A numerical correction cannot justify every condition. Source: §13.11 Integrated Path Acceptance (p. 7554)

Why this term is required: “limitations” completes the stated technical proposition.

Question context: Where the installed match or dynamic range is inadequate, the correction record should state quantitative _____

Basis and qualification: Chapter 13 — Integrated Path Acceptance.

Review: Chapter 13 — Integrated Path Acceptance.

Copyright 2026, James M. Atkinson

V011-C13-FIB-094. An antenna-terminal conducted claim can be strong while the installed field claim remains more _____.

Answer: limited. The second measurand depends on additional geometry and coupling evidence. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

Why this term is required: “limited” completes the stated technical proposition.

Question context: An antenna-terminal conducted claim can be strong while the installed field claim remains more _____

Basis and qualification: Chapter 13 — A constructed acceptance case for the assembled chain.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

Copyright 2026, James M. Atkinson

V011-C13-ESSAY-001. Design a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish.

- Opening: Present a thesis that answers this precise question: Design a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish. Identify which evidence would falsify the proposed conclusion Source: §13.2 Define a complete path at named planes (p. 7537)
- Core terminology and scope: Define Design, traceable, three-part in the question's particular technical setting; explain how record, assembly, part differ if that distinction would change the analysis of "Design a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish" Source: §13.2 Define a complete path at named planes (p. 7537)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Identify assembly serials and order; electrical and environmental state; correction planes, frequency grid, interpolation and uncertainty Source: §13.2 Define a complete path at named planes (p. 7537)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish to the claimed result, following "13. Ten worked examples in integrated antenna-to-receiver measurements"; name the intermediate states and measurable outputs Source: §13.18 Ten worked examples in integrated antenna-to-receiver measurements (p. 7565)

Copyright 2026, James M. Atkinson

- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish. Explain why a photograph or certificate alone cannot substitute for all three and show how a correction is assigned once Source: §13.18 Ten worked examples in integrated antenna-to-receiver measurements (p. 7565)
- Analytical framework: Identify the equation, calibration or evidential decision test in “Remote amplification requires electrical and installed checks” that resolves the question about a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish; derive the relevant result with units and stated validity conditions Source: §13.6 Remote amplification requires electrical and installed checks (p. 7545)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish. Explain why a photograph or certificate alone cannot substitute for all three and show how a correction is assigned once Source: §13.2 Define a complete path at named planes (p. 7537)
- Worked application or illustrative case: Build a worked example of “a traceable three-part record for an antenna-to-receiver assembly and explain what each part can and cannot establish”, addressing this associated condition: Identify assembly serials and order; electrical and environmental state; correction planes, frequency grid,....

V011-C13-ESSAY-012. Develop a capability-matched optical-isolation comparison.

- Opening: Present a thesis that answers this precise question: Develop a capability-matched optical-isolation comparison. Identify which evidence would falsify the proposed conclusion Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)
- Core terminology and scope: Define capability-matched, optical-isolation, terminology in the question's particular technical setting; explain how computational, relationships, theory differ if that distinction would change the analysis of "Develop a capability-matched optical-isolation comparison" Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Characterize optical gain, noise, bandwidth, timing and power state Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting a capability-matched optical-isolation comparison to the claimed result, following "Common-Mode Current and Installed-Path Effects"; name the intermediate states and measurable outputs Source: §13.9 Common-Mode Current and Installed-Path Effects (p. 7550)
- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for a capability-matched optical-isolation comparison. Use a relevant weak reference in both configurations, preserve untreated data and

compare the anomaly Source: §13.9 Common-Mode Current and Installed-Path Effects (p. 7550)

- Analytical framework: Identify the equation, calibration or evidential decision test in “13. Verification, records and the interpretation of negative observations” that resolves the question about a capability-matched optical-isolation comparison; derive the relevant result with units and stated validity conditions Source: §13.19 Verification, records and the interpretation of negative observations (p. 7576)
- Evidence and method: Specify the native observations, control records and calculations that would resolve a capability-matched optical-isolation comparison. Explain why a noisier path losing both reference and anomaly offers little discrimination Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)
- Worked application or illustrative case: Build a worked example of “a capability-matched optical-isolation comparison”, addressing this associated condition: Characterize optical gain, noise, bandwidth, timing and power state. Characterize optical gain, noise, bandwidth, timing and power state Source: §13.9 Common-Mode Current and Installed-Path Effects (p. 7550)
- Alternative explanations and failure modes: Construct two plausible technical explanations for “a capability-matched optical-isolation comparison”. Using “13. Verification, records and the interpretation of negative observations”, specify a discriminator and the result expected under each explanation Source: §13.19 Verification, records and the interpretation of negative observations (p. 7576)

Copyright 2026, James M. Atkinson

- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to a capability-matched optical-isolation comparison, including the effect of missing measurements and inconsistent operating conditions Source: §13.8 Treat connections and unused branches as part of the network (p. 7548)
- Scholarly synthesis and implications: Explain what the result about a capability-matched optical-isolation comparison authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)
- Closing: Conclude by answering “Develop a capability-matched optical-isolation comparison” using only the demonstrated evidence; state the remaining decisive verification step Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

V011-C13-DISCUSSION-001. A team wants to accept an installed chain because every component has an in-date certificate. What assembled evidence should you request?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A team wants to accept an installed chain because every component has an in-date certificate. What assembled evidence should you request?” Put this particular dispute to the panel: A team wants to accept an installed chain because every component has an in-date certificate. What assembled evidence should you request. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §13.23 Controlled qualification of the installed network (p. 7589)

- 02. Student A, terminology and scope: Agree the operational meanings of accept, installed, chain and certificate, assembled, request in “A team wants to accept an installed chain because every component has an in-date certificate. What assembled evidence should you request”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §13.23 Controlled qualification of the installed network (p. 7589)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A team wants to accept an installed chain because every component has an in-date certificate; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “A constructed acceptance case for the assembled chain”. Explain connection, loading and coupling gaps; retain the certificates as support while limiting acceptance to tested conditions Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original

Copyright 2026, James M. Atkinson

trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A team wants to accept an installed chain because every component has an in-date certificate; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §13.16 Integrated reference-plane analysis and system-level acceptance (p. 7561)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “A constructed acceptance case for the assembled chain”. Explain connection, loading and coupling gaps; retain the certificates as support while limiting acceptance to tested conditions Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Ask for the actual serial order, electrical state, correction ownership and named-plane reference measurements Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate

Copyright 2026, James M. Atkinson

between them without changing the measurand. Source: §13.23 Controlled qualification of the installed network (p. 7589)

- 08. Student D, answer to Student E: Design a discriminating experiment involving A team wants to accept an installed chain because every component has an in-date certificate: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §13.23 Controlled qualification of the installed network (p. 7589)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A team wants to accept an installed chain because every component has an in-date certificate; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §13.16 Integrated reference-plane analysis and system-level acceptance (p. 7561)

Copyright 2026, James M. Atkinson

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A team wants to accept an installed chain because every component has an in-date certificate: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §13.23 Controlled qualification of the installed network (p. 7589)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A team wants to accept an installed chain because every component has an in-date certificate, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A team wants to accept an installed chain because every component

Copyright 2026, James M. Atkinson

has an in-date certificate: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §13.23 Controlled qualification of the installed network (p. 7589)

- 13. Student I, uncertainty and inferential limits: Assess uncertainty and evidential scope for A team wants to accept an installed chain because every component has an in-date certificate. Explain connection, loading and coupling gaps; retain the certificates as support while limiting acceptance to tested conditions Explain the relevant statistical or calibration uncertainty, the range of defensible claims, and why the question cannot be settled by visual appearance or a single unqualified reading. Source: §13.16 Integrated reference-plane analysis and system-level acceptance (p. 7561)

- 14. Student J, Socratic challenge to Student I: For the precise observation involving A team wants to accept an installed chain because every component has an in-date certificate, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Ask Student I whether the proposed uncertainty statement accounts for the actual receiver state, sample coverage and possible instrumental artifacts. Request an explicit statement of what evidence would reverse the

Copyright 2026, James M. Atkinson

conclusion. Source: §13.15 A constructed acceptance case for the assembled chain (p. 7559)

- 15. Student I, quantified and qualified reply: Assess uncertainty and evidential scope for A team wants to accept an installed chain because every component has an in-date certificate. Explain connection, loading and coupling gaps; retain the certificates as support while limiting acceptance to tested conditions Respond point by point to Student J. Distinguish a verified observation from a conditional inference and name the missing datum, sensitivity test or uncertainty term that limits confidence. Source: §13.16 Integrated reference-plane analysis and system-level acceptance (p. 7561)

- 16. Student K, authority and evidential discipline: Determine which authority, calibration and reporting safeguards apply to the particular claim about A team wants to accept an installed chain because every component has an in-date certificate and What assembled evidence should you request; exclude protections irrelevant to the scenario Question Student F about the custody and reproducibility of the proposed records and ask Student G whether the discriminatory test remains within authorised laboratory and field boundaries. Source: §13.19 Verification, records and the interpretation of negative observations (p. 7576)

Copyright 2026, James M. Atkinson

- 17. Peer panel, negotiated consensus and residual dissent: Draft a narrow consensus about “A team wants to accept an installed chain because every component has an in-date certificate”, addressing “What assembled evidence should you request”; specify the exact measurement or evidential gap on which the speakers still differ Require Students A, B, D, G and I to respond to at least one objection raised by another speaker before voting. Record both the narrow agreement and the specific contested proposition that remains unresolved. Source: §13.23 Controlled qualification of the installed network (p. 7589)

- 18. Moderator, reasoned disposition and follow-up: Record a final recommendation on “A team wants to accept an installed chain because every component has an in-date certificate. What assembled evidence should you request”, specifying the next test, responsible measurement record and limit of the conclusion Summarise the strongest evidence for and against the resolution of “A team wants to accept an installed chain because every component has an in-date certificate. What assembled evidence should you request”. Allocate the next measurement and documentary action to named student roles, and require each participant to distinguish accepted evidence from an unsupported assertion. V011-C13-DISCUSSION-009. A ferrite improves a weak-feature measurement. How would you avoid overstating what the improvement means?

- 01. Moderator, opening proposition: Introduce the exact dispute, “A ferrite improves a weak-feature measurement. How would you avoid overstating what the improvement means?” Put this particular dispute to the panel: A ferrite improves a weak-feature measurement. How would you avoid overstating what the improvement means. Ask speakers to identify the result or operational decision at stake Invite two students to propose competing answers, and ask each to name a measurable consequence that could disprove the position. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

- 02. Student A, terminology and scope: Agree the operational meanings of ferrite, improves, avoid and overstating, improvement, means in “A ferrite improves a weak-feature measurement. How would you avoid overstating what the improvement means”; state which definitions materially change the competing positions Ask Student B which definition would most materially change the outcome and request a specific example from the stated receiver scenario. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Copyright 2026, James M. Atkinson

- 03. Student B, affirmative technical position: Ask one participant to defend and another to challenge the proposed treatment of A ferrite improves a weak-feature measurement; require both to name a decisive instrument observation Give a defensible initial conclusion, identify the instrument state on which it depends, and pass a direct question to Student C about a plausible weakness. Source: §13.19 Verification, records and the interpretation of negative observations (p. 7576)

- 04. Student C, first Socratic examination of Student B: Debate the governing receiver or signal mechanism in “13. Verification, records and the interpretation of negative observations”. Distinguish a useful mitigation from a unique causal explanation or external-source identification Ask Student B two focused questions: Which physical or digital stage could produce the observed result, and what independent observation could contradict that explanation? Do not accept a repeat of the opening claim as an answer. Source: §13.19 Verification, records and the interpretation of negative observations (p. 7576)

- 05. Student B, evidence-based answer to Student C: Respond directly to the mechanism and falsification questions. Specify the original trace, I/Q record, calibration state or field note actually needed to

test the alternative interpretations of A ferrite improves a weak-feature measurement; explain what each record can establish State what the existing record establishes, what it does not establish, and which further measurement would change your opinion. Source: §13.16 Integrated reference-plane analysis and system-level acceptance (p. 7561)

- 06. Student D, competing mechanism: Debate the governing receiver or signal mechanism in “13. Verification, records and the interpretation of negative observations”. Distinguish a useful mitigation from a unique causal explanation or external-source identification Explain a materially different receiver or signal mechanism, state its predicted signature, and invite Student E to challenge whether it fits the same observed trace or native sample record. Source: §13.19 Verification, records and the interpretation of negative observations (p. 7576)

- 07. Student E, cross-examination of the competing mechanism: Identify the competing options in the question. Check intended-path response, geometry and sensitivity, and document the exact intervention Put two specific questions to Student D about the stated competing options and the instrument configuration. Ask which setting or observation would discriminate between them without changing the measurand. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Copyright 2026, James M. Atkinson

- 08. Student D, answer to Student E: Design a discriminating experiment involving A ferrite improves a weak-feature measurement: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Respond to both cross-examination questions, specify the independent control condition and expected result, and identify how you would document an unexpected observation. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

- 09. Student F, original evidence and provenance: Specify the original trace, I/Q record, calibration state or field note actually needed to test the alternative interpretations of A ferrite improves a weak-feature measurement; explain what each record can establish Describe the native record, metadata and calibration evidence that the panel must actually examine. Ask Student G which datum should be collected first and what uncertainty remains if it is missing. Source: §13.16 Integrated reference-plane analysis and system-level acceptance (p. 7561)

- 10. Student G, discriminatory measurement design: Design a discriminating experiment involving A ferrite improves a weak-feature measurement: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion

Copyright 2026, James M. Atkinson

Present a repeatable, authorised test with the receiver settings, controlled variable, expected responses and a rejection criterion. Ask Student H to identify an alternative that could survive the proposed test. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

- 11. Student H, adversarial challenge and confounding alternatives: For the precise observation involving A ferrite improves a weak-feature measurement, formulate an instrumental artifact or confounding alternative, then identify the control measurement that would expose it Question Student G about a specific artifact or uncontrolled variable. Demand a control experiment that would expose a false positive or incorrect source attribution. Source: §13.19 Verification, records and the interpretation of negative observations (p. 7576)

- 12. Student G, revised experimental answer: Address Student H's confounding mechanism by revising the controlled test described in the preceding prompt. Design a discriminating experiment involving A ferrite improves a weak-feature measurement: specify the altered receiver state or source condition, predicted change, test statistic and rejection criterion Say precisely what observation would lead the panel to retain, qualify or reject the conclusion. Source: §13.10 Separate the intended coaxial path from installed coupling (p. 7551)

Chapter 13 Answer Keys and Guidance

The essay and discussion guidance below identifies expected mechanisms, methods and evidence. A defensible alternative conclusion must state its assumptions, reasoning and limitations.

Copyright 2026, James M. Atkinson

Essay Guidance

V011-C13-ESSAY-001 — Identify assembly serials and order; electrical and environmental state; correction planes, frequency grid, interpolation and uncertainty. Explain why a photograph or certificate alone cannot substitute for all three and show how a correction is assigned once.

Review: Chapter 13 — Define a complete path at named planes.

V011-C13-ESSAY-002 — Separate aggregate transfer from stage-dependent noise weighting and admitted levels. Discuss cable before versus after remote amplification, identify vulnerable stages, and require actual linear-state evidence rather than infer sensitivity from gain equality.

Review: Chapter 13 — Define a complete path at named planes.

V011-C13-ESSAY-003 — Define terminal voltage or power convention, antenna factor or aperture, matching, polarization, direction, field region and installation. Separate conducted downstream validation from field conversion and give limits for near-field or altered mounting conditions.

Review: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-ESSAY-004 — Define the two quantities and the source/load conditions. Explain the possible factor-two voltage discrepancy in a matched case, its approximately 6.02 dB level effect, and why an unknown impedance cannot be repaired by assuming that factor universally.

Review: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-ESSAY-005 — Explain downstream-noise weighting, exposure of the first active stage to blockers, reverse leakage, gain and compression limits, bias and stability. Compare preselection benefits with its loss and thermal-noise cost and identify the required assembled tests.

Review: Chapter 13 — External Preamplifiers, Bias, and Stability.

Copyright 2026, James M. Atkinson

V011-C13-ESSAY-006 — List supply ripple, conductive coupling, instability and leakage as alternatives. Use selective bias and load controls, independent output observation and maintained desired references. Explain why disappearance after a multi-property substitution is not a unique cause determination.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-ESSAY-007 — Include actual antenna and cable impedances, supply at the remote device, temperature and mechanical states. Use opening and closing references and consequential-change checks. Distinguish bounded understood drift correction from unexplained intermittent failures and identify affected intervals.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-ESSAY-008 — Discuss finite isolation, unused terminations, reflections and branch loading. Propose tests changing one termination while preserving intended response, record network state, and identify when vector or empirical multiport characterization is warranted.

Review: Chapter 13 — Treat connections and unused branches as part of the network.

V011-C13-ESSAY-009 — Account for desired loss, physical-temperature noise and altered source impedance. Explain possible improvements in match and possible deterioration of sensitivity; require a complete uncertainty and noise comparison rather than a universal improvement claim.

Review: Chapter 13 — Treat connections and unused branches as part of the network.

Copyright 2026, James M. Atkinson

V011-C13-ESSAY-010 — Describe inside-shield fields and exterior-shield current paths involving antenna, enclosure and nearby conductors. Explain why a matched insertion-loss result can coexist with route sensitivity, and design a controlled intervention with reference-transfer checks.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-ESSAY-011 — Explain which intervention sensitivity is observed and which alternative impedance, geometry and coupling changes remain. Require recorded placement, preserved desired response and further selective evidence; state a bounded conclusion without claiming unique current distribution or source identity.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-ESSAY-012 — Characterize optical gain, noise, bandwidth, timing and power state. Use a relevant weak reference in both configurations, preserve untreated data and compare the anomaly. Explain why a noisier path losing both reference and anomaly offers little discrimination.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-ESSAY-013 — Progress from receiver connector to assembled antenna-terminal reference to installed antenna observation. Define planes, serialized network, geometry, state, uncertainty and limits. Explain why passing a narrower stage does not accept all broader scopes.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

V011-C13-ESSAY-014 — Explain why losses are added and gains subtracted when referring an indication upstream. Use a fully specified hypothetical case, identify frequency and state applicability, and keep mismatch and correction uncertainty explicit rather than absorbed into an unexplained residual.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-ESSAY-015 — State the far-field, matching and polarization conditions for power density times aperture. Include a dimensional calculation, distinguish available from delivered power, and explain why near fields, multipath and changed geometry may require further treatment.

