instrument state. They are richer than a power average for some questions, but they are not an unfiltered history of the external field. An architecture should therefore preserve the most informative representation justified by the task and its constraints, with an explicit account of what has not been acquired.

Dr. Atkinson, this leads to a useful distinction between a retention choice and a measurement defect. Deliberately reducing valid data according to an authorised, declared operation is a choice whose consequences can be stated. Discovering that the original acquisition clipped is a different problem because the intended representation may already have failed. The first should not be excused by calling it perfect preservation, and the second should not be normalised by describing it as ordinary compression.

For the present case, I would retain a mapping from each reported statistic to its source interval and processing definition, even where the source samples are not retained indefinitely. That mapping cannot recreate discarded phase, but it prevents an unsupported phase claim. Dr Bode, the distinction now passes naturally to you: what must the network preserve if a correction is to recover more than an attractive numerical result?

I thank the questioning colleague for that important distinction. The chronology of selection of receiver architecture for the investigative measurand is indispensable. Assume for a moment that a superheterodyne conversion product can masquerade as a new radio emission. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We

Copyright 2026, James M. Atkinson

should compare direct-conversion and superheterodyne capture on the same calibrated stimulus, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs image response, LO plan, RF preselection and conversion loss. If a true external feature retains its RF coordinate while an internal image follows the oscillator plan, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states.

Hendrik Wade Bode

Network memory, inverse sensitivity, and the choice of reference plane

Professor Bridgman, thank you. Dr. Atkinson, the circuit diagram must be interpreted as a set of transformations with operating conditions, not as a procession of nominal gains. Two paths can have the same settled gain and different transient responses. An internal reference can traverse the stages correctly while failing to reproduce their loading at the external boundary. An inverse can exist mathematically while magnifying measurement error beyond the tolerance of the intended result. These distinctions determine whether an architecture is merely capable of producing data or capable of supporting the correction that the analyst proposes to apply.

Let us first distinguish a known deterministic transformation from the information available to invert it. If y = Hx + e for a single real component, x and y are voltages, H is a known dimensionless transfer coefficient, and e is output-referred error in volts. Division by H gives an input estimate only when H is nonzero. The error in that estimate includes e divided by H. The third worked application sets H = 0.02, y = 0.20 millivolts, and an output error bounded in magnitude by 0.01 millivolts. The corrected estimate is 10 millivolts, but the corresponding contribution to its error bound is 0.5 millivolts. A small displayed disturbance has become important at the inferred input. In the display below, delta x denotes the error in the inferred input voltage.

$$\hat{x} = \frac{y}{H} = \frac{0.20}{0.02} = 10\,mV$$

$$|\delta x| \leq \frac{0.01}{0.02} = 0.50\,mV$$

Copyright 2026, James M. Atkinson

The example does not say that equalisation is illegitimate. It says that a channel with a deep response minimum can impose an unfavourable inverse problem. Improving output numerical precision does not reduce an independently imposed analogue error. At H = 0, the same scalar model supplies no observation of x at all. A constraint on x may permit a selected estimate, but that constraint must be distinguished from information furnished by this channel. A receiver architecture intended for quantitative reconstruction should therefore consider the transfer where the intended signal lies, not only the maximum gain elsewhere in its band.

Now consider the fourth worked application, a stipulated discrete-time system with memory. Let x[n] and y[n] be input and output voltages in millivolts, where n is an integer sample index. Define y[n] = 0.5y[n-1] + 0.5x[n], and let the preceding output be zero. A constant input of 10 millivolts gives successive outputs of 5, 7.5, and 8.75 millivolts. Its settled gain is unity, yet treating the first output as the instantaneous input would be wrong. The current sample is an observation of a state-dependent response, not a complete instantaneous description of its cause.

$$y_n = 1/2\, y_{n-1} + 1/2\, x_n;\; x_n = 2\, y_n - y_{n-1}$$

With the stipulated recurrence and preceding output known, the inverse recovers 10 millivolts from each of those steps. But if measurement errors in adjacent output values are independent with identical standard deviation s, the reconstructed error has standard deviation the square root of five times s. The coefficients two and minus one square to four and one. If those errors are correlated, their covariance changes this result. Thus retaining the preceding state makes inversion identifiable under the model, while the

Copyright 2026, James M. Atkinson

error calculation determines whether the identified inverse is useful. These are distinct tests and neither should be omitted.

Dr. Atkinson, an internal calibration that observes only a settled tone may identify the unity gain of this example without identifying its recurrence. That calibration is suitable for a settled-amplitude claim but not automatically for reconstructing the beginning of a burst. A test sequence must excite the behaviour that matters. The proposed receiver should permit reference signals at the relevant input boundary, with histories and transitions representative of the intended task. This is a measurement-design inference from our stipulated model, not a universal prescription for a particular commercial circuit.

Architectural redundancy can help when different paths retain complementary information. A protected low-gain path may remain linear during an excursion that saturates a high-gain path; the latter may provide better resolution for smaller inputs. Joining their records requires a calibrated overlap, compatible timing, and an explicit selection rule. Merely choosing whichever output appears preferable can conceal the switching boundary and create a reconstruction whose provenance is unclear. The same reasoning applies to frequency slices: a coverage diagram is not evidence of continuity of complex response across their interfaces.

A useful diagnostic is to calculate the forward prediction as well as the inverse estimate. The inferred input, passed through the declared model with its retained state, should reproduce the observation within the stated residual allowance. Agreement is necessary but not sufficient: a nonunique model can admit many inputs that all reproduce the same output. This

Copyright 2026, James M. Atkinson

check detects inconsistent implementation without claiming to establish unique physical origin.

I would therefore evaluate a candidate architecture through three questions. Which transformations does it apply? Which states and inputs does it observe sufficiently to support the intended inverse? How sensitive is that inverse to the remaining uncertainty? A larger retained word cannot answer the second question, and a lower residual on fitted calibration data cannot alone answer the third. Dr Shannon, may I invite your challenge concerning the information that a chosen inverse appears to recover when the forward transformation has discarded distinctions?

Claude Elwood Shannon

Peer question 3 to Hendrik W. Bode

Dr Bode, your distinction between existence and sensitivity of an inverse is useful, but the reconstruction algorithm may introduce additional assumptions without announcing them. Suppose the low-gain path is missing during a short interval, and the software fills the gap by selecting the smoothest waveform consistent with the remaining observations. The resulting curve can look physically reasonable and can join its neighbours without an obvious discontinuity. Does that curve constitute recovered measurement information, or a prediction conditional on a smoothness assumption? I would ask you to identify what must be preserved so that an examiner can tell the difference. In particular, how should the method treat two distinct input histories that generate the same retained outputs but imply different peak amplitudes? A single plotted answer cannot itself establish that the other admissible history has been excluded. The exported record should make

Copyright 2026, James M. Atkinson

the additional assumption discoverable without access to a proprietary display.

Hendrik Wade Bode

Answer to Claude E. Shannon

Thank you for identifying the principal uncertainty in this evidence. Thank you for that question. Dr Shannon, the smooth curve is a model-conditioned reconstruction, not an additional observation. It may be useful if the smoothness restriction is supported for the signal class and if the conclusion is stated accordingly. The defect is presenting the selected history as uniquely measured when the retained data and admitted model allow alternatives. I would preserve the measured intervals separately from the predicted interval, the rule that selected the prediction, and a description of the alternatives relevant to the intended claim. A peak-amplitude conclusion deserves particular care because smoothness preferences can suppress precisely the excursion whose magnitude matters.

For the recurrence just discussed, the missing preceding state provides a simple illustration. A present output can be produced by different combinations of current input and earlier output. The inverse equation does not cease to be algebraically valid; it contains an unobserved quantity. Assigning that quantity its settled value makes a conditional estimate. The assignment may be justified by an independently known quiet interval, but it cannot be justified solely because it produces a plausible reconstruction. The missing premise must be supplied by evidence or remain explicit in the conclusion.

Copyright 2026, James M. Atkinson

Dr. Atkinson, a practical implementation should mark predicted samples or intervals in a way that survives export and later analysis. It should not permit a rendered trace to become a replacement for the original record without a transformation history. Where several admissible histories imply materially different peaks, the report should retain a bound or alternative results rather than resolve the disagreement by aesthetics. Numerical optimisation chooses according to its objective; it does not independently demonstrate that the objective describes the source.

The same discipline applies when regularisation stabilises an inverse near a response minimum. Stability can be purchased by restricting the solution class, but the restriction becomes part of the evidential model. We should evaluate its consequences using cases that challenge the restriction, not only cases chosen to satisfy it. Professor Wiener, may I invite your question about the additional difficulty when the receiver's own controller changes the transformation while the event is occurring?

Norbert Wiener

Peer question 4 to Hendrik W. Bode

Dr Bode, thank you. Suppose an automatic gain controller responds to the same input whose amplitude we wish to infer. Its gain is therefore not merely an external setting; it is a state affected by preceding observations. Dr. Atkinson's question then seems to involve a coupled system rather than a fixed cascade. The recorded gain command may also differ from the actual analogue gain during settling. What is the minimum distinction required between controller intention, physical

Copyright 2026, James M. Atkinson

response, and the correction applied after acquisition? I should also like you to address a possible circular argument. If the analyst infers an unlogged gain state from the waveform that the correction is meant to recover, what independent evidence prevents the assumed waveform from dictating the gain history and then returning as an apparently measured result? Please distinguish a state that is measured independently from one that is inferred only by assuming the desired conclusion.

Hendrik Wade Bode

Answer to Norbert Wiener

Professor Wiener, the command is an input to the controlled system, not proof of its achieved state. A model of the controller and analogue path may connect the two, but its parameters, delays, and range must be established. I would therefore distinguish requested gain, confirmed configuration, and any measured or modelled settling interval. The correction should identify which of these supplied its state information. Treating the command timestamp as the instant of completed physical change can misassign samples even where the eventual gain is exactly what was requested.

Inference from the waveform is not necessarily invalid, but it makes the problem joint. If both input amplitude and gain are unknown, their product can fail to distinguish them. A known pilot, an independent state measurement, a constrained controller history, or a second calibrated path might supply the missing information. Which method is adequate depends on the unknowns and observations. A waveform assumption chosen after seeing the desired answer does

Copyright 2026, James M. Atkinson

not supply independent support. The calculation should reveal the ambiguity rather than hide it inside a gain-estimation routine.

Dr. Atkinson, the architecture should therefore expose the controller's relevant state where that state materially affects the intended result. It need not log every internal variable. It must retain those quantities, or validated bounds upon them, without which different permissible input histories remain indistinguishable. A fixed-gain mode can simplify some measurements, while a characterised adaptive mode can be appropriate for others. Neither is universally superior independently of the task and the surrounding signal conditions.

A state estimator can be tested against independently recorded conditions, with its failures retained. Agreement only with its own corrected output would not be an independent check.

Finally, the validation should include transitions with independently known inputs. Testing only the equilibrium points would leave the disputed interval unexamined. If the transition cannot be qualified for amplitude reconstruction, it may still support a narrower observation, provided its limitation is preserved. Dr Nyquist, may I now pass the floor to you for the related question of what the sampling and frequency-conversion architecture admits before any reconstruction begins?

I thank the questioning colleague for that important distinction. Before offering an opinion about selection of receiver architecture for the investigative measurand, I would define the measurand and its

Copyright 2026, James M. Atkinson

uncertainty. The proposed rival mechanism is that a superheterodyne conversion product can masquerade as a new radio emission. Consequently a calibration certificate for one nominal receiver setting does not settle the question. The more informative operation is to compare direct-conversion and superheterodyne capture on the same calibrated stimulus, with image response, LO plan, RF preselection and conversion loss reported in units and tied to an input reference plane. The adverse prediction is concrete: a true external feature retains its RF coordinate while an internal image follows the oscillator plan. I would challenge it across a range of input powers and hold one independently measured source constant throughout the switching sequence. A correction estimated after seeing the unknown feature may assist an exploratory analysis; it must not be presented as though it had been fixed before acquisition. Where systematic effects share a reference, their covariance belongs in the reported uncertainty rather than being silently assumed zero. This is the distinction between an instrument number that appears stable and a defensible physical measurement.

Copyright 2026, James M. Atkinson

Harry Nyquist

Admitted frequency, digital representation, and irreversible ambiguity

Dr Bode, thank you. Dr. Atkinson, I would locate the first sampling question before the converter. What set of analogue inputs is permitted to reach it, and which of those inputs must remain distinguishable for the intended measurement? A nominal sampling rate does not answer either part. It specifies a succession of sampling instants under a timing model. The restriction that makes those samples informative about an analogue waveform must come from the admitted signal class, the physical filtering, and the calibration of the actual path. A frequency label attached afterwards cannot distinguish alternatives that already produced the same sequence.

The fifth worked application makes the ambiguity exact. Let x[n] denote samples of a unit-amplitude real cosine, let n be an integer, and stipulate an exact sampling frequency f_s of 100 megasamples per second. A cosine at 10 megahertz and one at 110 megahertz produce the same sample values at every integer n under this ideal sampling model. Adding one complete cycle per sample leaves the cosine unchanged. We have not shown that a physical receiver admits both signals with equal gain; we have shown why its analogue admission and frequency response must be part of the explanation of the retained sequence.

$$\cos\left(2\pi\frac{110}{100}n\right)=\cos\left(2\pi\frac{10}{100}n\right)$$

If a characterised input network excludes the higher-frequency possibility to a justified level, the ambiguity can be constrained for the intended result. If the network is unknown, assigning the lower frequency is a convention or hypothesis rather than a conclusion established by the

Copyright 2026, James M. Atkinson

samples alone. This is particularly important in a survey seeking unexpected signals. The fact that the desired transmitter was expected in one band does not establish that all other energy was excluded. A test should challenge the relevant unwanted bands through the actual input path, not merely inject a convenient digital waveform after the ambiguous transformation.

The sixth worked application moves the same issue to a different boundary. Suppose a real stream at 100 megasamples per second contains a desired 5-megahertz component and an unwanted 30-megahertz component. Retaining every fourth sample without adequate prior filtering produces an output rate of 25 megasamples per second. At that output, the 30-megahertz cosine is indistinguishable in frequency from a 5-megahertz cosine because their frequencies differ by one output sampling rate. Both can therefore contribute to the same retained component. Increasing the precision of the output representation does not restore their separate amplitudes.

$$f_{out}=\frac{100}{4}=25\,MS/s;30-25=5\,MHz$$

The first ambiguity concerned what reached the original sampling operation. The second concerns a later sample-rate reduction. A receiver can satisfy the first requirement and fail the second. Conversely, a perfect digital decimation filter cannot remove an ambiguity already established by analogue sampling. The architecture must therefore identify each change in sampling rate, its associated filtering, and the signal interval actually retained. The assumptions belong at their respective boundaries rather than being collected under a general assertion that the receiver obeys a sampling theorem.

Copyright 2026, James M. Atkinson

Dr. Atkinson, a complex representation adds another boundary to preserve: the sign convention connecting its frequency coordinate to the physical input. The definition of the in-phase and quadrature channels, any conjugation, and the local-oscillator convention determine that connection. The familiar shape of a magnitude spectrum does not independently verify it. A controlled offset from a known reference can challenge the mapping, but the reference must enter before the operation being tested. Again, a successful software-only test validates software against supplied samples without proving that the hardware acquired the samples under the claimed convention.

I would not infer that broader acquisition is inherently less trustworthy. It can preserve simultaneous context that a tuned narrow channel misses. The burden is to demonstrate the combination actually used: admission, dynamic range, timing, sustained throughput, and processing history. A broad path that clips under a strong neighbouring signal does not preserve useful context simply because its file is large. A narrower path may miss that neighbour and therefore fail to explain an artefact. Complementary paths can help, but their joint interpretation must preserve timing and reference relationships rather than combine whichever displays look most persuasive.

The qualification must also survive a change in configuration. An analogue filter accepted for one sampling rate may not establish the same exclusions after a rate change. A digital filter whose coefficients are retained can still be misinterpreted if its rate, decimation phase, or frequency translation is omitted. Consequently, the architecture includes the means of retaining its actual configuration, not merely the hardware capable of implementing several possible configurations.

Copyright 2026, James M. Atkinson

For architectural selection, the practical test is whether the requested distinction survives each irreversible step. Once only a power average remains, phase history is not generally available. Once two admitted frequencies coincide in the sampled representation, an independent restriction is required to separate them. Once clipping maps different inputs to the same code, the code alone does not determine their peaks. Professor Gabor, may I invite your challenge concerning the temporal detail needed when the instrument must characterise a short event rather than merely establish that some spectral energy was present?

Dennis Gabor

Peer question 5 to Harry Nyquist

Dr Nyquist, your examples establish frequency ambiguity, but an examiner may instead lose the distinction through the observation interval. Suppose the architecture offers a narrow spectral estimate obtained from a long record and a rapidly updated estimate obtained from a shorter record. A brief event appears in both, although its displayed width and peak differ. What prevents the operator from selecting the more attractive representation and describing its apparent duration as a property of the source? I would ask for a concrete connection between the retained waveform, the window applied, and the temporal claim. It seems that frequency admission alone cannot determine whether the measurement preserves an onset, a burst maximum, or an average over several events. How should the architectural requirement specify the temporal distinction that the later analysis is expected to make? The measurement requirement should

Copyright 2026, James M. Atkinson

make that distinction before the analyst sees which representation produces the clearest event.

Harry Nyquist

Answer to Dennis Gabor

Thank you for that question. Professor Gabor, the requirement should identify the temporal quantity and the operation used to estimate it. The first sample exceeding a threshold after filtering is not automatically the physical onset at the input. A duration measured from a displayed intensity region is not automatically the duration of the source waveform. In each case, the filter response, window, overlap, threshold, and time assignment enter the interpretation. The architecture should retain sufficient samples and state information to reproduce that operation and test it against events whose timing properties are independently specified.

I would preserve an acquisition time coordinate separately from the presentation coordinate. A rapid screen update can reuse much of the preceding data; it need not represent a new independent observation interval. Conversely, a long record can contain a short event without giving every estimator applied to it the same temporal response. The analyst should be able to trace a displayed feature to the exact source interval and response that generated it. Changing the estimator then changes a documented analysis, not the past physical acquisition.

Dr. Atkinson, a defensible architectural specification could require recognition of an event class with stated durations and amplitudes,

Copyright 2026, James M. Atkinson

together with a maximum permitted timing error under declared conditions. Its validation would vary event alignment relative to acquisition boundaries rather than always place the event conveniently at the centre of a record. Such variation tests an omission that a single attractive demonstration can conceal. No universal temporal resolution follows merely from the number of displayed FFT bins.

The requirement should also identify whether timing refers to the input boundary, the filtered output, or the display. Those coordinates need not coincide even when every timestamp is stored correctly.

Where the retained representation is inadequate for the requested onset, the report can still describe a filtered detection interval or another supported quantity. That is preferable to silently reversing an unqualified temporal response. Dr Shewhart, may I now pass the floor to you to examine a different continuity question: how do we know that the calibrated response governing these operations remained applicable throughout the observation?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart

The calibrated regime and the record of change

Dr Nyquist, thank you. Dr. Atkinson, a calibration describes a relationship under conditions, while an operational record must establish where those conditions continued to apply. It is tempting to treat a receiver as one object with one enduring response. Yet the same enclosure can present different gains, temperatures, filter states, or control histories. The practical problem is to determine which variations belong to an adequately characterised regime and which indicate a change that alters the interpretation. Without that distinction, repeated measurements can be combined because they share a filename rather than because they share a measurement law.

For the seventh worked application, use a deliberately simple voltage model with zero offset. In state A the dimensionless gain is 100; in state B it is 110. An output of 22 millivolts therefore corresponds to an input of 0.22 millivolts in A and 0.20 millivolts in B. Suppose checks before and after the disputed interval identify A, but no state record exists during the interval. The endpoint observations do not logically exclude an excursion into B and back. Selecting A throughout may be a justified stability assumption after suitable characterisation, but it is not a consequence of the two endpoint values alone.

$$x_A = \frac{22}{100} = 0.22\,mV\,;\, x_B = \frac{22}{110} = 0.20\,mV$$

This does not require treating every fluctuation as a failure. The intended tolerance may accommodate both states, or a recorded state transition may permit separate valid corrections. What matters is whether the distinction affects the conclusion. A coarse discovery task and a fine amplitude

Copyright 2026, James M. Atkinson

comparison can therefore have different validity classifications for the same interval. The classification should follow the measurement objective rather than a general description of the receiver as operational or defective. A state can be serviceable for one purpose and insufficiently characterised for another.

The eighth worked application concerns an error shared by two readings. Let a and b be two voltage estimates, each with a standard uncertainty of 0.20 millivolts. For their difference d = a - b, suppose the correlation coefficient of their errors is rho = 0.90. Under the declared joint uncertainty model, the variance of the difference is the sum of the individual variances minus twice their covariance. The resulting standard uncertainty is approximately 0.0894 millivolts. If the errors were independent it would instead be approximately 0.2828 millivolts. The sign of the sensitivity to a shared input matters; root-sum-of-squares without the covariance would answer a different model. [M2-2]

$$u(d)=\sqrt{0.20^2+0.20^2-2(0.90)(0.20)(0.20)}$$

$$u(d)\approx 0.08944\,mV$$

The small difference uncertainty does not establish equally small uncertainty in either absolute reading. A common correction error can cancel in the difference while surviving in both values. Conversely, adding positively correlated quantities increases the contribution rather than cancelling it. Therefore, two agreeing receiver channels do not independently establish their common input calibration. The covariance is a description to justify, not a numerical setting chosen to make the budget attractive. Its relevant value depends on the conditions, interval, and error sources represented in the comparison.

Copyright 2026, James M. Atkinson

Dr. Atkinson, I would organise the operating record around changes capable of defeating an applicable correction. Temperature may be one variable, but it should not become a universal surrogate for state. A stable temperature trace does not prove that a relay, gain command, input loading, or software coefficient remained unchanged. Nor does a change in one of those variables necessarily invalidate every measurand. The proposed record should connect the variable to a specific dependence or qualification in the model, so that the reviewer can understand why an interval was retained, separated, or excluded.

A check source is especially useful when its path is selected to challenge the suspected change. A source that shares a drifting reference with the receiver can leave certain common errors hidden. A reference that bypasses the affected stage can remain stable while the desired path changes. These are reasons to design checks with known scope, not reasons to abandon them. Independent physical variation, recorded state, and a suitable uncertainty model can together provide a stronger argument than any one favourable indicator.

There is a further distinction between evidence that a process changed and evidence about why it changed. A check discrepancy can justify separating an interval before its cause is known. Calling the change thermal, however, requires additional support. Preserving this distinction permits timely protective action without promoting an early diagnosis into an established physical explanation. The eventual cause can then be investigated against the retained state and comparison records.

The resulting procedure should preserve the chronology of changes and the acceptance rule used to interpret them. It should not reconstruct that

Copyright 2026, James M. Atkinson

rule after seeing which intervals contain desired detections. Nor should statistical smoothing erase evidence of a state transition by treating it as an inconvenient outlier. Professor Pearson, may I invite your question about how a laboratory should distinguish an appropriate adaptation of its model from a retrospective adjustment that conceals a failure of the procedure under test?

Egon Sharpe Pearson

Peer question 6 to Walter A. Shewhart

Dr Shewhart, thank you. Suppose a laboratory notices that residual errors become larger after a particular gain transition. It adds a settling exclusion and obtains much better agreement. The revised procedure may be genuinely better, yet the same observations have suggested the exclusion and demonstrated its apparent success. What conclusion can be drawn from that development record? I would also ask whether a fixed adaptation rule should be treated differently from discretionary intervention. A receiver may be designed to alter its threshold whenever a documented reference statistic changes. If that rule is frozen and tested as part of the complete procedure, adaptation need not be a defect. Please distinguish those cases and explain what additional testing would support a performance claim without condemning every scientifically justified revision as improper manipulation. Please also distinguish evidence that the change improves accepted-interval accuracy from evidence that it preserves the required event coverage.

A final evidential safeguard is that a stepped reference-source comparison at each declared reference plane. The unattested voltage and phase before unknown transfer functions remain outside the direct

Copyright 2026, James M. Atkinson

observation. If the examiner reports only those cases in which the indicated feature agreed with the preferred model, what correction would you require to the exposure denominator, alternative-hypothesis analysis, and reproducibility account?