Review: Chapter 13 — Quantitative Model for Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-ESSAY-016 — Reconstruct −92.0 − 6.4 + 20.1 dBm and the +8.3 dB discrepancy. Investigate gain state, correction ownership, overload and installed coupling with independent references. Do not turn the residual into an unconditional correction or source attribution.

Review: Chapter 13 — Hypothetical Applied Calculation: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-ESSAY-017 — Explain what termination and cable-length sensitivity constrain. Retain competing active, conductive, radiated and leakage hypotheses; propose independent amplifier-output and controlled-load observations with adequate sensitivity. State the strongest conclusion before those follow-ups.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

Copyright 2026, James M. Atkinson

V011-C13-ESSAY-018 — Identify the 44 dB linear desired transfer and named planes. Preserve input, output, correction and uncertainty; then separately address noise, blocker transfer and installed geometry. Explain why receiver-connector injection bypasses the remote path.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-ESSAY-019 — For unchanged gain with increased noise, inspect source spectrum and reciprocal mixing; for changed gain, examine gain control or compression; for route-sensitive anomaly with stable reference, examine installed coupling. Keep each conclusion conditional and preserve measured evidence.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-ESSAY-020 — Distinguish a known modeled drift from an unexplained failure, identify the interval and states at risk, and retain both reference observations. Discuss bounded corrections only where justified and avoid silently extending later calibration to unknown earlier conditions.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-ESSAY-021 — Key files to serial assembly, selected path, gain and bias state, temperature range, planes and frequency grid. Record interpolation and uncertainty, prevent duplicate accessory corrections, and require renewed verification after consequential substitutions.

Review: Chapter 13 — Integrated Path Acceptance.

Copyright 2026, James M. Atkinson

V011-C13-ESSAY-022 — Explain the certificates' real supporting role and gaps from connections, order, operating state, loading and installed coupling. Define an assembled reference test whose conclusion is limited to the performed measurement and uncertainty.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-ESSAY-023 — Track which gain, loss and noise contributions lie downstream of each plane, distinguish raw output from referred input, and show one hypothetical correction. Discuss why field conversion is a separate additional model rather than merely another arbitrary plane label.

Review: Chapter 13 — Define a complete path at named planes.

V011-C13-ESSAY-024 — Identify tested ranges, state-specific limitations and the effect on quantitative claims. Retain usable bounded results, avoid unsupported correction extrapolation, and describe what new characterization would be needed to extend acceptance.

Review: Chapter 13 — Integrated Path Acceptance.

V011-C13-ESSAY-025 — Separate desired transfer, noise, blocker loading, state stability and field coupling. Use the constructed acceptance table to assign evidence to each and identify what an otherwise correct displayed reference cannot establish.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

Discussion Guidance

V011-C13-DISCUSSION-001 — Ask for the actual serial order, electrical state, correction ownership and named-plane reference measurements. Explain connection, loading and coupling gaps; retain the certificates as support while limiting acceptance to tested conditions.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-DISCUSSION-002 — Compare noise weighting and blocker levels at vulnerable stages, then verify actual desired transfer and linear state. Avoid deciding solely from the equal gain sum; identify preselection and remote-bias tradeoffs.

Review: Chapter 13 — Define a complete path at named planes.

V011-C13-DISCUSSION-003 — Reproduce a documented route intervention while retaining intended geometry and reference response, preserve both observations, and check exterior-shield coupling. Recognize that routing itself can alter the local environment and avoid unique attribution.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-DISCUSSION-004 — Recover definitions and impedance conditions, correct only under the supported loading model, and recompute uncertainty. Discuss the possible factor-two example without assuming it for an arbitrary source/load combination.

Review: Chapter 13 — Keep field conversion separate from terminal power.

Copyright 2026, James M. Atkinson

V011-C13-DISCUSSION-005 — Measure admitted blocker levels before the active stage, desired gain under loading, preselection and bias behavior. Consider nonlinear or reciprocal-mixing mechanisms and maintain capability when comparing passive and active configurations.

Review: Chapter 13 — External Preamplifiers, Bias, and Stability.

V011-C13-DISCUSSION-006 — Identify changed conductive and ground paths as well as supply spectrum. Propose selective controls and independent output observations, preserve the successful intervention, and state only its demonstrated sensitivity until alternatives are separated.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-DISCUSSION-007 — Treat appearance as insufficient validity evidence; identify unknown state and drift history, bound affected records and repeat or qualify where necessary. Apply corrections only when a supported evolution model exists.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-DISCUSSION-008 — Compare required termination and open state with a stable desired reference, measure changed loss or noise, and record finite isolation and branch coupling. Use the actual multiport state if consequential.

Review: Chapter 13 — Treat connections and unused branches as part of the network.

Copyright 2026, James M. Atkinson

V011-C13-DISCUSSION-009 — Check intended-path response, geometry and sensitivity, and document the exact intervention. Distinguish a useful mitigation from a unique causal explanation or external-source identification.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-DISCUSSION-010 — Evaluate whether the original feature would remain detectable, use an appropriate weak reference, and characterize gain, bandwidth and timing. Treat disappearance as inconclusive if capability is inadequate.

Review: Chapter 13 — Separate the intended coaxial path from installed coupling.

V011-C13-DISCUSSION-011 — Keep the receiver pass scoped to its connector, then inspect remote gain, cable, adapters, switch state and correction ownership with intermediate planes or substitutions. Avoid blaming the receiver or antenna from the broad failure alone.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-DISCUSSION-012 — Check whether any adapter, switch or gain term was included twice, compare raw output against independently known input, and verify plane boundaries. Agreement alone can result from compensating errors and is not proof of correct ownership.

Review: Chapter 13 — Define a complete path at named planes.

Copyright 2026, James M. Atkinson

V011-C13-DISCUSSION-013 — Retain certified behavior only within its conditions, assess changed pattern and coupling, and seek installed reference evidence. Report terminal results separately from any more uncertain field conversion.

Review: Chapter 13 — Keep field conversion separate from terminal power.

V011-C13-DISCUSSION-014 — Combine match improvement with added loss, thermal noise and input-equivalent sensitivity. Use the measurement's required detection and uncertainty goals rather than declare the pad universally beneficial.

Review: Chapter 13 — Treat connections and unused branches as part of the network.

V011-C13-DISCUSSION-015 — Check actual source/load impedances, cable length, bias voltage, temperature and independent output. The bench result remains valid for its scope but does not establish installed stability.

Review: Chapter 13 — Remote amplification requires electrical and installed checks.

V011-C13-DISCUSSION-016 — State the tested downstream scope and add antenna-terminal and installed geometry checks for broader claims. Explain precisely which remote and field-conversion elements were bypassed.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

V011-C13-DISCUSSION-017 — Inspect blocker source spectrum and predicted reciprocal mixing, verify actual admitted levels and stable state, and keep noise and gain observations distinct. Avoid diagnosing compression solely from a noise increase.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-DISCUSSION-018 — Examine gain control or compression and stage loading before using a quiet-state noise budget. Record the reference and operating state, and identify the linearity boundary rather than correcting the loss as ordinary cable attenuation.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-DISCUSSION-019 — Report sensitivity to the installed active and bias path, list plausible instability, pickup and leakage mechanisms, and propose independent output and selective-load checks. Avoid a unique source or oscillation diagnosis.

Review: Chapter 13 — Hypothetical Case Adjudication: Antenna, Preamplifier, Attenuator, Filter, Cable, and Reference-Plane Integration.

V011-C13-DISCUSSION-020 — Compare whether the changed geometry affects desired transfer or common mode, preserve serialized and state records, and obtain installed evidence for each consequential configuration. Equal hardware identity alone is insufficient.

Review: Chapter 13 — Integrated Path Acceptance.

Copyright 2026, James M. Atkinson

V011-C13-DISCUSSION-021 — Retain separate results for desired transfer, noise, blocker response and installed coupling because they support different claims. Relate each to intended use and uncertainty rather than invent an unsupported aggregate score.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

V011-C13-DISCUSSION-022 — Request the measured grid, interpolation method, state applicability and uncertainty near the transition, and seek finer characterization if needed. Do not infer an exact response from sparse data or smooth plotting.

Review: Chapter 13 — Define a complete path at named planes.

V011-C13-DISCUSSION-023 — Treat relocation as potentially consequential to installed coupling, examine geometry and common mode, and renew applicable acceptance. Stable scalar loss does not settle the installed field response.

Review: Chapter 13 — Integrated Path Acceptance.

V011-C13-DISCUSSION-024 — Distinguish demonstrated assembled transfer at tested conditions from unverified component properties and formal applicability. State the bounded current evidence and unresolved limits without either discarding the reference or claiming it establishes every certificate property.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Copyright 2026, James M. Atkinson

V011-C13-DISCUSSION-025 — Name separate measurands, planes, states, uncertainty and supporting tests; identify the field-geometry and coupling limits. Explain why different evidential strength is appropriate and avoid extending the stronger conducted result into untested field conditions.

Review: Chapter 13 — A constructed acceptance case for the assembled chain.

Chapter Glossary

ANTENNA FACTOR: Frequency-dependent relationship used to convert antenna-terminal voltage to incident electric-field strength under stated conditions.

ANTENNA TERMINAL PLANE: The declared electrical boundary between an antenna and the receiving path. A conducted reference applied there can test the downstream chain under the stated loading. It does not by itself characterize the antenna's conversion from an incident field, which also depends on direction, polarization, geometry and environment.

ASSEMBLY RECORD: Identification and order of the physical components, connections, and terminations that form a measurement path.

AVAILABLE POWER: The power a source can make available under the applicable matching convention. The chapter's ideal effective-aperture relation uses this quantity for the stated receiving-antenna conditions. It must not be interchanged with power actually delivered to an arbitrary load, particularly when mismatch or an installed coupling path is significant.

BIAS DELIVERY: The actual supply path and operating state used to power a remote active component. Cable resistance, protection elements and coupling to other equipment can make the remote condition differ from the source-terminal indication. Record the feed arrangement and available monitoring rather than inferring the amplifier's state from supply voltage alone.

BIAS TEE: Network combining or separating direct-current power and RF on a common conductor.

Copyright 2026, James M. Atkinson

BLOCKER-TRANSFER VERIFICATION: Characterization of the interfering-signal levels admitted up to the vulnerable stages under the stated assembly and state. It complements desired-signal transfer because a narrow downstream channel does not protect every earlier component. Retaining the desired reference during a blocker challenge helps distinguish changed gain from a raised noise contribution.

CALIBRATION BOUNDARY: The part of a measurement path and its stated conditions covered by a calibration. Components or effects outside that scope require additional treatment. An adapter included in an antenna calibration must not be corrected again, while a field cable beyond a receiver's calibrated connector remains outside the receiver calibration.

COMMON-MODE CURRENT: Current flowing on conductors together with respect to an external reference or surrounding structure.

CONDUCTED REFERENCE: Known signal applied at a specified electrical port to verify the transfer or response of the downstream path.

CONNECTOR REPEATABILITY: The consistency of a connection's electrical response when it is assembled again under controlled conditions. Reconnection, torque, contamination or mechanical strain can alter loss or reflection. A previous calibration remains relevant only to the extent that the resulting installed connection satisfies the required transfer and uncertainty conditions.

Copyright 2026, James M. Atkinson

CORRECTION OWNERSHIP: The assignment of each gain, loss or conversion to the calibration or processing step responsible for it. Explicit boundaries prevent omission and double correction when antenna, accessory and receiver records overlap. The correct assignment follows the actual measured assembly and quantity, not merely the presence of a certificate or file.

CORRECTION RECORD: The record identifying a correction's measured transfer, reference planes, frequency grid, interpolation, uncertainty and serialized applicability. It establishes which measured path and state the correction describes. It must distinguish corrections already applied from those still required and retain raw observations where needed to reconstruct the result.

DELIVERED POWER: The power transferred into the specified load under the actual source and load conditions. It can differ from available power when impedances are mismatched. A receiver indication and a calibration factor must refer to compatible loading before a terminal or field conversion is assigned.

DESIRED-TRANSFER VERIFICATION: A check of the response to a known desired signal between stated planes in the relevant configuration. It establishes the traversed path at the check time and supports comparisons whose detection capability is retained. An injection at the receiver connector bypasses upstream components and cannot verify their contribution.

EFFECTIVE APERTURE: Equivalent receiving area relating incident power density to available antenna power.

Copyright 2026, James M. Atkinson

EFFECTIVE HEIGHT: A receiving-antenna conversion quantity relating incident electric field to a specified terminal-voltage response under declared direction, polarization and loading conventions. It answers a voltage question, unlike effective aperture's power-density relationship. Its use requires the applicable antenna convention and field conditions rather than treating all antenna conversion factors as interchangeable.

FIELD-TO-TERMINAL CONVERSION: The relationship between an incident field and the electrical quantity at an antenna's terminals under stated conditions. Pattern, polarization, field region, loading and installation affect its applicability. A sound terminal-power measurement therefore does not automatically support an equally sound field-strength estimate in an uncharacterized environment.

INSERTION LOSS: The reduction in transferred signal associated with inserting a specified path under declared calibration planes, source and load conditions, frequency and level. Its measured value is conditional on those arrangements. Reconnection, strain, mismatch or a different selected branch can change the installed transfer.

INSTALLED RESPONSE: Behavior of the receiving assembly in its actual mounting, cable, grounding, and environmental arrangement.

LOAD-DEPENDENT STABILITY: The dependence of an active assembly's stable behavior on the impedance and network connected to it. An amplifier may respond differently to an antenna, matched termination, switch branch or cable. Stability evidence therefore covers the configurations actually tested and does not follow solely from one favorable bench arrangement.

Copyright 2026, James M. Atkinson

LOADED VOLTAGE: The terminal voltage under a declared connected load. Antenna factors and voltage-to-power conversions must use the compatible impedance and calibration convention. A nominal impedance label does not remove the need to state whether the calibration describes loaded voltage, open-circuit voltage, available power or delivered power.

NOISE PARAMETERS: A set of quantities used to describe how a device's noise behavior varies with source impedance under a specified model and reference plane. The cited vector-corrected method uses such characterization with measured reflections. Their role marks a boundary of the matched scalar cascade, whose simpler assumptions cannot silently supply them.

OPEN-CIRCUIT VOLTAGE: The terminal voltage defined with no load drawing current in the stated antenna or source model. It is not the same as the voltage across a specified receiver load. Applying a calibration intended for a loaded voltage to an open-circuit estimate can introduce a systematic conversion error.

OPTICAL ISOLATION COMPARISON: A controlled comparison in which an optical link removes a particular conductive path while its own gain, noise, bandwidth, timing and power state are characterized. Disappearance of a weak feature is inconclusive if the replacement lacks adequate sensitivity. A preserved desired reference makes the comparison more informative but does not identify every mechanism uniquely.

PATH CORRECTION: Measured gain or loss assigned to a specific serialized signal path and state.

Copyright 2026, James M. Atkinson

POLARIZATION COUPLING: The dependence of antenna response on the relationship between incident-field polarization and the antenna's receiving orientation. Rotation can change terminal level without a change in source strength. An installed comparison must therefore retain or deliberately vary orientation according to the stated measurement question.

REFERENCE PLANE: A named physical or modeled boundary at which a signal quantity, transfer or noise contribution is specified. Changing the reporting plane changes which downstream components belong to the correction. Two results must address compatible planes and quantities before their difference can be interpreted as improved measurement performance.

REMOTE PREAMPLIFIER: An active gain stage installed near the sensing element to reduce the effect of downstream cable loss and receiver noise. Its input is also exposed to signals throughout its admitted band. Gain, noise, blocker transfer, bias, protection and stability must therefore be assessed together in the installed arrangement.

RETURN LOSS: A logarithmic indication of reflection at a specified port and reference impedance, conventionally larger for a smaller reflected fraction. Improved matching can reduce some reflection effects, but an attenuator used to obtain it also lowers desired signal and adds thermal noise. The full measurement consequence must therefore be evaluated.

REVERSE ISOLATION: The limitation on signal transfer from a device's output side back toward its input under stated conditions. In a remote receiving assembly, insufficient isolation can allow downstream leakage to propagate toward the antenna. A forward-gain measurement alone does not establish this reverse-path behavior.

Copyright 2026, James M. Atkinson

SCALAR CASCADE: Ordered power-transfer and noise model with one effective channel per stage and explicitly bounded matching, state, and correlation assumptions.

SOURCE-IMPEDANCE DEPENDENCE: The change in a receiver's transfer or added-noise response when the impedance driving its input changes. Mismatch can therefore affect both delivered source power and the receiver contribution. A single scalar loss adjustment may be inadequate when the required noise-measurement accuracy depends on this interaction.

SPLITTER ISOLATION: The degree to which a signal or load change at one splitter branch is prevented from affecting another under stated port conditions. Finite isolation and coupled output loads can make unused branches consequential. Selected-path gain alone does not establish the behavior of the complete multiport assembly.

STATE RECORD: The record of the switch, gain, attenuation, bias, temperature and receiver settings relevant to an observation. It connects an assembled path to the transfer and noise behavior applicable at that time. Physical component identities alone cannot establish this state, especially across switching, warmup or remote-control transitions.

SUPPLY-PATH CONFOUNDING: Ambiguity introduced when a power-source comparison changes more than the noise on the supply. Replacing a supply with a battery can also alter conductive coupling and grounding. A changed receiver indication supports sensitivity to the intervention, but a more selective test is needed to identify which changed mechanism caused it.

Copyright 2026, James M. Atkinson

SWITCH LEAKAGE: Signal coupling through a nominally unselected switch path under specified conditions. A strong signal on an unused branch may remain observable despite selection of another branch. The switch state, port terminations and relevant isolation must therefore be included in the path model and acceptance record.

TERMINATED-INPUT TEST: An observation made with a specified load replacing the usual input source or antenna. It can constrain hypotheses about pickup, leakage or instability, but it also changes the source impedance and installed coupling. The comparison must retain the detection capability and operating conditions needed by the question.

UNUSED-PORT TERMINATION: Load condition at a nonselected network port that can affect leakage, matching, or coupling into the selected path.

VECTOR NOISE CORRECTION: A noise-measurement treatment that retains the relevant impedance and receiver-noise relationships rather than reducing all mismatch effects to one scalar loss. The cited method separates delivered source power from changes in receiver response. Applying such a method requires its additional characterization; citing it does not make that information available for an unmeasured assembly.

Teddington: National Physical Laboratory, December 2004. https://www.npl.co.uk/getmedia/24ef3e37-7c5f-40e6-84c9-4ad159e058f9/gpg73_antennas.pdf.

Annotation. Introduction and sections 3.3, 4.1 and 9.10, printed pages 2, 9, 11–13 and 64. The cited antenna, mounting, feed-cable, coupling and use-uncertainty limitations support the distinction between calibration and installation. Historical EMC geometries, standards references and numerical examples are not asserted as current universal survey requirements. This measurement guide places antenna calibration in the context of the test environment, mounting geometry, cable paths and frequency-dependent response. A receiver comparison should track antenna factors, mismatch and phase-centre conventions at the declared reference plane rather than regard an antenna reading as a direct field value. Any extrapolation from laboratory calibration to a different installation requires documented geometry and uncertainty. In this chapter the citation should be read against the local receiver model and the expressly defined quantities, not as a general endorsement of every design choice.

Annotation. Sections II–IV and equations (1)–(7), printed pages 2253–2256. The four-page NIST-hosted scan supports the distinction between mismatch effects on delivered source power and on receiver gain/noise response. The chapter cites the vector method to identify the boundary of Model 2B’s matched scalar approximation; it does not claim the additional receiver parameters were measured for an unspecified installation. The cited work treats receiver noise as a gain- and bandwidth-dependent measurement problem, including equivalent input noise or cascaded stages. Input and output reference planes, source temperature, impedance match, receiver gain and effective detector bandwidth must all be stated. Noise-figure figures from a particular test setup do not establish minimum detectable signals or calibrated sensitivity in every field installation. Its use here is bounded by the physical reference plane, implementation version and the evidentiary proposition being tested.

Chapter 14. Calibration, Gain, Amplitude and Phase Accuracy, Noise Figure, and Uncertainty

Copyright 2026, James M. Atkinson

14.1 Calibration Model and Traceability

Calibration relates receiver indication to reference quantities under stated configurations. It does not certify every possible frequency, level, bandwidth, detector, gain, modulation, or environmental condition. A calibration certificate should identify the instrument, option set, firmware where relevant, standards, methods, results, uncertainties, and dates. The practitioner determines whether the intended measurement lies within that scope.[1]

Traceability is a documented chain of comparisons with stated uncertainties, not a label attached to an instrument. External cables, filters, preamplifiers, antennas, digitizers, and software corrections extend the measurement chain beyond the calibrated receiver. Their characterization and stability must be included. A field check with a known source verifies present function but does not replace a full calibration.

1 United States Navy, Navy Electricity and Electronics Training Series, Module 17: Radio-Frequency Communications Principles, NAVEDTRA 14189 (September 1998), 2-10–2-14, reproduced in SIGINTRADARTSCM.pdf, compilation pages 8388–8392; title and edition at page 8345. These passages establish receiver functions and superheterodyne IF and detection architecture. The complete configuration and evidence boundary in this paragraph is the author's synthesis, developed through Chapters 2–16; the historical training source does not certify a modern instrument or legal conclusion.

Copyright 2026, James M. Atkinson

14.2 Attach calibration to a stated measurement result

A calibration plan begins with the quantity to be reported. Receiver-terminal power, antenna-terminal power, field strength, carrier frequency, relative channel phase, noise figure, and detection probability require different evidence. They may share hardware and reference standards, but they do not share one universal correction. Write the measurement equation first, identify the inputs that materially affect it, and then select the calibrations and checks that support those inputs. This order prevents a collection of certificates from being mistaken for a complete argument about the final result.

The VIM defines calibration through the relation between standards, indications, and their uncertainties, and distinguishes it from adjustment and verification. It defines metrological traceability as a property of a result supported by a documented calibration chain, with uncertainty contributed along that chain. It also cautions that traceability alone does not ensure adequate uncertainty or freedom from mistakes. These distinctions are directly relevant to a receiver whose calibrated components may be used in an unverified assembly.[2]

A calibration scope should therefore be read as a set of conditions. Identify the instrument serial, options, firmware or processing version where relevant, frequency range, level range, gain and attenuation states,

---

2 Joint Committee for Guides in Metrology, International vocabulary of metrology: Basic and general concepts and associated terms, VIM3 online edition, entries 2.48, 2.49 and 2.53, https://jcgm.bipm.org/vim/en/2.48.html, https://jcgm.bipm.org/vim/en/2.49.html and https://jcgm.bipm.org/vim/en/2.53.html, read November 2, 2026. These entries support the measurement-model, measurement-function and correction distinctions. Model 1A and its synthetic cases are independently developed here.

Copyright 2026, James M. Atkinson

bandwidths, detector or data reduction, reference planes, and environmental limits. Determine which corrections are already applied by the instrument and which remain external. A certificate can be entirely valid while omitting the particular state used in a survey. In that case, characterize the missing state or narrow the reported claim; do not imply coverage by association.

Traceability records and configuration records answer complementary questions. The first links numerical values to references and uncertainties. The second establishes which values belong to the observation. A precisely calibrated cable correction applied to the wrong cable is a configuration error, not a small uncertainty contribution to be hidden in a budget. Likewise, a software sign error can invalidate a corrected level even when every calibration input is excellent. Independent recomputation of a small set of representative records is a useful way to reveal such implementation mistakes.

Copyright 2026, James M. Atkinson

A. An illustrative 50-Ω receiver chain

Reference plane: the antenna terminals, not the receiver display.

B. Corrections and uncertainty

$$P_{antenna} = P_{meter} + L_{cable} - G_{LNA}$$

$$= -110 + 3 - 20 = -127\,\text{dBm}$$

$$u_c = \sqrt{0.5^2 + 0.2^2 + 0.4^2} = 0.67\,\text{dB}$$

C. Traceability checks

Preserve frequency, attenuation, gain state, uncertainty and calibration dates.

The uncertainty example assumes uncorrelated standard uncertainties in dB; correlation and systematic effects require separate treatment.

Figure 74. Calibrated receiver reference plane.

14.3 Amplitude Response and Linearity

Amplitude calibration covers frequency response, input attenuation, preamplifier gain, reference level, detector, IF bandwidth, impedance, and display scaling. Measurements at one level do not prove linearity across the range. Verification uses multiple levels and frequencies, including points near band boundaries and gain-state transitions. The source path and power sensor must have better or independently understood accuracy.

Mismatch introduces frequency-dependent error through reflections among source, cable, accessories, and receiver. Adding attenuation can improve match while changing noise and level. Vector correction may be necessary for high-accuracy work. At low levels, noise and detector statistics dominate; at high levels, compression and intermodulation dominate. The uncertainty model should change accordingly.

14.4 Build a correction chain with signs that can be checked

Use the level-transfer relation in Equation 26 to move a measurement to an earlier plane. Loss is added when referring a downstream reading backward, and gain is subtracted. This sign rule follows from the physical forward path. It should be verified by predicting a downstream reading from a known upstream reference, then reversing the calculation. The forward check is particularly useful when a correction file mixes positive loss entries with signed gain entries or when instrument software already applies one of the corrections.

Consider a constructed conducted measurement at 915 MHz. The raw receiver indication is −72.60 dBm. The receiver's residual amplitude correction is +0.20 dB. Ahead of it are a 2.40 dB cable loss, a 17.80 dB external amplifier gain, and a 1.10 dB input-filter loss, all defined for the selected assembly and frequency. Referring the result to the filter input gives $-72.60+0.20+2.40-17.80+1.10$, or −86.70 dBm. The same model predicts a receiver-plane power of −72.40 dBm from that upstream value, agreeing with the corrected indication.

This example is a calculation record, not an actual calibrated result. A real record would need the measured values and uncertainty statements for those exact components, evidence that the receiver and amplifier were linear at the applied levels, and the matching or mismatch treatment appropriate to the interfaces. A filter or amplifier measured at another bias, temperature, or switch state may require a different correction. When a correction is interpolated between calibration frequencies, the interpolation

Copyright 2026, James M. Atkinson

method and any unresolved response structure belong in the measurement model.

Calibrate amplitude over the level range that matters, not only at a convenient strong reference. A level sequence can reveal compression near the upper end and noise or detector bias near the lower end. Repeat relevant points across attenuator and preamplifier transitions. The desired outcome is a response whose residual behavior is understood within the claimed range. A straight line fitted across a compressed region can produce small average residuals while misrepresenting the weak-signal and strong-signal endpoints. Retain the individual observations and the rationale for the accepted range.

Copyright 2026, James M. Atkinson

14.5 Frequency and Phase Calibration

Frequency calibration compares receiver tuning or measured components with a reference whose uncertainty and stability are known over the observation interval. Phase calibration includes channel delay, filter response, cable phase, converter phase, clock alignment, and any phase resets. A receiver can have accurate average frequency while losing deterministic phase after each retune or trigger.

Multichannel phase calibration is performed over frequency and repeated after cable or configuration changes. Phase unwrapping, interpolation, and reference-plane movement are documented. A single calibration tone cannot establish broadband group delay or phase matching. When only relative phase is required, the reference and stability requirement are stated explicitly.

Copyright 2026, James M. Atkinson

14.6 Frequency, phase, and delay require their own observables

Frequency calibration concerns the relation between an observed frequency and an appropriate reference over a stated interval. The reference's calibration, stability, distribution path, and the receiver's estimation process can all matter. A reference input labeled as locked establishes a state indication; it does not alone quantify the residual error of a measured carrier. Compare a known signal using the actual observation duration and estimator, and retain the reference source and timing conditions. If the reference is shared by source and receiver, identify the errors that cancel and those that remain common.

Phase calibration has a different scope. Relative phase between channels requires a defined simultaneous input relationship and a repeatable reference plane for each channel. Cable delay, filter phase, conversion phase, and digitizer alignment all contribute. A single tone tests the phase relation at one frequency. It cannot establish broadband delay or distinguish all phase ambiguities. A frequency-dependent characterization is needed when a waveform spans a band, and the analysis must preserve the phase-unwrapping and interpolation conventions used to obtain the correction.

A receiver may return to the same amplitude after a retune while its conversion phase changes. Triggering, reference reacquisition, sample-rate changes, or a reset can likewise alter the relationship between records. Test repeatability across the actual operations that precede a measurement. If only within-record phase is reproducible, state that limit and avoid treating separately acquired records as a single coherent observation. Chapter 12

Copyright 2026, James M. Atkinson

develops timing and coherence in detail; the calibration record here identifies the state changes for which its corrections have been demonstrated.

Separate instrument delay from an event's arrival time. A known signal introduced at the receiver connector tests a different path from a signal introduced at an antenna or remote converter. Moving a timing reference plane requires accounting for the intervening path and its uncertainty. If that path can change with temperature or routing, a one-time correction has a limited scope. A time stamp in a file is useful only with its relation to the sampled signal, trigger, and reference clock documented well enough for the intended comparison.

Copyright 2026, James M. Atkinson

14.7 Noise Figure and System Sensitivity Calibration

Noise-figure calibration requires a known noise source or alternative method, stable bandwidth and gain, and linear response. Loss between the source and receiver is corrected at the reference plane. A preamplifier, switch, or filter changes the cascade and may require a new system measurement. Noise-source excess-noise ratio and receiver hot/cold readings contribute to uncertainty.

System sensitivity verification can use a calibrated coherent signal at several levels and detection statistics. This approach tests the complete path and decision rule, although it does not by itself separate noise contributions. In field configurations, a portable reference source and coupler can reveal drift or wrong correction files. The test must be arranged so that the reference does not radiate outside the controlled path or mask the environmental measurement.

Copyright 2026, James M. Atkinson

14.8 Calibrate noise without confusing it with detection

Applications 2B.8 through 2B.10 show the entire scalar hot/cold calculation, a gain-state failure, and a local uncertainty propagation. A practical implementation should preserve the same structure. Record both output powers, not only the computed noise figure; retain the source temperatures at the receiver plane, the source calibration, and the loss corrections that produced those temperatures. This permits an independent calculation and reveals impossible ratios, incorrect logarithmic conversion, or a change in the assumed cold temperature.

A useful sequence includes enough repeated source states to reveal drift and switching behavior. Settling time should be established from the observed response rather than assumed from a software delay alone. A receiver that changes gain after the source switches invalidates the simple ratio even when it eventually settles. The measurement may still be possible with a more complete state-dependent model, but the equal-gain inversion cannot be used until its conditions are demonstrated. Check the highest noise-power state for compression, since the cold-state response can remain apparently normal.

Mismatch deserves a separate decision. If the hot and cold source impedances differ materially, their delivered powers and the receiver's noise response can differ as well. A matched attenuator may reduce this sensitivity at a noise cost; vector characterization may support a more complete correction. The choice depends on the target uncertainty and available characterization. The vector noise-temperature work cited in Chapter 13 establishes why both source and receiver mismatch can matter. It does not

Copyright 2026, James M. Atkinson

authorize applying a vector correction without the required measured parameters.

A sensitivity verification then asks a different question: whether the complete system and its decision rule detect the intended reference under stated conditions. Use a calibrated signal with defined waveform, duration, frequency, and level at the selected plane. Retain detections and misses, including the receiver's observation schedule. A noise-figure result helps explain performance, but it cannot substitute for this verification when acquisition timing, interference, modulation, or threshold behavior matters. Conversely, a successful detection trial does not uniquely identify the receiver's equivalent noise temperature.

Copyright 2026, James M. Atkinson

14.9 Uncertainty Budgets and Decision Rules

An uncertainty budget begins with a measurement model and identifies quantities that affect the result. Typical terms include calibration, frequency response, attenuator and preamplifier state, cable loss, antenna conversion, mismatch, detector statistics, repeatability, temperature, bandwidth, clock, geometry, and analysis. Sensitivity coefficients express how each input changes the measurand. Correlation is considered where terms share a calibration or physical mechanism.

Expanded uncertainty and coverage factor are reported with the result when appropriate. Detection and compliance decisions may use guard bands so that uncertainty near a limit is not ignored. A result can be indeterminate rather than forced into pass or fail. The report distinguishes measured value, correction, standard uncertainty, expanded uncertainty, decision rule, and residual limitations.

Copyright 2026, James M. Atkinson

14.10 Use covariance and model sensitivity deliberately

Equation 27 expresses a first-order uncertainty propagation. Its sensitivity coefficients carry the signs and units of the measurement function; they are not always one. The JCGM guidance distinguishes uncorrelated inputs from inputs sharing a calibration or influence, and requires significant covariance to be retained. Common influences can alternatively be represented as explicit inputs to the measurement function. This is useful because a shared error may cancel in a difference but reinforce in a sum. The signs come from the model, not from a preference for a larger or smaller reported uncertainty.[3]

Return to the constructed −86.70 dBm correction chain. Assign standard uncertainties of 0.12 dB to the indication, 0.20 dB to the residual receiver correction, 0.10 dB to the cable loss, 0.18 dB to the amplifier gain, and 0.08 dB to the filter loss. With zero covariances, the variance is $0.0144 + 0.0400 + 0.0100 + 0.0324 + 0.0064$ equal to 0.1032 square decibel, giving 0.321 dB combined standard uncertainty. The amplifier coefficient is minus one; its squared contribution is still positive.

Now stipulate, for a second version of the same constructed budget, a correlation coefficient of +0.60 between the residual receiver correction and the measured amplifier gain. Their standard uncertainties remain 0.20 and 0.18 dB. Because their coefficients have opposite signs, the covariance term

3 Barry N. Taylor and Chris E. Kuyatt, Guidelines for Evaluating and Expressing the Uncertainty of NIST Measurement Results, NIST Technical Note 1297, 1994 edition (September 1994), Appendix A, A.1–A.5, https://www.nist.gov/pml/nist-technical-note-1297/nist-tn-1297-appendix-law-propagation-uncertainty. The functional and covariance framework is used within its stated scope; the synthetic ranges, examples and recoverability conclusions are original.

Copyright 2026, James M. Atkinson

is −2 times 0.20 times 0.18 times 0.60, or −0.0432 square decibel. The total variance becomes 0.0600 square decibel and the standard uncertainty becomes 0.245 dB. This reduction is justified only if that positive correlation is supported by the actual calibration model or evidence. Choosing a favorable correlation without support is not uncertainty evaluation.

The numerical example also shows why a budget should not count a common reference uncertainty twice as independent while separately adding a covariance for it. Either represent the common reference explicitly in the measurement equation or use a consistent covariance matrix for the derived inputs. Inspect whether the same correction has already been included in an instrument specification or calibration statement. A complete-looking table can otherwise exaggerate or understate the result through double counting, even when every individual number has a legitimate source.

NIST's uncertainty guidance emphasizes that the measurement function must represent the measurement process, including significant corrections and influences. It also distinguishes uncertainty in an applied correction from the error that the correction addresses. For this receiver case, known significant offsets should be corrected with their uncertainty retained. Enlarging an uncertainty interval to conceal an unapplied correction would make the reported central value less informative and could change a decision near a limit.[4]

Randa, Uncertainties in NIST Noise-Temperature Measurements, NIST Technical Note 1502 (March 1998), §§3.9–3.10, 16–17, https://nvlpubs.nist.gov/nistpubs/Legacy/TN/nbstechnicalnote1502.pdf. These sources distinguish receiver noise from source and path contributions; the scalar assumptions and

Copyright 2026, James M. Atkinson

First-order propagation needs a local adequacy check. In Application 2B.10, the inversion is evaluated well away from Y equal to one, and the stipulated uncertainties are small enough to motivate a local calculation. Near the singular boundary, symmetric input uncertainty can produce a strongly asymmetric output distribution. Use an appropriate nonlinear propagation method when the linear approximation does not represent the problem, and state the input distributions and dependencies that method requires. A simulation can propagate assumptions accurately while the assumptions themselves remain unsupported.

synthetic cases are stated in Model 2B.

14.11 Declare the decision rule before seeing the result

Expanded uncertainty adds a coverage convention to the standard uncertainty, as Equation 28 states. A factor of two is often convenient, but its interpretation depends on the output distribution and the uncertainty estimate. NIST's guidance gives the approximately normal, adequately known standard-uncertainty case in which it corresponds to about 95 percent coverage. Report the factor and the basis for its use. A coverage statement for a measured level is also distinct from a false-alarm or detection probability for a search procedure.[5]

5 H. T. Friis, “Noise Figures of Radio Receivers,” Proceedings of the IRE 32, no. 7 (July 1944): 419–22, https://doi.org/10.1109/JRPROC.1944.232049. The publisher’s abstract was read for the historical network, component, mismatch, and measurement framing. The full paper was not accessed; Model 2B supplies its own stated derivation and working conventions.

Copyright 2026, James M. Atkinson

A defensible decision rule names the measurand, uncertainty, coverage assumptions and consequences of a false acceptance.

Figure 76. Uncertainty guard bands and acceptance risk.