Walter Andrew Shewhart

Answer to Egon S. Pearson

Professor Pearson, the development observations support the reason for revising the procedure and permit examination of its behaviour on those observations. They do not independently establish its performance on fresh cases drawn from the intended operating conditions. I would preserve the original discrepancy, the proposed explanation, the revised exclusion rule, and the outcomes before and after revision. A further test should then challenge the fixed revised procedure with conditions selected to expose the explanation, not simply replay the case that inspired it. This separates learning from certification without treating learning as misconduct.

A predetermined adaptive rule is part of the procedure being tested. The validation should include its state evolution, the reference observations that drive it, and the conditions under which its threshold can change. Testing only a constant-threshold surrogate would not establish the adaptive procedure's performance. Conversely, allowing an operator to alter exclusions without recording those decisions leaves no single procedure whose trial outcomes can be interpreted consistently. The important boundary is specified operation versus unrecorded discretion, not adaptation versus immobility.

Copyright 2026, James M. Atkinson

Dr. Atkinson, residual analysis can reveal structure that challenges a calibration relationship, but a favourable overall fit statistic is not a complete validation. The official statistical guidance we consulted specifically treats residual patterns and assumptions as relevant to model assessment. Our proposed receiver test extends that principle to gain transitions by conditioning the comparisons on their histories. It is an authored application, not a claim that the source evaluated this particular instrument. [M2-3]

Where the revised exclusion is substantial, its coverage consequence should be a separate reported outcome rather than hidden inside an improved error statistic.

If a revised settling exclusion removes important portions of the observation interval, the report must retain the resulting loss of coverage. Improved accuracy on accepted intervals does not establish improved capture of every event. It may be the correct trade-off, but its consequence belongs in the performance claim. Professor Neyman, may I pass the floor to you for the final question of what the resulting calibration and validation evidence actually permits us to infer?

I thank the questioning colleague for that important distinction. There is a statistical difficulty in the assertion concerning selection of receiver architecture for the investigative measurand: we have not yet ruled out the possibility that a superheterodyne conversion product can masquerade as a new radio emission. The investigation should record its chosen detector threshold, visit schedule, selection of frequencies and expected failure modes before the prospective

Copyright 2026, James M. Atkinson

confirmatory test. To examine the difference we should compare direct-conversion and superheterodyne capture on the same calibrated stimulus, collecting image response, LO plan, RF preselection and conversion loss over a predeclared range rather than selecting the most attractive subset afterward. An observation in which a true external feature retains its RF coordinate while an internal image follows the oscillator plan would strengthen a restricted causal account, but it cannot certify every unvisited frequency-time interval. I would state which recordings are dependent, which have been excluded as invalid, and which inferences rely upon a model of rare events or stationary interference. A numerical interval can have impeccable arithmetic and still misdescribe the physical world if its sampling population was chosen because the signal already looked unusual. We should therefore preserve exploratory leads separately from independently designed validation evidence.

Copyright 2026, James M. Atkinson

Jerzy Neyman

Identifiability, tested decisions, and the remaining alternatives

Dr Shewhart, thank you. Dr. Atkinson, I would distinguish a parameter estimate, a model adequate for the observations, and a decision procedure with demonstrated performance. These are not interchangeable achievements. A calculation can return a unique set of coefficients because the software imposes a preference, while the observations permit several physically distinct explanations. A model can fit the calibration observations closely while giving inadequate predictions elsewhere. A corrected estimate can be precise enough for one decision and insufficient for another. The final report should identify which of these propositions its evidence supports.

The ninth worked application makes parameter ambiguity explicit. Let x and y be input and output voltages in millivolts and assume y = gx + b, with dimensionless gain g and offset b in millivolts. A single calibration observation x = 10, y = 11 is compatible with g = 1, b = 1 and with g = 0.9, b = 2. Repeating precisely that level without other information can reduce uncertainty about its response while leaving gain and offset inseparable. The ambiguity is structural. It is not removed simply by acquiring a larger number of copies of the same equation.

A second level x = 20, y = 21 distinguishes those two pairs in the stipulated exact model. Subtracting the two equations gives g = (21 - 11)/(20 - 10) = 1, and substitution gives b = 1 millivolt. With uncertain calibration inputs and outputs, the fitted coefficients would carry uncertainty and dependence. Moreover, two exact points identify the affine parameters only after the affine form has been assumed. They do not establish that the

Copyright 2026, James M. Atkinson

physical receiver is affine between those points or beyond them. An independent challenge to the functional form remains necessary. [M2-4]

$$g=\frac{21-11}{20-10}=1\,;b=11-g(10)=1\,mV$$

The tenth worked application concerns a bounded correction rather than a probability distribution. Suppose the observed output lies between 21 and 23 millivolts, the additive output offset between 1 and 3 millivolts, and the positive dimensionless gain between 90 and 110. Under x = (y - b)/g and these independent admissible ranges, monotonicity gives an input interval from 18/110 to 22/90 millivolts, approximately 0.1636 to 0.2444 millivolts. A claim that the input exceeded 0.20 millivolts is not established across that interval. Choosing the midpoint would create a point estimate without resolving the bounded alternatives.

$$x_{min}=\frac{21-3}{110}\approx 0.16364\,mV$$

$$x_{max}=\frac{23-1}{90}\approx 0.24444\,mV$$

If instead the output interval is 26 to 28 millivolts with the same bounds on gain and offset, the input interval becomes approximately 0.2091 to 0.3000 millivolts. It lies entirely above the stipulated decision value. The calculation now supports that bounded claim, provided the assumptions and ranges are valid. Neither interval is a confidence interval merely because it is written with two endpoints. We have supplied allowed ranges, not a sampling distribution or posterior distribution. A numerical interval must retain the interpretation justified by the method that produced it.

Copyright 2026, James M. Atkinson

$$x_{min} = \frac{26-3}{110} \approx 0.20909\, mV$$

$$x_{max} = \frac{28-1}{90} = 0.30000\, mV$$

Dr. Atkinson, the architectural implication is that additional information should be selected to resolve the uncertainty relevant to the decision. More repeated output samples may reduce random variation without constraining an unknown gain state. A second calibration level can identify parameters under a model without proving its applicability over frequency. A second receiver can share the same reference error. The purpose of an additional observation must therefore be stated: which alternative does it constrain, under what assumptions, and by how much? An experiment that cannot distinguish the important alternatives may be elaborate without being informative.

This also affects how validation trials are counted. A collection of successful tests is meaningful only relative to the population of conditions and the decision rule exercised. A receiver used for weak bursts near gain transitions should not be validated solely with strong steady carriers. If the procedure adapts, the adaptive mechanism belongs in the tested object. If the analyst chooses a new procedure after seeing a failure, the revision can be valuable, but its performance requires an appropriately separated assessment. The distinction is between a supported improvement and an inference whose test has been selected by its desired outcome.

Where a joint distribution is used instead of bounded ranges, the dependency assumptions require the same scrutiny as the marginal uncertainties. Gain and offset estimated from one calibration are not automatically independent. Their joint variation can matter when applying

Copyright 2026, James M. Atkinson

the inverse away from the centre of the calibration interval. The method should carry the estimated relationship into the final result rather than retain only the two most convenient standard errors.

I would accept a correction when the quantity is defined, the relevant parameters are identifiable to the required extent, the functional and operating assumptions have been challenged, and the remaining uncertainty permits the intended conclusion. Where these conditions are only partly met, a narrower result or an indeterminate decision can be the scientifically correct outcome. Sir Karl, may I invite your final challenge concerning how such a conditional acceptance remains open to criticism without becoming either an impossible demand for certainty or an excuse for every unfavourable result?

Sir Karl Raimund Popper

Peer question 7 to Jerzy Neyman

Professor Neyman, your account identifies several premises on which a correction depends. My concern is that the investigator might protect the preferred conclusion by changing those premises whenever a challenge fails. An unexpected response could be assigned to a different gain state, an unmodelled transient, or a newly restricted signal class. Each explanation might be physically possible. Taken together, they could make the original claim resistant to every practical objection. How should a laboratory distinguish an informative refinement from an adjustment that merely preserves the conclusion? Please identify what must be stated before the challenge and what must remain visible afterwards. I would also ask whether rejecting one correction model requires rejecting the entire observation, or whether a narrower,

Copyright 2026, James M. Atkinson

independently supported result may survive without allowing that survival to conceal the original model's failure. An explanation that can accommodate every outcome seems unable to discriminate among the competing causes we set out to examine.

Jerzy Neyman

Answer to Karl R. Popper

Sir Karl, the challenge should state the proposed claim, the conditions under which it is expected to hold, and outcomes that would require revision or rejection. A subsequent refinement is informative when it explains the discrepancy through an independently examinable relationship and is exposed to further tests capable of distinguishing it from alternatives. It is not enough that the refinement can be made to reproduce the original observation. The laboratory should preserve the failed prediction and its original scope, so that the history of the claim remains visible rather than being rewritten into an uninterrupted sequence of successes.

A rejected model need not erase every observation. If the file reliably records a receiver-output disturbance, that finding can survive failure of an attempted input-amplitude reconstruction. The narrower result must be stated at its actual boundary, with no implication that the failed inference has been restored. This is not an escape from criticism; it is a distinction between propositions. A model failure should limit the proposition that depended on it, while independent evidence remains available for other conclusions.

Copyright 2026, James M. Atkinson

Dr. Atkinson, we should likewise avoid making uncertainty a universal defence. An uncertainty statement must arise from a defined model and justified information, not expand opportunistically until every outcome is accommodated. If a new state is invoked, evidence about that state and its relevance should be sought. If the applicable signal class is narrowed, the validation and conclusion must adopt the narrower class openly. The cost of revision can include loss of previously claimed coverage or precision.

The acceptance decision is therefore revisable but not arbitrary. It rests on stated boundaries, identifiable quantities, observable checks, and an explicit account of unresolved alternatives. Further evidence can strengthen it or show that it was too broad. That is a discipline of accountable inference rather than a promise of certainty. Professor Atkinson, I return the floor to you for the closing synthesis and for the consequences this discussion should carry into the next examination of a changing receiver record.

I thank the questioning colleague for that important distinction. I should distinguish the physical occurrence under inquiry from the information actually retained when studying selection of receiver architecture for the investigative measurand. Because a superheterodyne conversion product can masquerade as a new radio emission, more than one historical account may produce the same saved trace. The controlled comparison should be to compare direct-conversion and superheterodyne capture on the same calibrated stimulus, preserving image response, LO plan, RF preselection and conversion loss at the measurement point and in the evidential

Copyright 2026, James M. Atkinson

metadata. If a true external feature retains its RF coordinate while an internal image follows the oscillator plan, that result would narrow the admissible explanations, not establish a uniquely identified emitter outside the tested conditions. A subsequent software reconstruction may recalculate a statistic from retained samples, yet it cannot recover components rejected by the front-end filter or intervals never recorded. I would make those distinctions explicit in the final report and invite an independent examiner to reproduce the challenge, including its failed steps. Scientific restraint is not a weakness of the investigation. It prevents a detector output, however striking on the screen, from becoming a claim about unobserved activity that the original measurement never established.

Percy Williams Bridgman, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, may I press the distinction between a reference plane selected for convenience and one selected because its measured quantity answers the actual inquiry? A cascade can be calibrated with admirable precision at its digitiser input while the antenna, attenuator, preselector and cable before that interface remain uncharacterised. If we move the nominal input boundary after an inconvenient component, the instrument's displayed accuracy may improve merely because we have excluded the principal cause of uncertainty. The question is not whether the later plane is legitimate; it is what physical proposition that plane entitles us to infer. How should a measurement model handle a lossy, mismatch-sensitive network when neither its reverse transfer nor its time-dependent operating state is fully known? Would you permit a calibrated inverse to reconstruct the earlier

Copyright 2026, James M. Atkinson

input at all, or insist on reporting only the directly supported downstream value?

Hendrik Wade Bode, Cross-Peer Answer to Percy Williams Bridgman: Professor Bridgman, I agree that the plane must follow the declared question, not the prettier residual error. We should distinguish three propositions. One is the value measured at the accessible receiver connector; another is an estimate of what reached the antenna terminals; the third is a purported property of the remote emitter. These have different dependencies, and the first cannot be silently promoted into the third. In a small-signal, linear and time-invariant regime one may represent the intervening network by a measured complex transfer function H(f). Reconstructing an upstream spectral component from the downstream component means dividing by H(f), and that operation becomes fragile wherever the magnitude of H approaches zero or the calibration uncertainty is large. If H is estimated with uncertainty, its phase and amplitude covariance enters the reconstruction, not just an average insertion-loss correction. If gain compression, switching, reflections or temperature drift make the network nonstationary, a single H is an inadequate model. I would record the connector result as directly measured, present any upstream reconstruction as conditional on the verified transfer state, and state frequencies at which inversion is not defensible. A second test could inject a calibrated source at the intended upstream plane while recording the full network response and an independent level measurement. Such a challenge establishes a bounded relationship for those settings, not a universal certificate for unknown waveforms. The uncertainty budget must follow the

Copyright 2026, James M. Atkinson

entire measurement path, including coupled quantities, before we claim that two receiver architectures agree.

Harry Nyquist, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, how should an investigator define a genuinely comparable statistical experiment when two receiver architectures admit different bands and accumulate different dwell times? A narrow receiver may provide more reliable estimates inside its passband than a broadband receiver, yet the two are not sampling identical sets of events. Their plots may share a frequency label while differing in preselector history, analysis window, detector response and exclusion intervals. A difference in recorded detections is then partly a difference in exposure, not necessarily a difference in sensitivity. I ask how the acceptance design should record the transfer function and observation opportunity before analysts compare means or construct alarm thresholds. Can a post hoc filter applied to one instrument make the two outcomes comparable when the original analogue path clipped or failed to observe a short burst?

Walter Andrew Shewhart, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the answer requires an experimental protocol that was fixed before the resulting traces were inspected. I would begin with a written comparison table: physical input reference, calibrated gain regime, admitted bandwidth, equivalent noise bandwidth, time windows, trigger dead time, detector statistic and the definition of a positive event. These are not merely settings to be copied between instruments. They define the population to which each recorded observation pertains. Common-input trials should include weak steady carriers, known transient pulses, strong adjacent blockers and deliberately empty intervals. We would measure the fraction of

Copyright 2026, James M. Atkinson

opportunities actually observed and report detection probability conditional upon each waveform class. In particular, a receiver that visits a narrow channel for one millisecond each second cannot be judged to have remained silent throughout the other 999 milliseconds. Nor can a digital filter repair an unrecorded pulse or reverse analogue saturation. If paired observations share the same source or reference oscillator, their errors may be correlated; the uncertainty of the difference must include that covariance rather than simply treating the two outputs as independent. I would retain both raw measurements and the inclusion/exclusion rules, and investigate a disagreement before replacing it with an averaged aggregate. Only when the observation sets are adequately matched should the resulting comparison be called a sensitivity or fidelity test. Otherwise the conclusion must be qualified as an architectural coverage comparison.

Jerzy Neyman, Cross-Peer Question to Percy Williams Bridgman: Professor Bridgman, I should like to place a decision problem upon your definition of the measurand. Suppose the operator is asked whether a suspected emitter was present during a four-hour investigation, but the apparatus was calibrated to measure power at a connector for several narrower intervals. A threshold on that connector power is not a direct decision rule for the historical existence of an emitter. Even with a well-calibrated reading, the alternative explanations include internally generated spurs, unrelated transmitters, multipath and unobserved intervals. How would you restate the question so that the reported measurement remains relevant to the investigator without claiming a conclusion for which the observation model supplies no identifiable parameter? I am particularly concerned that the

Copyright 2026, James M. Atkinson

word 'absence' sounds definitive even where the apparatus offers only a small set of negative measurements.

Percy Williams Bridgman, Cross-Peer Answer to Jerzy Neyman: Dr Neyman, I would insist on a precise operational statement before choosing a threshold. 'A component at the receiver input exceeded a specified calibrated level during an admitted observation interval' is one measurable claim. 'A particular external emitter operated anywhere throughout the four hours' is not the same claim; it requires an account of interception opportunity, source attribution and competing causes. The instrument can support the former through traceable calibration and a defined detection rule. It may contribute evidence towards the latter but cannot convert missing exposure into an observation of absence. I would formulate the report using nested statements: what the system physically admitted, what it recorded, what the software classified, what independent challenges were performed and which explanations survived. The classification stage should preserve false-alarm and missed-detection qualifications, and any inference to an external source should be conditional on tests of image products, leakage and overload. An investigator is entitled to an answer that is useful, but usefulness is not served by disguising uncertainty with unqualified language. A narrow, accurately formulated observation may be more valuable than an imposing but scientifically untestable assertion. This distinction also protects the ability of another examiner to repeat the analysis or dispute the proposed interpretation on the recorded evidence.

Claude Elwood Shannon, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, your transfer-function analysis is a persuasive way to relate analogue planes, but I ask how you would distinguish invertible distortion from

Copyright 2026, James M. Atkinson

information irretrievably discarded before the recording stage. A sampled complex stream may preserve amplitude and phase within its admitted passband, yet it has no unique inverse for an out-of-band signal removed by a preselector or for two different analogue inputs folded onto the same sampled coordinate. A strong signal can also cause clipping, producing new components that resemble external emissions. Suppose the archive includes metadata describing the nominal filter and digitiser rate but has no independent evidence of their actual state during the event. Under what conditions would you allow the recording to support a reconstruction of the external waveform, and where must the analyst stop at a limited equivalence class?

Hendrik Wade Bode, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, I would draw a boundary between numerical inversion and physical identifiability. Given a verified linear network with a nonzero transfer over the band of interest, a computational inverse may estimate the admitted input, subject to its noise amplification and calibration uncertainty. That mathematical possibility does not imply recovery of information rejected by analogue filtering or overwritten through clipping and quantisation. In the alias case, several distinct RF histories can lead to the same sampled sequence. Their equivalence cannot be broken by post-processing that sees only that sequence; additional constraints must come from the preselector, an independent receiver, a controlled retune or a known calibration stimulus. I would therefore require that the metadata identify actual, not merely commanded, filter state, gain, oscillator frequency and sample clock, ideally with reliable change boundaries. The record must preserve raw complex samples before irreversible detection

Copyright 2026, James M. Atkinson

and provide integrity evidence for those bytes. An inferred upstream reconstruction should specify which input classes are compatible with the observation and test whether plausible alternatives remain. If the analogue chain suffered hard clipping, an elegant inversion algorithm can still produce a plausible waveform, but that plausibility is not proof of the missing amplitude or phase. Forensically, the principled outcome is to preserve the measured stream, document the tested model and state explicitly what cannot be reconstructed.

Dr. James M. Atkinson

Closing synthesis

Professor Bridgman, Dr Bode, Dr Nyquist, Dr Shewhart, Professor Neyman, and our questioning colleagues, thank you. The panel has made architectural selection answer to the intended measurement rather than the other way round. It has not identified one universally superior receiver. It has shown how to ask which physical and numerical distinctions must survive for the proposed conclusion, and which reference observations can demonstrate that survival. This is a more demanding comparison than a catalogue of maximum specifications, but it is also more useful because it connects the chosen arrangement to a testable result.

The ten constructed applications exposed different failures. Ambiguous voltage conventions changed the inferred power. An offset applied at the wrong plane changed the correction itself. A small transfer coefficient amplified error; a system with memory required preceding state. Analogue sampling and later decimation introduced distinct ambiguities at different boundaries. An unobserved gain excursion survived endpoint checks. Shared uncertainty affected a difference differently from either absolute

Copyright 2026, James M. Atkinson

reading. A repeated single calibration level failed to identify two parameters. Finally, bounded correction intervals showed when a threshold claim remained indeterminate and when the supplied bounds supported it.

The peer challenges prevented those calculations from becoming isolated demonstrations. An earlier calibration required an applicability argument. A sufficient record remained sufficient only for specified questions. A smooth reconstruction could embody an assumption rather than recovered information. A controller command did not establish its achieved analogue state. A displayed duration required a temporal measurement model. Adaptation could be legitimate when tested as part of a declared procedure. A failed correction model did not erase every observation, but neither could a surviving narrower observation be used to conceal that failure.

The unresolved trade-offs remain real. Broader coverage may preserve context while imposing different demands on dynamic range and sustained recording. Narrower acquisition may support a particular comparison while excluding relevant events elsewhere. More detailed retention may enable later questions without restoring anything lost before recording. Additional calibration can constrain an important error or merely repeat a comparison that leaves it untouched. These choices should be evaluated against the actual task, with the resulting scope preserved in the report rather than hidden behind a single adjective such as accurate or sensitive.

The governing sources support a discipline of explicit modelling and assessment. The receiver arrangements and ten numerical cases remain our independently constructed applications. Their value is that they expose

Copyright 2026, James M. Atkinson

testable premises; their arithmetic does not establish that an unspecified instrument satisfies those premises in operation.

Our conclusion is a chain of accountable decisions. Define the quantity and boundary; choose an architecture that can preserve it; identify the state and transfer required by the correction; test the assumptions at the relevant interfaces; and report the uncertainty and alternatives that remain. The next question will examine how that chain is preserved when the receiver changes state during the observation itself. A correct diagram at the beginning is not yet a faithful history of the measurement. We shall therefore turn from selecting the architecture to retaining a record that permits its changing operation to be reconstructed and challenged.

Ten worked engineering applications | Question 002

Application 01. Filter or cable rejection referred to a physical input

In the illustrative 002.01 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. For an admitted input P_i = -44 dBm and separately measured loss L = 26 dB, the linear prediction is $P_o = P_i - L$ = -70 dBm. In SI power this becomes 10^((-70 − 30)/10) = 1e-10 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. State which architecture-specific limits the physical evidence actually tested.

Application 02. Cascade gain and observed headroom

In the illustrative 002.02 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. A first amplifier contributes G_1 = 11 dB, an intentional attenuation contributes G_2 = -7 dB, and a later stage contributes G_3 = 16 dB. The small-signal sum is 11 + (-7) + 16 = 20 dB. For P_i = -71 dBm, the ideal output is P_o = -51 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. State which architecture-specific limits the physical evidence actually tested.

Application 03. Thermal reference noise in a declared measurement bandwidth

In the illustrative 002.03 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. Take the equivalent noise bandwidth B = 12,000 Hz and calibrated noise figure NF

Copyright 2026, James M. Atkinson

= 2.90 dB at an assumed 290 K. The thermal-reference estimate is N = $-174 + 10 \log_{10}(B/1\ \text{Hz}) + NF$ = -130.31 dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. State which architecture-specific limits the physical evidence actually tested.

Application 04. Alias-location prediction and its non-unique inverse

In the illustrative 002.04 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. For an actual sampling frequency f_s = 19 MHz and analogue input f_i = 60.040 MHz, the nearest-replica folding rule gives $f_a = |f_i - \text{round}(f_i/f_s)f_s|$ = 3.040 MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. State which architecture-specific limits the physical evidence actually tested.

Application 05. Combined and expanded measurement uncertainty

In the illustrative 002.05 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. For independent standard-uncertainty contributions 0.59, 0.36 and 0.43 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.59^2 + 0.36^2 + 0.43^2)}$ = 0.814 units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c$ = 1.628 units. State which architecture-specific limits the physical evidence actually tested.

Copyright 2026, James M. Atkinson

Application 06. Accumulated sample-clock time error

In the illustrative 002.06 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. A free-running sample clock with fractional rate error $\varepsilon = 0.860$ ppm over $T = 336$ s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T = 0.2890$ ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. State which architecture-specific limits the physical evidence actually tested.

Application 07. The frequency dependence of aperture-jitter-limited SNR

In the illustrative 002.07 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. At sinusoidal input frequency $f = 275$ MHz with uncorrelated rms aperture jitter $\sigma_t = 1.14$ ps, the idealised jitter-imposed ceiling is $SNR_j = -20 \log_{10}(2\pi f \sigma_t) = 54.11$ dB. A common clock source may correlate errors across parallel ADC channels, so treating their outputs as independent for noise cancellation would need an additional experiment. Converter nonlinearity and thermal noise can make actual performance worse. State which architecture-specific limits the physical evidence actually tested.

Application 08. Frequency-bin spacing versus independent information

In the illustrative 002.08 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. With

Copyright 2026, James M. Atkinson

sampled bandwidth f_s = 7 MS/s and N = 16,384 transform samples, the discrete-frequency grid is $\Delta f = f_s/N$ = 427.246 Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. State which architecture-specific limits the physical evidence actually tested.

Application 09. Gain allocation and blocker headroom

In the illustrative 002.09 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. Assume a calibrated digital full-scale equivalent of -9 dBm, a blocker applied at -35 dBm, and net analogue gain 32 dB. The projected converter input is -3 dBm and remaining margin is -9 − (-3) = -6 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. State which architecture-specific limits the physical evidence actually tested.

Application 10. Difference between two instruments relative to stated uncertainty

In the illustrative 002.10 test, two unlike receiver architectures are compared under a known common electromagnetic stimulus. The paired instrument contrast is Δ = 1.390 dB. Set independent standard uncertainties u_1 = 0.380 dB and u_2 = 0.520 dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)}$ = 0.644 dB, giving the dimensionless ratio $\Delta/u\Delta$ = 2.158. This ratio is not automatically a significance test: correlated calibration errors and non-

Copyright 2026, James M. Atkinson

normal uncertainty require separate treatment. State which architecture-specific limits the physical evidence actually tested.

Copyright 2026, James M. Atkinson

QUESTION 003

Copyright 2026, James M. Atkinson

What must be preserved when a receiver changes state during an investigation?

Source: V011_Roundtable_Q001-Q011_CP011_Integrated_Candidate(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Constructed educational dialogue. The speeches are newly authored, not historical quotations or a transcript. Numerical cases are hypothetical and do not certify an instrument.

Dr. James M. Atkinson

Opening question

Mr Hartley, can you comment on what must be preserved when a receiver changes state while an investigation is running? The preceding discussion established that an architecture must answer to the intended measurement. We must now examine the history of that architecture. A diagram can identify its possible paths without telling us which path operated during a particular event. A file can contain intact samples while omitting the gain change, clock interruption, retuning interval, or selection decision that gives those samples their physical meaning. The question is therefore not whether the record is large, but whether its relevant dependencies remain reconstructible.

Our case is again hypothetical. A wideband acquisition is running when an unexpected component prompts the operator to alter gain and retain a narrower channel. Some data are held in a circular buffer, some are already on disk, and some derived displays are updated from overlapping windows. A reference clock adjustment occurs during the same period. Later, a second examiner is given an exported recording with a plausible start time, a nominal sample rate, and a statement that it contains the event. We must

Copyright 2026, James M. Atkinson

identify which claims can be reconstructed from that package and which require information that its apparent continuity does not supply.

The consulted recording specification distinguishes stored sample positions from indices in an original stream, while the evidence-preservation guidance distinguishes the protected object and its history from a merely convenient copy. These are bounded source contributions. Our acquisition ledger, timing calculations, and proposed tests are original applications for this volume, not claims that either source certifies a receiver. We must also distinguish the preservation of bytes from the correctness of the physical declarations attached to them. [M3-1, M3-2]

Mr Hartley will address the record's identity and coordinates. Professor Wiener will examine control actions and achieved states. Professor Gabor will separate acquisition time from the time assigned by analysis and display. Professor Pearson will consider the population of decisions created by overlapping and selective observations. Dr Shannon will examine the transformations connecting original data to an export, including the point at which a useful derivative ceases to support the earlier question. Seven colleagues will test these arguments through immediate questions and answers.

The resulting record must permit later corrections without obscuring what was originally observed, declared, inferred, or changed. Those categories should remain distinct throughout the discussion.

I ask the panel to retain the chronology rather than treat every change as a new unrelated file. Conversely, no one should join incompatible intervals merely to produce a smooth trace. Ten worked applications will use

Copyright 2026, James M. Atkinson

stipulated counts, rates, and transformations, so that an examiner can check the arithmetic and identify the assumptions. We shall distinguish count discontinuity from elapsed-time uncertainty, a requested state from a settled state, and a reproducible calculation from a verified acquisition. The desired conclusion is a practical record capable of supporting criticism, not a demand to document every internal operation without regard to its significance. Mr Hartley, please begin by identifying what a sample position actually denotes after acquisition has been interrupted, cropped, or exported.

Copyright 2026, James M. Atkinson

Ralph Vinton Lyon Hartley

A recording needs both identity and coordinates

Dr. Atkinson, thank you. A position in a stored array identifies an element of that array. It does not, without a mapping, identify the element's place in the original physical acquisition. The distinction becomes important whenever samples are discarded, files are divided, or a selected interval is exported. Reassigning the first retained sample the convenient index zero is harmless if the relation to the original stream is retained. It becomes misleading when the new ordinal is treated as though no earlier acquisition or intervening loss existed. A recording needs coordinates as well as content.

For the first worked application, suppose one retained segment begins at source index 10,000 and contains 1,000 consecutive samples. Its final source index is therefore 10,999. The next retained segment begins at source index 11,250. The missing source indices are 11,000 through 11,249, a total of 250. At an exactly stipulated sampling frequency of one million samples per second, the omitted sample slots represent 250 microseconds. If the second segment is simply placed after the first in a file, its first stored ordinal may be 1,000. That ordinal must map to source index 11,250, not to 11,000.

$$N_{gap} = 11250 - (10000 + 1000) = 250$$

$$T_{gap} = \frac{250}{10^6} = 250\,\mu s$$

The calculation presumes a reliable source counter and unchanged sampling interval. A counter generated after the point of loss may not reveal the missing samples. An error flag can indicate a discontinuity without establishing its length. The source of the count is therefore part of the

Copyright 2026, James M. Atkinson

record. The signal-metadata specification offers a distinction between sample position in the retained dataset and a corresponding global stream index. That distinction permits documentation of this kind of gap; it does not itself prove that a recorder populated the fields correctly. [M3-1]

The second worked application considers a finite counter. Stipulate a counter modulus M of 65,536, and two successive retained samples with counter values 65,530 and 10. If there was at most one wrap and no reset, their advance is 16 sample intervals. Fifteen samples between them are therefore absent from this retained pair. If the elapsed time could permit additional complete wraps, or if the device could reset the counter, the same pair of values no longer establishes that unique advance. A numerical rollover calculation is useful only with the conditions that make it identifiable.

$$\Delta n = (10 - 65530) \bmod 65536 = 16 \,;\, N_{missing} = 16 - 1 = 15$$

These examples concern different questions. The first maps a known gap between segments. The second shows an ambiguity in the coordinate mechanism itself. The recording should not hide the latter by selecting the shortest plausible advance unless a timing bound or other evidence justifies that selection. A monotonically increasing derived index can be convenient for software, but it should not replace the observed counter values and reset information. The transformed coordinate is a conclusion, and its inputs should remain available where the conclusion matters to the measurement.

Dr. Atkinson, data identity requires similar care. A digest can help establish whether a particular byte sequence has changed relative to a protected reference digest. It does not establish that the bytes describe the claimed antenna, sample rate, or time. The reference digest itself needs

Copyright 2026, James M. Atkinson

trustworthy preservation if it is to support comparison. The consulted evidence-preservation guidance discusses retaining origin information, hashes, and controls over those hashes; our application is to preserve these records for the acquisition and its derivatives. The receiver's metrological validity remains a separate question. [M3-2]

I would accordingly bind a recording to its configuration and coordinate history through an explicit manifest. Each retained segment would identify its source, its place in the original stream, the applicable state record, and any known loss or qualification. The precise implementation can vary. The requirement is that a later examiner can determine which observations underlie a reported feature without relying on an operator's recollection or a misleadingly continuous display. A manifest is useful because it preserves relationships, not because the word itself confers authority.

Coordinates also require a declared representation. Signed and unsigned words, byte order, interleaved real and imaginary components, and padding can assign different values to identical bytes. A versioned schema should define those choices and their relation to physical units. The manifest should bind that interpretation to the correct segment, not merely to the folder in which several incompatible recordings happen to reside. A checksum of the sample file alone does not resolve a disagreement between competing descriptions of its encoding.

A derivative should retain both its own identity and the mapping back to its parent. Cropping, reordering, and conversion can produce a valid new object, but the relationship should identify what changed. If the original data are unavailable, the derivative may still support a limited analysis; it should not be described as proof that nothing relevant was omitted. This is

Copyright 2026, James M. Atkinson

a question of evidential scope rather than an automatic rejection of every reduced record. Professor Bridgman, may I invite your challenge concerning which parts of that history can be treated as information about the event rather than merely information about the file?

Percy Williams Bridgman

Peer question 1 to Ralph V. L. Hartley

Mr Hartley, your proposed manifest identifies the origin and ordering of samples, but origin information can itself be generated incorrectly. Suppose two exports carry identical data and different sample-rate declarations, and both declarations were signed by the same acquisition software. The files are internally well formed and each has a correct digest. What additional proposition would establish which declaration governs the physical event? Dr. Atkinson has asked that the record support criticism, so I should like you to distinguish a test of internal consistency from a test of the claimed relationship to the receiver. Must an external timing observation always be available, or can a validated clock and configuration history suffice? Please explain how the conclusion should change when only the internally consistent export survives and the physical acquisition history has been lost.

In particular, would agreement between two descriptions generated from the same untested configuration supply any independent support for either description?

Copyright 2026, James M. Atkinson

Ralph Vinton Lyon Hartley

Answer to Percy Williams Bridgman

Thank you for identifying the principal uncertainty in this evidence. Thank you for that question. Professor Bridgman, internal consistency can show that the files conform to their respective descriptions, but it cannot choose between contradictory physical declarations merely because both are signed. The missing proposition concerns the connection between the declared rate and the actual acquisition timing. A calibrated reference and validated configuration history may support that connection without an independent timing observation in every record. The claim should state the evidence and conditions on which the connection rests. A digital signature identifies an authenticated declaration under its verification assumptions; it does not convert a mistaken declaration into a physical fact.

An independent observation can be valuable when it challenges the disputed relationship. A timing marker acquired through a known path, a hardware counter with a characterised clock, or a suitable reference waveform may constrain the ambiguity. None should be treated as universally sufficient. The marker might share the same erroneous clock assumption; the reference waveform might be interpreted through an incorrect frequency mapping. The test needs to distinguish the alternatives actually at issue, not merely add another internally consistent label.

Dr. Atkinson, if only the contradictory exports survive, the honest result may be two possible time interpretations or a narrower statement in sample coordinates. Some analyses remain meaningful

Copyright 2026, James M. Atkinson

in index space even when absolute time is uncertain. Others, including an asserted event duration in seconds, may require qualification. The loss of timing support should attach to the claims that depend on it, rather than being hidden or used to dismiss every retained observation indiscriminately.

A consistency test can still be useful as a screening test. Contradictory declarations can reveal a defect even before the physical truth is established. Passing that screening removes one detected inconsistency; it does not positively establish every remaining declaration. Its value should be retained without enlarging its scope.

The proposed manifest is therefore part of the evidence, not an oracle. It should preserve the source of each material declaration and permit conflicts to remain visible. An examiner can then distinguish recorded fact, validated configuration, and later inference. Mr Weston, may I invite your question about how this preservation discipline should treat a hardware change made during the observation?

Edward Weston

Peer question 2 to Ralph V. L. Hartley

Mr Hartley, suppose the operator replaces an input attenuator between two retained segments while keeping the same receiver and software settings. The resulting files could appear to form one continuous acquisition, and the replacement might be remembered only when the analysis reveals an amplitude discrepancy. How should the

Copyright 2026, James M. Atkinson

record accommodate a later correction to its configuration history without making the correction indistinguishable from a contemporaneous observation? I would not wish a mistaken initial entry to become permanent merely because it has already been hashed. Yet replacing it silently would erase evidence of what was known at the time. Please distinguish a legitimate amendment from an alteration that obscures provenance, and explain whether the two segments can be combined before the replacement component's effect has been characterised for the intended measurement.

The distinction matters even when the revised component value seems small compared with the range shown on the receiver display.

Ralph Vinton Lyon Hartley

Answer to Edward Weston

Mr Weston, preserving an initial record does not require perpetuating its error as the current interpretation. A later amendment should identify the original entry, the revised assertion, the evidence supporting the change, the time of amendment, and the responsible author. The earlier entry remains part of the history. The current analysis can use the correction while disclosing that it was established retrospectively. This approach distinguishes an improved account from a rewritten account whose uncertainty and chronology have disappeared.

The hardware replacement creates a physical comparison to resolve. If its effect has not been characterised sufficiently for a common amplitude reference, the segments should not be combined

Copyright 2026, James M. Atkinson

as though they shared one calibrated path. They can still be retained as separate observations with their respective uncertainty or qualification. A later comparison may justify a transfer between them, but that transfer should remain an explicit operation in the analysis. It should not be encoded solely by changing a number in a global header and leaving the earlier interpretation unrecoverable.

Dr. Atkinson, a retrospective statement based only on memory should be distinguished from one supported by an equipment log, photograph, or retained component identification. The particular evidence may be adequate for a limited purpose without establishing every relevant characteristic. An attenuator's nominal value does not prove its complete response over the band. The amendment should therefore correct what it can support and preserve what remains unknown, rather than convert a recovered recollection into an unqualified calibration.

A revision identifier can connect the old and new accounts to their respective analyses. The later report can then show which result changes and which remains invariant. That comparison is more informative than either suppressing the correction or asserting that every earlier conclusion survives it unchanged.

The record can evolve responsibly when its versions and their relationships remain intelligible. Integrity protects the history needed to assess the correction; it does not forbid correction. Professor Wiener, may I pass the floor to you for the more continuous version of this problem, in which the receiver's controller changes the acquisition state without a physical component being replaced?

Copyright 2026, James M. Atkinson

A further constraint follows from preservation of receiver state and acquisition metadata through changes of configuration. I would add the following qualification to my answer. A second instrument adds evidential force only to the extent that its error mechanisms are independent or adequately modelled. Two receivers supplied by the same antenna network can share impedance anomalies, a local oscillator reference, or a strong interfering field. If they report the same feature, the comparison is valuable but must not be represented as two independent confirmations until those common pathways are examined. Where practical, vary a reference source, a cable route or a gain state under controlled conditions, and assess whether the observed changes conform to the proposed transfer relations. In this particular question, the controlled observation is a sequence of timestamped settings, control events, instrument outputs, and raw capture blocks, whereas the material uncertainty concerns the transient analogue response occurring between state commands and valid samples. Consequently the adversarial comparison ought to include a replayable transition log tied to a stable reference signal and its failed as well as successful outcomes. I would not advise treating a change in the displayed indication as an authenticated physical attribution until its causal mechanism has been experimentally distinguished.

Copyright 2026, James M. Atkinson

Norbert Wiener

Control actions are part of the observation history

Mr Hartley, thank you. Dr. Atkinson, the receiver's control history belongs to the experiment whenever it affects what can be observed or retained. A gain command, retuning request, or trigger decision is not external commentary upon an otherwise fixed measurement. It can change the transformation through which the next signal is acquired. We should therefore retain both the action and the evidence of its effect. The central distinction is causal: what the system was instructed to do, what it physically did, and what a later correction assumes it did need not coincide at one instant.

The third worked application supplies exact indices to avoid that confusion. Suppose a gain command is issued at source index 50,000, its receipt is acknowledged at 50,040, and an independent acceptance criterion is first satisfied at 50,120. At one million samples per second, the interval from command to accepted state is 120 microseconds. Excluding the half-open range from index 50,000 through just before 50,120 removes 120 sample slots. Using acknowledgement as the settled-state boundary would instead retain 80 slots whose validity has not been established by the stipulated criterion. The numbers concern this constructed chronology, not a universal receiver settling time.

$$T_{settle} = \frac{50120 - 50000}{10^6} = 120\,\mu s$$

There is an additional assumption in that exclusion: it treats all earlier samples as valid under the prior state and all later samples as valid under the new state for the defined objective. If the command has uncertain

Copyright 2026, James M. Atkinson

timing, if the previous state was already overloaded, or if recovery occurs differently for phase and amplitude, the classification requires refinement. A validity boundary is not established by selecting a convenient integer. It is established by evidence about the measurement properties that the interval must support.

The fourth worked application shows why state-dependent correction must precede an inappropriate aggregate. Stipulate two equal-duration segments with dimensionless voltage gains 10 and 100. Their input amplitude estimates are 1 and 3 millivolts, producing outputs 10 and 300 millivolts. The mean of the two segment-level input amplitude estimates is 2 millivolts. Dividing the mean output, 155 millivolts, by the mean gain, 55, gives approximately 2.818 millivolts instead. Averaging the labels has not preserved the relationship between each observation and its state.

$$\frac{1}{2}\left(\frac{10}{10}+\frac{300}{100}\right)=2\,mV$$

$$\frac{155}{55}\approx 2.81818\,mV$$

That mean is specifically the mean of two segment-level amplitude estimates. If each segment contains a sinusoid with the stated RMS amplitude and the desired quantity is the RMS value over both equal-duration segments, the result is the square root of five multiplied by one millivolt, approximately 2.236 millivolts. These results are not contradictory. They refer to different aggregation rules. The example therefore joins control history to measurand definition: preserving the gains is necessary, but the final operation must still correspond to the quantity requested.

Dr. Atkinson, adaptation can be valuable. A controller may protect a path or concentrate analysis on a candidate event. The record should retain how

Copyright 2026, James M. Atkinson

the adaptation changes observation capability. When a broad discovery channel triggers a narrow recording, later statements must distinguish the broad interval actually acquired from the narrower interval retained for detail. The trigger is a selection operation. Its successful detection of one event does not establish that every other event would have caused the same retention, especially where controller state affects sensitivity or dead time.

A useful design would maintain a state ledger connected to source indices and would preserve the inputs relevant to major control decisions. The ledger need not contain every internal arithmetic operation. It should contain enough information to reconstruct the changes that materially alter the measurement law, calibration applicability, or capture opportunity. Where a state is inferred rather than directly observed, that distinction belongs in the ledger. Otherwise a model's estimate of the state can later be mistaken for an independent measurement of it.

The identity of a state must also be stable across subsystems. A hardware gain code, software scale factor, and exported label may all refer to a setting called high gain while denoting different combinations. The record should connect their meanings and identify the point at which a change takes effect. A shared state identifier is useful only if its interpretation is controlled. Reusing an old identifier after altering its coefficients can make a formally complete ledger describe the wrong transformation. This failure would not necessarily appear as a missing log entry.

I would test the record with deliberately timed changes near event boundaries, not only with comfortable intervals between signals. The test should determine whether state entries and sample coordinates remain

Copyright 2026, James M. Atkinson

aligned, whether requested and achieved values are distinguished, and whether processing delays are accounted for. A trace that appears continuous is not the acceptance criterion. The criterion is that a reviewer can assign each relevant observation the correct supported interpretation. Dr Bode, may I invite your challenge concerning the history required when filters and control loops carry memory across a recorded state boundary?

Hendrik Wade Bode

Peer question 3 to Norbert Wiener

Professor Wiener, the ledger may identify a new coefficient set at a precise sample index, yet the filter's internal state can still contain contributions from earlier samples. Suppose the software changes its coefficients and preserves its delay elements; another implementation resets those elements at the same declared boundary. Their subsequent outputs can differ even when their configuration logs list identical new coefficients. What must the record preserve to make the transition reproducible? I would also ask how the analyst should handle an export beginning immediately after the change, when the state inherited from the earlier interval is absent. Is it sufficient to discard a fixed number of samples, or must that number follow a model of the particular response and the error permitted by the intended measurement? Please distinguish reproducible processing from justified physical interpretation.

A correct coefficient list may otherwise conceal the precise memory contribution that dominates the first few outputs retained after a transition.

Copyright 2026, James M. Atkinson

Norbert Wiener

Answer to Hendrik W. Bode

Thank you for that question. Dr Bode, coefficients describe the rule of evolution but not necessarily its initial state. The record should identify whether the implementation preserved, reset, or transformed its state at the boundary, and retain the information required to reproduce that action. For a finite filter, the relevant preceding samples may be sufficient. For another implementation, a saved state vector and its defined meaning may be required. Merely recording that a filter changed does not establish which output sequence followed from the change.

A fixed exclusion can be justified where the response and permitted error support it for the intended input class. It should not be selected only because the trace appears settled after that many samples in one example. A finite-memory operation may permit an exact boundary; an operation with a longer tail requires a tolerance and model. The record should preserve the acceptance condition and the assumptions about preceding excitation. Otherwise an interval chosen for convenience can be mistaken for a demonstrated recovery period.

Dr. Atkinson, an export that lacks the preceding state may still support analysis after a qualified startup interval. The unsupported interval should remain visible, and the processing should not silently invent earlier samples as though they had been acquired. Zero padding is a numerical choice, not evidence that the physical input

Copyright 2026, James M. Atkinson

was zero. If the choice affects the reported event, the conclusion must carry that dependence or rely on additional retained information.

Where an implementation reports a saved state, its coordinate convention must be documented. A list of delay-register values is not automatically a list of preceding physical inputs. Restoring it under a different realisation can produce an incorrect transient even though both filters have the same settled frequency response.

Reproducing the same output from the same declared numerical inputs is an implementation test. Showing that those numerical inputs and state describe the physical acquisition is a further measurement test. Both are necessary for a strong reconstruction claim, but neither substitutes for the other. Dr Shewhart, may I invite your question concerning how these state qualifications should be used without retrospectively selecting only the intervals that favour the proposed finding?

Walter Andrew Shewhart

Peer question 4 to Norbert Wiener

Professor Wiener, suppose an operator marks several intervals invalid after noticing unusual amplitudes, then reports excellent stability over the retained record. The exclusions may have sound physical causes, but their selection has depended upon the same observations used to describe stability. Dr. Atkinson's question requires the record to support a later examination of this process. What should be retained about the decision to exclude, and how should discovery of a previously unknown failure mode affect earlier conclusions? I would distinguish an interval

Copyright 2026, James M. Atkinson

excluded by an already validated overload rule from one excluded after an investigator decides that its result is inconvenient. Yet there may be legitimate cases between those extremes. Please explain how the ledger can preserve that distinction without making a necessary scientific reassessment look equivalent to arbitrary deletion.

The retained result should make this distinction inspectable without requiring the reviewer to accept an unrecorded explanation supplied after the event.

Norbert Wiener

Answer to Walter A. Shewhart

Dr Shewhart, the ledger should record both the excluded interval and the basis of exclusion. A predeclared overload rule, a later diagnosis supported by an independent test, and an unresolved concern are different entries. They should not all become one unlabeled blank. The original observations remain available within the authorised retention scheme, together with the time at which the classification was made and any change in that classification. This permits a reviewer to distinguish a physically motivated revision from selection that merely favours a desired result.

Discovery of a new failure mode can legitimately require reassessment. The laboratory should identify which earlier results depended on the affected condition, examine them under the revised understanding, and preserve the original conclusions and their amendments. It should not imply that the later knowledge was present during the original examination. Nor should every earlier

Copyright 2026, James M. Atkinson

result be discarded automatically. The scope of reassessment follows the demonstrated failure mechanism and the claims that relied on it.

Dr. Atkinson, stability of the retained record is then a conditional statement about retained intervals. It does not establish stability during excluded intervals or complete-period capture capability. If those omissions are related to strong events, they may preferentially remove circumstances relevant to the investigation. That dependence should be examined rather than hidden by a reduced variance. A smaller reported spread can result from selecting the observations, not from improving the instrument.

It is useful to retain both the original classification and the current analytical mask. The first records the operational judgement; the second expresses the later, supported interpretation. Neither should be overwritten by the other. Their difference identifies exactly where reassessment has altered the evidential use of the acquisition.

The control ledger therefore records more than machine commands. It also records material analytical decisions and their chronology. That is not an invitation to replace physics with paperwork; it preserves the information required to test how the physics was interpreted. Professor Gabor, may I pass the floor to you to examine the different time coordinates introduced when those retained observations are filtered, windowed, and displayed?