For a constructed decision example, let the upper permitted input level be −86.50 dBm. Predeclare three outcomes: accept when the interval's upper end is no greater than the limit, reject when its lower end is greater than the limit, and otherwise report indeterminate. Using the correlated budget

Copyright 2026, James M. Atkinson

above with an illustrative factor of two gives −86.70 dBm with an expanded uncertainty of about 0.49 dB. Its upper end is −86.21 dBm, so the result does not meet the acceptance condition even though the central value is below the limit. The interval overlaps the limit; the stipulated rule yields an indeterminate outcome, not evidence that the actual level necessarily exceeds the limit.

The response to an indeterminate result should follow the measurement purpose. A better characterized path, a more suitable reference, or repeated observations addressing the dominant random contribution may reduce uncertainty. Repeating the same measurements does not reduce an unchanged calibration uncertainty, and moving the limit after observing the result defeats the declared decision rule. Retain the original result and the reason for any additional measurement. If a different rule is adopted for a later decision, identify it as a different rule rather than rewriting the earlier outcome.

Copyright 2026, James M. Atkinson

14.12 Calibration Lifecycle and Change Control

Calibration intervals are determined by stability, use, transport, environment, repair history, measurement consequence, and observed drift rather than by calendar alone. Intermediate checks use independent references selected to reveal likely failures in frequency, amplitude, attenuation, noise, phase, and sample continuity. A failed check quarantines affected data back to the last valid verification unless evidence supports a narrower interval.

Correction files and calibration constants are controlled as configuration items. Their version, serial applicability, units, interpolation, uncertainty, and software implementation are reviewed before use. A firmware update, option change, repair, or accessory replacement can invalidate prior corrections even when the receiver passes a basic self-test.

Copyright 2026, James M. Atkinson

14.13 Quantitative Model for Calibration, Gain, Amplitude and Phase Accuracy, Noise Figure, and Uncertainty

Equation 1. Combined standard uncertainty

$$u_c(y)=\sqrt{\sum_i (c_i u_i)^2+2\sum_{i<j} c_i c_j u_i u_j r_{ij}}$$

Combined standard uncertainty u_c includes sensitivity coefficients c_i, input standard uncertainties u_i, and correlation coefficients r_{ij}. The model should reflect the actual measurement equation and distributions.

Equation 2. Expanded uncertainty

$$U=k_{\mathrm{cov}} u_c$$

Expanded uncertainty U equals combined standard uncertainty u_c multiplied by coverage factor k_{cov} selected for the stated coverage convention and effective degrees of freedom. The factor should not be assumed without justification.

Model 14B below distinguishes exact affine covariance propagation from the local approximation represented by Equation 27 and links ten worked applications of that same relation. Equation 28 adds a declared coverage factor; it does not independently establish a coverage probability or an acceptance decision.

Copyright 2026, James M. Atkinson

14.14 Model 14B: exact covariance and local uncertainty propagation

Copyright 2026, James M. Atkinson

B. Exact affine two-input propagation

$$u_c^2 = u_1^2 + u_2^2 + 2\rho u_1 u_2$$

Same marginal uncertainties, different covariance, different result.

Shared standards and common calibration chains can produce correlated errors. Root-sum-square is valid only after relevant covariances are justified as negligible; sign conventions in the measurement function matter.

Figure 77. Correlated uncertainty in two-term corrections.

The uncertainty law in Equation 27 connects the preceding calibration cases. Its domain deserves the same care as a receiver gain or noise model. Let X be a finite vector of real input quantities, with finite second moments, mean vector μ, and covariance matrix Σ. Each component retains its own unit. A superscript T denotes transpose. The covariance entry Σ_{ij} has the product of

Copyright 2026, James M. Atkinson

the units of X_i and X_j. A physically admissible covariance matrix is symmetric and positive semidefinite; independently plausible pairwise correlations do not by themselves guarantee that a whole proposed matrix is admissible. The effect of covariance is illustrated in Figure 63.

For an affine measurement function $Y = a + c^{\mathrm{T}} X$, the constant a has the output unit and each coefficient c_i has the output unit divided by the corresponding input unit. Subtract the mean and expand the square of c^{T}\($X - \mu$ \). Linearity of expectation yields Equation 27A exactly. Independence and a normal distribution are unnecessary. Zero covariance removes a cross term, while a shared input can cancel or reinforce according to its signed coefficients.[6]

Equation 27A. Exact affine mean and covariance

$$Y = a + c^{\mathrm{T}} X, \mathrm{E}[Y] = a + c^{\mathrm{T}} \mu$$
$$\mathrm{Var}(Y) = c^{\mathrm{T}} \Sigma c$$

A nonlinear function g requires a different statement. At an input estimate x, use the gradient J, with component J_i equal to the partial derivative of g with respect to x_i. The linearized output is g\(x \)$+ J$\($X - x$ \), and its variance is $J \Sigma J^{\mathrm{T}}$. Treating that variance as the uncertainty of g\(X \) requires the neglected nonlinear remainder to be adequately small for the intended result. A derivative can vanish while curvature remains consequential.

6 International Electrotechnical Commission, CISPR 16-1-1:2019, Specification for Radio Disturbance and Immunity Measuring Apparatus and Methods, Part 1-1: Radio Disturbance and Immunity Measuring Apparatus: Measuring Apparatus, 5th ed. (May 22, 2019), official publication scope, https://webstore.iec.ch/en/publication/60774, checked November 1, 2026. The public scope identifies the 9 kHz–18 GHz apparatus range and EMI receivers and spectrum analyzers. No access to or clause-by-clause compliance review of the complete standard is claimed.

Copyright 2026, James M. Atkinson

Equations 27A and 27B therefore distinguish a mathematical identity from a local approximation.[7]

Equation 27B. Local nonlinear propagation

$$Y_{\text{lin}} = g(x) + J(X - x)$$
$$J_i = \frac{\partial g}{\partial x_i}, u_{\text{lin}}{}^2 = J \Sigma J^{\text{T}}$$

Standard uncertainty describes dispersion under the stated input information. It is not a maximum error bound. An expanded interval additionally needs the factor, distributional or coverage justification, and decision rule discussed earlier under “Declare the decision rule before seeing the result.” A calibration input does not become independent merely because it occupies a separate row of a budget, and repetition does not remove a common correction uncertainty. The examples below state such dependencies explicitly.

TECHNICAL INTERPRETATION

A symmetric input uncertainty may yield a skewed output interval after a nonlinear calibration. Linearized uncertainty may misdescribe coverage.

Figure 78. Nonlinear measurement-uncertainty propagation.

Copyright 2026, James M. Atkinson

14.14.1 Four worked applications already developed in the calibration chain

Application 14B.1 is the signed correction chain in “Build a correction chain with signs that can be checked” and its independent budget in “Use covariance and model sensitivity deliberately.” The five terms give −86.70 dBm; their squared standard-uncertainty contributions sum to 0.1032 dB^2, giving 0.321248 dB. This is exact affine propagation under the declared zero covariances. The negative amplifier coefficient changes the central correction sign while its individual variance contribution remains positive.

Application 14B.2 is the correlated version immediately following that budget. A +0.60 correlation between the +0.20 dB correction uncertainty and the subtracted 0.18 dB gain uncertainty contributes −0.0432 dB^2. The remaining 0.0600 dB^2 gives 0.244949 dB. The following decision example uses this same result. The covariance is an input to be supported by the calibration method, not a free adjustment chosen to obtain acceptance.

Application 14B.3 is the four-component RSS screen under this chapter’s hypothetical applied calculation. Its terms 0.35, 0.25, 0.20, and 0.15 dB give 0.2475 dB^2 and 0.497494 dB. The expanded value at the stipulated factor of two is 0.994987 dB. This simpler screening budget isolates independent additive contributions and rounding; the stated factor alone does not create a probability guarantee.

Application 14B.4 is Application 2B.10, “Propagate the local calibration uncertainty.” Equations 4N–4P retain the signs and units of the hot/cold inversion sensitivities. The displayed 266.54, 1.19, and 12.84 K^2 contributions give approximately 16.75 K, followed locally by 0.0921 dB noise-figure

Copyright 2026, James M. Atkinson

standard uncertainty. Unlike the preceding affine budgets, this calculation is local and can fail near the inversion's $Y = 1$ singularity. Its original inputs, derivation, and coverage limitation remain in Chapter 2.

Copyright 2026, James M. Atkinson

14.14.2 Worked applications with hypothetical inputs

Copyright 2026, James M. Atkinson

14.14.3 Application 14B.5: cancel a shared phase reference correctly

Two calibrated channels report phases of 34° and 11° on one explicitly unwrapped branch. Their difference is 23°. Stipulate mutually uncorrelated residual channel errors with standard uncertainties 0.30° and 0.40°, and an identical additive reference contribution with standard uncertainty 0.80° in both channels. Subtraction cancels that common input exactly. The remaining variance is \($0.30^2 + 0.40^2$ \) $\text{degree}^2 = 0.25\ \text{degree}^2$, and the standard uncertainty is 0.50°.

The same answer follows from the channel covariance matrix. Its diagonal entries are $0.30^2 + 0.80^2 = 0.73$ and $0.40^2 + 0.80^2 = 0.80$ degree squared, and the off-diagonal entry is $0.80^2 = 0.64$ degree squared. Applying coefficients +1 and −1 gives $0.73 + 0.80 - 2$ \(0.64 \) $= 0.25$. Treating the two marginal channel uncertainties as independent instead gives 1.23693°, which double counts the common contribution. Cancellation depends on the identical coupling and shared state; different reference paths or an unresolved phase branch invalidate that simplification.

Copyright 2026, James M. Atkinson

14.14.4 Application 14B.6: propagate phase-slope delay uncertainty

For a characterized constant-delay path, define Φ as phase at the lower frequency minus phase at the higher frequency, on the established unwrapped branch, in degrees. Let Δf be the positive frequency separation in hertz. Then $\tau = \frac{\Phi}{360\,\Delta f}$ in seconds. Stipulate $\Phi = 36.0^{\circ}$, $\Delta f = 100\ \text{MHz}$, standard uncertainties 0.20° and 10 kHz, and zero covariance. The delay estimate is 1.000 ns. The signed sensitivity coefficients are $\frac{1}{360\,\Delta f} \approx 2.77778 \times 10^{-11}\ \text{s/degree}$ and $-\frac{\Phi}{360\,\backslash(\Delta f\,\backslash)^2} = -1.00000 \times 10^{-17}\ \text{s/Hz}$.

Equation 27C. Local uncertainty of an unwrapped phase-slope delay

$$c_{\Phi} = \frac{1}{360\,\Delta f},\ c_{\Delta f} = -\frac{\Phi}{360\,(\Delta f)^2}$$

$$u_{\tau}^{2} \approx c_{\Phi}^{2} u_{\Phi}^{2} + c_{\Delta f}^{2} u_{\Delta f}^{2} + 2\,c_{\Phi}\,c_{\Delta f}\,\mathrm{Cov}(\Phi, \Delta f)$$

The uncertainty contributions before squaring are +5.55556 ps and −0.10000 ps. Their squared sum gives a standard uncertainty of 5.55646 ps. The frequency-separation relative standard uncertainty is only 0.0001 in this constructed case, supporting a local denominator approximation; the phase-to-delay map is already linear in Φ. Neither the calculation nor a small result chooses the phase branch, proves a constant delay across a wider band, or establishes the receiver’s phase-repeatability after retuning. Those conditions require the timing checks developed in Chapter 12.

Copyright 2026, James M. Atkinson

14.14.5 Application 14B.7: retain endpoint covariance in a correction interpolation

A correction file has values of +0.60 and +1.00 dB at adjacent frequencies. At a fixed fractional position $w = 0.25$ between them, linear interpolation gives $[0.75 \backslash (0.60 \backslash) + 0.25 \backslash (1.00 \backslash)]\ \mathrm{dB} = +0.70\ \mathrm{dB}$. Stipulate endpoint standard uncertainties 0.15 and 0.20 dB, correlation +0.40, and a separately characterized zero-mean interpolation residual with standard uncertainty 0.08 dB, uncorrelated with both endpoints. Denote the resulting correction by C, the endpoint standard uncertainties by u_0 and u_1, their correlation by r, and the residual standard uncertainty by u_{res}. The residual represents imperfect interpolation of the physical response; the formula alone does not establish its size.

Equation 27D. Correlated interpolation with a separate response residual

$$u_C{}^2 = (1-w)^2 u_0{}^2 + w^2 u_1{}^2 + 2\,w\,(1-w)\,r\,u_0 u_1 + u_{\mathrm{res}}{}^2$$

The two endpoint variance terms are 0.01265625 and 0.00250000 dB². Their covariance contribution is +0.00450000 dB², so the endpoint-only standard uncertainty is 0.140201 dB. Adding $0.08^2\ \mathrm{dB}^2$ for the residual gives 0.02605625 dB² and 0.161419 dB. The result shows why endpoint uncertainty and response-model inadequacy answer different questions. A dense enough characterization or an independently supported smoothness bound is needed to justify the residual term. If w is uncertain or extrapolation is used, the measurement equation must include that changed condition.

Copyright 2026, James M. Atkinson

14.14.6 Application 14B.8: identify the uncertainty that averaging cannot remove

Let a corrected level be the arithmetic mean of n readings in dBm plus one common calibration correction. Stipulate independent zero-mean reading errors with standard deviation 0.40 dB and a zero-mean common correction uncertainty of 0.30 dB independent of those errors. Use σ_{rep} for the reading-error standard deviation and u_{cal} for the common calibration standard uncertainty. The calibration contribution is the same random input in every corrected reading. For $n=16$, a mean indication of −80.20 dBm and a +0.15 dB correction give −80.05 dBm.

Equation 27E. Mean variance with a common calibration contribution

$$\mathrm{Var}\left(Y_{\mathrm{mean}}\right)=u_{\mathrm{cal}}{}^{2}+\frac{\sigma_{\mathrm{rep}}{}^{2}}{n}$$

The variance is \(0.30^2+\frac{0.40^2}{16} \) $\mathrm{dB}^2=0.1000\ \mathrm{dB}^2$, so the standard uncertainty is 0.316228 dB. Increasing the count to 64 gives 0.0925 dB² and 0.304138 dB. As the positive integer n grows, the standard uncertainty approaches 0.30 dB. The same result follows from a full reading covariance matrix: distinct corrected readings share covariance 0.09 dB². Averaging removes neither that common term nor an unrecognized bias. Correlated reading errors, drifting corrections, or averaging powers before logarithmic conversion require a different model; Chapter 8 distinguishes the last operation from a mean of levels.

Copyright 2026, James M. Atkinson

14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm

Under the fixed-transfer and additive-power conditions of Model 11B, suppose paired on-state and off-state estimates are 1.30 and 1.00 nW. Their standard uncertainties u_{on} and u_{off} are 0.04 and 0.03 nW, with correlation +0.80 justified here by an explicit constructed joint law. Let Z_1 and Z_2 be independent uniform variables on $[-\sqrt{3}, \sqrt{3}]$, each with zero mean and unit variance. Set the off estimate to $\backslash(1.00 + 0.030\, Z_1 \backslash)\ \text{nW}$ and the on estimate to $\backslash(1.30 + 0.032\, Z_1 + 0.024\, Z_2 \backslash)\ \text{nW}$. These definitions give the stated variances and covariance 0.00096 nW².

Equation 27F. Exact power-difference variance and local logarithmic sensitivity

$$D = P_{\text{on}} - P_{\text{off}}, u_D{}^2 = u_{\text{on}}{}^2 + u_{\text{off}}{}^2 - 2\,\text{Cov}\left(P_{\text{on}}, P_{\text{off}}\right)$$

$$L_{\text{dBm}} = 10 \log_{10}\left(\frac{D}{1\ \text{mW}}\right), \frac{\partial L}{\partial D} = \frac{10}{\ln(10)\, D}$$

The estimated additional power is 0.300 nW. Its exact affine variance is $[0.04^2 + 0.03^2 - 2\backslash(0.00096\backslash)]\ \text{nW}^2 = 0.00058\ \text{nW}^2$, giving 0.0240832 nW standard uncertainty. More strongly, its complete stipulated support is $[0.300 \pm \sqrt{3}\backslash(0.002 + 0.024\backslash)]\ \text{nW}$, with approximate endpoints [0.254967, 0.345033] nW. Every value is positive, so a logarithmic transform is defined throughout this particular input domain. That property comes from the joint law, not merely from the positive central estimate.

Converting 0.300 nW to dBm gives −65.228787 dBm. The local logarithmic coefficient is $\frac{10}{\ln\backslash(10\backslash) \times 0.300}\ \text{dB/nW} \approx 14.476483\ \text{dB/nW}$, giving approximately 0.348640 dB standard uncertainty. This is a local propagation, not the exact standard deviation of the transformed distribution. The exact transformed

Copyright 2026, James M. Atkinson

support has approximate endpoints [−65.935166, −64.621390] dBm and is asymmetric around the transformed central value. No coverage probability is assigned to a multiple of the local standard uncertainty. If a different on/off budget admits zero or negative differences, this logarithmic result cannot be carried across that boundary; retain the linear difference and resolve its interpretation first.

Copyright 2026, James M. Atkinson

14.14.8 Application 14B.10: expose a zero-sensitivity failure of the local law

Consider the static power quantity $P=\frac{X^2}{R}$ for an exactly known positive resistance $R=50\ \Omega$. Stipulate a Gaussian voltage quantity X with mean μ and standard deviation $\sigma=1.00\ \mathrm{mV}$. This is an uncertainty example for a nonlinear transformation, not a specification of a temporal noise process. Write $X=\mu+\varepsilon$, where the Gaussian centered moments are $\mathrm{E}[\varepsilon]=0$, $\mathrm{E}[\varepsilon^2]=\sigma^2$, $\mathrm{E}[\varepsilon^3]=0$, and $\mathrm{E}[\varepsilon^4]=3\sigma^4$. Expanding X^2 and X^4 gives the exact mean and variance in Equation 27G.

Equation 27G. Exact squared-Gaussian moments and the retained local term

$$\mathrm{E}[P]=\frac{\mu^2+\sigma^2}{R}$$
$$\mathrm{Var}(P)=\frac{4\mu^2\sigma^2+2\sigma^4}{R^2}$$
$$u_{\mathrm{lin}}{}^2=\left(\frac{2\mu}{R}\right)^2\sigma^2$$

At $\mu=10.0\ \mathrm{mV}$, evaluating the power function at the mean gives 2.000 μW, whereas the expected power is 2.020 μW. The local standard uncertainty is 0.400000 μW; the standard uncertainty from the exact model is approximately 0.400999 μW. The additional 0.020 μW mean shift and the small variance correction arise from curvature. Whether they may be neglected depends on the required result, not on the apparent precision of the input estimate.