I thank the questioning colleague for that important distinction. The chronology of the chain of custody for SDR operating state as well as samples is indispensable. Assume for a moment that an apparently

Copyright 2026, James M. Atkinson

simultaneous feature may reflect a gain change or retuning gap. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should reproduce the original gain and filter sequence while retaining independently clocked samples, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs gain register, sample indices, firmware settings, filter configuration and timestamp confidence. If a feature confined to receiver transition intervals suggests an instrumental cause rather than an external arrival, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states.

Copyright 2026, James M. Atkinson

Dennis Gabor

The time coordinate must follow the operation

Professor Wiener, thank you. Dr. Atkinson, a time attached to a displayed feature can refer to several different events: the sampling instant, the centre of an analysis window, the output of a causal filter, the arrival of a block at a host, or the moment at which a display was refreshed. These times need not coincide. The record should identify which one is asserted and how it relates to the original observation. Merely printing more decimal places cannot resolve an unstated convention. A timestamp is useful only when its meaning survives the transformations that produced the reported feature.

The fifth worked application uses a simple causal operation whose entire response is known. Let the input sequence be x[n], and let y[n] be the mean of its current value and four preceding values. The sampling interval is one microsecond. Suppose all input samples are zero except for a unit impulse at index 100. Nonzero output appears at indices 100 through 104, each with amplitude one fifth of the input impulse. The centre of that symmetric response lies at index 102. Its displacement from the original impulse is two microseconds, although the first nonzero output occurs at index 100.

$$y[n]=\frac{1}{5}\sum_{k=0}^{4} x[n-k]$$

$$n_{centre}=102;\tau_{centre}=2\mu s$$

A timestamp assigned to the centre of this response therefore differs from one assigned to the first nonzero output. Neither is necessarily a mistake. The mistake would be to call both the input-event time without retaining the applicable convention. The example does not establish a universal two-sample onset correction for arbitrary signals or thresholds. An

Copyright 2026, James M. Atkinson

extended input, a different filter, or a threshold crossing can require a different interpretation. A known linear phase delay supports a stated relationship; it does not abolish the distinction between a waveform feature and a physical event.

The sixth worked application concerns retained sampling phase. Let z[n] be an already filtered stream acquired at ten million samples per second. Define a decimated output by w[m]=z[3+10m], where n and m are integer sample indices. The output rate is one million samples per second, but its origin is displaced by three input samples. Output index 100 corresponds to input index 1,003, or 100.3 microseconds after the stipulated input origin. Assigning only the output interval and index would produce 100 microseconds and omit the retained phase.

$$w(m)=z(3+10m);t_{100}=\frac{1003}{10^7}=100.3\,\mu s$$

That mapping refers to samples of z, not automatically to an event at the antenna. Any preceding filter delay and input reference-plane delay remain separate quantities. They should not be corrected twice, once in a timestamp and again in an analyst's subtraction, nor omitted because the output rate looks familiar. A transformation ledger can carry the index map, its time origin, and the declared response convention explicitly. The same numerical sequence may then support several derived representations without forcing all their timestamps into one undocumented definition.

Dr. Atkinson, a spectrogram introduces another convention. Each displayed column represents an operation over an interval, not an instantaneous observation of every plotted frequency. Its assigned time may be the beginning, centre, or end of the contributing sample window.

Copyright 2026, James M. Atkinson

That choice can be harmless when stated and consequential when a short event is compared with a physical action. A visible line extending across neighbouring columns can reflect overlapping analysis windows as well as the source's duration. The examiner should recover the contributing sample intervals before reporting a temporal association.

Processing latency must also be distinguished from signal delay. A block can wait in a queue before its analysis begins without changing the sampling times of the data it contains. A display can update late while correctly labelling the earlier interval. Conversely, a prompt display can carry an incorrect time origin. Measuring host arrival or screen refresh can characterise system responsiveness, but it cannot alone establish the original sampling coordinate. A useful record preserves the distinction rather than subtracting an average latency and assuming every event followed it.

The time origin must be preserved when records from different channels are compared. An identical sample rate does not establish a shared epoch, and equal host arrival times do not establish simultaneous sampling. Each channel needs a supported mapping to the comparison coordinate. Where only relative timing is known, report relative timing. A later assignment of a civil-time label should not acquire greater accuracy than the observations connecting it to the source indices.

My proposed validation would inject events at known positions relative to block, filter, and decimation boundaries, then compare each reported coordinate with the operation that defines it. The examiner should test events near starts, stops, and state changes as well as those centred comfortably within a record. The aim is not to demand a single preferred

Copyright 2026, James M. Atkinson

timestamp for all analyses. It is to make each timestamp reconstructible and to carry its limitations into comparisons with other evidence. Dr Nyquist, may I invite your question concerning what remains recoverable when the retained stream has already discarded some of the original samples?

Harry Nyquist

Peer question 5 to Dennis Gabor

Professor Gabor, your decimation example preserves a precise mapping for retained output samples, but an investigator may ask about an event that occurred between those samples or outside the retained passband. Suppose the export contains only the decimated channel and its timing metadata, while the wideband parent has been overwritten. The output interval and filter coefficients are known. Does that knowledge permit reconstruction of the earlier waveform, or merely description of the transformation that would have produced the export? Please distinguish a valid reconstruction within an explicitly restricted signal class from an attempt to recover arbitrary discarded information. I would also ask whether a smooth interpolated trace should be retained as evidence of intermediate measured voltages. Our concern is not to deny the usefulness of interpolation, but to prevent its numerical completeness from concealing the physical assumptions on which its interpretation depends, particularly around a transient or an acquisition gap.

Copyright 2026, James M. Atkinson

Dennis Gabor

Answer to Harry Nyquist

Thank you for that question. Dr Nyquist, knowledge of an operation is not the same as possession of its inverse on every possible input. A properly restricted signal class may permit reconstruction from retained samples under a stated sampling model. That result depends on the admissible bandwidth, continuity, timing, and other conditions of the model. It does not imply that an arbitrary wideband parent can be recovered from a narrow channel merely because the channel's coefficients are known. Several different parent records can produce the same retained result.

An interpolated trace should therefore be identified as derived. Its intermediate values are consequences of retained samples and an interpolation rule, not additional voltages directly observed at those instants. This distinction need not diminish its legitimate use. Interpolation can support estimation within a justified model and can make a record intelligible. The problem arises when the representation is offered as evidence independent of the assumptions used to construct it. A dense plot does not increase the number of independently acquired samples.

Dr. Atkinson, the overwritten parent also limits later questions. The retained channel can support those measurements that survive its documented bandwidth and processing. It cannot certify absence of a contemporaneous signal outside that band. A transient crossing an acquisition gap may remain ambiguous even if the display joins the edges smoothly. The analyst should preserve the gap and identify

Copyright 2026, James M. Atkinson

which conclusions depend on a proposed completion. Alternative completions can be examined as hypotheses, but they are not recovered observations.

An interpolation rule should also identify its treatment of record edges. Extending an assumed periodic signal, padding zeros, or truncating an interpolation kernel can produce different estimates near a boundary. Those choices are not new data. Where they matter to the finding, retain and test them explicitly.

The strongest record links an export to its supported purpose and retains the parent where the authorised investigation requires future questions beyond that purpose. Where only the derivative remains, the conclusion should contract to its information content rather than expand to match the examiner's later curiosity. Professor Pearson, may I pass the floor to you to examine how overlapping analysis and selective retention change the number and character of the observations counted in a performance claim?

Copyright 2026, James M. Atkinson

Egon Sharpe Pearson

A frame count does not define an experiment's exposure

Professor Gabor, thank you. Dr. Atkinson, a count becomes evidence only after we identify what has been counted. Ten plotted spectra, ten threshold decisions, and ten independent acquisitions are not interchangeable units. A system can generate many decisions from largely shared samples, or retain only decisions that caused a trigger. Neither operation is inherently improper, but each changes the population to which the results refer. The experimental record should distinguish the available source observations from the analytical opportunities created by the procedure.

The seventh worked application makes the overlap explicit. Let each analysis frame contain N=4,096 samples, let the sampling frequency be 2.048 million samples per second, and let successive frames begin H=1,024 samples apart. Each frame spans two milliseconds in the sample-slot convention, while successive starts are separated by half a millisecond. Ten consecutive frames use a union of N+9H=13,312 sample slots, corresponding to 6.5 milliseconds. Adding the ten frame durations would instead report twenty milliseconds of exposure and count shared samples repeatedly.

$$T_{union} = \frac{N + (K-1)H}{f_s}$$

$$T_{union} = \frac{4096 + 9(1024)}{2.048 \times 10^6} = 6.5\,ms$$

Here K=10 is the frame count and f_s is the sampling frequency in samples per second. The duration convention assigns one sampling interval to each slot; the elapsed time between the first and last sample instants is one

Copyright 2026, James M. Atkinson

interval shorter. State the convention when that distinction matters. More importantly, the shared input creates possible statistical dependence between decisions. The union duration does not supply a universal effective number of independent tests. That number, or a more complete joint model, depends on the statistic, window, overlap, and underlying process.

The eighth worked application concerns invalid intervals. During a ten-second acquisition, suppose the ranges [1,1.003) seconds and [1.002,1.006) seconds are independently marked invalid for the same measurement. Their union is [1,1.006), lasting six milliseconds. Summing the individual durations would give seven milliseconds by counting their one-millisecond overlap twice. Under the stipulated classification, accepted duration is therefore 9.994 seconds. This is a duration for the identified channel and measurement, not proof of simultaneous observation across every frequency the receiver could tune.

$$T_{invalid} = 0.006\,s\,;\,T_{accepted} = 10 - 0.006 = 9.994\,s$$

An event whose required detection window crosses the invalid boundary introduces a further question. Counting its start time as accepted may not establish that the entire observation required by the detector was available. The acceptance function should correspond to the event class and detection procedure. An interval adequate for detecting a long carrier may be inadequate for measuring the onset of a short burst. Thus the record should retain the geometry of the intervals rather than only their total duration. A scalar total can discard information needed for a later exposure calculation.

Dr. Atkinson, triggering creates selection as well as convenience. If only positive decisions cause retention, the resulting archive is not a complete record of the opportunities that failed to trigger. It can document the

Copyright 2026, James M. Atkinson

retained events without directly estimating a missed-detection rate. A background channel, scheduled checks, or a validated trigger-performance record may supply additional information, but their contribution should be stated separately. An archive containing only successful captures cannot prove that capture was successful whenever the stipulated event occurred.

The same issue appears when an analyst revises a threshold after inspecting the record. The revision may be scientifically sensible, but the observations used to choose it are no longer a wholly independent assessment of its performance. Preserve the development history and identify which observations test the frozen procedure. Otherwise a succession of increasingly favourable results may merely reflect repeated accommodation to one dataset. The appropriate response is a transparent experimental distinction, not an assumption that every adjustment invalidates all previous work.

An event catalogue introduces its own counting rule. Several adjacent positive frames may belong to one physical burst, while a gap between positive frames may reflect a threshold crossing within a continuous transmission. The rule that joins or separates them should be retained with the original decisions. Otherwise a reported event rate can change when an undocumented clustering parameter changes, even though the acquisition itself is identical. The catalogue is a derived classification of observations, not an independent set of arrivals.

The same care applies across channels. If neighbouring filtered outputs respond to one emission, counting every channel decision as a separate source can inflate the catalogue. A merging rule may be justified, but it must preserve the evidence for association and the possibility that two distinct

Copyright 2026, James M. Atkinson

events overlap. Counting should follow the question being answered, not the convenience of the output table.

I would require the performance record to identify the trial unit, inclusion rule, applicable receiver state, and treatment of incomplete observations. Decisions sharing data should retain their common ancestry. Exclusions should preserve their reasons and chronology. Confidence statements should then follow the resulting experimental design rather than the visual abundance of plotted frames. Professor Neyman, may I invite your question about the uncertainty that remains when a carefully counted exposure is combined with a detection probability estimated from separate trials?

Jerzy Neyman

Peer question 6 to Egon S. Pearson

Professor Pearson, suppose the investigation preserves its accepted intervals exactly and then weights them by a detection probability estimated from a finite validation experiment. The product is reported as effective detection exposure. The analyst subsequently uses zero detections to calculate an upper bound on event occurrence. Where should the uncertainty of the validation probability enter that conclusion? A precise time counter does not make the weight exact, and the validation population may differ from the field population in signal amplitude or duration. Please distinguish uncertainty within an applicable model from uncertainty about the model's transfer to the investigation. I would also ask whether multiplying two separately stated confidence limits preserves their advertised confidence level. The purpose of my challenge is to keep a legitimate exposure calculation

Copyright 2026, James M. Atkinson

from acquiring more certainty than its least well established input, especially when the final report expresses a strong negative finding.

A further constraint follows from preservation of receiver state and acquisition metadata through changes of configuration. The transient analogue response occurring between state commands and valid samples remain outside the direct observation. If the examiner reports only those cases in which the indicated feature agreed with the preferred model, what correction would you require to the exposure denominator, alternative-hypothesis analysis, and reproducibility account?

Egon Sharpe Pearson

Answer to Jerzy Neyman

Thank you for that question. Professor Neyman, the validation estimate must remain an estimate in the exposure model. Treating it as a known constant can omit an uncertainty contribution that is material to the final bound. A joint analysis can address the validation outcomes and field count together, or a conservative construction can allocate error probabilities to separate bounds with its dependence assumptions stated. Two intervals each labelled ninety-five per cent do not automatically produce a ninety-five per cent statement about their product or a derived rate.

That statistical treatment presupposes applicability. If validation used long, strong signals while the field claim concerns short, weak bursts, the uncertainty is not repaired merely by calculating a narrower interval around the validation success fraction. The fraction estimates performance for the population actually tested under its

Copyright 2026, James M. Atkinson

design. Transfer to another population requires evidence or a model whose assumptions remain open to examination. The report should distinguish an uncertain parameter inside a supported model from an unsupported change in what the parameter describes.

Dr. Atkinson, accepted-time bookkeeping supplies one necessary part of this analysis, not the entire inference. An exact duration and a well-formed formula cannot compensate for a missing relationship between field events and validation conditions. Where that relationship is unresolved, a bounded qualitative conclusion may be more defensible than a numerical rate limit. The investigator can still state what was observed and which detection capability was demonstrated, without asserting that every possible event class shared it.

The final statement should also identify its conditioning variables. An amplitude-dependent detection curve may support a bound for a stipulated amplitude class without supporting a bound for arbitrarily weak signals. Preserving that qualification is not a weakness of the result. It states which experiment the numerical conclusion actually describes.

The record should preserve the inputs needed for later reassessment: validation trials, condition labels, interval masks, detector version, and the population definition. A future analyst can then revise the calculation when additional evidence becomes available without pretending the earlier model was certain. Dr Shannon, may I pass the floor to you to consider the information retained across the sequence of exports and transformations, and to

Copyright 2026, James M. Atkinson

distinguish a reproducible derivative from a recoverable original acquisition?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon

The processing history defines which questions remain answerable

Professor Pearson, thank you. Dr. Atkinson, a derivative is useful when it preserves the distinctions needed for its intended purpose. It becomes misleading when its convenient representation is treated as though it preserved every distinction available in the parent record. Cropping, filtering, resampling, averaging, and conversion can each change the set of questions that remain answerable. A processing history should identify those changes without implying that a perfectly documented loss has thereby been reversed. Documentation can establish what was done; it cannot generally recreate what was discarded.

The ninth worked application concerns a clock declaration. Let a record contain a separation of N=10,000,000 sample intervals. Its nominal rate is f_0=1,000,000 samples per second, but the stipulated actual rate is two parts per million above that nominal rate. The true elapsed time for those intervals is approximately 9.99998000004 seconds, whereas the nominal calculation gives ten seconds. The difference is approximately 19.99996 microseconds. A correct file digest does not choose between those time mappings, because the discrepancy belongs to the physical rate declaration rather than the sample bytes.

$$t = \frac{10^7}{10^6\left(1+2\times 10^{-6}\right)} \approx 9.99998000004\, s$$

The example assumes a constant rate error. A varying error requires a model or observation of its evolution, not merely the same correction applied globally. The record should preserve whether the rate is requested, nominal, estimated, or calibrated, and the scope of the supporting evidence.

Copyright 2026, James M. Atkinson

A corrected time axis can be a legitimate improvement while remaining a derived result. Its relation to the originally declared axis should be retained so that another analyst can reproduce either interpretation and understand the reason for the change.

The tenth worked application shows that operation order matters even when every operation is individually specified. Define q[n] as the average of x[n] and its three preceding samples. Stipulate x[97]=x[98]=0, x[99]=4 millivolts, and x[100]=0. Filtering the original stream gives q[100]=1 millivolt. If the raw stream is first cropped to begin at index 100 and unavailable preceding values are replaced by zero, filtering that altered input gives zero at its first output. Identical coefficients have produced different results because the histories differ.

$$q[100]=\frac{x[100]+x[99]+x[98]+x[97]}{4}=1\,mV$$

This is not a numerical rounding dispute. Crop-then-filter with an assumed initial history and filter-then-crop are different transformations. Their provenance should identify the ordering, crop coordinates, state policy, and any padding. A processor that faithfully reproduces the wrong assumed history is reproducible in one sense and unsuitable for the physical claim in another. The example is especially consequential near an event boundary, where a seemingly harmless export can alter a transient's estimated onset or amplitude.

Dr. Atkinson, preservation should follow the chain of dependence. An export manifest can identify parent objects, operations, parameters, and resulting objects. Where software or coefficients influence the result, retain their identifiers and the particular settings used. Where a human selection

Copyright 2026, James M. Atkinson

determines which interval survives, preserve the selection rule or annotation. These proposals concern the evidence needed for this receiver problem. The consulted preservation guidance supports protecting origins and integrity records; it does not independently certify the physical truth of every metadata assertion. [M3-2]

There is also a distinction between an executable history and a meaningful history. A sequence of software calls may reproduce a file while leaving the physical units, complex-frequency convention, or input reference plane unspecified. Conversely, a clear mathematical description may fail to reproduce a particular implementation because its rounding, initialisation, or state reset differs. A strong record addresses both levels. It identifies the scientific transformation being claimed and the concrete procedure used to realise it, including qualifications where their correspondence has not been established.

Software identity alone may be insufficient for exact replay when numerical execution depends on additional settings. The record should retain precision choices, coefficient versions, initial conditions, and any stochastic seed where those features materially affect the output. This does not require claiming bit-for-bit equivalence between every computing platform. It requires distinguishing exact replay from agreement within a declared numerical tolerance, then selecting the criterion appropriate to the measurement.

Likewise, a visually identical export can omit distinctions retained in a numerical parent. Rounding a marker to a display label, saving an image instead of complex samples, or retaining peak hold without its contributing times can preserve appearance while reducing answerable questions. The

Copyright 2026, James M. Atkinson

derivative should therefore be described by its content and transformation, not merely called a copy of the acquisition.

I would not require indiscriminate retention of every possible intermediate. The retention decision should follow the investigation's authorised objectives and the consequences of irreversible reduction. Preserve sufficient parent information or validated alternatives to answer the questions the report actually raises. When a later question exceeds that scope, acknowledge the limit rather than treating a compact derivative as a universal surrogate. A file's small size is not its defect; an unsupported expansion of its evidential meaning is. Sir Karl Popper, may I invite your challenge concerning how to test a reconstruction without merely confirming the same assumptions that produced it?

Sir Karl Raimund Popper

Peer question 7 to Claude E. Shannon

Dr Shannon, a laboratory can reproduce an export exactly with the software and settings recorded in its manifest. Yet the software may consistently implement an incorrect sign convention, or both the original run and the reconstruction may use the same mistaken clock declaration. What experiment would expose such an error rather than merely confirm the repeatability of the procedure? I ask particularly about the temptation to declare a record complete when every internal consistency check passes. Completeness should be relative to a claim, but that claim must face a possible adverse result. Please identify a challenge that distinguishes correct physical correspondence from agreement between dependent implementations, and explain what the examiner should report when the parent acquisition has been lost so that the decisive

Copyright 2026, James M. Atkinson

challenge can no longer be performed. We should preserve useful evidence without making its interpretation immune to criticism through the disappearance of the test that could refute it.

Claude Elwood Shannon

Answer to Karl R. Popper

Sir Karl, the challenge should introduce information whose relevant relationship is established independently of the suspected convention. A known frequency displacement can test complex-frequency sign; a timed stimulus compared through a separately characterised path can test the mapping from sample indices to time. The particular design must identify its own uncertainty and shared dependencies. Merely running a second program that inherits the same definition does not guarantee independence. The experiment is discriminating when the competing interpretations predict observably different outcomes under the chosen conditions.

An exact replay remains valuable. It can establish that a retained procedure produces the same derivative from the same declared inputs. The report should state that limited achievement without promoting it into complete physical validation. A reference comparison or challenge test supplies a different proposition. The strongest result connects both: a reproducible transformation and evidence that its assumptions corresponded to the acquisition for the quantity under examination.

Dr. Atkinson, where the parent has been lost, the scope of possible challenge may narrow. Surviving references, logs, and independent

Copyright 2026, James M. Atkinson

observations can still constrain some interpretations. They should be examined rather than assuming that loss renders every conclusion worthless. But a missing distinction must remain missing when no evidence restores it. A later simulation can show what alternative inputs would have done; it cannot establish which unobserved input actually occurred. The retained derivative should be assessed for the questions it still supports, with the unresolved alternatives stated.

The challenge record should retain adverse as well as favourable outcomes. If a sign or timing discrepancy is discovered, the affected derivations can be corrected and their scope reviewed. Removing the failed test would preserve a more persuasive narrative while destroying information needed to assess the correction.

The scientific discipline is therefore to preserve the possibility of relevant criticism while evidence exists, and to describe honestly what remains when it does not. The record need not answer every imaginable future question. It must not imply answers to questions whose decisive information was never retained. Professor Atkinson, may I return the floor for the closing account of the state history, timing conventions, and evidential limits that this discussion has established?

Ralph Vinton Lyon Hartley, Cross-Peer Question to Norbert Wiener: Professor Wiener, I ask how a recorder should bind an operator's gain-change command to the physical instant when the changed state actually influences the stored samples. The software log may timestamp the requested value, while the control path passes through a queue and the analogue gain element settles over a finite interval. A sample counter

Copyright 2026, James M. Atkinson

identifies order, not necessarily the relevant analogue state. If the recorder has a ring buffer and transmits data in packets, a packet stamped after the transition may still contain earlier samples. What evidence would allow an analyst to divide the recording into valid regimes without converting a commanded state into an asserted achieved state? Please also address the case in which the control event and the digitiser share neither a reliable clock nor a common epoch.

Norbert Wiener, Cross-Peer Answer to Ralph Vinton Lyon Hartley: Mr Hartley, the history should be treated as a dynamical experiment rather than an administrative diary. I would separate at least four timestamps: command issuance, hardware acknowledgement, independently observable onset of the analogue response and the earliest sample demonstrated to have reached the stable new state. Their order may be established in a local monotonic clock, but translation to sample indices requires measured clock relationships, not an assumption that wall-clock strings coincide. Where the controller and ADC are asynchronous, a test signal or recorded digital marker can establish a mapping and its uncertainty. The output immediately following a gain change may reflect the prior state through filter memory, AGC hysteresis or queued samples, so the validation must define a guard interval. I would not simply remove a fixed number of samples without checking the worst relevant settling process. A repeatable controlled transition, measured across temperatures and signal levels, can provide a bounded interval after which the achieved state is credible. If that test is unavailable, mark the affected samples as transition data and retain them with a qualification, rather than assigning them retrospectively to one regime. Keep the source sequence counter, packet receive order, command

Copyright 2026, James M. Atkinson

log and state-change record independent in the archive so later reviewers can detect disagreements. These distinctions serve both reproducibility and the proper interpretation of any apparent burst occurring at the transition.

Dennis Gabor, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, your account of recording history raises a question about the apparent precision of later transformations. A long narrowband FFT applied to a stored I/Q segment can locate a persistent component finely in frequency, but a short pulse embedded in that segment may require a much shorter time aperture to locate its onset. Analysts sometimes present a smooth 30 Hz spectrum and assume that its narrow bins prove the absence of wideband bursts during the same interval. How should the original recording preserve both kinds of evidence, particularly where a trigger retains only selected time windows and deletes most samples labelled as dead air? Can the metadata alone supply information that was never stored?