At $\mu=0$ with the same σ and R, the derivative $\frac{2\mu}{R}$ vanishes and first-order propagation returns zero. Yet the exact mean power is 20.0 nW and the

Copyright 2026, James M. Atkinson

exact model gives a standard deviation of approximately 28.2843 nW. The exact variance is $8.00 \times 10^{-16}\ \mathrm{W}^2$. This counterexample identifies the missing term rather than treating a zero derivative as a perfect measurement. A nonlinear expectation is generally different from the function evaluated at the input expectation. The same warning applies near receiver calibration singularities, physical boundaries, and strongly curved transformations.

Table 1. Chapter 14 receiver controls and interpretation limits

Control or quantity	Measurement or record	Interpretation value	Failure or limitation
Calibration scope	Instrument, options, firmware, ranges, bandwidths, methods, standards, and uncertainties	Defines where traceability applies	A valid certificate may not cover the selected configuration
Amplitude and linearity	Frequency points, levels, gain states, detector, match, and compression check	Supports corrected power or voltage	One-level calibration does not establish linearity
Phase and timing	Reference, channel delay, filters, cables, retune state, and repeatability	Supports coherence, delay, and DF measurements	A narrowband tone cannot define broadband phase
Uncertainty and rule	Model, inputs, distributions, correlation, coverage, guard band, and decision	Makes the conclusion quantitatively reviewable	A point result near a limit can be indeterminate

Copyright 2026, James M. Atkinson

14.15 Hypothetical Applied Calculation: Calibration, Gain, Amplitude and Phase Accuracy, Noise Figure, and Uncertainty

A hypothetical corrected signal level is −82.4 dBm. Stipulate independent additive standard-uncertainty contributions of 0.35 dB calibration, 0.25 dB path correction, 0.20 dB repeatability, and 0.15 dB detector statistics. Their variance sum is $0.1225+0.0625+0.0400+0.0225\ \mathrm{dB}^2=0.2475\ \mathrm{dB}^2$, giving 0.497494 dB, or about 0.50 dB. An illustrative coverage factor of two gives 0.994987 dB, rounded to 1.0 dB, so the stated expanded result is −82.4 dBm ±1.0 dB. This is Application 14B.3. A 95 percent interpretation additionally requires a justified output distribution and uncertainty estimate; it does not follow from multiplication alone.

Copyright 2026, James M. Atkinson

14.16 Hypothetical Case Adjudication: Calibration, Gain, Amplitude and Phase Accuracy, Noise Figure, and Uncertainty

Two analyzers disagree by 2.8 dB on a weak signal. Review shows that one trace uses an external preamplifier correction measured at room temperature, while the outdoor preamplifier has warmed by 35 degrees Celsius and changed gain. A temperature-characterized correction reduces the difference to 0.6 dB, within the combined uncertainty.

Copyright 2026, James M. Atkinson

14.17 System-Level Vector Calibration and Uncertainty

Published experimental example. In a 2025 study, Kast and colleagues calibrated a 28 GHz VSA over a 160 MHz measurement band using a traceably characterized sampling oscilloscope. They derived complex corrections with a multisine and tested a 64-QAM waveform, carrying magnitude, phase, mismatch, cable, and repeatability contributions through a Monte Carlo calculation that retained correlations. The reported mean EVM decreased from about 3.2% to below 0.7% after calibration. Including calibration uncertainty also widened the distribution relative to the repeatability-only result.[8]

The experiment gives Models 7A and 14B a concrete calibration setting. Repeatability alone did not represent the full measurement uncertainty. The same oscilloscope served as calibration and comparison receiver, so agreement could retain common reference errors. The reported correction was linear and depended on the instrument state. For an installed survey chain, the corresponding questions are whether the reference, correction, covariance, and processing apply to that exact state, and whether a remaining nonlinear response has been separately bounded. The published result supports this method; it does not validate the hypothetical receiver configurations used elsewhere in this volume.

14.18 Close the calibration record across the working interval

The validity of a correction extends through a period and a configuration, not indefinitely through possession of a certificate. Identify changes that can alter the model: repair, firmware or processing changes, a replaced cable or adapter, a moved reference plane, a different gain state, or a changed remote power arrangement. The consequence may be a targeted recharacterization rather than a complete recalibration, but that choice requires evidence about which quantities changed. A self-test that checks internal function does not necessarily verify an external path or its correction file.

Intermediate references are most useful when they challenge likely failure modes independently. A reference that passes through the same incorrect correction file as the measurement may reproduce the error. Retain a raw comparison and an independent calculation at selected points. Before and after checks can bound a working interval, while checks after consequential changes can narrow the period affected by a failure. If a closing reference is inconsistent, preserve the affected data and investigate the last demonstrated valid state before assigning a correction retrospectively.

A complete release record links the raw observation, configuration, correction values, source certificates, uncertainty calculation, decision rule, and final reported result. For the constructed amplitude example, another analyst should be able to reproduce −86.70 dBm, identify why the amplifier term is subtracted, calculate either stated uncertainty case, and see why the conservative decision remains indeterminate. For a noise result, the same analyst should be able to reconstruct Y from the linear powers and check its

Copyright 2026, James M. Atkinson

physical domain. Reproducibility at that level is the practical connection between calibration and defensible receiver evidence.

Copyright 2026, James M. Atkinson

14.19 Nonlinear measurement models and defensible uncertainty intervals in RF metrology

Many receiver corrections are affine in logarithmic units only within a fixed physical model. Real metrological inference frequently contains nonlinear steps: inversion of a hot/cold noise ratio, correction of power near a zero-subtraction boundary, conversion from measured voltage to power, nonlinear phase unwrapping and geometrical inversion of timing differences into position. An expression for combined standard uncertainty obtained from first derivatives is a local approximation. When the measurement function has appreciable curvature over the uncertainty region, the output distribution can be asymmetric or can encounter a region where the inverse ceases to exist. The 2026 amendment to JCGM 100 explicitly addresses nonlinearity in measurement models; its applicability should be evaluated using the official text and a model-specific argument rather than inferred from the existence of a publication date alone.

A simple inverse example establishes the issue without relying on equipment-specific data. Let $z = 1/(Y - 1)$ for Y greater than one. At nominal $Y = 1.10$, $z = 10$. If Y is constrained instead to the interval [1.05, 1.15], then the exact transformed interval is approximately [6.667, 20], strongly asymmetric about ten. The first derivative at the central value is -100 per unit Y; multiplying it by a symmetric input half-width of 0.05 would suggest a local variation of five, producing [5,15], which does not enclose the true upper bound. The example shows that apparently prudent linear propagation can misrepresent an ill-conditioned inverse. It does not supply a probability

Copyright 2026, James M. Atkinson

distribution or an expanded uncertainty without additional assumptions about the input quantities.

A useful RF uncertainty dossier begins by specifying the measurand, actual observation state, all input variables, known dependencies, the validity domain and numerical processing. For compatible uncertainties, the first-order covariance propagation u_y squared = g transpose C g uses a vector g of sensitivities and a covariance matrix C, but may need nonlinear propagation or a distributional method where g changes substantially across the relevant region. An interval obtained from worst-case parameter bounds is not equivalent to a confidence or coverage interval. Conversely, a Monte Carlo distribution propagated through a model cannot repair an unmeasured amplifier state or a missing sample interval, because those are problems of missing physical evidence or model adequacy, not simply numerical propagation.

Documentation must preserve uncertainty from both laboratory calibration and field installation. Correlated corrections should not be double counted as independent contributions; several traces depending on the same cable calibration share part of their uncertainty. For a bounded source attribution, the final inference may be a set of physically compatible locations or receiver-origin hypotheses, not a single point estimate with a misleading number of digits. The report should distinguish conditional metrological uncertainty, alternative model structures and what was never observed. This is essential for claims whose legal or operational consequence exceeds the precision of the underlying receiver indication.

14.20 Nonlinear uncertainty propagation, model uncertainty and decision guard bands

The conventional first-order propagation formula is a local approximation to a measurement function, not a guarantee that all resulting uncertainty intervals are symmetric or well represented by one standard deviation. Consider a derived quantity y = f(x_1,...,x_n), with estimates x, covariance matrix U and gradient vector g of sensitivity coefficients. For sufficiently small input uncertainty over a region where f is adequately differentiable, u_y squared is approximately g transposed U g. A source-to-output physical model must still be valid: covariance propagation cannot rescue a frequency conversion with the wrong image branch, a clipped ADC record or an unspecified antenna calibration plane. Inverse models may also be ill conditioned, especially where two measured powers nearly cancel or where a denominator approaches zero. These limitations belong in the released uncertainty statement before any confidence percentage is supplied.

The 2026 JCGM amendment on nonlinear measurement models makes especially relevant the distinction between first-order estimates and methods that account for curvature. For an illustrative positive random quantity X with mean mu and variance sigma squared, the expectation of f(X) may differ from f(mu); the leading curvature correction is approximately one half f''(mu) sigma squared when the assumptions of a sufficiently local expansion apply. Such a correction is not a universal fix. Non-Gaussian, truncated or multimodal input distributions, discontinuous instrument-state changes and substantial model uncertainty may require direct numerical propagation or explicit feasible-set methods. One should document the

Copyright 2026, James M. Atkinson

chosen distribution, parameter dependence, sampling convergence, admissible domain and handling of physically impossible draws. A Monte Carlo output histogram is only as trustworthy as the input model supplied to it.

A numerical example illustrates asymmetric bounds. Suppose the calibrated measured power P is known only to lie between 9 and 11 arbitrary linear power units. Reported level is $L = 10 \log10(P/P_0)$, where $P_0 = 1$ power unit. The level interval is [9.5424, 10.4139] dB. The logarithm of the midpoint power is 10 dB, but the lower and upper deviations are -0.4576 and +0.4139 dB, respectively. The asymmetry is entirely due to the nonlinear transformation. It is not justified to convert a symmetric ±1-unit input bound into a symmetric dB interval without checking the transformation. Nor may the bounded result be described as a standard uncertainty or 95 per cent interval without further probability information.

Calibration terms shared across devices require covariance rather than independent root-sum-square bookkeeping. Two instruments calibrated by one reference source inherit some common amplitude error. Their difference can cancel a common offset, while their average retains it. If one estimates an absolute field level from their average and treats the shared calibration as independent, the uncertainty may appear to shrink artificially. If one estimates the difference and instead adds the shared error twice, the uncertainty may be overstated. The correct direction follows from explicit sensitivities with signed covariance terms. Repeated observations under an unchanged calibration state do not average away that shared component, and a more sophisticated numerical propagation method cannot substitute for correct dependency identification.

Copyright 2026, James M. Atkinson

Decision guard bands connect metrology to operational release. Suppose a receiver test requires a measured error not to exceed threshold T. With uncertainty around the reported error, treating every central estimate just below T as an unconditional pass can create unacceptable false acceptance. A guard-band rule can define an acceptance region strictly inside the tolerance, with risk treatment based on a stated distribution or conservative bound. The chosen decision rule is part of the intended claim: an interval overlapping the threshold may require retest or a qualified result rather than a forced pass/fail. The laboratory should state which quantities were corrected, which effects remained systematic or unmodelled, and the relationship between uncertainty and the acceptance criterion.

A complete uncertainty section should compare linear propagation, nonlinear numerical propagation and deterministic enclosure on the same synthetic examples, exposing where and why they disagree. It should not label a convenient output range as a standard uncertainty or infer a precise coverage probability from a coverage factor alone. Retain the measurement function, calibrated input datasets, dependencies and processing revision so that a later independent reviewer can reproduce the reported uncertainty, challenge one assumption and see how the final conclusion changes.

Copyright 2026, James M. Atkinson

14.21 Additional study: nonlinear metrology and decision uncertainty beyond first-order propagation

A calibration calculation is not necessarily a reliable measurement equation merely because each of its input quantities has an assigned uncertainty. Many RF reductions combine logarithms, ratios, positive-power differences, complex magnitudes, phase unwrapping and the inverse of a nonlinear transfer law. Such functions can be nearly linear over one operating region and badly conditioned near a boundary. The familiar first-order uncertainty formula is valuable when the local derivatives provide an adequate approximation over the plausible input range. It is not a universal guarantee that output uncertainty is symmetric, Gaussian or fully described by one standard deviation. Postgraduate receiver metrology must distinguish input uncertainty, measurement-model adequacy, computational approximation and decision consequences as separate questions.

Let the measurand Y be defined by a model $f(X_1, \ldots, X_n)$, where each X_i is an input quantity with declared units, estimates and relevant dependence. A first-order local approximation near x gives output variance $u_Y^2 \approx J\,U\,J^T$, with J the row vector of sensitivities $\partial f/\partial X_i$ and U the input covariance matrix. This is the full covariance form, not the simplified independent-input sum. It can be exact for an affine model with finite second moments even when inputs are non-Gaussian. For a nonlinear model it is a local approximation. It may perform poorly near a singularity, a discontinuous phase wrapper, the boundary of positive power or a decision threshold. Reporting the value of u_Y without examining the model's operating domain

Copyright 2026, James M. Atkinson

can give false assurance about the validity of the uncertainty calculation itself.

Consider a corrected level $y = p + l - g$, where p is the indicated dBm value, l is a passive loss in dB and g is an applicable gain in dB. This relation is affine in those logarithmic coordinates. When p, l and g have finite covariance under the stated model, the variance given by the signed sensitivities is exact: $var(y) = var(p)+var(l)+var(g)+2cov(p,l)-2cov(p,g)-2cov(l,g)$. Correlated calibration terms may cancel or reinforce one another according to their signs. Applying the same common gain correction to two measured levels can cancel that common uncertainty in their difference, but not in each absolute level. Conversely, treating a shared correction as independent on every occasion can understate or overstate the uncertainty of a derived comparison. The covariance structure is a statement about physical and documentary common causes, not a discretionary numerical adjustment.

Now consider a measured power difference $P_{sig} = P_{total} - P_{background}$, where both inputs are in watts. Its arithmetic difference is affine and may have a well-defined variance, yet the subsequent level $y = 10 \log10(P_{sig}/1\ mW)$ is nonlinear and defined only for positive P_{sig}. If the plausible difference includes zero or negative values, a standard uncertainty in dBm derived by evaluating a derivative at a small positive central difference can become enormous or misleading. A clipped negative difference set to an arbitrary epsilon before taking the logarithm does not create physical evidence of a weak positive signal. The appropriate result may be an upper bound, a one-sided interval, or an explicit inconclusive inference under a stated noise model. It cannot be repaired by reporting more digits in the logarithmic display.

Copyright 2026, James M. Atkinson

A similar issue arises when a phase measurement is represented by arg(z) for a complex phasor z. Far from the origin and with a well-separated phase distribution, a local approximation may be adequate. Near zero complex amplitude, phase becomes poorly identified, and the distribution of the estimated angle can become nearly uniform. The mathematical discontinuity at ±π radians is a representation convention, not necessarily a physical phase step. Unwrapping requires a validated continuity assumption; a pulse gap or lost samples can invalidate that assumption. Therefore amplitude and phase uncertainties should be evaluated jointly where both are used to infer time delay, channel coherence or direction. The corresponding covariance cannot be reconstructed from two independent error bars if the original complex observations have been discarded.

JCGM 100:2008 Amendment 1:2026 addresses nonlinearity in measurement models, while JCGM 101 describes propagation of distributions by Monte Carlo simulation. The published guidance supports considering higher-order terms or distribution propagation where local linearisation is inadequate; it does not certify a particular RF calibration simply because software draws a Monte Carlo histogram. The analyst must define the joint input distribution, including dependence, truncation and constraints, justify that description from calibration and measurement evidence, and ensure that the numerical algorithm reproduces the chosen function and its domain. A simulation with a million draws from an unjustified distribution is a precise computation of an unsupported model.

A suitable validation procedure begins with dimension and range checks. Confirm that logarithms act on dimensionless ratios, that positive physical powers are not represented by negative watts, and that calibration

Copyright 2026, James M. Atkinson

parameters refer to the actual receiver state. Next calculate the output with the nominal inputs, determine the local sensitivities, and inspect their variation over an interval supported by calibration. If the sensitivities change materially or the model has a nearby boundary, retain a more complete method. Propagation of distributions can then sample the joint input model, evaluate the actual nonlinear function, and report the output distribution or a suitable interval. Every rejected or undefined realisation must be counted and explained; silently discarding it will condition the result on a more favourable population.

A constructed example makes the issue concrete. Let total measured power be 2.00 ± 0.05 pW and background power be 1.90 ± 0.05 pW, with independent Gaussian measurement errors for this demonstration. The nominal difference is 0.10 pW. The standard uncertainty of the difference is $\mathrm{sqrt}(0.05^2+0.05^2) = 0.07071$ pW. Although the nominal ratio to its uncertainty is approximately 1.414, a substantial lower tail of the Gaussian difference model lies at or below zero. A normal cumulative approximation gives $P(P_sig \leq 0) \approx \Phi(-1.414) \approx 0.07865$. Thus a log-power calculation is undefined on approximately 7.9 percent of this stipulated input distribution. Reporting a symmetric dBm interval obtained by differentiating the logarithm at 0.10 pW would hide that domain failure. A physically more complete model could constrain the latent signal power and estimate it from the observations, but that requires explicit additional assumptions rather than clipping the observed difference.

A second synthetic example concerns two correlated level corrections. Let an indicated level have standard uncertainty 0.20 dB, a loss correction 0.15 dB and a gain correction 0.15 dB. Suppose the loss and gain corrections

Copyright 2026, James M. Atkinson

share calibration information with correlation coefficient +0.8, and the indication is independent of both. The output variance is $0.20^2 + 0.15^2 + 0.15^2 - 2(0.8)(0.15)(0.15) = 0.0490\ \text{dB}^2$, giving u_y = 0.22136 dB. A calculation that discards the covariance obtains sqrt(0.0850) = 0.29155 dB. The difference illustrates cancellation through opposite signs. If the same covariance entered two corrections with the same sensitivity sign, it would instead increase uncertainty. A claim of zero covariance requires evidence about shared instruments, common calibration data and processing, not the mere fact that inputs appear in separate spreadsheet cells.

A third example examines a nonlinearity that does not have a singularity. Suppose a detector amplitude calibration is locally $y = a\,x^2$ with a known positive coefficient a, x positive, and x is a normally distributed input with mean μ and standard deviation σ. The exact mean is $E[y] = a(\mu^2+\sigma^2)$, while a naive plug-in value gives $a\mu^2$. The difference $a\sigma^2$ is a second-order bias under this stipulated distribution. If μ = 2.0 V, σ = 0.2 V and a = 0.5 V^{-1}, the plug-in result is 2.00 V, whereas the exact expected output is 2.02 V. The first-order sensitivity is 2aμ = 2 in dimensionless output/input terms, so its predicted standard uncertainty is 0.40 V; the exact variance for Gaussian x is $a^2(4\mu^2\sigma^2+2\sigma^4)$, giving standard deviation approximately 0.400998 V. The central-value bias is small but real. Near smaller μ relative to σ the discrepancy grows, and a physically positive-only calibration input might require a truncated rather than unrestricted normal model.