Claude Elwood Shannon, Cross-Peer Answer to Dennis Gabor: Professor Gabor, the archive must distinguish information preserved in samples from summaries computed from them. If raw I/Q is present, a later examiner can choose different window lengths, demodulation algorithms and detection statistics, within the bandwidth and dynamic-range limits of the original hardware. If the original data were reduced to averaged FFT magnitudes, much of the instantaneous phase and waveform timing is lost; a metadata description of the averaging process cannot reconstruct those missing degrees of freedom. Nor does a 30 Hz bin width imply microsecond pulse sensitivity, because the associated observation aperture and averaging rule may dilute a brief event. The defensible design is a continuously operating fast candidate detector that controls a sample ring buffer, alongside a

Copyright 2026, James M. Atkinson

slower high-resolution spectral estimator. Each retained event should carry pretrigger and post-trigger I/Q, precise sample indices, actual configuration history, and the decision statistic that caused retention. Intervals excluded from storage should still have verifiable monitoring and loss records, including detector health, blind intervals and threshold changes. One cannot describe those intervals as signal-free merely because the algorithm found nothing worth preserving. A false-negative audit using injected, labelled waveforms across pulse widths and signal levels is indispensable to any claim about the coverage of selective recording. The stored spectrum is a useful index; it is not a substitute for absent complex samples.

Walter Andrew Shewhart, Cross-Peer Question to Egon Sharpe Pearson: Dr Pearson, when a receiver changes state the total observation period may include periods of settling, lost acquisition packets and intervals for which the trigger algorithm was disabled. Suppose a report counts detections per hour while excluding invalid samples from its denominator, but it does not explain that the excluded intervals were disproportionately associated with strong-signal overload. The selection is then coupled to precisely the phenomenon being investigated. What statistical summary should replace the naive hourly event rate, and how should an examiner express uncertainty about the unobserved periods without inventing the missing emissions?

Egon Sharpe Pearson, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, I would retain separate denominators for nominal elapsed time, instrument-operational time, valid observation exposure and exposure eligible under the specified detection criterion. A rate based on valid exposure can be meaningful for the stated regime, but it must not be

Copyright 2026, James M. Atkinson

represented as an unconditional rate over the whole investigation when exclusions are informative. The report should identify the reasons, locations and durations of invalid intervals. If overload causes a gap, the unseen event rate during that gap need not match the rate during quiet operation; imputing an equal rate is a model assumption that ought to be labelled and stress-tested. An appropriate display could show the observed count and valid-exposure rate, then a sensitivity analysis under explicitly bounded hypothetical event rates for excluded intervals. It is also wise to distinguish a threshold crossing from a physically independent emitter event, because one transmission can produce many detections across adjacent channels or overlapping FFT windows. The uncertainty should include selection, calibration, false-alarm and time-mapping effects, not just a Poisson interval around the counted positives. If the data cannot identify a meaningful full-period rate, the academically sound conclusion is a partial observation statement. Such an admission is not a failure of mathematics; it is a recognition that the experiment did not observe the required quantity.

Harry Nyquist, Cross-Peer Question to Percy Williams Bridgman: Professor Bridgman, let us examine what the word 'same' means when an archived dataset is transferred from one computing system to another. Two files can produce nearly identical amplitude spectra even if one reverses the sign of Q, swaps the I and Q channels, assumes the wrong sample rate or misinterprets signed data as unsigned. A digest certifies byte identity relative to a known reference but cannot establish that either file was decoded with the correct physical meaning. How should the manuscript define the evidential object so that source sample indices, sample

Copyright 2026, James M. Atkinson

representation, actual receiver settings and the intended electrical reference plane remain linked even after later extraction or channelisation?

Percy Williams Bridgman, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the evidential object must contain more than an unlabelled array of numbers. I would preserve the original unmodified bytes together with a protected manifest specifying datatype, signedness, endianness, I/Q ordering, sample rate, centre frequency, gain, analogue filtering and the physical reference plane. Each item should state whether it comes from a measured hardware register, a commanded setting, a validated configuration or a later inference. The sample coordinate of a retained file is not necessarily the coordinate of the original acquisition: a source counter or equivalent mapping is needed to distinguish genuine continuity from a file made by joining selected segments. The distinction is explicit in the SigMF vocabulary, which separates dataset-local sample positions from source-stream indices when the latter are available. A cryptographic digest is useful to demonstrate the continued identity of particular bytes but does not verify the correctness of the acquisition, the timing or the semantic annotations. I would therefore require a reproducible decoding test using a known complex calibration signal. A sign inversion in Q or an erroneous sample rate will then produce a predictable discrepancy, allowing the encoding to be challenged. Every later channelised product should preserve a documented derivation chain to the immutable source segment and its metadata, rather than silently replacing the original recording. Only this linked record allows the result to be interpreted at the declared physical input plane.

Dr. James M. Atkinson

Closing synthesis

Thank you, Dr Shannon, and thank you to the panel. The discussion has distinguished six relationships that a continuous-looking record can conceal: stored position and source position; requested state and achieved state; sampling time and analysis time; frame count and independent observation; retained exposure and detection capability; and reproducible processing and verified physical correspondence. These distinctions are connected, but none can be settled merely by verifying another. A valid digest cannot determine the clock rate, and a precise clock cannot restore a discarded frequency interval.

Mr Hartley's examples established why coordinates must survive cropping and discontinuity. A retained ordinal is not automatically an original stream index, and a finite counter requires conditions that make its rollover interpretation unique. His exchange with Mr Weston also preserved the possibility of legitimate retrospective correction. An erroneous entry need not remain the accepted account, but its amendment should retain chronology, supporting evidence, and unresolved uncertainty rather than silently replacing the historical record.

Professor Wiener treated control actions as part of the measurement. Acknowledgement of a command did not establish a settled response, and averaging gains before correction did not reproduce correction of the observations in their actual states. Dr Bode's challenge extended that reasoning to filter memory. Dr Shewhart required exclusions to preserve their cause and time of classification, so that a stable retained subset cannot be mistaken for an equally stable complete acquisition.

Copyright 2026, James M. Atkinson

Professor Gabor separated the time coordinates introduced by filtering, decimation, and display. His cases supplied explicit mappings, not universal corrections for every waveform. Dr Nyquist's challenge identified the point at which a derivative's documented origin ceases to make its parent recoverable. Professor Pearson then distinguished shared analysis windows from independent trials and interval unions from duplicated duration. Professor Neyman showed why a known interval mask cannot make an estimated detection weight exact or establish its applicability to another signal population.

Dr Shannon's final cases joined these issues to processing provenance. A nominal clock and an actual clock can assign different times to unchanged bytes. Cropping before filtering can alter an event because initial history has been removed. Sir Karl's challenge required tests that distinguish physical correctness from repeated execution of a shared assumption. The panel has consequently proposed a record that preserves meaningful dependencies, not merely a long list of files or an unqualified certificate of integrity.

These requirements also leave room for proportionate recording. A declared limited purpose can justify reduction, provided the later report does not silently claim the broader capability that the reduction has removed.

The practical conclusion is bounded. Preserve the observations, coordinates, consequential state history, reference evidence, transformations, and reasons for exclusions that support the actual claims. Mark unknown relationships explicitly. A reduced record may still be useful, but its use must follow what it retains. The next question will examine how an investigator designs a controlled challenge that separates competing

Copyright 2026, James M. Atkinson

explanations without simultaneously changing the ability to observe the signal. That problem follows naturally: once the history is intelligible, the experiment must make the rival interpretations answer differently.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 003

Application 01. Accumulated sample-clock time error

In the illustrative 003.01 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. A free-running sample clock with fractional rate error ε = 0.980 ppm over T = 164 s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T$ = 0.1607 ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 02. Preserved sample continuity across an acquisition interval

In the illustrative 003.02 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. A converter expected to retain f_s = 1.70 million samples/s for T = 0.85 s should supply $f_s T$ = 1,445,000 complex sample instants. If 63 sequence positions are missing, the retained count is 1,444,937 and loss fraction is 0.00436%. A low fractional loss cannot exclude a highly relevant short burst coinciding with the gap. Position and timing of each missing block must therefore be preserved. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 03. Stored-sample volume and the limits of retrospective analysis

In the illustrative 003.03 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive.

Copyright 2026, James M. Atkinson

With complex sample rate f_s = 5 MS/s, duration T = 21 s, and 16-bit in-phase plus 16-bit quadrature integers, the raw payload is $f_sT \times 4$ bytes = 420,000,000 bytes, or 0.420 GB (decimal). The calculation excludes timestamps, metadata, framing and file-system overhead. Maintaining a wideband buffer of this capacity does not establish that upstream analogue clipping was absent. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 04. Difference between two instruments relative to stated uncertainty

In the illustrative 003.04 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. The paired instrument contrast is Δ = 1.580 dB. Set independent standard uncertainties u_1 = 0.420 dB and u_2 = 0.520 dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)}$ = 0.668 dB, giving the dimensionless ratio Δ/uΔ = 2.364. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 05. Combined and expanded measurement uncertainty

In the illustrative 003.05 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. For independent standard-uncertainty contributions 0.66, 0.36 and 0.46 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.66^2 + 0.36^2 + 0.46^2)}$ = 0.881 units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c$ = 1.763 units. Preserve the full

Copyright 2026, James M. Atkinson

instrument state history so a different examiner can reproduce the decision.

Application 06. Observed exposure fraction of a channel scanner

In the illustrative 003.06 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. Let the channel be observed on n = 189 valid visits, each lasting d = 8 ms, with revisit spacing R = 0.85 s. Valid exposure is nd/1000 = 1.512 s across the nominal interval nR = 160.65 s. The observed fraction of elapsed time is therefore 0.94%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 07. Cascade gain and observed headroom

In the illustrative 003.07 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. A first amplifier contributes G_1 = 12 dB, an intentional attenuation contributes G_2 = -7 dB, and a later stage contributes G_3 = 21 dB. The small-signal sum is 12 + (-7) + 21 = 26 dB. For P_i = -68 dBm, the ideal output is P_o = -42 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 08. Family-wise probability when many candidates are searched

In the illustrative 003.08 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. If

Copyright 2026, James M. Atkinson

each of M = 215 independent pre-specified search opportunities has false-alarm probability α = 0.0008, the probability of one or more false positives is 1 − (1 − α)^M = 0.15808, or 15.81%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 09. Frequency-bin spacing versus independent information

In the illustrative 003.09 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. With sampled bandwidth f_s = 8 MS/s and N = 20,480 transform samples, the discrete-frequency grid is $\Delta f = f_s/N$ = 390.625 Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. Preserve the full instrument state history so a different examiner can reproduce the decision.

Application 10. First-order recovery envelope after a state change

In the illustrative 003.10 test, a field sdr changes gain, preselector state and software detector while retaining a complex-sample archive. If an illustrative recovery follows $A(t) = A_0 \exp(-t/\tau)$, let A_0 = 1.30 V and τ = 12.00 ms. At t = 30.00 ms the residual is 1.30e^(−30.00/12.00) = 0.1067 V. Real automatic gain control often has nonlinear or multi-time-constant behaviour, so this exponential is a test model, not a universal

Copyright 2026, James M. Atkinson

reconstruction of the input during overload. Preserve the full instrument state history so a different examiner can reproduce the decision.

Copyright 2026, James M. Atkinson

QUESTION 004

Copyright 2026, James M. Atkinson

When does agreement among receivers constitute independent corroboration?

Source: V011_Roundtable_Q001-Q011_CP011_Integrated_Candidate(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Constructed educational dialogue. Numerical cases are hypothetical, not instrument certifications.

Dr. James M. Atkinson

Opening question

Professor Wiener, can you comment on the circumstances in which agreement between two receiver records constitutes independent corroboration, rather than two presentations of the same unexamined dependency? Our earlier discussions established the intended quantity and the need to preserve acquisition history. We now encounter a tempting inference: a feature appears on two displays, and the investigator therefore considers its external origin confirmed. The second display is useful evidence, but precisely what it adds depends upon the route by which its observations were obtained. Two independent computations of one recording, two digitizers supplied by one amplifier, and two separately calibrated acquisition chains are different experimental arrangements. None should inherit the evidential description of another merely because each produces two traces.

The hypothetical arrangement has two receivers connected through a common distribution network. Their clocks may share a reference; their calibration corrections may derive from the same source; and their event lists may use the same threshold estimate. A weak feature appears

Copyright 2026, James M. Atkinson

simultaneously in both records. We have not stipulated whether it entered through the intended antenna terminals, arose in the shared network, or followed a common disturbance elsewhere. These alternatives are neither equally probable by declaration nor exhaustively disproved by the visual agreement. We must decide which additional measurements could discriminate among them while preserving the ability to observe the weak feature.

Professor Wiener will distinguish shared signal from shared measurement error. Dr Bode will examine the network connecting the receivers and the limits of what a difference measurement can reveal. Professor Neyman will consider dependence between detection decisions and explain why multiplying individual false-alarm probabilities may be unjustified. Dr Shewhart will propose an experimental arrangement that separates configuration effects from time-dependent change. Sir Karl Popper will then examine the precise claim that survives when corroboration has eliminated some explanations but not others. Seven colleagues will challenge these accounts before we draw a conclusion.

The ten worked applications are constructed examples, not measurements of an actual apparatus. Their purpose is to make the assumptions visible: common and private error, cancellation in a cross-spectrum, mixtures of operating states, and comparisons whose apparent agreement is built into their design. Where physical literature supplies an example of correlated instrumentation noise, its relevance must remain confined to the mechanism actually demonstrated. It is not evidence that every matching receiver trace is an artefact. Equally, an unusual mechanism cannot be excluded merely because the operator did not expect it.

Copyright 2026, James M. Atkinson

Our final account should replace the unqualified adjective independent with a description of the dependency that was tested. It should identify which observation would challenge a shared-path explanation, which comparison remains sensitive only to receiver differences, and which remaining uncertainty prevents a stronger attribution. Professor Wiener, may I invite you to begin with the distinction between correlation in the desired phenomenon and correlation in the errors of its measurement?

A further constraint follows from the distinction between genuinely independent corroboration and common-mode instrument error. The written conclusion must separate a directly retained observation from an inferred physical explanation. A short anomaly may be real in the stored digital sequence yet originate in quantisation, analogue recovery or the acquisition policy. Conversely, the absence of an alarm cannot establish the absence of an event outside valid temporal and frequency coverage. Such limitations do not make the work futile. They guide a useful next test, specify the conditions in which the present record is persuasive and protect the evidential chain against later exaggeration. At the close of this discussion I would require the published conclusion to identify cross-correlation, residual dependence, independent sensor coverage, and false-alarm conditioning and explain which claims remain untested because shared calibration dependencies, antennas, oscillators, power supplies, and reporting software. Such candour is not weakness but the condition under which this roundtable can inform a rigorous TSCM investigation.

Copyright 2026, James M. Atkinson

Norbert Wiener

Shared observations and shared errors are not the same covariance

Dr. Atkinson, thank you. The first discipline is to name the random quantities before discussing their correlation. When two receivers observe the same fluctuating source, correlated outputs are expected and may be the object of the investigation. That fact tells us little, by itself, about the dependence of their errors after the common source contribution has been accounted for. Conversely, two output streams can be correlated because an unwanted disturbance reaches both measurement paths. An empirical covariance is therefore not self-interpreting. Its physical meaning follows from a model of the quantities whose variation has entered the calculation.

Consider a simple real-valued model for repeated measurements of the same constant voltage s. Receiver outputs are $x_1 = s + c + e_1$ and $x_2 = s + c + e_2$. The term c is a zero-mean common error in volts; e_1 and e_2 are zero-mean private errors, also in volts. For the first application only, suppose all three errors are mutually independent, c has variance four square microvolts, and each private error has variance one square microvolt. Each receiver then has error variance five. Their covariance is four, giving an error correlation of 0.8. Averaging their outputs leaves the common error unchanged and halves the combined private contribution. The mean consequently has error variance 4.5, not 2.5, and its standard uncertainty is about 2.121 microvolts. The apparent two-channel improvement is modest because most of the uncertainty belongs to a shared term.

$$var\left(\frac{x_1+x_2}{2}\right)=4+\frac{1+1}{4}=4.5\left(\mu V\right)^2$$

Copyright 2026, James M. Atkinson

In the second application retain these assumptions but subtract the receivers. The constant voltage and common error cancel, leaving x_1 minus x_2 equal to e_1 minus e_2. Its variance is two square microvolts and its standard deviation is about 1.414 microvolts. Now imagine making both private variances one hundred times smaller while leaving the common variance unchanged. The differential standard deviation becomes approximately 0.1414 microvolts, although the average still has variance 4.005. Exceptionally close channel agreement is therefore compatible with an essentially unchanged two-microvolt common uncertainty. These are exact consequences of the stipulated linear model, not claims that all error distributions are Gaussian. [M4-1]

$$var\left(x_1 - x_2\right) = 1 + 1 = 2\left(\mu V\right)^2$$

The point is not to discourage difference measurements. Their ability to reject common terms makes them valuable for examining differential behaviour. The error is to use a result about the difference as though it measured what the subtraction deliberately removed. A calibration programme could exploit both operations: use channel differences to investigate private instabilities, and a separately established reference to investigate common accuracy. The second experiment supplies information missing from the first. Merely collecting more difference records cannot reveal a term whose coefficient in every such record is zero.

Dr. Atkinson, the constant-source assumption also deserves attention. With a time-varying source, the covariance of the uncorrected outputs includes source variation. To infer error covariance, one needs a defensible way to separate the source contribution or a sufficiently specified repeated-input experiment. A laboratory source may itself fluctuate; a common

Copyright 2026, James M. Atkinson

splitter may contribute another term. Calling that source stable is a hypothesis to support over the relevant amplitude, bandwidth, and duration, not a numerical operation that removes its uncertainty. The modelling decision determines whether the resulting covariance can be carried into a later weak-signal calculation.

A finite covariance estimate introduces a further question. It describes the observed records under their conditions and does not guarantee the same dependence after the system changes state. If the shared disturbance appears only during a thermal transition, a quiet settled test may miss it. If a common gain correction changes both records together, the effect may be systematic over one run rather than a zero-mean fluctuation. A single random-error model must not be used to conceal these distinct mechanisms. The record should distinguish corrected bias, uncertainty about that correction, and fluctuations represented by the chosen covariance.

There is an additional distinction between dependence of observed fluctuations and uncertainty about a fixed correction. A correction can remain constant throughout a recording, producing no time-series covariance that exposes its error, while its uncertain value is common to both reported results. Estimating covariance from within-run fluctuations alone would omit that contribution. The uncertainty model must therefore include information from the calibration process and not merely what varies visibly during the event. A quiet record cannot measure every uncertainty shared by its interpretations.

A final evidential safeguard is that a deliberately independent reference path and documented perturbation of shared dependencies. A second

Copyright 2026, James M. Atkinson

instrument adds evidential force only to the extent that its error mechanisms are independent or adequately modelled. Two receivers supplied by the same antenna network can share impedance anomalies, a local oscillator reference, or a strong interfering field. If they report the same feature, the comparison is valuable but must not be represented as two independent confirmations until those common pathways are examined. Where practical, vary a reference source, a cable route or a gain state under controlled conditions, and assess whether the observed changes conform to the proposed transfer relations. Applied to the present engineering problem, one coupled source of error propagating through apparently independent records may create a spectrum or timestamp that looks persuasive while leaving shared calibration dependencies, antennas, oscillators, power supplies, and reporting software inaccessible. The experimental answer lies in a deliberately independent reference path and documented perturbation of shared dependencies, carried out with explicit controls and independent retention of all the relevant receiver states. The account should quantify cross-correlation, residual dependence, independent sensor coverage, and false-alarm conditioning, separating input-referred values from software-derived quantities. If the calculation assumes constant noise statistics or a linear front end, an overload or irregular interference challenge should test that premise. The examiner should preserve negative outcomes and show why the proposed mechanism is better supported than the surviving alternatives. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Finally, a second receiver adds evidence even when it is not independent in every respect. It can localize some errors to an individual branch, show

Copyright 2026, James M. Atkinson

that a feature survives a changed conversion path, or constrain the timing of an event. Its contribution should be expressed at that level. Independence is not an honour bestowed upon an instrument; it is a relation among specified observations under specified conditions. Dr Shannon, may I invite your challenge concerning whether a second representation of the same acquired samples adds any new information about their physical origin?

Claude Elwood Shannon

Peer question 1 to Norbert Wiener

Professor Wiener, thank you. Two processing chains may be designed independently yet receive exactly the same digital recording. Their agreement can expose some implementation errors, but neither has observed the analogue input independently. I would ask you to distinguish the information added by algorithmic diversity from the information added by another physical acquisition. Dr. Atkinson has placed both within the general question of corroboration, and it would be easy to let the useful independence of programmers become an unsupported independence of observations. Suppose the two chains agree on a candidate frequency after using different numerical methods. What has been strengthened, and what has not? Please also consider whether a second method that shares an undocumented convention about scaling or sample time could repeat the same interpretative error. How should the report describe the additional evidence without either dismissing the comparison or counting it as a second observation of the external field?

Copyright 2026, James M. Atkinson

Norbert Wiener

Answer to Claude E. Shannon

I welcome that careful objection and shall address it directly. Thank you for that question. Dr Shannon, the comparison can strengthen a claim about the calculation performed on the retained recording. If independently implemented methods converge upon the same frequency under explicitly matched conventions, some classes of numerical or implementation mistake become less plausible. The result remains conditional upon the recording and its coordinate definitions. It does not establish that the analogue input was unclipped, that a frequency translation was correctly documented, or that the feature was not generated before the digital branch point. Those questions require information that neither processing chain received.

Dr. Atkinson, the relevant boundary should therefore appear in the report: independently processed, not independently acquired. The qualification is not disparaging. It identifies exactly where diversity was introduced. An independent calculation can be exceptionally valuable when a disputed result depends on subtle normalization, windowing, or reconstruction. Its evidential force is increased by preserving the inputs and conventions and by testing the implementations on cases with known outcomes, not by broadening its description beyond the boundary it actually challenges.

Shared assumptions deserve their own examination. Two teams may use different software while adopting the same mistaken sample rate supplied in a configuration file. Agreement then supports

Copyright 2026, James M. Atkinson

consistency with that stated rate, not its physical accuracy. The appropriate additional test might compare the acquisition clock with an independent reference or inspect the receiver's verified frequency mapping. Changing only the numerical method does not vary the uncertain clock. The same logic applies to a common amplitude calibration or a shared rule for interpreting missing samples.

The records of this comparison should also identify which test cases were selected independently of the disputed event. Otherwise a method developed to reproduce that event may appear to validate it through agreement that its development process was designed to obtain.

I would preserve a dependency diagram rather than award one undifferentiated count of corroborating methods. Identify common data, common metadata, common calibration, and separately exercised operations. Then state which alternatives each comparison addresses. The phrase independent evidence is useful only after its relevant independence has been specified. Dr Nyquist, may I invite you to examine whether apparently matching spectral peaks can conceal different admitted frequencies or acquisition bands?

Harry Nyquist

Peer question 2 to Norbert Wiener

Professor Wiener, the dependency diagram should include frequency mappings, not merely shared boxes. Two receivers can display the same numerical frequency while admitting different analogue bands, or display different numerical frequencies for the same physical input after

Copyright 2026, James M. Atkinson

different conversions. Agreement of labels would then conceal rather than establish an agreement of observations. Suppose each receiver has a different sample rate and its own input filter, but the analysis converts both results to an absolute frequency scale using incomplete configuration records. What evidence would make that comparison meaningful? In particular, should we require a controlled signal to traverse each relevant path before describing the observations as corroborating, or can a sufficiently complete model supply the missing connection? Please distinguish a common alias that survives similar architectures from genuinely complementary frequency coverage, and explain how to preserve the information that could later expose a mistaken mapping.

A further constraint follows from the distinction between genuinely independent corroboration and common-mode instrument error. Shared calibration dependencies, antennas, oscillators, power supplies, and reporting software remain outside the direct observation. If the examiner reports only those cases in which the indicated feature agreed with the preferred model, what correction would you require to the exposure denominator, alternative-hypothesis analysis, and reproducibility account?