Copyright 2026, James M. Atkinson

14.22 Decision rules, calibration applicability and publication evidence

A tolerance decision asks a different question from reporting an estimate. Suppose a device is acceptable only when a quantity lies below limit L. A measured estimate y with uncertainty does not by itself prescribe an acceptance probability or a guard band. The rule must identify which risk is being controlled, the distributional or bounded model used, and the consequence of false acceptance and false rejection. A guard band can reduce false acceptance at the expense of false rejection; this trade-off is not a universal numerical constant. When the calibration is used in forensic reporting rather than manufacturing conformity, a conclusion should additionally distinguish instrument performance assurance from attribution of a particular external signal.

A constructed guarded-decision illustration assumes a one-sided upper tolerance of 10.0 dB for an error quantity, a reported estimate of 9.6 dB, and a valid normally distributed standard uncertainty of 0.3 dB. The probability that the true error exceeds 10.0 dB under this assumed posterior-style normal model is $1-\Phi((10.0-9.6)/0.3)$, approximately 0.0912. This number is model-dependent and is not automatically a frequentist probability for a fixed unknown quantity merely because the uncertainty was labelled standard. If the adopted policy requires an estimated exceedance risk below 0.05 under the declared probabilistic model, this observation would not meet that policy. A different evidence model or calibrated guard band could change the decision. The method and chosen risk convention must be recorded before inspecting an attractive result.

Copyright 2026, James M. Atkinson

A second decision illustration avoids an invented probability distribution. Let the true response error be known only to lie within a deterministically bounded interval [9.1, 10.2] dB. A rule requiring error no greater than 10.0 dB cannot certify that requirement from these bounds because a valid endpoint exceeds the limit. It also cannot conclude definite nonconformity because a valid endpoint is below the limit. The appropriate category under an interval-only policy is indeterminate, unless an explicit decision rule authorises a different treatment of overlapping bounds. Assigning the midpoint 9.65 dB as an exact value or assuming a uniform distribution within the interval would introduce information not present in the bound.

Calibration applicability requires a state-space ledger. The measured system may change preselector, gain, detector, temperature, clock reference, sample rate or firmware. A correction derived under one combination may be transferable to another if its physical dependence and uncertainty have been demonstrated, but not merely because the instrument retains the same model number. A practical ledger lists the nominal model, the measurements supporting it, the operating range, applicable calibration files, software version, untested transitions, and any resulting invalid intervals. It also records whether corrections have already been embedded in an export. Applying a cable loss or gain correction twice is a bookkeeping failure that can remain invisible when all reported numbers have plausible units.

Finally, an independently reviewable uncertainty statement should retain the original observations, the exact measurement function, parameter estimates, covariance model or joint distribution, numerical code revision, simulation seed where relevant, rejected-realisation policy, and the interval

Copyright 2026, James M. Atkinson

or decision rule. Where a correction is subsequently revised, the original derived report should remain reproducible from the earlier input and code, while the new estimate receives its own version identity. Reproducibility does not by itself guarantee scientific correctness; it makes incorrect assumptions discoverable and enables their correction without erasing evidence. This is the standard by which an advanced receiver calibration becomes defensible rather than simply numerically elaborate.

Copyright 2026, James M. Atkinson

14.23 Advanced technical expansion. Nonlinear uncertainty propagation and decision risk

Uncertainty analysis must begin with an explicit measurement function, not a spreadsheet of convenient percentages. A scalar level correction may be approximately affine in decibels under a known linear path, but a frequency-dependent vector calibration, noise-temperature inversion or source-location estimate can be strongly nonlinear. Let the output vector y be computed from input quantities x by y = f(x); a first-order covariance approximation uses $J \Sigma_x J^T$, where J is the Jacobian of f evaluated at the stated input estimate. This formula is only as good as the local linear approximation and the input covariance matrix. It does not create a probability distribution or rescue a measurement equation whose physical state is invalid. The NIST Technical Note 1297 framework explicitly includes covariance among input quantities, and that dependence is essential when several corrections share the same calibration source or time reference.

An illustrative positive-power conversion demonstrates a difficulty hidden by logarithmic notation. Suppose a receiver output contains 2.0 pW total power, while an independently measured additive contribution is 1.8 pW under conditions permitting linear-power subtraction. The inferred signal-only power is 0.2 pW. If both estimates have standard uncertainty 0.15 pW and are provisionally uncorrelated, the uncertainty of their difference is about 0.212 pW, comparable to or larger than the inferred signal. A symmetric Gaussian approximation for that difference assigns nonzero probability to physically negative signal power. Simply taking the logarithm of the central 0.2 pW and reporting a symmetric dB uncertainty would

Copyright 2026, James M. Atkinson

disguise the boundary. A more defensible result may preserve the linear-power measurement and a constrained interval or detection decision, while explicitly explaining the limits of the additive-noise model and the chosen statistical treatment. The numbers are invented for metrological illustration.

Monte Carlo propagation can be valuable when a local Jacobian cannot represent the plausible input range, but simulation alone does not establish reliable uncertainty. One must specify each input distribution, the dependence between inputs, constraints imposed by physical states, and the rule for treating simulated points outside the model's domain. If a Y-factor inversion becomes singular as hot and cold powers approach equality, a simulation may generate extremely broad or asymmetric output values. Silently deleting such outcomes and renormalising the remaining sample set is an analytical selection that can be material to the result. The model should distinguish a conditional estimate valid within a restricted state from evidence that the state itself was never established. Simulated uncertainty describes the stipulated inputs and model; it does not certify that the laboratory actually measured them.

Complex amplitude and phase require covariance-aware reporting. An RF transfer function H(f) has real and imaginary components, or equivalently magnitude and phase under a locally valid transformation. Uncertainty in cable delay and receiver frequency reference can rotate the same complex phasor, coupling the resulting amplitude and phase estimates when nonlinear operations are involved. A phase near the wrap boundary is not well represented by an ordinary symmetric interval without attention to circular statistics. Repeatedly measuring a reference derived from the same oscillator may produce very low short-term scatter while leaving common

Copyright 2026, James M. Atkinson

systematic phase error unchanged. If coherent channel comparisons matter, the report should include the relevant cross-channel covariance and the physical source of shared calibration uncertainty.

Decision rules require another distinction. A measurement result of 9.9 dB against a requirement of at least 10 dB is not a pass simply because the value rounds to 10 dB; neither is a result of 10.1 dB automatically an unqualified pass if relevant uncertainty straddles the boundary. Guard bands and conditional acceptance rules allocate the risk of accepting a deficient condition or rejecting a compliant one. Their choice depends on the decision context and the stated measurement capability, and must not be disguised as a property of the instrument alone. A technical-security report should identify the acceptance rule selected before testing, the applicable uncertainty model, and any inconclusive state. An examiner who changes the decision threshold after seeing the most favourable reading creates an additional selection bias outside the numerical calibration calculation.

A reproducible uncertainty budget includes original estimates and units, probability or bound interpretations, sensitivity coefficients, covariances, correlations, state-validity evidence, numerical method, significant digits and results of independent arithmetic checks. For source-supported statements about reporting conventions, identify the actual edition of the guidance consulted and the material accessible to the reviewer. Do not describe the public summary of a closed standard as though a complete clause-by-clause review had been performed. The strongest engineering conclusion is one that states precisely which tested domain is supported and

Copyright 2026, James M. Atkinson

what additional observation would be needed to narrow the remaining uncertainty.

Copyright 2026, James M. Atkinson

Chapter Summary

Calibration supports a defined configuration, not the receiver in the abstract. Amplitude, phase, noise, and timing corrections must be connected to the complete chain and expressed through an uncertainty-aware decision rule.

Begin with the intended quantity and its measurement equation. Calibration, adjustment and verification serve different purposes, and traceability belongs to a supported result. Signed corrections must follow the actual path, state and applied processing. Independent forward and reverse calculations can reveal wrong planes, duplicate corrections or software mistakes that an uncertainty budget cannot repair.

Model 14B makes covariance explicit. For a fixed affine relation, propagation of finite second moments is exact. For a nonlinear relation, gradients provide a local approximation whose adequacy depends on curvature, boundaries and the input domain. Common references can cancel or reinforce, while repeated readings do not remove an unchanged calibration contribution. Preserve those dependencies rather than selecting favorable correlations.

Report standard uncertainty, the chosen coverage convention and the predeclared decision rule separately. An interval overlapping a limit can support an indeterminate outcome. Noise calibration and sensitivity verification likewise answer different questions. Maintain configuration and correction records across changes, retain raw checks, and investigate inconsistent closing references before extending validity to earlier observations.

Chapter 14 Assessments

This section contains 250 items: 100 multiple-choice, 100 fill-in-the-blank, 25 essay and 25 discussion. Choose one best answer for each multiple-choice item. Supply the requested technical term, quantity or condition for each blank. For essay and discussion responses, explain the governing mechanism, assumptions, evidence and limits of the claim. Numerical assessment cases use hypothetical inputs unless an item explicitly identifies a published source. Retain units and distinguish power, voltage and logarithmic quantities. Answers, rationales and response guidance follow the complete question set; their review links lead to the supporting text.

Multiple-Choice Questions

V011-C14-MCQ-001. Does exact affine variance propagation require Gaussian inputs?

A. No; finite second moments and the stated covariance suffice

B. Yes; all inputs must be independent Gaussians

C. Yes; every marginal must be symmetric

D. No; even infinite input variances always give finite output variance

Answer: A. For an affine function the covariance identity follows by expansion; coverage claims require additional information. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why the selected alternative fits: No; finite second moments and the stated covariance suffice.

Distinguishing consideration: compare this with option B, “Yes; all inputs must be independent Gaussians”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-002. Why does the shared phase-reference contribution cancel in Application 14B.5?

A. Phase errors cancel whenever both channels have equal gain

B. The reference uncertainty is numerically smaller than both residuals

C. Any two standards called common are statistically independent

D. It is the same additive input with equal coupling and opposite coefficients in the difference

Answer: D. Cancellation follows the actual measurement equation and shared state, not a label. Source: §14.14.3 Application 14B.5: cancel a shared phase reference correctly (p. 8135)

Why the selected alternative fits: It is the same additive input with equal coupling and opposite coefficients in the difference.

Distinguishing consideration: compare this with option A, “Phase errors cancel whenever both channels have equal gain”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.5: cancel a shared phase reference correctly.

Review: Chapter 14 — Application 14B.5: cancel a shared phase reference correctly.

V011-C14-MCQ-003. Can the calculated 5.55646 ps local delay uncertainty select the correct unwrapped phase branch?

A. No; the estimate and propagation are conditional on an established branch

B. No; delay uncertainty can never be calculated from phase

C. Yes; the smallest uncertainty always selects the physical branch

D. Yes; positive frequency spacing removes all integer ambiguity

Answer: A. The branch is a model input requiring separate evidence. Source: §14.14.4 Application 14B.6: propagate phase-slope delay uncertainty (p. 8136)

Why the selected alternative fits: No; the estimate and propagation are conditional on an established branch.

Distinguishing consideration: compare this with option B, “No; delay uncertainty can never be calculated from phase”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.6: propagate phase-slope delay uncertainty.

Review: Chapter 14 — Application 14B.6: propagate phase-slope delay uncertainty.

V011-C14-MCQ-004. Why retain an interpolation residual beyond endpoint calibration uncertainties?

A. It removes the need to specify the frequency location

B. It is always exactly zero for linear arithmetic

C. It represents inadequacy of the between-point response model

D. It is a second copy of the same endpoint calibration uncertainty

Answer: C. Endpoint values and physical response between them are different uncertainty questions. Source: §14.14.5 Application 14B.7: retain endpoint covariance in a correction interpolation (p. 8137)

Why the selected alternative fits: It represents inadequacy of the between-point response model.

Distinguishing consideration: compare this with option A, “It removes the need to specify the frequency location”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.7: retain endpoint covariance in a correction interpolation.

Review: Chapter 14 — Application 14B.7: retain endpoint covariance in a correction interpolation.

V011-C14-MCQ-005. What establishes positivity throughout the power-difference domain in Application 14B.9?

A. The fact that dBm is a logarithmic unit

B. The positive central difference alone

C. A positive local estimate minus two standard uncertainties for any distribution

D. The explicit bounded joint input law

Answer: D. The complete stipulated support stays above zero; arbitrary positive estimates do not prove this. Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)

Why the selected alternative fits: The explicit bounded joint input law.

Distinguishing consideration: compare this with option A, “The fact that dBm is a logarithmic unit”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-006. Why is zero local uncertainty inadequate for squared Gaussian voltage at zero mean?

A. A zero mean voltage necessarily implies zero expected power

B. The first derivative vanishes but quadratic randomness remains

C. A larger coverage factor recovers all omitted curvature

D. The voltage variance must also be zero

Answer: B. The exact second and fourth moments retain nonzero power mean and variance. Source: §14.14.8 Application 14B.10: expose a zero-sensitivity failure of the local law (p. 8141)

Why the selected alternative fits: The first derivative vanishes but quadratic randomness remains.

Distinguishing consideration: compare this with option A, “A zero mean voltage necessarily implies zero expected power”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Review: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

V011-C14-MCQ-007. Why does metrological traceability attach to a measurement result?

A. It depends on the actual model, configuration and documented comparison chain with uncertainties

B. It is a permanent property of an instrument regardless of use

C. It follows solely from an unexpired certificate date

D. It guarantees adequate uncertainty for every decision

Answer: A. A component certificate alone does not establish the final assembled result. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

Why the selected alternative fits: It depends on the actual model, configuration and documented comparison chain with uncertainties.

Distinguishing consideration: compare this with option B, “It is a permanent property of an instrument regardless of use”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 14 — Attach calibration to a stated measurement result.

V011-C14-MCQ-008. Why is amplifier gain subtracted when a receiver indication is referred upstream?

A. Amplifier power gain is a passive loss

B. The gain increased the downstream level and must be removed

C. All calibrated corrections are subtracted by convention

D. Gain uncertainty is always negative

Answer: B. The sign follows reversal of the physical forward transfer. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why the selected alternative fits: The gain increased the downstream level and must be removed.

Distinguishing consideration: compare this with option A, “Amplifier power gain is a passive loss”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

V011-C14-MCQ-009. What can a single phase-calibration tone establish directly?

A. Every cable's temperature coefficient

B. Broadband group delay without ambiguity

C. Phase repeatability after every retune

D. The phase relationship at that frequency under the tested state

Answer: D. A broadband or changed-state claim needs additional frequency and repeatability evidence. Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why the selected alternative fits: The phase relationship at that frequency under the tested state.

Distinguishing consideration: compare this with option A, “Every cable's temperature coefficient”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

V011-C14-MCQ-010. Why preserve hot and cold powers alongside reported noise figure?

A. They permit independent ratio, domain, state and conversion checks

B. They eliminate all mismatch corrections

C. They make source temperature calibration unnecessary

D. They guarantee equal gain in both source states

Answer: A. The final scalar result conceals important inputs and validity conditions.

Source: §14.8 Calibrate noise without confusing it with detection (p. 8116)

Why the selected alternative fits: They permit independent ratio, domain, state and conversion checks.

Distinguishing consideration: compare this with option B, “They eliminate all mismatch corrections”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Calibrate noise without confusing it with detection.

Review: Chapter 14 — Calibrate noise without confusing it with detection.

V011-C14-MCQ-011. When can positive input correlation reduce output variance?

A. When the relevant sensitivity coefficients have opposite signs

B. Whenever the inputs appear in separate budget rows

C. Whenever the desired decision is acceptance

D. Only when all individual variances are negative

Answer: A. The cross term includes the product of the signed coefficients and supported covariance. Source: §14.10 Use covariance and model sensitivity deliberately (p. 8119)

Why the selected alternative fits: When the relevant sensitivity coefficients have opposite signs.

Distinguishing consideration: compare this with option B, “Whenever the inputs appear in separate budget rows”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Use covariance and model sensitivity deliberately.

Review: Chapter 14 — Use covariance and model sensitivity deliberately.

V011-C14-MCQ-012. Does multiplying standard uncertainty by two always create 95 percent coverage?

A. Yes; covariance automatically makes every output Gaussian

B. Yes; the multiplier alone defines the probability

C. No; expanded uncertainty can never carry a coverage statement

D. No; interpretation depends on distribution and uncertainty information

Answer: D. The chosen factor and its justification must be stated separately. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why the selected alternative fits: No; interpretation depends on distribution and uncertainty information.

Distinguishing consideration: compare this with option A, "Yes; covariance automatically makes every output Gaussian"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

V011-C14-MCQ-013. For −86.70 dBm ±0.49 dB and an upper limit of −86.50 dBm, what does the chapter's predeclared three-outcome rule give?

A. Accept because the central value is below the limit

B. Indeterminate

C. Reject because the interval upper end exceeds the limit

D. Accept because the uncertainty is less than 1 dB

Answer: B. The interval overlaps the limit; neither full acceptance nor full rejection condition holds. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why the selected alternative fits: Indeterminate.

Distinguishing consideration: compare this with option A, “Accept because the central value is below the limit”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

V011-C14-MCQ-014. A closing reference fails after cable replacement. What is the appropriate treatment of earlier records?

A. Preserve them and establish the last valid state and consequential-change time

B. Discard the failed check if the instrument self-test passes

C. Treat the replacement as irrelevant when connector types match

D. Apply the new correction uniformly to every prior record

Answer: A. Evidence may bound a narrower affected interval; retrospective correction requires support. Source: §14.18 Close the calibration record across the working interval (p. 8147)

Why the selected alternative fits: Preserve them and establish the last valid state and consequential-change time.

Distinguishing consideration: compare this with option B, “Discard the failed check if the instrument self-test passes”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Close the calibration record across the working interval.

Review: Chapter 14 — Close the calibration record across the working interval.

V011-C14-MCQ-015. What should a calibration plan identify before choosing certificates?

A. The largest number of calibrated accessories

B. The instrument with the longest certificate

C. The smallest available uncertainty regardless of scope

D. The intended measurand and its measurement equation

Answer: D. The equation identifies which inputs and conditions require supporting evidence. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

Why the selected alternative fits: The intended measurand and its measurement equation.

Distinguishing consideration: compare this with option A, “The largest number of calibrated accessories”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 14 — Attach calibration to a stated measurement result.

V011-C14-MCQ-016. A precisely calibrated correction is applied to the wrong cable. How should this be classified?