Norbert Wiener

Answer to Harry Nyquist

Dr Nyquist, matching labels are not enough. A meaningful comparison requires a supported mapping from each retained coordinate to the analogue reference plane being discussed. A model can supply that mapping when its architecture, settings, and

Copyright 2026, James M. Atkinson

operating state are sufficiently established, but the model's applicability must be tested where uncertainty could change the conclusion. A controlled signal is useful precisely because it can challenge the mapping through the physical path. Its value depends on traversing the ambiguous stages and covering the relevant branch, not simply producing an expected marker somewhere on the display.

Dr. Atkinson, a shared alias can be a common consequence of shared sampling and filtering assumptions. Using different sample rates or preselection may separate some candidate analogue frequencies, provided the resulting observations are compared through their actual admissible mappings. It is not enough to say that the hardware differs. One should state how the competing candidate frequencies predict different outcomes under the chosen change. If both candidates remain admissible after every configuration tested, the ambiguity has not been resolved by acquiring another trace.

The record should retain native sample coordinates, selected analogue bands, conversion frequencies and signs, sample rates, and the transformations used to produce the common frequency display. Retaining only the final labels prevents a later examiner from reconsidering the mapping. A reconstructed absolute-frequency axis should remain a derived product with identifiable inputs. That is especially important where software combines several tuned intervals into a display that appears simultaneous although the acquisitions were sequential.

Copyright 2026, James M. Atkinson

Where the original configuration cannot be recovered, retain alternative admissible mappings instead of choosing the mapping that makes the two traces agree. Their agreement is then conditional, and an unresolved branch remains a real limitation on the proposed corroboration.

I would not impose one universal calibration ritual on every comparison. The evidence required follows the uncertainty that could defeat the claim. A well-supported fixed mapping may need only appropriate verification; a changed or incompletely logged path may require new measurements or a restricted conclusion. Dr Bode, may I now invite your examination of how the shared network itself can generate agreement, disagreement, or cancellation that neither receiver's individual specification predicts?

Copyright 2026, James M. Atkinson

Hendrik Wade Bode

The shared network is part of the corroboration experiment

Professor Wiener, thank you. Dr. Atkinson, the common network cannot be treated as an invisible connection between otherwise independent instruments. It has a transfer relation, loading conditions, internal sources, and possible paths by which one branch influences another. A comparison intended to identify the origin of a weak feature should therefore include the network's boundaries. Removing it may answer one question while also changing the source loading or the noise presented to each receiver. A test that alters several relevant quantities at once can remain informative, but its outcome requires a model broad enough to include those changes.

For application three, let two real, zero-mean random voltages be s and c, mutually independent with variances S and C. Define branch observations x_1 = s + c and x_2 = s minus c. Their covariance is S minus C, while each individual variance is S plus C. Choose S = C = one square microvolt. Each branch has variance two, yet their cross-covariance is zero. The wanted contribution has not vanished from either input; its contribution to the cross statistic is cancelled by the oppositely coupled contribution. If the same algebra is applied at a frequency to uncorrelated stationary processes, S and C denote compatible spectral densities rather than integrated variances. The units and bandwidth convention must change accordingly.

$$cov(x_1, x_2) = S - C = 1 - 1 = 0 (\mu V)^2$$

This constructed example has a relevant physical counterpart. NIST researchers report that thermal noise from a common power splitter can enter cross-spectrum measurement channels with anticorrelated contributions and cause underestimation or collapse of the measured noise

Copyright 2026, James M. Atkinson

spectrum. That published result concerns the tested measurement configuration. It supplies a mechanism worth checking, not a universal explanation for every unexpectedly low cross-spectrum. [M4-2]

Application four introduces directional leakage instead of an oppositely coupled common term. Let independent real noise variables n1 and n2 each have variance one square microvolt. Define x_1 = n1 and x_2 = n2 + k n1, where the dimensionless leakage coefficient k is 0.1. The covariance is 0.1 square microvolt; the variances are one and 1.01. Their correlation is about 0.09950, and its square is approximately 0.009901. There is no separate external common signal in this construction. The nonzero correlation is created by leakage. This is an elementary scalar analogue of a frequency-dependent channel-coupling problem, not a replacement for a complete spectral model.

$$r = \frac{0.1}{\sqrt{1 \times 1.01}} \approx 0.09950 \, , r^2 \approx 0.009901$$

Dr. Atkinson, these two examples warn against opposite mistakes. A strong correlation need not identify an external common source, and a small cross statistic need not establish absence of a wanted contribution. The distinction requires knowledge of how the relevant components enter both branches. Merely comparing their individual noise floors does not supply those signs, phases, or transfer paths. Nor does a lower result automatically deserve preference because it resembles improved sensitivity. A measurement should be accepted through a supported model and challenge tests, not through the attractiveness of its numerical outcome.

A practical experiment can vary the location of a reference injection, the branch termination, or a verified isolating element while documenting the

Copyright 2026, James M. Atkinson

transfer changes. If a feature appears in a terminated branch when the other branch is driven, that observation can constrain coupling. If replacing a splitter changes the cross statistic, one must still examine altered insertion loss, impedance, and reference conditions before attributing the entire change to one mechanism. This proposal is a test of competing transfer models. It does not assume that replacing a component produces a perfectly selective intervention.

The test should retain the complex cross quantity where the measurement supports it. Reducing it immediately to a magnitude can conceal signs or phase changes important to a cancellation argument. Finite-record fluctuations should also be distinguished from an expected cross term. A single small estimate does not establish a zero expectation, while a stable nonzero estimate does not identify its source. The relevant experimental question is which controlled change would make the candidate components respond differently and whether the observed response matches that prediction within the stated uncertainty.

Another hazard appears when software corrects the two branches by dividing by estimated transfer functions. A transfer minimum can make a small calibration error dominate a corrected cross quantity. Agreement after that correction is not necessarily stronger than agreement before it. The laboratory should retain both representations and the uncertainty of the correction, especially near response minima. A calibration derived by forcing the branches to agree cannot then use that same agreement as independent evidence that the correction is right.

I would conclude that corroboration is a property of the whole arrangement, including common components, rather than of receiver serial

Copyright 2026, James M. Atkinson

numbers. The network can provide a useful common input for comparing branches, yet that very commonality may conceal a shared error. Its benefits and limitations should be stated together. Dr Gabor, may I invite your question concerning the time and phase information that must be retained before a cross-spectrum can be treated as a physically meaningful comparison?

Dennis Gabor

Peer question 3 to Hendrik W. Bode

Dr Bode, thank you. The cross-spectrum requires a relationship between records, but that relationship may be estimated after acquisition rather than physically preserved. An analyst can shift one record in time or rotate its phase to maximize agreement. Such alignment may compensate a genuine known delay, yet it can also make a weak common feature appear more persuasive by selecting the transformation that favours it. What distinguishes a calibrated alignment from a fitted alignment whose uncertainty and selection are part of the result? Please consider a short transient rather than a stationary carrier. The two records have different filtering and uncertain trigger origins. Under those conditions, which properties must be established before their apparent common structure is evidence of the same event? How should the analyst record failed alignments and alternative delays, rather than preserving only the most attractive overlay?

May I press the principal contributor on independence of electromagnetic corroboration between two receiving systems? The chronology of independence of electromagnetic corroboration between two receiving systems is indispensable. Assume for a moment that

Copyright 2026, James M. Atkinson

common-oscillator phase noise or an antenna splitter might reproduce one false feature in both streams. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should repeat a common-stimulus test after separating power, frequency references and physical antenna paths, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs shared dependency graph, calibration offsets, correlated noise and near-threshold decisions. If purported independent agreement fails when the common error path is removed, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Hendrik Wade Bode

Answer to Dennis Gabor

Thank you for that question. Dr Gabor, an alignment derived from an independently characterised delay and applied within its supported state is a correction with a defined evidential basis. An alignment estimated from the event being examined is part of the

Copyright 2026, James M. Atkinson

inference. It may be useful, but the search range, criterion, degrees of freedom, and residual ambiguity must be retained. A favourable match obtained after trying many transformations cannot be described as though the correct transformation had been specified beforehand. The calibration and the event must not exchange roles without disclosure.

Dr. Atkinson, for a transient I would first identify the acquisition time origins and the filter responses that determine what each record preserves. A delay defined for a narrowband phase comparison may not align a broadband pulse whose components experience different group delays. If the response is not adequately known, the comparison may support only a limited correspondence of timing or structure. It should not be forced into sample-by-sample agreement by an unconstrained transformation that can absorb the very differences under investigation.

Preserve the original records, the alignment objective, candidate delays, admissible transformations, and the criterion used to select a result. Retain sufficient intermediate information to examine whether several alignments fit comparably well. A held-out portion or independent reference event can test whether the fitted relationship generalizes, provided its relevance is justified. Such validation does not make the original fit independent, but it supplies a new opportunity for the proposed mapping to fail.

The time tolerance should likewise be chosen for the stated claim. A broad coincidence window may establish that activity occurred in

Copyright 2026, James M. Atkinson

the same general interval while providing little evidence that the receivers captured the same short physical event.

Failed alignments matter when the method allowed them to influence the selected result. Reporting only the successful overlay can exaggerate uniqueness. The final statement should distinguish an observed correspondence from an inferred common event and state the transformations upon which that inference depends. Mr Weston, may I invite you to question how changing branch loading affects the interpretation of the reference measurements proposed for this shared network?

A further constraint follows from the distinction between genuinely independent corroboration and common-mode instrument error. I would add the following qualification to my answer. The written conclusion must separate a directly retained observation from an inferred physical explanation. A short anomaly may be real in the stored digital sequence yet originate in quantisation, analogue recovery or the acquisition policy. Conversely, the absence of an alarm cannot establish the absence of an event outside valid temporal and frequency coverage. Such limitations do not make the work futile. They guide a useful next test, specify the conditions in which the present record is persuasive and protect the evidential chain against later exaggeration. In this particular question, the controlled observation is two or more nominally separate receiver indications, whereas the material uncertainty concerns shared calibration dependencies, antennas, oscillators, power supplies, and reporting software. Consequently the adversarial comparison ought to include a

Copyright 2026, James M. Atkinson

deliberately independent reference path and documented perturbation of shared dependencies and its failed as well as successful outcomes. I would not advise treating a change in the displayed indication as an authenticated physical attribution until its causal mechanism has been experimentally distinguished.

Edward Weston

Peer question 4 to Hendrik W. Bode

Dr Bode, the investigator may disconnect one receiver, fit a terminator, and interpret the remaining trace as a clean test of branch independence. Yet the substituted load may not resemble the operating receiver, particularly across the frequency range under examination. Dr. Atkinson's question therefore requires a distinction between a convenient control state and a physically comparable one. How would you demonstrate that a change attributed to leakage or splitter noise is not simply the consequence of altered loading? Please address a case in which the common source itself responds to the changed impedance. Would measurements at additional reference planes be necessary, and how would their own connections be prevented from changing the experiment? I am asking for a practicable hierarchy of checks, not a demand that every parasitic quantity be known exactly before any useful conclusion is allowed.

May I press the principal contributor on independence of electromagnetic corroboration between two receiving systems? Before offering an opinion about independence of electromagnetic corroboration between two receiving systems, I would define the measurand and its uncertainty. The proposed rival mechanism is that

Copyright 2026, James M. Atkinson

common-oscillator phase noise or an antenna splitter might reproduce one false feature in both streams. Consequently a calibration certificate for one nominal receiver setting does not settle the question. The more informative operation is to repeat a common-stimulus test after separating power, frequency references and physical antenna paths, with shared dependency graph, calibration offsets, correlated noise and near-threshold decisions reported in units and tied to an input reference plane. The adverse prediction is concrete: purported independent agreement fails when the common error path is removed. I would challenge it across a range of input powers and hold one independently measured source constant throughout the switching sequence. A correction estimated after seeing the unknown feature may assist an exploratory analysis; it must not be presented as though it had been fixed before acquisition. Where systematic effects share a reference, their covariance belongs in the reported uncertainty rather than being silently assumed zero. This is the distinction between an instrument number that appears stable and a defensible physical measurement. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Hendrik Wade Bode

Answer to Edward Weston

Mr Weston, the first check is to identify the loading property that matters to the proposed comparison and the uncertainty within which it must remain comparable. A nominal resistance printed on a terminator does not establish its complete complex impedance at

Copyright 2026, James M. Atkinson

every relevant frequency. The operating receiver may also present a state-dependent input response. One should therefore measure or otherwise support the admissible loading range and ask whether variation within that range could account for the observed change. The answer determines whether further characterization is necessary.

Dr. Atkinson, an additional reference-plane measurement is useful when it separates hypotheses that would otherwise remain confounded. It is not automatically benign. A coupler, probe, or adapter becomes part of the arrangement and requires its own transfer and loading assessment. The measurement plan should explain why its disturbance is acceptably small or how the disturbance enters the correction. When that explanation cannot be supported, the extra reading may create another uncertain boundary rather than resolve the first.

A practicable hierarchy begins with the existing circuit description and component characterisation, follows with a bounded sensitivity calculation, and introduces new measurements where the predicted uncertainty could alter the conclusion. Controlled substitutions should span plausible operating loads rather than merely contrast the original apparatus with an idealized termination. Repetition can then determine whether the response is stable within each declared state. These are proposed engineering controls, not a guarantee that every source can be interrogated without changing it.

The hierarchy should end when the remaining loading uncertainty is demonstrably immaterial to the particular conclusion, not when every possible parameter has been measured. The acceptance

Copyright 2026, James M. Atkinson

criterion supplies that stopping point and keeps a practical investigation from becoming an unbounded component survey.

The report should preserve what the substitution establishes. It may show that the feature depends on a branch condition without proving which internal mechanism causes that dependence. That narrower result can guide the next test. Professor Neyman, may I now return the statistical question to you: when two detection decisions share a fluctuating background or calibration state, how should their joint false-alarm probability be evaluated?

A final evidential safeguard is that a deliberately independent reference path and documented perturbation of shared dependencies. I would add the following qualification to my answer. A second instrument adds evidential force only to the extent that its error mechanisms are independent or adequately modelled. Two receivers supplied by the same antenna network can share impedance anomalies, a local oscillator reference, or a strong interfering field. If they report the same feature, the comparison is valuable but must not be represented as two independent confirmations until those common pathways are examined. Where practical, vary a reference source, a cable route or a gain state under controlled conditions, and assess whether the observed changes conform to the proposed transfer relations. In this particular question, the controlled observation is two or more nominally separate receiver indications, whereas the material uncertainty concerns shared calibration dependencies, antennas, oscillators, power supplies, and reporting software. Consequently the adversarial

Copyright 2026, James M. Atkinson

comparison ought to include a deliberately independent reference path and documented perturbation of shared dependencies and its failed as well as successful outcomes. I would not advise treating a change in the displayed indication as an authenticated physical attribution until its causal mechanism has been experimentally distinguished.

Copyright 2026, James M. Atkinson

Jerzy Neyman

Agreement must be evaluated under the relevant joint model

Dr Bode, thank you. Dr. Atkinson, the probability of two false alarms is not determined by the two marginal probabilities alone. Multiplication is justified only under the relevant independence condition. Separate receiver enclosures, different programs, and separate operators do not establish that condition. A common environmental state can affect both decisions even if their private fluctuations are independent once the state is specified. The distinction between conditional independence and unconditional independence is particularly important when a validation campaign combines quiet and disturbed operating periods.

Application five supplies an explicit construction. Let Z identify a common state: quiet with probability 0.99, disturbed with probability 0.01. Conditional on Z, suppose the two detectors make independent false-alarm decisions, each with probability 0.001 in the quiet state and 0.5 in the disturbed state. The unconditional false-alarm probability of either detector is 0.99 times 0.001 plus 0.01 times 0.5, or 0.00599. Their joint probability is instead 0.99 times 0.001 squared plus 0.01 times 0.5 squared, which equals 0.00250099. Squaring the marginal probability gives only 0.0000358801. The true joint probability in this construction is about 69.7 times that product.

$$p = 0.99(0.001) + 0.01(0.5) = 0.00599$$

$$P(A \cap B) = 0.99(0.001)^2 + 0.01(0.5)^2 = 0.00250099$$

Here A and B denote the respective false-alarm events. The probabilities, including the common-state mixture, are stipulated for instruction; they are not estimates from field data. The example demonstrates how agreement can be dominated by rare shared conditions that a marginal performance

Copyright 2026, James M. Atkinson

summary conceals. Requiring both detectors to respond has reduced false alarms relative to either detector alone, but not by the factor predicted through an invalid multiplication. The fusion rule is not useless; its claimed operating characteristic was wrong.

Application six considers the case in which only the two marginal probabilities are known, both equal to 0.01. Basic probability bounds give a joint probability between zero and 0.01. The lower bound follows because probabilities cannot be negative and the sum of the marginals is less than one. The upper bound follows because the intersection is contained within each event. An independence value of 0.0001 lies inside that interval, but is only one admissible choice. Perfectly coincident false alarms achieve the upper bound; disjoint false alarms achieve the lower bound. Marginal validation alone does not select among them.

$$max\left(0, p_A + p_B - 1\right) \leq P\left(A \cap B\right) \leq min\left(p_A, p_B\right)$$

Dr. Atkinson, the natural experiment is to validate the actual fusion procedure under relevant common states, retaining paired decisions rather than only individual totals. A joint record can be analysed for coincidences, timing offsets, and the conditions surrounding them. If the operational rule allows detections within a time tolerance to count as coincident, that tolerance belongs to the tested procedure. Enlarging it after observing the events changes the experiment. So does searching many frequency tolerances and retaining the one that yields the strongest apparent agreement.

The trial population remains central. A joint false-alarm rate measured on a terminated bench input need not describe a site containing common interferers. A useful validation specifies the signal-absent condition and the

Copyright 2026, James M. Atkinson

disturbances admitted under it. Signal absent does not necessarily mean all electromagnetic input absent. The hypothesis should exclude the signal class of interest while retaining plausible nuisance processes. Otherwise the test may demonstrate rejection of private receiver noise while leaving common environmental false alarms almost unexamined.

One should also avoid treating the joint false-alarm probability as the probability that a particular event is false. Those are different conditional statements. The latter requires an inference about competing hypotheses and their prior or sampling context; it does not follow from a detector operating characteristic alone. The report can state the tested rate and the conditions supporting it without assigning an unsupported probability to source attribution. That restraint is especially necessary when the observed event prompted changes in the procedure that were not represented in validation.

Paired validation should retain detections in which only one branch responded, not merely the coincident subset. Those discordant outcomes help identify coverage, sensitivity, and timing differences. Removing them before estimating performance changes the population to one selected for agreement. Similarly, a detector disabled during a shared disturbance cannot contribute a negative decision as though it had remained valid. Joint outcomes should include the acquisition state needed to determine which decision combinations were possible, and uncertainty about that state should remain visible rather than being filled with convenient zeros.

Dr. Atkinson, I would frame the problem as follows. There is a statistical difficulty in the assertion concerning independence of electromagnetic corroboration between two receiving systems: we have not yet ruled out the

Copyright 2026, James M. Atkinson

possibility that common-oscillator phase noise or an antenna splitter might reproduce one false feature in both streams. The investigation should record its chosen detector threshold, visit schedule, selection of frequencies and expected failure modes before the prospective confirmatory test. To examine the difference we should repeat a common-stimulus test after separating power, frequency references and physical antenna paths, collecting shared dependency graph, calibration offsets, correlated noise and near-threshold decisions over a predeclared range rather than selecting the most attractive subset afterward. An observation in which purported independent agreement fails when the common error path is removed would strengthen a restricted causal account, but it cannot certify every unvisited frequency-time interval. I would state which recordings are dependent, which have been excluded as invalid, and which inferences rely upon a model of rare events or stationary interference. A numerical interval can have impeccable arithmetic and still misdescribe the physical world if its sampling population was chosen because the signal already looked unusual. We should therefore preserve exploratory leads separately from independently designed validation evidence.

Finally, finite paired trials create uncertainty about the joint rate. An absence of observed coincidences is evidence under the trial model, not proof that coincidences are impossible. Dependence across repeated trials can reduce the information in their count, just as dependence between receivers changes the information in their agreement. Mr Pearson, may I invite you to challenge how the proposed joint validation should handle a common-state mechanism that is suspected but not directly recorded?

Copyright 2026, James M. Atkinson

Egon Sharpe Pearson

Peer question 5 to Jerzy Neyman

Professor Neyman, the common-state example is persuasive because its state labels and probabilities are supplied. In an actual record the investigator may see clustered coincidences without a logged disturbance that explains them. Fitting an unobserved mixture afterward could describe the data, but many mixtures might do so. How should the laboratory use such a model without mistaking explanatory flexibility for identified mechanism? Please distinguish an empirical estimate of the joint false-alarm rate from a causal account of why the false alarms coincide. Also consider a threshold selected after inspecting these clusters. Can the same observations then establish the revised procedure's operating characteristic, or should they be treated as development data? I would welcome a concrete account of what remains reportable when no unique hidden-state interpretation is justified, yet the original independence assumption has clearly ceased to be credible.

May I press the principal contributor on independence of electromagnetic corroboration between two receiving systems? I should distinguish the physical occurrence under inquiry from the information actually retained when studying independence of electromagnetic corroboration between two receiving systems. Because common-oscillator phase noise or an antenna splitter might reproduce one false feature in both streams, more than one historical account may produce the same saved trace. The controlled comparison should be to repeat a common-stimulus test after separating power, frequency references and physical antenna paths, preserving shared dependency graph,

Copyright 2026, James M. Atkinson

calibration offsets, correlated noise and near-threshold decisions at the measurement point and in the evidential metadata. If purported independent agreement fails when the common error path is removed, that result would narrow the admissible explanations, not establish a uniquely identified emitter outside the tested conditions. A subsequent software reconstruction may recalculate a statistic from retained samples, yet it cannot recover components rejected by the front-end filter or intervals never recorded. I would make those distinctions explicit in the final report and invite an independent examiner to reproduce the challenge, including its failed steps. Scientific restraint is not a weakness of the investigation. It prevents a detector output, however striking on the screen, from becoming a claim about unobserved activity that the original measurement never established. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Jerzy Neyman

Answer to Egon S. Pearson

Mr Pearson, the paired observations can support an empirical description of joint decisions even when their causal mechanism is unresolved. That description should retain the uncertainty appropriate to the actual sampling plan and dependence across trials. A fitted latent-state model may help formulate further tests or interpolate within a justified regime, but a satisfactory fit does not identify the physical state uniquely. The report must separate

Copyright 2026, James M. Atkinson

observed clustering, the statistical representation adopted, and the causal explanation proposed for it.

Dr. Atkinson, the inability to name the common cause does not restore an independence assumption contradicted by the paired record. One can replace the product calculation with directly estimated joint performance for the specified population, or report bounds where the data do not support a precise estimate. What cannot be justified is selecting a convenient latent model solely because it supplies a reassuring tail probability, while concealing other models that fit the observations comparably well and imply different risks.

Changing the threshold after studying the clusters belongs to development. The same records remain informative about what motivated the change, but an independent assessment should test the resulting frozen rule. Its operating characteristic may differ from the apparent performance on the data used to choose it. A sound record preserves the earlier rule, the selection procedure, and the new rule, making clear which observations evaluated which version. The requirement concerns the inference, not an administrative preference for separate file names.

The validation set should include complete paired outcomes, including discordance and invalid acquisition, under its declared sampling plan. A catalogue containing only retained coincidences cannot estimate how frequently the fusion rule failed or how often it had a valid opportunity to decide.

Copyright 2026, James M. Atkinson

Further experiments should seek measurements capable of separating candidate causes: common reference behaviour, branch coupling, environmental activity, or a shared reference estimate. They need not resolve every mechanism before the laboratory reports the observed joint behaviour. An honest unresolved cause is preferable to a falsely precise explanation. Dr Shewhart, may I invite your account of arranging those experiments so that receiver changes are not systematically entangled with time, temperature, or operator sequence?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart

Corroboration requires a comparison design, not merely repeated agreement

Professor Neyman, thank you. Dr. Atkinson, the experimental plan should make the comparison of interest possible before the observations arrive. If one receiver is tested only in the morning and another only in the afternoon, a difference between their results cannot be assigned uniquely to the receiver. If a suspect shared component is present in every warm run and absent in every cool run, component and temperature effects are similarly entangled. Repeating each arrangement many times can estimate the corresponding combined effect precisely while leaving the desired separation unavailable.

A useful design identifies the primary change and the nuisance conditions that can plausibly alter its result. Conditions that can be held sufficiently comparable may define blocks within which the primary alternatives are exercised. Randomisation can help prevent remaining variations from being systematically assigned to one alternative. These principles are described in the NIST treatment of randomized block designs. Their application here is a proposed receiver experiment, not a claim that a statistical design can eliminate unmeasured physical interactions. [M4-3]

Application seven demonstrates the problem with invented measurements in arbitrary but consistent indication units. Receiver A produces 8 and 9 in one period; receiver B produces 12 and 13 in a later period. The difference of means is four units. Under an additive model in which the later period adds five units independently of receiver, the receiver effect B minus A would instead be minus one unit. The original design does

Copyright 2026, James M. Atkinson

not determine which decomposition is correct. Four is an observed contrast between receiver-and-period combinations, not an identified receiver effect. Neither sample mean is arithmetically wrong; the attribution is unsupported.

Now consider application eight. Exercise both receivers in each of three blocks and stipulate negligible within-block change and an additive block effect. The paired readings are A = 10, 20, 30 and B = 12, 22, 32. Each within-block difference is two units, so their average is two. The block levels vary substantially, yet the contrast is invariant in this constructed model. Compare this with taking A only from the first block and B only from the third: the apparent difference would be 22 units. Pairing has supplied the comparison that the latter selection cannot provide. It has not proved that real receiver effects are additive or that a block can be made arbitrarily long.

$$\bar{d}=\frac{(12-10)+(22-20)+(32-30)}{3}=2\,units$$

Dr. Atkinson, a switching experiment introduces its own dynamics. Changing a path can alter impedance, control state, or settling, so the accepted observation interval should be specified for each transition. Alternating rapidly is not automatically superior to slower blocked operation. The choice must preserve the quantity under comparison. If the source itself changes faster than the switching experiment can resolve, simultaneous observation may be needed, with the common network's limitations explicitly assessed. The design has to respect the physical time scales rather than treating run order as a purely statistical abstraction.

Interactions deserve attention because they can make the desired attribution state-dependent. Removing a shared amplifier may improve one

Copyright 2026, James M. Atkinson

receiver's result but degrade another's because their downstream noise contributions differ. A test that averages over both receivers without retaining the interaction can conceal this behaviour. A complete factorial experiment may be impracticable, but a reduced design should state which effects are confounded and which negligible-interaction assumptions permit the proposed interpretation. The NIST discussion of fractional designs makes that trade-off explicit; our receiver plan must identify its own relevant factors rather than borrow the language without the design. [M4-4]

The record should preserve failures and unusable states as outcomes, not simply remove them from the comparison. If one arrangement cannot sustain valid acquisition during a disturbance, that loss is part of its operating performance. Restricting the analysis to intervals where both arrangements behaved well may answer a useful conditional question, but it does not answer which arrangement provides better overall coverage. The analysis population should be declared, and any exclusions should retain their physical reasons and their effect on the question being asked.

A useful record distinguishes the planned allocation from the allocation actually executed. Failed transitions, reordered runs, and interrupted blocks can destroy the balance assumed in the analysis. Their occurrence need not invalidate every observation, but the final model must follow the executed experiment. Reproducing the planned schedule in a report while silently analysing a different sequence would confer design properties that the data do not possess.

There is also a practical limit to precision. Additional repeats cannot compensate for a contrast that the design never isolates. Conversely, a carefully selected small set of interventions can establish a limited but

Copyright 2026, James M. Atkinson

valuable fact without characterizing every possible source of variation. The objective is to create observations whose competing explanations differ, then measure those differences with suitable controls. Dr Bridgman, may I invite your challenge concerning whether swapping components preserves the same measurand, or inadvertently changes the physical question we intended to investigate?

Percy Williams Bridgman

Peer question 6 to Walter A. Shewhart

Dr Shewhart, thank you. Your design assumes that the measurements being compared continue to represent the same intended quantity. Yet changing an antenna network, an input impedance, or a filter may change which physical field components reach the receiver and how the specified quantity is realized. A well-balanced experiment could then estimate the effect of changing the measurement definition, rather than isolate an error in a common definition. How would you distinguish these possibilities? Please consider a proposed independence test that replaces a shared antenna distribution system with two different antennas. The new arrangement has less shared electronics but different spatial and polarization responses. What can its agreement establish, and what would its disagreement leave unresolved? I ask how the experimental plan should carry the measurand across this change without pretending that the two physical arrangements are identical.

May I press the principal contributor on independence of electromagnetic corroboration between two receiving systems? I am concerned with independence of electromagnetic corroboration between two receiving systems. The unresolved alternative is that common-

Copyright 2026, James M. Atkinson

oscillator phase noise or an antenna splitter might reproduce one false feature in both streams. I should therefore separate the physical input from its representation on the receiver display. Let us repeat a common-stimulus test after separating power, frequency references and physical antenna paths, ensuring that the operator records shared dependency graph, calibration offsets, correlated noise and near-threshold decisions. The anticipated discriminating observation is that purported independent agreement fails when the common error path is removed. A failure of this test would not compel us to accept a more dramatic transmitter hypothesis; it would instead mean that our proposed transfer-path model is incomplete. I would retain the measured contrary result and identify the exact connector, stimulus, receiver settings and elapsed intervals in the report. Such a procedure has a modest but valuable result: it converts an initially persuasive visual indication into an experimentally bounded account of what could have produced the retained data. Our duty is not to force agreement but to specify which physical explanations are still consistent with the recorded state. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Walter Andrew Shewhart

Answer to Percy Williams Bridgman

Dr Bridgman, the distinction must be written into the experiment before its results are compared. A substitution may preserve the intended measurand while changing the measurement method, or it may create a different measurand. If the target is terminal power at a

Copyright 2026, James M. Atkinson

specified connector, replacing the antenna system can change the input itself. If the target is evidence of an emission within a defined region and interval, differently situated antennas may supply complementary observations, but their amplitudes need not agree. The inference must follow the question actually common to the arrangements.

Dr. Atkinson, in the proposed example, agreement could support the presence of a feature through two distinct reception paths after their frequency and time mappings have been established. It does not automatically establish equal field strength, common polarization, or a unique source position. Disagreement may arise from the antenna responses or propagation as well as from the shared electronics being tested. These alternatives should be specified rather than allowing whichever explanation favours the investigator's initial expectation to be chosen afterward.

One approach is to separate the experiment into narrower comparisons. Characterise the receiving paths with appropriate references, preserve the observations at their own declared boundaries, and test a proposition for which the expected relationship is supported. That relationship might concern timing or frequency rather than amplitude. A separate conducted test can examine the electronics without pretending to reproduce the full radiated path. The different tests then constrain different parts of the causal account.

A disagreement can therefore be productive when it identifies the boundary at which the two measurement definitions diverge. The

Copyright 2026, James M. Atkinson

appropriate next step is to test that divergence, not to average the incompatible readings into a fictitious common quantity.

No balance of run order cures a mismatched measurement definition. Design and metrology must agree about the quantity being compared. Their collaboration is what gives a statistical contrast physical meaning. Sir Karl Popper, may I invite your examination of the remaining inferential question: after a comparison excludes one shared-path explanation, how should its result be stated without implying that all alternatives have been eliminated?

I thank the questioning colleague for that important distinction. The chronology of independence of electromagnetic corroboration between two receiving systems is indispensable. Assume for a moment that common-oscillator phase noise or an antenna splitter might reproduce one false feature in both streams. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should repeat a common-stimulus test after separating power, frequency references and physical antenna paths, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs shared dependency graph, calibration offsets, correlated noise and near-threshold decisions. If purported independent agreement fails when the common error path is removed, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the

Copyright 2026, James M. Atkinson

opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states.

Copyright 2026, James M. Atkinson

Sir Karl Raimund Popper

A corroborated proposition must remain narrower than the explanations not tested

Dr Shewhart, thank you. Dr. Atkinson, the most useful conclusion may be a carefully bounded proposition rather than an impressive attribution. If a feature persists after replacing one suspected component, that observation challenges an explanation requiring that component under the tested conditions. It does not establish that the feature originated from an independent transmitter, still less identify an owner or intention. The experiment has altered one part of the explanatory landscape. Its success should be expressed through that alteration, not through a leap to an explanation whose alternatives were never exposed to the test.

For application nine, consider three explicitly constructed hypotheses about a spectral feature. Hypothesis E assigns it to an input common to both receivers; hypothesis S assigns it solely to a particular shared distribution element; hypothesis R assigns it solely to receiver one's private chain. Suppose all three predict the original detection at receiver one, but only E and S predict a detection at receiver two. Observing the second detection excludes R within this stipulated deterministic prediction model. Two hypotheses remain. Repeating the same two-receiver configuration a hundred times, with the same predictions and no added model of stochastic error, does not distinguish E from S. The number of matching records is not the number of independent explanations eliminated.

A second intervention now removes the specified distribution element while preserving an independently verified path for the input feature. Stipulate that E predicts continued detection and S predicts its absence.

Copyright 2026, James M. Atkinson

Continued detection rejects S within this model, leaving E among these three hypotheses. The qualification among these three is indispensable. An omitted common disturbance or an incorrect transfer assumption might still require examination. This example works through a finite prediction table in words; it does not assign invented probabilities to hypotheses. Its force is logical and conditional upon the stated predictions, including the validity of the replacement path.

Application ten shows why apparently corroborating numerical results need not possess overlapping uncertainty intervals. Let two stipulated bounds for the same scalar quantity be the closed intervals [9, 11] and [10, 12] in microvolts. Their intersection is [10, 11]. If both bounds are valid deterministic constraints on the same quantity, the intersection is the admissible set satisfying both, and it is narrower than either. Replace the second interval with [12, 14]; the intersection becomes empty. One cannot repair the contradiction by averaging the centres and silently reporting 11.5. At least one bound, the shared-quantity assumption, or another premise needs reconsideration.

These are bounds, not confidence intervals. Intersecting two confidence intervals does not automatically preserve either interval's stated coverage probability. That would require a joint statistical argument. The example concerns the logic of simultaneously asserted constraints and the discipline required when they conflict. It also clarifies that agreement can mean several things: similar estimates, overlapping uncertainty regions, compatible hypothesis predictions, or reproducibility of a processing result. A report should identify which sense is intended instead of sliding between them.

Copyright 2026, James M. Atkinson

Dr. Atkinson, a test can be severe for one explanation and weak for another. The proposed intervention is informative only if the explanation challenged would ordinarily predict a distinguishable outcome under it. A nominal component replacement that preserves an unrecognised common coupling may not challenge the mechanism the investigator imagines. This is why the technical accounts offered by my colleagues are not optional decorations to the argument. They determine whether the intended counterexample was physically possible and whether a failure to observe it has any discriminatory force.

The report should also preserve unresolved disagreement. One investigator may consider a common-path alternative insufficiently tested while another judges the remaining uncertainty immaterial to a limited detection claim. Those positions can coexist if the propositions differ. The useful response is to state the claim each accepts, the premise each disputes, and an observation that could narrow the disagreement. Compelling everyone to endorse a broad phrase such as independent confirmation conceals rather than resolves the issue.

There is no contradiction between demanding a severe test and acknowledging uncertainty in its predicted outcome. A physical prediction usually occupies an admissible range rather than one exact number. The challenge is to state that range before the result is interpreted and explain how it follows from supported assumptions. Expanding it afterward solely to accommodate every result deprives the test of discrimination. Conversely, rejecting an explanation because of a discrepancy smaller than its admitted uncertainty gives numerical difference more significance than the experiment supports.

Copyright 2026, James M. Atkinson

I would therefore ask for a conclusion that names the tested alternatives, the observation that challenged each, and the alternatives still compatible with the record. It should distinguish empirical support from the adoption of an operating decision. A laboratory may act cautiously on an unresolved candidate without claiming to have proved its source. That distinction protects both scientific candour and practical judgement. Mr Hartley, may I invite your final challenge concerning whether a compressed corroboration summary preserves enough information for another examiner to reconsider those alternatives?

Ralph Vinton Lyon Hartley

Peer question 7 to Karl R. Popper

Sir Karl, a final report cannot reproduce every sample and every unsuccessful trial. It must compress the record into a statement that a reader can understand. Yet compression can erase precisely the distinctions you require: the branches that share a reference, the intervals excluded from comparison, or the hypotheses that predicted identical results. What should a concise corroboration claim retain in its visible text, and what can properly remain in linked supporting material? Please distinguish omission for readability from omission that changes the meaning of the conclusion. An expert reviewer may consult detailed files, whereas another decision-maker may read only the summary. How can the same report serve both without offering the latter an apparently categorical attribution that the former would discover to be heavily qualified? I ask for an evidential structure, not simply a recommendation to attach more pages.

Copyright 2026, James M. Atkinson

Professor, the proposal to treat two receiver readings as independent corroboration needs a more demanding physical test. Suppose both receivers share one rooftop antenna through a common distribution amplifier, and the amplifier itself oscillates briefly when a nearby high-power transmission begins. The two downstream displays may show remarkably similar narrowband events, yet their agreement would have arisen before the signal paths separated. How would your proposed corroboration test distinguish this common-mode artefact from a field emitter? I would ask you to compare simultaneous measurements through electrically separate antennas, independent power supplies and independently characterised front ends, while preserving a shared timing standard only where its own uncertainty is documented. Would you regard agreement in absolute frequency and onset time as sufficient, or require an intervention that changes one receiver chain without changing the electromagnetic environment? Finally, how should a forensic report describe dependence when some of those shared components cannot be removed without altering the original observation conditions?

Sir Karl Raimund Popper

Answer to Ralph V. L. Hartley

Thank you for that question. Mr Hartley, the visible conclusion should retain every qualification necessary to prevent a materially different proposition from being inferred. The measured feature, the interval and reference boundary, the tested basis for corroboration, and the principal unresolved alternative belong in that account when they limit its meaning. Detailed settings, calculations, and complete

Copyright 2026, James M. Atkinson

records may reside in identified supporting material. Their location should permit a reviewer to reconstruct the argument without searching an undifferentiated archive. Brevity is compatible with precision when it preserves the logical structure rather than merely the favourable outcome.

Dr. Atkinson, a useful summary might state that the feature was observed through two separately characterised receiver branches, survived a specified shared-component substitution, and remains unassigned to a physical source. That is stronger than saying only that an unexplained line appeared, but narrower than saying that an external covert transmitter was confirmed. The specific wording must follow the actual tests; this is an illustrative structure, not a prescribed conclusion for an unperformed investigation. Its limitations are visible rather than relegated to a footnote that reverses the headline.

Supporting material should distinguish observations, transformations, and judgements. Provide stable references to the relevant records and state the version of the analysis. Preserve adverse results and excluded intervals when they affect the scope. A reviewer should be able to determine which premises are documented, which are model assumptions, and which remain disputed. The report need not display every intermediate number to accomplish that task, but it must not make the argument impossible to inspect.

An evidence map can serve both audiences: one short statement of each tested proposition, its supporting record, and its principal

Copyright 2026, James M. Atkinson

qualification. Its purpose is to preserve the route of reasoning, not to replace the measurements with another unexplained score.

The decision-maker who reads only the summary should receive the same proposition as the specialist, though not every derivation supporting it. If the shortened version asserts more, it is not a summary but a different claim. Professor Atkinson, I return the floor to you for the closing account of what this discussion establishes about independent corroboration and what it deliberately leaves unresolved.

Hendrik Wade Bode, Cross-Peer Question to Jerzy Neyman: Professor Neyman, I should like to test the statistical meaning of a cross-spectrum that becomes unexpectedly small. In a constructed pair of channels, a desired common process contributes positive cross-power, while a splitter's thermal contribution is anti-correlated between the outputs. Their signed contributions can oppose one another. An average near zero may therefore arise even though neither process is negligible. If we select only the most reassuring frequency bins or average away the phase, we risk mistaking cancellation for independent confirmation that nothing was present. What inferential model would you require before calling the two instruments independent corroborators, and how would you compare results before and after changing the splitter without treating that change as if it had no other physical consequences?

Jerzy Neyman, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, an estimated cross-spectrum is a statistic with a joint sampling distribution and a physical measurement model, not a self-evident count of corroborating witnesses. One must retain its complex value, averaging convention and

Copyright 2026, James M. Atkinson

estimator uncertainty, and explain what positive and negative contributions are permitted by the circuit. Failure of a test against zero does not prove that every constituent signal vanishes, particularly when an opposing contribution can cancel it. I should require a declared model under the null and relevant alternatives, then an intervention which changes the suspected common-path contribution in a known or bounded way. A revised splitter, isolator or termination may change insertion loss and impedance match as well as its noise behaviour, so the before-and-after comparison requires its own transfer measurements. Repeated records taken through the unchanged splitter are useful observations, but their number cannot convert the same unresolved model error into independent evidence. The educational illustration is consistent with published NIST work on splitter-induced cross-spectral collapse; it is not a historical statement by either of us.

Walter Andrew Shewhart, Cross-Peer Question to Percy Williams Bridgman: Professor Bridgman, a validation committee has two spectra from separate receivers but only one calibration laboratory, one ambient-temperature record and one reference oscillator. It wishes to call the records independently measured, while its traceability file cannot separate receiver-specific correction errors from the common calibration source. How would you define the operation which the adjective independent is meant to describe? More importantly, what additional experiment would disclose whether apparent agreement survives a genuinely different calibration path, without changing so many experimental conditions that one cannot tell which difference caused the result?

Copyright 2026, James M. Atkinson

Percy Williams Bridgman, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, I would begin with an operational distinction. Separate digitiser boards do not constitute independent metrological evidence for every proposition if they inherit the same uncertain reference. Specify whether the inquiry concerns a frequency coordinate, an amplitude at a named terminal, a detection decision or the alleged origin of the emission. For each, draw the chain of instruments and corrections actually used. Then vary one suspected dependency at a time, or use a planned comparison whose combinations of reference, receiver and date can separate the effects. A second traceability route, a different physical transfer path, and an unchanged check artefact can reveal a bias concealed by the shared reference; however, none provides magical independence if it merely repeats the same calibration assumption. The result should state precisely which uncertainty terms were independently constrained and which covariance terms remain. That is a stronger report than a categorical assurance issued because two displays look alike.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, suppose the laboratory keeps two separately named recordings, derived from different receiver cards. A common timing daemon writes the sample-rate label to both containers; the cards are not phase locked, and the daemon has recorded a nominal rate rather than the actual realised rate of either card. A downstream program nevertheless aligns their spectral peaks on an apparently identical hertz scale. The two files are independent in storage, yet their displayed coordinates may share a software assumption. What information has genuinely been corroborated, and what acquisition

Copyright 2026, James M. Atkinson

record must survive before the match can be promoted from a numerical coincidence into a physical frequency comparison?

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, storage duplication and instrument diversity support different claims. The two raw sample sequences may represent distinct conversions of an external field, provided their analogue input paths and actual acquisition states warrant that description. The numbers assigned to their spectral axes are nevertheless conditional on the clock model and metadata. If the common daemon supplies one unsupported sampling frequency, agreement of displayed hertz values does not validate the physical rate. Preserve each card's native sample index, measured or independently bounded clock rate, timestamp origin, analogue preselection and any digital resampling history. Where absolute timing is uncertain, compare invariant or directly measured quantities and disclose the uncertainty instead of forcing coordinates to agree. A deliberately different clock or independently checked frequency reference may distinguish a common labelling error from a physical signal, but the comparison must retain its changed response and uncertainty. Two separately hashed files prove file identity at most. The dependency graph, not the number of file names, establishes the scope of corroboration.

Sir Karl Raimund Popper, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, let us confront a receiver pair which agrees perfectly until the investigator changes the splitter termination, after which the disputed narrow feature disappears. One interpretation is that the first observation was a splitter artefact; another is that the termination altered the impedance environment, so a genuine input became too weak to detect. A

Copyright 2026, James M. Atkinson

third is that the changed arrangement drove a different mixer or amplifier state. Which adverse comparison is capable of putting these alternatives at risk rather than simply exchanging one unverified explanation for another, and what evidence should remain in the record when the proposed falsification yields an ambiguous outcome?

Hendrik Wade Bode, Cross-Peer Answer to Sir Karl Raimund Popper: Sir Karl, the experiment should be designed as a system identification problem before it is used as a verdict. Measure the forward gain, return loss, isolation, noise contribution and operating state under both terminations, so far as practicable over the relevant frequency and power conditions. Apply a known independent challenge through a declared injection plane and demonstrate that a comparable small signal remains observable after the change; check that the reference stimulus is not coupled through the suspect path. If the feature vanishes while the known challenge survives and the altered dependency is measured, a shared-path explanation gains support. If both vanish, the experiment has not discriminated between artefact and sensitivity loss. If clipping or intermodulation changes, that alternative must be modelled rather than ignored. Retain the pre-change samples, control measurements, negative controls, configuration and exact timing. The appropriate conclusion may be that the present evidence cannot distinguish the causes. A disconfirming test is valuable only when its own physical opportunity to reveal a failure is supported.

Dr. James M. Atkinson

Closing synthesis

Professor Wiener, Dr Bode, Professor Neyman, Dr Shewhart, and Sir Karl Popper, thank you. Our discussion establishes that a second trace is an

Copyright 2026, James M. Atkinson

additional observation only in a specified sense. It may supply independent computation, another branch of a shared acquisition network, or a substantially different physical measurement. Those contributions have different evidential reach. The correct description identifies the boundary at which diversity entered and the alternatives that the comparison could distinguish. It does not count screens, receiver enclosures, or software packages as interchangeable units of independent evidence.

The ten constructed applications make the limitations concrete. A common error survives averaging while disappearing from a difference. Oppositely coupled contributions can cancel in a cross statistic, and leakage can create correlation without the separate external source imagined by the observer. Conditional independence within a known operating state does not imply independence after states are mixed. Marginal false-alarm probabilities do not specify their joint probability. A receiver comparison entangled with time or another nuisance condition may estimate a combined effect rather than the intended one. Finally, repeated observations that leave two hypotheses making identical predictions cannot resolve their disagreement merely through repetition.

These conclusions do not diminish the value of multiple receivers. They identify how that value should be developed. Characterise the shared and private paths; preserve frequency and time mappings; compare the actual fusion rule under relevant conditions; and design interventions whose competing predictions differ. A common input can be useful for testing branch differences, provided it is not then treated as independent evidence of the common input's accuracy. A changed antenna can supply

Copyright 2026, James M. Atkinson

complementary reception, provided the different spatial response is not mistaken for an electronic calibration error.

The panel has also preserved several unresolved matters. No universal criterion for independence was proposed, because the required independence depends upon the claim and the model. No probability of source identity was inferred from the joint false-alarm rate. No specific receiver was certified by the hypothetical calculations. The physical cross-spectrum literature supplies a demonstrated mechanism, not an accusation against every apparatus. These boundaries are part of the result, not reasons to abandon useful measurement.

A useful acceptance record would also preserve discordant outcomes, invalid intervals, and the uncertainty of corrections common to both branches. These are not embarrassing exceptions to be removed from a corroboration story. They identify where the story is conditional and where another test could add information. The resulting account can be decisive about a limited proposition without pretending to be final about every possible source.

For practice, the report should carry a compact dependency account: what was shared, what was changed, what was measured independently, and what remained observationally equivalent. Its headline and technical appendix must support the same proposition. A bounded statement that a feature survives specified challenges is more informative than an unqualified assertion of independent confirmation. Our next question turns from agreement to deliberate challenge: how should a validation campaign be designed so that its successes, failures, and exclusions genuinely test the claim the investigator intends to make?

Ten worked engineering applications | Question 004

Application 01. Difference between two instruments relative to stated uncertainty

In the illustrative 004.01 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. The paired instrument contrast is $\Delta = 1.500$ dB. Set independent standard uncertainties $u_1 = 0.460$ dB and $u_2 = 0.370$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.590$ dB, giving the dimensionless ratio $\Delta/u\Delta = 2.541$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The contrast supports a calibrated difference estimate, but its evidential interpretation requires a model for shared uncertainty.