A. A small random term automatically covered by RSS

B. A harmless consequence of traceability

C. A covariance benefit

D. A configuration error to resolve

Answer: D. A budget cannot legitimize using the wrong physical input. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

Why the selected alternative fits: A configuration error to resolve.

Distinguishing consideration: compare this with option A, “A small random term automatically covered by RSS”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 14 — Attach calibration to a stated measurement result.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-017. What distinguishes a present-function field check from full calibration?

A. It establishes all long-term stability

B. It replaces all traceability records

C. It proves all range and state corrections

D. It verifies selected current behavior within a limited scope

Answer: D. The check is useful but does not cover every calibration quantity and condition. Source: §14.1 Calibration Model and Traceability (p. 8104)

Why the selected alternative fits: It verifies selected current behavior within a limited scope.

Distinguishing consideration: compare this with option A, “It establishes all long-term stability”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Calibration Model and Traceability.

Review: Chapter 14 — Calibration Model and Traceability.

V011-C14-MCQ-018. An instrument certificate is valid but omits the gain state used in a survey. What is supported?

A. Characterize the missing state or narrow the claim

B. Add an arbitrary uncertainty until acceptance occurs

C. Apply the nearest state correction without stating the substitution

D. Assume every gain state is covered by the same serial number

Answer: A. Calibration scope is conditional, not universal by association. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

Why the selected alternative fits: Characterize the missing state or narrow the claim.

Distinguishing consideration: compare this with option B, “Add an arbitrary uncertainty until acceptance occurs”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 14 — Attach calibration to a stated measurement result.

V011-C14-MCQ-019. Why independently recompute representative corrected records?

A. To expose implementation errors such as signs or wrong correction ownership

B. To eliminate physical calibration uncertainty

C. To infer source identity from arithmetic agreement

D. To prove all untested frequencies are valid

Answer: A. Excellent calibrated inputs can still be implemented incorrectly. Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

Why the selected alternative fits: To expose implementation errors such as signs or wrong correction ownership.

Distinguishing consideration: compare this with option B, “To eliminate physical calibration uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Attach calibration to a stated measurement result.

Review: Chapter 14 — Attach calibration to a stated measurement result.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-020. What is the difference between a known correction and its uncertainty?

A. The uncertainty should replace every nonzero correction

B. The correction addresses a known offset; uncertainty describes remaining information about that correction

C. They are interchangeable numbers with opposite signs

D. A correction removes all residual uncertainty

Answer: B. A significant known offset should be corrected with its uncertainty retained. Source: §14.10 Use covariance and model sensitivity deliberately (p. 8119)

Why the selected alternative fits: The correction addresses a known offset; uncertainty describes remaining information about that correction.

Distinguishing consideration: compare this with option A, "The uncertainty should replace every nonzero correction"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 14 — Use covariance and model sensitivity deliberately.

V011-C14-MCQ-022. Why can a straight-line fit through compressed data be misleading?

A. Averaging fit residuals removes the physical compression

B. Compression changes only phase, never amplitude

C. Any straight-line fit proves local linearity everywhere

D. Small average residuals can hide invalid weak- and strong-level endpoints

Answer: D. Individual observations and accepted range limits must be retained.

Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why the selected alternative fits: Small average residuals can hide invalid weak- and strong-level endpoints.

Distinguishing consideration: compare this with option A, “Averaging fit residuals removes the physical compression”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

V011-C14-MCQ-023. Which effect tends to dominate amplitude uncertainty at very low levels?

A. Strong-signal compression alone

B. Noise and detector statistics

C. Intermodulation from the desired signal alone

D. A constant calibration term necessarily dominating every case

Answer: B. The model changes across operating regimes; low-level statistics differ from high-level nonlinearity. Source: §14.3 Amplitude Response and Linearity (p. 8108)

Why the selected alternative fits: Noise and detector statistics.

Distinguishing consideration: compare this with option A, “Strong-signal compression alone”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Amplitude Response and Linearity.

Review: Chapter 14 — Amplitude Response and Linearity.

V011-C14-MCQ-024. What is the corrected upstream value for the chapter's −72.60+0.20+2.40−17.80+1.10 dBm chain?

A. −87.10 dBm

B. −86.70 dBm

C. −79.70 dBm

D. −51.10 dBm

Answer: B. The signs remove gain and restore upstream losses after the receiver residual correction. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why the selected alternative fits: −86.70 dBm.

Distinguishing consideration: compare this with option A, "−87.10 dBm"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

V011-C14-MCQ-026. Why perform a forward prediction after computing an upstream correction?

A. It supplies missing component calibration values

B. It guarantees that the amplifier stayed linear

C. It proves mismatch is absent

D. It checks the physical sign and plane convention independently

Answer: D. A reverse/forward arithmetic closure tests implementation, while physical assumptions need separate evidence. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why the selected alternative fits: It checks the physical sign and plane convention independently.

Distinguishing consideration: compare this with option A, “It supplies missing component calibration values”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-027. What is required if a gain correction was measured at a different bias or temperature?

A. An assumption that gain is unchanged because the amplifier model matches

B. Only the same frequency label

C. Evidence of applicability or a state-appropriate correction

D. A larger averaging count at the original state

Answer: C. Correction scope follows actual operating state. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why the selected alternative fits: Evidence of applicability or a state-appropriate correction.

Distinguishing consideration: compare this with option A, “An assumption that gain is unchanged because the amplifier model matches”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Build a correction chain with signs that can be checked.

V011-C14-MCQ-044. For a covariance matrix of real finite-variance inputs, which property is required?

A. Symmetry and positive semidefiniteness

B. Every diagonal entry must equal one

C. All off-diagonal entries must be positive

D. Every pairwise correlation must be zero

Answer: A. A physically admissible matrix must give nonnegative variance for every linear combination. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why the selected alternative fits: Symmetry and positive semidefiniteness.

Distinguishing consideration: compare this with option B, “Every diagonal entry must equal one”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-045. Do individually plausible pairwise correlations guarantee an admissible whole matrix?

A. No; joint positive semidefiniteness must also hold

B. Yes; positive correlations cannot conflict

C. Yes; each lying between −1 and +1 is sufficient

D. No; covariance matrices are never useful for mixed units

Answer: A. Pairwise bounds alone do not ensure global consistency. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why the selected alternative fits: No; joint positive semidefiniteness must also hold.

Distinguishing consideration: compare this with option B, "Yes; positive correlations cannot conflict"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-C14-MCQ-046. For an affine result $Y = a + c^T X$, what is its exact variance?

A. The sum of standard deviations without coefficients

B. $a + c^T \mu$

C. $c^T \Sigma c$

D. The square of the mean

Answer: C. The constant drops out and covariance propagates through the signed coefficients. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why the selected alternative fits: option C contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-C14-MCQ-054. Why may a common reference be represented either explicitly or by covariance, but not inconsistently both?

A. The numerical units of the reference become arbitrary

B. Covariance representation always removes calibration uncertainty

C. Otherwise the same contribution can be counted twice

D. Explicit inputs are necessarily independent

Answer: C. The alternatives must describe the same underlying dependency without duplication. Source: §14.10 Use covariance and model sensitivity deliberately (p. 8119)

Why the selected alternative fits: Otherwise the same contribution can be counted twice.

Distinguishing consideration: compare this with option A, “The numerical units of the reference become arbitrary”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Use covariance and model sensitivity deliberately.

Review: Chapter 14 — Use covariance and model sensitivity deliberately.

V011-C14-MCQ-075. A mean indication is −80.20 dBm and correction +0.15 dB. What is the corrected mean?

A. −80.20 dBm

B. −80.35 dBm

C. −79.90 dBm

D. −80.05 dBm

Answer: D. The common additive correction changes the central level once. Source: §14.14.6 Application 14B.8: identify the uncertainty that averaging cannot remove (p. 8138)

Why the selected alternative fits: −80.05 dBm.

Distinguishing consideration: compare this with option A, "−80.20 dBm"; that competing statement does not meet the question's stated requirement.

Basis and limitation: Chapter 14 — Application 14B.8: identify the uncertainty that averaging cannot remove.

Review: Chapter 14 — Application 14B.8: identify the uncertainty that averaging cannot remove.

V011-C14-MCQ-076. For on/off estimates 1.30 and 1.00 nW, what is the added linear power?

A. 1.13943 dB

B. 2.300 nW

C. 0.300 nW

D. 1.300 nW

Answer: C. Physical subtraction precedes any logarithmic conversion. Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)

Why the selected alternative fits: 0.300 nW.

Distinguishing consideration: compare this with option A, “1.13943 dB”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-077. Given on/off standard uncertainties 0.04 and 0.03 nW and covariance 0.00096 nW^2, what is difference variance?

A. 0.00442 nW^2

B. 0.00058 nW^2

C. 0.0025 nW^2

D. 0.00154 nW^2

Answer: B. Compute 0.0016+0.0009−2 times 0.00096. Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)

Why the selected alternative fits: 0.00058.

Distinguishing consideration: compare this with option A, “0.00442”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-078. What is the level of 0.300 nW relative to 1 mW?

A. Approximately −95.228787 dBm

B. Approximately −5.228787 dBm

C. Approximately −65.228787 dBm

D. Approximately −60.000000 dBm

Answer: C. 0.300 nW is 3 times 10 to the minus seven mW. Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)

Why the selected alternative fits: Approximately −65.228787 dBm.

Distinguishing consideration: compare this with option A, “Approximately −95.228787 dBm”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-C14-MCQ-079. At positive difference D, what is the derivative of its dBm level with respect to D?

A. 10 divided by ln(10) times D in the denominator

B. 1 divided by D with no logarithmic scale factor

C. 10 times ln(10) times D

D. D divided by 10 ln(10)

Answer: A. Differentiating 10 log 10(D/1 mW) gives $\frac{10}{[\ln(10)D]}$. Source: §14.14.7

Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)

Why the selected alternative fits: 10 divided by ln(10) times D in the denominator.

Distinguishing consideration: compare this with option B, “1 divided by D with no logarithmic scale factor”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-C14-MCQ-080. If a different on/off uncertainty domain includes zero or negative differences, what should be retained first?

A. The linear difference and its interpretation

B. A fixed extra 3 dB correction

C. The positive central logarithm as valid for the whole domain

D. A logarithm of the absolute difference without qualification

Answer: A. The logarithmic map cannot be extended through the nonpositive boundary by assertion. Source: §14.14.7 Application 14B.9: subtract paired powers before propagating a logarithm (p. 8139)

Why the selected alternative fits: The linear difference and its interpretation.

Distinguishing consideration: compare this with option B, “A fixed extra 3 dB correction”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

Review: Chapter 14 — Application 14B.9: subtract paired powers before propagating a logarithm.

V011-C14-MCQ-081. For Gaussian X with mean μ, SD σ and known positive R, what is $E[\frac{X^2}{R}]$?

A. $\frac{(\mu^2+\sigma^2)}{R}$

B. $\frac{\sigma}{R}$

C. $\frac{\mu^2}{R}$

D. $\frac{(\mu+\sigma)^2}{R}$

Answer: A. Curvature adds the variance contribution to the expected squared quantity. Source: §14.14.8 Application 14B.10: expose a zero-sensitivity failure of the local law (p. 8141)

Why the selected alternative fits: option A contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Review: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-082. For the same model, what term is omitted by first-order power variance propagation?

A. $\frac{\mu^2}{R}$

B. $\frac{4\mu^2\sigma^2}{R^2}$

C. $\frac{2\sigma^4}{R^2}$

D. $\frac{2\mu}{R}$

Answer: C. The exact variance includes both the linear sensitivity term and this curvature term. Source: §14.14.8 Application 14B.10: expose a zero-sensitivity failure of the local law (p. 8141)

Why the selected alternative fits: option C contains the mathematical expression shown in the question; its interpretation depends on the stated equation and units.

Distinguishing consideration: evaluate the other displayed alternatives against the original formula and its operating assumptions; no equivalence is established by the answer letter alone.

Basis and limitation: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Review: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-083. At μ=0, σ=1 mV and R=50 ohms, what is expected power?

A. 0 nW

B. 20 μW

C. 20 nW

D. 2 nW

Answer: C. $\frac{\sigma^2}{R}$ equals 10 to the minus six divided by 50 watts. Source: §14.14.8 Application 14B.10: expose a zero-sensitivity failure of the local law (p. 8141)

Why the selected alternative fits: 20 nW.

Distinguishing consideration: compare this with option A, “0 nW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Review: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-084. At that zero-mean point, what is exact power standard deviation?

A. 20 nW

B. 40 nW

C. About 28.2843 nW

D. 0 nW

Answer: C. The standard deviation is square root of two times $\frac{\sigma^2}{R}$. Source: §14.14.8 Application 14B.10: expose a zero-sensitivity failure of the local law (p. 8141)

Why the selected alternative fits: About 28.2843 nW.

Distinguishing consideration: compare this with option A, “20 nW”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

Review: Chapter 14 — Application 14B.10: expose a zero-sensitivity failure of the local law.

V011-C14-MCQ-086. Under the declared upper-limit rule, when is a result accepted?

A. Whenever any part of the interval is below the limit

B. Whenever the interval width is less than 1 dB

C. When the interval upper end is no greater than the limit

D. Whenever the central value is below the limit

Answer: C. The rule uses the full interval and was declared before observing the result. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why the selected alternative fits: When the interval upper end is no greater than the limit.

Distinguishing consideration: compare this with option A, “Whenever any part of the interval is below the limit”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-087. Under that rule, when is a result rejected?

A. When the interval lower end is greater than the limit

B. Whenever the upper end exceeds the limit

C. Whenever the central value equals the limit

D. Whenever uncertainty is nonzero

Answer: A. An overlapping interval is indeterminate rather than necessarily rejected. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why the selected alternative fits: When the interval lower end is greater than the limit.

Distinguishing consideration: compare this with option B, “Whenever the upper end exceeds the limit”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-088. What is the role of repeated observations after an indeterminate outcome?

A. They can reduce a dominant random term if the model supports it

B. They prove the original result was wrong

C. They authorize moving the limit afterward

D. They necessarily remove common calibration uncertainty

Answer: A. The response should address actual uncertainty sources while retaining the original record. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why the selected alternative fits: They can reduce a dominant random term if the model supports it.

Distinguishing consideration: compare this with option B, “They prove the original result was wrong”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

V011-C14-MCQ-089. Which statement about an expanded level interval and a search false-alarm probability is correct?

A. They are identical whenever the coverage factor is two

B. The search false-alarm rate determines every calibration correction

C. They are different probabilistic claims requiring their respective models

D. The level interval supplies the search false-alarm rate automatically

Answer: C. Coverage of a measured quantity is distinct from decision behavior in a search procedure. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why the selected alternative fits: They are different probabilistic claims requiring their respective models.

Distinguishing consideration: compare this with option A, “They are identical whenever the coverage factor is two”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Copyright 2026, James M. Atkinson

V011-C14-MCQ-090. What should happen if a later decision adopts a different rule?

A. Use whichever rule produces the desired decision without disclosure

B. Rewrite the earlier outcome as though the new rule always applied

C. Identify the new rule and preserve the original outcome

D. Delete the earlier uncertainty calculation

Answer: C. Decision-rule changes are part of the record. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why the selected alternative fits: Identify the new rule and preserve the original outcome.

Distinguishing consideration: compare this with option A, “Use whichever rule produces the desired decision without disclosure”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Declare the decision rule before seeing the result.

V011-C14-MCQ-092. Why can a firmware update require renewed correction review?

A. A passing self-test proves all external corrections unchanged

B. It may change processing or state behavior covered by prior calibration

C. Only hardware replacements can change calibration scope

D. Software cannot affect calibrated measurements

Answer: B. Correction applicability depends on the implemented measurement chain. Source: §14.12 Calibration Lifecycle and Change Control (p. 8125)

Why the selected alternative fits: It may change processing or state behavior covered by prior calibration.

Distinguishing consideration: compare this with option A, “A passing self-test proves all external corrections unchanged”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Calibration Lifecycle and Change Control.

Review: Chapter 14 — Calibration Lifecycle and Change Control.

V011-C14-MCQ-093. What makes an intermediate reference genuinely informative about implementation errors?

A. Only confirming the file exists

B. Using the same correction path twice and calling agreement independent

C. Only checking the final reported value

D. A raw comparison and independent recomputation that do not simply repeat the same faulty correction

Answer: D. Shared implementation errors can survive repeated self-comparisons.

Source: §14.18 Close the calibration record across the working interval (p. 8147)

Why the selected alternative fits: A raw comparison and independent recomputation that do not simply repeat the same faulty correction.

Distinguishing consideration: compare this with option A, “Only confirming the file exists”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Close the calibration record across the working interval.

V011-C14-MCQ-094. What did the published vector-calibration example illustrate about repeatability-only uncertainty?

A. It always overestimates complete uncertainty

B. It removes common-reference concerns

C. It omitted calibration contributions that widened the full uncertainty distribution

D. It is automatically identical to traceable calibration uncertainty

Answer: C. The chapter uses the example to distinguish repeatability from the wider calibration model. Source: §14.17 System-Level Vector Calibration and Uncertainty (p. 8145)

Why the selected alternative fits: It omitted calibration contributions that widened the full uncertainty distribution.

Distinguishing consideration: compare this with option A, “It always overestimates complete uncertainty”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — System-Level Vector Calibration and Uncertainty.

V011-C14-MCQ-095. Why can agreement with the same oscilloscope used for calibration retain common errors?

A. The comparison and calibration share a reference contribution

B. A vector correction always removes all nonlinear response

C. Repeated measurements make all reference errors independent

D. Every oscilloscope has zero uncertainty

Answer: A. Common dependence must remain visible when interpreting agreement. Source: §14.17 System-Level Vector Calibration and Uncertainty (p. 8145)

Why the selected alternative fits: The comparison and calibration share a reference contribution.

Distinguishing consideration: compare this with option B, “A vector correction always removes all nonlinear response”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — System-Level Vector Calibration and Uncertainty.

Review: Chapter 14 — System-Level Vector Calibration and Uncertainty.

V011-C14-MCQ-096. Does a linear vector correction establish absence of receiver nonlinearity?

A. Yes; complex coefficients can represent any state-dependent nonlinearity

B. No; residual nonlinear behavior requires separate bounding

C. No; linear corrections are never useful

D. Yes; improved modulation error proves every level is linear

Answer: B. The correction has a linear, state-dependent scope. Source: §14.17 System-Level Vector Calibration and Uncertainty (p. 8145)

Why the selected alternative fits: No; residual nonlinear behavior requires separate bounding.

Distinguishing consideration: compare this with option A, “Yes; complex coefficients can represent any state-dependent nonlinearity”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — System-Level Vector Calibration and Uncertainty.

V011-C14-MCQ-097. What did the temperature-dependent preamplifier case demonstrate?

A. Room-temperature correction is always valid outdoors

B. An applicable state correction can resolve much of an analyzer disagreement

C. The initial 2.8 dB difference uniquely identified either analyzer as defective

D. Within-uncertainty agreement proves exact equality

Answer: B. The gain state changed with temperature; the updated correction reduced the discrepancy to 0.6 dB within combined uncertainty. Source: §14.16 Hypothetical Case Adjudication: Calibration, Gain, Amplitude and Phase Accuracy, Noise Figure, and Uncertainty (p. 8144)

Why the selected alternative fits: An applicable state correction can resolve much of an analyzer disagreement.

Distinguishing consideration: compare this with option A, “Room-temperature correction is always valid outdoors”; that competing statement does not meet the question’s stated requirement.

Basis and limitation: Chapter 14 — Hypothetical Case Adjudication: Calibration, Gain, Amplitude and Phase Accuracy, Noise Figure, and Uncertainty.

V011-C14-FIB-012. When referring the same reading upstream, amplifier gain is _____.

Answer: subtracted. The forward amplification must be removed. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why this term is required: “subtracted” completes the stated technical proposition.

Question context: When referring the same reading upstream, amplifier gain is _____

Basis and qualification: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

Copyright 2026, James M. Atkinson

V011-C14-FIB-013. The chapter's signed 915 MHz chain gives _____ dBm at the filter input.

Answer: −86.70. Compute −72.60+0.20+2.40−17.80+1.10. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why this term is required: "−86.70" completes the stated technical proposition.

Question context: The chapter's signed 915 MHz chain gives _____ dBm at the filter input

Basis and qualification: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

Copyright 2026, James M. Atkinson

V011-C14-FIB-014. Raw −72.60 dBm plus a +0.20 dB receiver correction gives _____ dBm.

Answer: −72.40. This is the corrected receiver-plane indication. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why this term is required: "−72.40" completes the stated technical proposition.

Question context: Raw −72.60 dBm plus a +0.20 dB receiver correction gives _____ dBm

Basis and qualification: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

Copyright 2026, James M. Atkinson

V011-C14-FIB-015. For the stated chain, total external gain minus losses is _____ dB.

Answer: 14.30. 17.80−2.40−1.10=14.30 dB. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why this term is required: “14.30” completes the stated technical proposition.

Question context: For the stated chain, total external gain minus losses is _____ dB

Basis and qualification: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

Copyright 2026, James M. Atkinson

V011-C14-FIB-016. Forward calculation from the upstream result is an independent check on correction _____ and planes.

Answer: signs. It follows the physical transfer direction. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why this term is required: “signs” completes the stated technical proposition.

Question context: Forward calculation from the upstream result is an independent check on correction _____ and planes

Basis and qualification: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

Copyright 2026, James M. Atkinson

V011-C14-FIB-017. At weak levels, detector statistics and _____ may dominate amplitude uncertainty.

Answer: noise. The uncertainty model should change with operating regime. Source: §14.3 Amplitude Response and Linearity (p. 8108)

Why this term is required: “noise” completes the stated technical proposition.

Question context: At weak levels, detector statistics and _____ may dominate amplitude uncertainty

Basis and qualification: Chapter 14 — Amplitude Response and Linearity.

Review: Chapter 14 — Amplitude Response and Linearity.

Copyright 2026, James M. Atkinson

V011-C14-FIB-018. At high levels, compression and _____ can dominate instead.

Answer: intermodulation. Strong-signal behavior can violate a linear calibration model. Source: §14.3 Amplitude Response and Linearity (p. 8108)

Why this term is required: “intermodulation” completes the stated technical proposition.

Question context: At high levels, compression and _____ can dominate instead

Basis and qualification: Chapter 14 — Amplitude Response and Linearity.

Review: Chapter 14 — Amplitude Response and Linearity.

Copyright 2026, James M. Atkinson

V011-C14-FIB-019. A line fitted through compressed response can hide invalid endpoint _____ behavior.

Answer: linearity. Small mean residuals do not prove validity over the range. Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)

Why this term is required: “linearity” completes the stated technical proposition.

Question context: A line fitted through compressed response can hide invalid endpoint _____ behavior

Basis and qualification: Chapter 14 — Build a correction chain with signs that can be checked.

Review: Chapter 14 — Build a correction chain with signs that can be checked.

V011-C14-FIB-020. A frequency reference marked locked does not alone quantify residual measurement _____.

Answer: error. Actual estimator and reference-path behavior still matter. Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why this term is required: “error” completes the stated technical proposition.

Question context: A frequency reference marked locked does not alone quantify residual measurement _____

Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-C14-FIB-021. Relative channel phase requires a defined simultaneous input _____ and channel reference planes.

Answer: relationship. The calibration must establish what phase relation is being compared. Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why this term is required: “relationship” completes the stated technical proposition.

Question context: Relative channel phase requires a defined simultaneous input _____ and channel reference planes

Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-C14-FIB-022. A single tone tests phase at one frequency, not broadband group _____.

Answer: delay. Frequency-dependent characterization is needed. Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why this term is required: “delay” completes the stated technical proposition.

Question context: A single tone tests phase at one frequency, not broadband group _____

Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-C14-FIB-023. Phase correction across a band must document its _____ convention.

Answer: unwrapping. Different branches can imply different slopes and delays.

Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why this term is required: “unwrapping” completes the stated technical proposition.

Question context: Phase correction across a band must document its _____ convention

Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

V011-C14-FIB-024. Retuning can preserve amplitude while changing conversion _____.

Answer: phase. Amplitude repeatability does not establish coherent record linkage.

Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why this term is required: “phase” completes the stated technical proposition.

Question context: Retuning can preserve amplitude while changing conversion _____

Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-C14-FIB-025. If only within-record phase repeats, separate records should not automatically be treated as _____.

Answer: coherent. Inter-record state changes can alter phase. Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why this term is required: “coherent” completes the stated technical proposition.

Question context: If only within-record phase repeats, separate records should not automatically be treated as _____

Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-C14-FIB-026. Moving a timing plane requires accounting for the intervening path's _____.

Answer: delay. The associated uncertainty and state dependence also belong in the model. Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)
Why this term is required: “delay” completes the stated technical proposition.
Question context: Moving a timing plane requires accounting for the intervening path's _____
Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.
Review: Chapter 14 — Frequency, phase, and delay require their own observables.

Copyright 2026, James M. Atkinson

V011-C14-FIB-027. A timestamp must be related to the samples, trigger and reference _____.

Answer: clock. A date field alone does not establish event timing. Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)

Why this term is required: “clock” completes the stated technical proposition.

Question context: A timestamp must be related to the samples, trigger and reference _____

Basis and qualification: Chapter 14 — Frequency, phase, and delay require their own observables.

Review: Chapter 14 — Frequency, phase, and delay require their own observables.

V011-C14-FIB-028. Noise-figure calculation should retain both hot and cold output _____.

Answer: powers. They permit independent ratio and validity checks. Source: §14.8 Calibrate noise without confusing it with detection (p. 8116)

Why this term is required: “powers” completes the stated technical proposition.

Question context: Noise-figure calculation should retain both hot and cold output _____

Basis and qualification: Chapter 14 — Calibrate noise without confusing it with detection.

Review: Chapter 14 — Calibrate noise without confusing it with detection.

Copyright 2026, James M. Atkinson

V011-C14-FIB-029. The simple hot/cold inversion assumes equal _____ between the two states.

Answer: gain. A source-state gain change invalidates that ratio model. Source: §14.8 Calibrate noise without confusing it with detection (p. 8116)

Why this term is required: “gain” completes the stated technical proposition.

Question context: The simple hot/cold inversion assumes equal _____ between the two states

Basis and qualification: Chapter 14 — Calibrate noise without confusing it with detection.

Review: Chapter 14 — Calibrate noise without confusing it with detection.

Copyright 2026, James M. Atkinson

V011-C14-FIB-030. The highest source-noise state must be checked for _____.

Answer: compression. The cold state can appear normal while the hot state is nonlinear. Source: §14.8 Calibrate noise without confusing it with detection (p. 8116)
Why this term is required: “compression” completes the stated technical proposition.
Question context: The highest source-noise state must be checked for _____
Basis and qualification: Chapter 14 — Calibrate noise without confusing it with detection.
Review: Chapter 14 — Calibrate noise without confusing it with detection.

Copyright 2026, James M. Atkinson

V011-C14-FIB-031. Source-state settling must be established from observed _____.

Answer: response. A software delay alone is not measurement evidence. Source: §14.8 Calibrate noise without confusing it with detection (p. 8116)

Why this term is required: “response” completes the stated technical proposition.

Question context: Source-state settling must be established from observed _____

Basis and qualification: Chapter 14 — Calibrate noise without confusing it with detection.

Review: Chapter 14 — Calibrate noise without confusing it with detection.

Copyright 2026, James M. Atkinson

V011-C14-FIB-032. Sensitivity verification tests the full path and its decision _____.

Answer: rule. It is distinct from separating receiver noise contributions. Source: §14.8 Calibrate noise without confusing it with detection (p. 8116)

Why this term is required: “rule” completes the stated technical proposition.

Question context: Sensitivity verification tests the full path and its decision _____

Basis and qualification: Chapter 14 — Calibrate noise without confusing it with detection.

Review: Chapter 14 — Calibrate noise without confusing it with detection.

V011-C14-FIB-036. An affine variance identity requires finite second _____.

Answer: moments. Gaussian inputs or independence are unnecessary for that identity. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why this term is required: “moments” completes the stated technical proposition.

Question context: An affine variance identity requires finite second _____

Basis and qualification: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Copyright 2026, James M. Atkinson

V011-C14-FIB-037. A valid covariance matrix is symmetric and positive _____.

Answer: semidefinite. Every linear combination must have nonnegative variance.

Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why this term is required: “semidefinite” completes the stated technical proposition.

Question context: A valid covariance matrix is symmetric and positive _____

Basis and qualification: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Copyright 2026, James M. Atkinson

V011-C14-FIB-038. The covariance entry for two inputs has the product of their _____.

Answer: units. Mixed-unit input vectors still have a consistent covariance law.

Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why this term is required: “units” completes the stated technical proposition.

Question context: The covariance entry for two inputs has the product of their _____

Basis and qualification: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Copyright 2026, James M. Atkinson

V011-C14-FIB-039. For $Y = a + c^T X$, the mean is a plus c^T times the input mean _____.

Answer: vector. Linearity of expectation gives the affine mean exactly. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why this term is required: "vector" completes the stated technical proposition.

Question context: For the mean is a plus times the input mean _____

Basis and qualification: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-C14-FIB-041. For a nonlinear function, the first-order coefficient vector is its local _____.

Answer: gradient. It is evaluated at the stated input estimate. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why this term is required: “gradient” completes the stated technical proposition.

Question context: For a nonlinear function, the first-order coefficient vector is its local _____

Basis and qualification: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Copyright 2026, James M. Atkinson

V011-C14-FIB-042. The local nonlinear variance expression is

_____ .

Answer: $J \Sigma J^T$. Its adequacy depends on the neglected remainder. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why this term is required: "Its adequacy depends on the neglected remainder" completes the stated technical proposition.

Question context: The local nonlinear variance expression is _____

Basis and qualification: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Copyright 2026, James M. Atkinson

V011-C14-FIB-043. Zero covariance removes a cross term but does not generally imply statistical _____.

Answer: independence. The affine variance identity does not require that stronger condition. Source: §14.14 Model 14B: exact covariance and local uncertainty propagation (p. 8127)

Why this term is required: “independence” completes the stated technical proposition.

Question context: Zero covariance removes a cross term but does not generally imply statistical _____

Basis and qualification: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

Review: Chapter 14 — Model 14B: exact covariance and local uncertainty propagation.

V011-C14-FIB-051. A factor of two gives expanded uncertainty approximately _____ dB for that correlated budget.

Answer: 0.489898. The factor is stipulated; coverage probability requires additional justification. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why this term is required: “0.489898” completes the stated technical proposition.

Question context: A factor of two gives expanded uncertainty approximately _____ dB for that correlated budget

Basis and qualification: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Copyright 2026, James M. Atkinson

V011-C14-FIB-052. The interval around −86.70 dBm with ±0.49 dB has upper end _____ dBm.

Answer: −86.21. Add the expanded uncertainty to the central value. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why this term is required: "−86.21" completes the stated technical proposition.

Question context: The interval around −86.70 dBm with ±0.49 dB has upper end _____ dBm

Basis and qualification: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Copyright 2026, James M. Atkinson

V011-C14-FIB-053. Against −86.50 dBm, that overlapping interval is _____ under the chapter's rule.

Answer: indeterminate. Neither the full interval-below nor interval-above condition holds. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why this term is required: “indeterminate” completes the stated technical proposition.

Question context: Against −86.50 dBm, that overlapping interval is _____ under the chapter's rule

Basis and qualification: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Copyright 2026, James M. Atkinson

V011-C14-FIB-054. The acceptance condition for the upper limit requires the interval's _____ end to be no greater than the limit.

Answer: upper. The rule was declared before seeing the data. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why this term is required: “upper” completes the stated technical proposition.

Question context: The acceptance condition for the upper limit requires the interval's _____ end to be no greater than the limit

Basis and qualification: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Copyright 2026, James M. Atkinson

V011-C14-FIB-055. Under the chapter's declared three-outcome upper-limit interval rule, rejection requires the interval's lower end to be _____ than the limit.

Answer: greater. An overlap alone is not the rejection condition. Source: §14.11 Declare the decision rule before seeing the result (p. 8122)

Why this term is required: “greater” completes the stated technical proposition.

Question context: Under the chapter's declared three-outcome upper-limit interval rule, rejection requires the interval's lower end to be _____ than the limit

Basis and qualification: Chapter 14 — Declare the decision rule before seeing the result.

Review: Chapter 14 — Declare the decision rule before seeing the result.

Essay Questions

[Essay instructions: Each essay must contain 3,500–5,000 words in total. Address the ten subject prompts below in the order presented, developing approximately 350–500 words for each prompt. Begin with an introduction establishing the question, scope and thesis. Conclude with a synthesis that draws together all ten prompts into one coherent closing argument. Count the introduction and conclusion within the overall word limit.]

V011-C14-ESSAY-001. Explain why calibration should be designed around a reported measurand rather than an instrument label.

- Opening: Present a thesis that answers this precise question: Explain why calibration should be designed around a reported measurand rather than an instrument label. Identify which evidence would falsify the proposed conclusion Source: §14.2 Attach calibration to a stated measurement result (p. 8105)
- Core terminology and scope: Define calibration, designed, reported in the question's particular technical setting; explain how measurand, instrument, label differ if that distinction would change the analysis of "Explain why calibration should be designed around a reported measurand rather than an instrument label" Source: §14.2 Attach calibration to a stated measurement result (p. 8105)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Define the measurement equation and required inputs for two distinct results, such as terminal power and relative phase Source: §14.2 Attach calibration to a stated measurement result (p. 8105)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting why calibration should be designed around a reported measurand rather than an instrument label to the claimed result, following "Calibration Model and Traceability"; name the intermediate states and measurable outputs Source: §14.1 Calibration Model and Traceability (p. 8104)
- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for why

calibration should be designed around a reported measurand rather than an instrument label. Distinguish calibration, adjustment and verification, and explain traceability scope, configuration applicability and uncertainty without claiming traceability guarantees correctness Source: §14.1 Calibration Model and Traceability (p. 8104)

- Analytical framework: Identify the equation, calibration or evidential decision test in “Frequency and Phase Calibration” that resolves the question about why calibration should be designed around a reported measurand rather than an instrument label; derive the relevant result with units and stated validity conditions Source: §14.5 Frequency and Phase Calibration (p. 8112)
- Evidence and method: Specify the native observations, control records and calculations that would resolve why calibration should be designed around a reported measurand rather than an instrument label. Distinguish calibration, adjustment and verification, and explain traceability scope, configuration applicability and uncertainty without claiming traceability guarantees correctness Source: §14.2 Attach calibration to a stated measurement result (p. 8105)
- Worked application or illustrative case: Build a worked example of “why calibration should be designed around a reported measurand rather than an instrument label”, addressing this associated condition: Define the measurement equation and required inputs for two distinct results, such as terminal power and.... Define the measurement equation and required inputs for two distinct results,

such as terminal power and relative phase Source: §14.1 Calibration Model and Traceability (p. 8104)

- Alternative explanations and failure modes: Construct two plausible technical explanations for “why calibration should be designed around a reported measurand rather than an instrument label”. Using “Frequency and Phase Calibration”, specify a discriminator and the result expected under each explanation Source: §14.5 Frequency and Phase Calibration (p. 8112)
- Uncertainty and evidential limits: Quantify or bound the uncertainties that matter to why calibration should be designed around a reported measurand rather than an instrument label, including the effect of missing measurements and inconsistent operating conditions Source: §14.6 Frequency, phase, and delay require their own observables (p. 8113)
- Scholarly synthesis and implications: Explain what the result about why calibration should be designed around a reported measurand rather than an instrument label authorises the investigator or engineer to claim, and what stronger proposition remains unsupported Source: §14.2 Attach calibration to a stated measurement result (p. 8105)
- Closing: Conclude by answering “Explain why calibration should be designed around a reported measurand rather than an instrument label” using only the demonstrated evidence; state the remaining decisive verification step Source: §14.2 Attach calibration to a stated measurement result (p. 8105)

V011-C14-ESSAY-002. Audit the chapter's constructed 915 MHz signed correction chain.

- Opening: Present a thesis that answers this precise question: Audit the chapter's constructed 915 MHz signed correction chain. Identify which evidence would falsify the proposed conclusion Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)
- Core terminology and scope: Define Audit, constructed, signed in the question's particular technical setting; explain how correction, chain, measurement differ if that distinction would change the analysis of "Audit the chapter's constructed 915 MHz signed correction chain" Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)
- Problem statement and purpose: Frame the actual measurement or decision in the question. Reproduce −86.70 dBm, identify the +0.20 residual and each loss/gain sign, predict the −72.40 dBm corrected receiver plane, and state linearity, mismatch and state assumptions Source: §14.4 Build a correction chain with signs that can be checked (p. 8110)
- Physical and computational context: Reconstruct the physical, mathematical or software mechanism connecting Audit the chapter's constructed 915 MHz signed correction chain to the claimed result, following "Close the calibration record across the working interval"; name the intermediate states and measurable outputs Source: §14.18 Close the calibration record across the working interval (p. 8147)
- Assumptions, conditions and reference planes: State the testable assumptions, configuration states and reference planes for Audit