Application 02. Combined and expanded measurement uncertainty

In the illustrative 004.02 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. For independent standard-uncertainty contributions 0.73, 0.48 and 0.40 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.73^2 + 0.48^2 + 0.40^2)} = 0.961$ units. Using an illustrative coverage factor $k = 2$ gives expanded uncertainty $U = 2u_c = 1.922$ units. The quoted coverage factor remains illustrative until the distributional assumptions and desired coverage probability are established.

Application 03. Family-wise probability when many candidates are searched

In the illustrative 004.03 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. If each of $M = 193$ independent pre-specified search

Copyright 2026, James M. Atkinson

opportunities has false-alarm probability $\alpha = 0.0011$, the probability of one or more false positives is $1 - (1 - \alpha)^M = 0.19137$, or 19.14%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. The family-wise figure concerns pre-specified independent opportunities, not an uncorrected sweep of dependent spectral bins.

Application 04. Observed exposure fraction of a channel scanner

In the illustrative 004.04 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. Let the channel be observed on $n = 194$ valid visits, each lasting $d = 13$ ms, with revisit spacing $R = 1.00$ s. Valid exposure is $nd/1000 = 2.522$ s across the nominal interval $nR = 194.00$ s. The observed fraction of elapsed time is therefore 1.30%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. Such sparse temporal access cannot independently corroborate a claim of continuous reception.

Application 05. Stored-sample volume and the limits of retrospective analysis

In the illustrative 004.05 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. With complex sample rate $f_s = 6$ MS/s, duration $T = 27$ s, and 16-bit in-phase plus 16-bit quadrature integers, the raw payload is $f_sT \times 4$ bytes = 648,000,000 bytes, or 0.648 GB (decimal). The calculation excludes timestamps, metadata, framing and file-system overhead.

Copyright 2026, James M. Atkinson

Maintaining a wideband buffer of this capacity does not establish that upstream analogue clipping was absent. An archive size establishes storage burden, not independent analogue acquisition or freedom from clipping.

Application 06. Accumulated sample-clock time error

In the illustrative 004.06 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. A free-running sample clock with fractional rate error ε = 1.100 ppm over T = 342 s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T$ = 0.3762 ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. Agreement of timestamps cannot establish independent clock accuracy when both receivers share a reference error.

Application 07. Preserved sample continuity across an acquisition interval

In the illustrative 004.07 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. A converter expected to retain f_s = 1.90 million samples/s for T = 1.35 s should supply $f_s T$ = 2,565,000 complex sample instants. If 125 sequence positions are missing, the retained count is 2,564,875 and loss fraction is 0.00487%. A low fractional loss cannot exclude a highly relevant short burst coinciding with the gap. Position and timing of each missing block must therefore be preserved. Sample-continuity evidence must be linked to the exact disputed event interval in each receiver.

Copyright 2026, James M. Atkinson

Application 08. Cascade gain and observed headroom

In the illustrative 004.08 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. A first amplifier contributes G_1 = 13 dB, an intentional attenuation contributes G_2 = -3 dB, and a later stage contributes G_3 = 14 dB. The small-signal sum is 13 + (-3) + 14 = 24 dB. For P_i = -70 dBm, the ideal output is P_o = -46 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The summed small-signal gain must be supplemented by stage-by-stage compression and common-path checks.

Application 09. Opportunity-limited detection under independent visits

In the illustrative 004.09 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. For n = 45 genuinely independent valid observation opportunities, each with stipulated event detection chance p = 0.06, the probability of no detections is $(1 - p)^n$ = 0.06177; its complement is 93.82%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The calculated capture probability cannot be transferred to phase-locked revisit schedules without a different event model.

Copyright 2026, James M. Atkinson

Application 10. Thermal reference noise in a declared measurement bandwidth

In the illustrative 004.10 test, two receivers apparently corroborate one spectrum feature although their power supplies and input splitter are shared. Take the equivalent noise bandwidth B = 13,500 Hz and calibrated noise figure NF = 3.75 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -128.95$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The noise estimate constrains a declared reference condition, not the presence or absence of an environmental emitter.

What makes a receiver challenge test capable of revealing a material failure?

Source: V011_Roundtable_Q001-Q011_CP011_Integrated_Candidate(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Constructed educational dialogue. Numerical cases are hypothetical, not instrument certifications.

Dr. James M. Atkinson

Opening question

Mr Weston, can you comment on what makes a receiver challenge test capable of revealing a material failure, rather than simply reproducing a favourable demonstration? We have discussed measurement boundaries, acquisition history, and the qualified meaning of corroboration. The next task is to design an experiment whose success would justify a specified claim. That task begins before a reference generator is connected. The investigator must identify the signal class, input boundary, operating conditions, decision rule, and failure criterion. Without those definitions, a collection of impressive detections can remain detached from the proposition it is offered to establish.

Consider a hypothetical receiver intended to discover weak, intermittent emissions while stronger legitimate activity occupies other portions of its admitted band. A laboratory demonstrates repeated detection of a continuous carrier in a quiet condition. The demonstration is genuine, but it does not reproduce every element of the intended task. A second test introduces bursts whose starting times are synchronized with the receiver's observation windows. A third changes the threshold until all selected

Copyright 2026, James M. Atkinson

examples are recognized. We must distinguish what each test actually establishes from the broader capability that an enthusiastic reader might infer.

Mr Weston will begin with the physical challenge and the location at which the reference enters the chain. Dr Shewhart will examine the composition of the trial population and the distinction between a stable laboratory procedure and representative operating conditions. Professor Neyman will explain what finite trials can establish about a detection probability, including simultaneous requirements across several conditions. Mr Pearson will then compare alternative procedures and distinguish an operating characteristic from the probability that a particular alarm represents a signal. Sir Karl Popper will examine whether changing or restarting the experiment after an unfavourable outcome has removed its capacity to test the original claim.

Our numerical applications use deliberately constructed observations and probability models. They are not evidence that a particular instrument achieves the calculated performance. The purpose is to expose choices that often remain invisible: the phase of a burst relative to a scan, the weights assigned to easy and difficult trials, the number of conditions claimed simultaneously, and the selection of successful experiments from a larger history. A test can be arithmetically correct and nevertheless answer a different question from the one printed in its conclusion.

The panel should also identify a practicable stopping rule. Validation must not require exhaustive knowledge of every conceivable electromagnetic circumstance, but neither may it certify an unlimited claim from a narrow demonstration. We need a declared operating envelope,

Copyright 2026, James M. Atkinson

explicit exclusions, and evidence sufficient for the conclusions actually required. Failures should produce diagnostic information and justified restrictions rather than disappear during revision of the summary. Mr Weston, may I invite your account of a physical challenge that preserves the intended measurand and provides a real opportunity for the receiver to fail?

A further constraint follows from designing receiver challenge tests that can reveal material failures. A useful adverse control changes a physical component while leaving the hypothesised emitter unchanged. It should predict an observation which is different under the leading alternative explanation. The investigator must record the condition preceding and following this intervention, since receiver recovery and retuning can mimic a source transition. A failure to obtain the anticipated difference should remain visible, rather than being removed as a supposedly unsuccessful measurement. This is the point at which a plausible narrative is converted into a proposition capable of being tested, revised or rejected by another laboratory. At the close of this discussion I would require the published conclusion to identify test coverage, detection probability, observed failures, and conditional error bounds and explain which claims remain untested because operating regions never exposed to the chosen challenge. Such candour is not weakness but the condition under which this roundtable can inform a rigorous TSCM investigation.

Copyright 2026, James M. Atkinson

Edward Weston

The challenge must traverse the part of the instrument being claimed

Dr. Atkinson, thank you. A reference stimulus is informative only about the path it actually exercises. If it enters after the vulnerable input amplifier, its successful detection cannot establish that amplifier's ability to preserve a weak signal during a strong disturbance. If it is introduced through a different filter state from the field acquisition, its amplitude calibration does not automatically apply to that acquisition. The first requirement is therefore a physical account of the connection, loading, admitted bandwidth, and receiver state. The experiment should make the uncertain mechanism observable rather than arrange for the reference to bypass it.

Application one concerns time coverage, a property easily concealed by a synchronized demonstration. Suppose a receiver observes a particular band for a window of length L = 10 milliseconds in each cycle of duration T = 100 milliseconds. A burst has duration d = 5 milliseconds, and its start is uniformly distributed over one cycle. Assume d and L are positive, d is no greater than L, and their sum is less than T. For any positive temporal overlap, the admissible start interval has length L plus d, so the overlap probability is 0.15. To retain the whole burst, its start must lie within a window of length L minus d, giving probability 0.05. These are geometric opportunities, not detection probabilities that include noise, settling, or triggering error.

$$P_{overlap}=\frac{10+5}{100}=0.15\,,P_{full}=\frac{10-5}{100}=0.05$$

Now synchronize every test burst to begin two milliseconds after the observation window opens. The entire five-millisecond burst lies inside the

Copyright 2026, James M. Atkinson

window on every trial. Repeated success is consistent with a perfect result for that phase condition, yet it does not establish either a fifteen-per-cent overlap opportunity or a five-per-cent full-capture opportunity for independently timed starts; those follow from the different uniform-start experiment. A report must preserve the distinction. A test source that always supplies the favourable timing can conceal an acquisition limitation without producing a single false numerical result.

Application two concerns a calibration model. Let u denote a dimensionless input coordinate running from zero to one, and let v denote a dimensionless output. Two proposed transfers are $v_1 = 2u$ and $v_2 = 2u + 4u(1 \text{ minus } u)$. Both give zero at u = 0 and two at u = 1. At u = 0.5 the first gives one while the second gives two. Thus two endpoint observations cannot distinguish the transfers. The second expression is a constructed counterexample, not a model asserted for an actual receiver. It proves that agreement at the selected calibration points does not by itself establish the assumed relationship between them.

$$v_1(0.5)=1, v_2(0.5)=1+4(0.5)(0.5)=2$$

Dr. Atkinson, these examples share a practical lesson. The selected reference conditions can leave the relevant failure mode untested. An engineer should therefore ask what variation would expose that mode. For timing, vary the event's relation to the observation schedule and record the achieved phase distribution. For transfer linearity, choose independent intermediate levels and relevant frequencies, including conditions near operating boundaries where the claim matters. The test plan need not use every possible input, but it should explain why its chosen inputs constrain the proposed model and where extrapolation remains unsupported.

Copyright 2026, James M. Atkinson

A strong blocker should also be characterized at the reference plane actually reaching the vulnerable stage. Nominal generator settings may differ from admitted levels because the path includes losses, mismatch, filters, or coupling. The desired probe and blocker can interact in the combining network before they reach the receiver. A product observed during the challenge may therefore originate in the test fixture. The laboratory should preserve fixture checks and alternative configurations capable of separating that possibility. This is a proposed validation precaution, not an assertion that every fixture is nonlinear.

The challenge should include recovery as well as the disturbance itself. A receiver may regain a familiar display before it regains the weak-signal performance required by the claim. Define the property whose restoration counts, and supply a probe capable of testing it. Preserve intervals in which that property remains unestablished. A successful detection after a long wait does not establish immediate recovery. Equally, a missed probe during a known invalid interval should be analysed as a coverage limitation rather than silently removed from the experiment's history.

The available stimulus should not dictate an unstated simplification of the claim. A convenient generator may reproduce amplitude and centre frequency while failing to reproduce crest factor or transition history. When that difference matters, qualify the test rather than treating the convenient waveform as interchangeable with the intended one.

Finally, calibrate the reference pathway independently of the result it is meant to test. Adjusting the injected amplitude until the receiver reports the expected value makes the receiver part of the reference definition. That may be suitable for a particular comparison, but it is not an independent

Copyright 2026, James M. Atkinson

verification of its absolute response. Dr Bridgman, may I invite your challenge concerning the precise claim that a challenge test should be required to realize?

Percy Williams Bridgman

Peer question 1 to Edward Weston

Mr Weston, thank you. A phrase such as weak-signal detection can conceal several different operations: noticing excess energy, retaining a complete burst, recognizing a waveform class, or measuring its amplitude. Your timing example distinguishes two of these, but a laboratory might still select whichever outcome looks most favourable after the trial. Dr. Atkinson's question requires a definition that survives that temptation. How should the intended claim be written so that a clear success cannot later be reclassified merely because another metric failed? Please also consider whether a test can legitimately have several acceptance criteria, such as detection probability and amplitude error, without conflating them. What should the record state when the receiver detects the signal reliably but does not preserve enough information for the promised quantitative characterization? I ask for a hierarchy of claims rather than one broad pass label.

A further constraint follows from designing receiver challenge tests that can reveal material failures. Operating regions never exposed to the chosen challenge remain outside the direct observation. If the examiner reports only those cases in which the indicated feature agreed with the preferred model, what correction would you require to the exposure denominator, alternative-hypothesis analysis, and reproducibility account?

Copyright 2026, James M. Atkinson

Edward Weston

Answer to Percy Williams Bridgman

Dr Bridgman, the claim should identify the observation that counts as success and the conditions under which it is required. Energy detection, complete capture, classification, and quantitative measurement should have separate criteria where they answer separate questions. A test may assess all of them, but its record must preserve their individual outcomes. Reliable detection can justify a detection statement even when amplitude accuracy fails; it cannot justify the amplitude claim merely because the instrument noticed something at the right time.

Dr. Atkinson, a hierarchy can state that a qualifying event was detected, that an adequate record was retained, and that the record supported specified further measurements. Each level requires its own evidence. The order need not imply that every investigation seeks the most demanding outcome. A discovery receiver may properly provide limited characterization. The error is to let the reader infer a higher level from a lower one, especially where the same word capture is used for both a trigger declaration and a complete waveform record.

Several acceptance criteria should be fixed before confirmatory testing. Their logical combination must also be stated: must all pass, or are different operating modes accepted for different uses? A test report should not select the favourable criterion after examining outcomes while leaving the original broader claim unchanged. Failed criteria should remain visible and may support a restricted release for

Copyright 2026, James M. Atkinson

a narrower task. Such a restriction is an engineering decision that should follow the evidence rather than appear as a retrospective redefinition of success.

A partial success should retain its practical value without borrowing a broader label. Separating outcomes makes that possible: it permits a justified detection finding while identifying the additional acquisition or calibration work required before quantitative characterization can be claimed.

The record should include the exact version of the rule applied to each trial. That makes a later revision legitimate and reviewable without rewriting the earlier result. A revised criterion can be tested anew; it does not alter what the prior experiment established. Dr Bode, may I invite your question about the combining network and the possibility that the challenge fixture, rather than the receiver, limits the apparent performance?

Hendrik Wade Bode

Peer question 2 to Edward Weston

Mr Weston, a weak probe and strong blocker must often share a path before they reach the receiver. The combining network may alter either signal through mismatch, isolation limitations, or nonlinear response. A clean generator output measured separately does not establish the combined condition at the receiver input. How should the laboratory determine whether a newly observed product belongs to the receiver, the reference source, or the fixture? Please distinguish a calibrated transfer correction from an unsupported assumption that the fixture

Copyright 2026, James M. Atkinson

remains linear for the applied waveform. I would also ask how the experiment can preserve adequate dynamic range in its monitoring instruments. A monitor that itself overloads may offer an apparently authoritative but corrupted account of the stimulus. What minimum evidence would let another examiner reconstruct the actual challenge without trusting every nominal setting as a physical measurement?

May I press the principal contributor on whether the adverse receiver challenge is capable of exposing the hypothesised error? The chronology of whether the adverse receiver challenge is capable of exposing the hypothesised error is indispensable. Assume for a moment that a test performed only on a convenient amplitude might miss overload or weak-signal suppression. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should apply calibrated stressors near threshold and near compression while preserving failed observations, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs input third-order intercept, overload settling, noise figure and detection probability. If the challenged receiver produces a false event or misses a reference event under the predicted stress, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a

Copyright 2026, James M. Atkinson

chronological comparison under named operating states. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Edward Weston

Answer to Hendrik W. Bode

Dr Bode, the reference pathway requires characterization under the combined conditions relevant to the claim. Separate low-level checks cannot establish that its response remains unchanged when the blocker is admitted. The laboratory should identify plausible generating stages and choose substitutions or monitoring points whose predictions differ among those stages. For example, varying the combination method or introducing a verified attenuation change at a particular boundary can help localize a product, provided the resulting gain and loading changes are also accounted for. No single manipulation is conclusive without its applicable model.

Dr. Atkinson, a monitoring receiver must be qualified for the measurement assigned to it. Its nominal amplitude range does not establish its own large-signal validity. A monitor may need independently verified attenuation, preselection, or a separate method suited to the relevant component. The record should state the monitor's limitations and avoid using its silence as proof that the fixture generates no smaller products than it could detect. Monitoring uncertainty is part of the stimulus description, not an exemption granted because the instrument is labelled a reference.

Copyright 2026, James M. Atkinson

At minimum, preserve the physical connections, calibrated levels at the declared plane, source identities and settings, combining-path characteristics, relevant operating states, and evidence of stimulus continuity. Distinguish measured quantities from values inferred through a correction. The correction should identify its supporting calibration and conditions of use. Preserve observations made with the probe absent and with the blocker absent when those comparisons help separate products. Such controls answer limited questions and should be interpreted accordingly.

The fixture check should include a statement of its own detection limit for unwanted products. A product not observed by the monitor is bounded only within the monitor experiment; it has not been shown physically absent at every amplitude and frequency.

Another examiner should be able to reconstruct not merely the nominal waveform but the uncertainty about what reached the receiver. Where that uncertainty could explain the result, the receiver claim remains qualified. Dr Shewhart, may I now invite your analysis of how the collection of individual trials should represent the operating task rather than merely the conditions most convenient for the laboratory?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart

The composition of the trial population determines the claim

Mr Weston, thank you. Dr. Atkinson, a collection of accurately executed trials can still provide a misleading summary if it overrepresents the easy conditions. The arithmetic fraction of successes is then correct for that collection but does not describe the mixture of conditions intended by the operational claim. The laboratory must specify whether it is estimating performance for a known population, characterizing performance across separate conditions, or screening for particular failure mechanisms. Those objectives require different allocations and should not share an unexplained overall percentage.

Application three uses two stipulated signal classes. In an illustrative test collection, 900 easy trials all succeed, while only ten of 100 difficult trials succeed. The pooled result is 910 successes in 1,000 trials, or 91 per cent. The difficult-class result is ten per cent. Neither fraction requires a complex statistical model, yet they support very different descriptions. A statement that the receiver detects 91 per cent of weak intermittent signals would be unsupported if the easy class consists of strong continuous carriers. The labels and the allocation belong beside the count.

$$\hat{p}_{pool}=\frac{900+10}{900+100}=0.91\,,\,\hat{p}_{difficult}=\frac{10}{100}=0.10$$

Application four distinguishes sample proportions from a population model. Stipulate, solely for this example, true detection probabilities of one for the easy class and 0.1 for the difficult class. A population containing 90 per cent easy events has detection probability 0.91. A population containing only 20 per cent easy events has detection probability 0.28. The receiver's

Copyright 2026, James M. Atkinson

conditional performance has not changed; the population weights have. In an actual analysis those probabilities and weights may be uncertain and require estimation. The construction demonstrates why transporting a pooled percentage between populations needs evidence, not merely the same receiver model number.

$$p_{field} = 0.20(1) + 0.80(0.10) = 0.28$$

Dr. Atkinson, a useful validation design therefore retains condition-specific outcomes even when an overall figure is required. Relevant conditions may include amplitude, duration, frequency location, spectral occupancy, gain state, and the timing relation between signal and acquisition. Their importance follows the intended task and plausible failure mechanisms. They should not be selected only after the aggregate result looks disappointing. Deliberately challenging a difficult boundary can be more informative for engineering diagnosis than adding many easy repeats that scarcely change the uncertainty about that boundary.

This does not require an equally weighted grid across every parameter. Such a grid may be wasteful or physically inappropriate. A proposed allocation should state its purpose: representative weighting for a specified event population, stratification to estimate several conditional probabilities, or targeted stress testing. A stress test can expose a mechanism without estimating its field prevalence. A representative sample can estimate average performance while missing a rare but consequential condition. The report should retain these distinctions and avoid converting diagnostic cases into an unsupported frequency estimate of operational failures.

The observation unit also matters. Reprocessing one captured burst a thousand times can test deterministic software reproducibility but does not

Copyright 2026, James M. Atkinson

supply a thousand independent physical acquisitions. Repeating an analogue acquisition without changing a shared source state may likewise provide less diversity than the nominal count suggests. Independence and exchangeability should be considered in relation to the estimated quantity. A procedure can be entirely suitable for regression testing while being insufficient for the broader probability statement attached to its results.

Changes made during development must be separated from the confirmatory experiment. When a detector's settings are tuned after inspecting failures, the revised detector is a new procedure for purposes of validation. The failures are valuable development information and should remain in its history. A later frozen version can be assessed on new or properly reserved observations. The mere existence of a file called test data does not make it independent if its content influenced the selection. A procedural record should state which observations were available to the designer at each decision point.

Operational prevalence is sometimes unknown, especially for unusual signal classes. In that case the laboratory can publish conditional performance and analyse several explicit mixtures rather than invent a single authoritative population. The differences between those mixtures are informative: they show which operational assumptions drive the overall result. A worst-case claim requires adequate control of the relevant worst case, not simply equal weighting of several chosen cases. The report should preserve the distinction between a measured condition, an interpolated condition, and an untested region.

I would also preserve the executed trial schedule, not only the intended one. Lost reference bursts, skipped difficult conditions, and periods of

Copyright 2026, James M. Atkinson

invalid receiver operation can alter the effective population. Their treatment should be determined by the claim and the reason for failure. Excluding them silently can improve a reported fraction by removing the occasions when the system was least capable. The experiment may report conditional performance among valid trials, but must also report the validity conditions needed for that interpretation. Professor Wiener, may I invite your question concerning dependence between repeated trials and the meaning of an apparently large validation sample?

Norbert Wiener

Peer question 3 to Walter A. Shewhart

Dr Shewhart, suppose a laboratory acquires many trials in rapid succession while a slow common disturbance remains nearly constant across them. The private receiver noise changes, but the reference amplitude, temperature, or common threshold estimate moves much more slowly. A large trial count may then explore one narrow state repeatedly. How would you separate the evidence concerning conditional repeatability from the evidence concerning performance across states? Please also consider a failure mechanism that appears only after prolonged operation. A short, dense sequence might contain more trials than a long-duration test while being less relevant to that mechanism. Can the design combine both objectives without inventing a single effective sample size that conceals the physical distinction? I would welcome an account of which variables should be retained so that later analysis can assess the dependence actually relevant to the performance claim.

Copyright 2026, James M. Atkinson

May I press the principal contributor on whether the adverse receiver challenge is capable of exposing the hypothesised error? Before offering an opinion about whether the adverse receiver challenge is capable of exposing the hypothesised error, I would define the measurand and its uncertainty. The proposed rival mechanism is that a test performed only on a convenient amplitude might miss overload or weak-signal suppression. Consequently a calibration certificate for one nominal receiver setting does not settle the question. The more informative operation is to apply calibrated stressors near threshold and near compression while preserving failed observations, with input third-order intercept, overload settling, noise figure and detection probability reported in units and tied to an input reference plane. The adverse prediction is concrete: the challenged receiver produces a false event or misses a reference event under the predicted stress. I would challenge it across a range of input powers and hold one independently measured source constant throughout the switching sequence. A correction estimated after seeing the unknown feature may assist an exploratory analysis; it must not be presented as though it had been fixed before acquisition. Where systematic effects share a reference, their covariance belongs in the reported uncertainty rather than being silently assumed zero. This is the distinction between an instrument number that appears stable and a defensible physical measurement. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart

Answer to Norbert Wiener

I welcome that careful objection and shall address it directly. Thank you for that question. Professor Wiener, the design should distinguish repetitions within a state from replications across states. Within-state trials can characterize private variability and conditional performance. Between-state observations address variation associated with the changed conditions. Pooling them into one count is not necessarily wrong, but its uncertainty calculation must represent the hierarchy and the intended population. A scalar effective sample size may approximate a particular statistic under a specified dependence model; it cannot replace the physical description of what was repeated and what was changed.

Dr. Atkinson, a long-duration failure mechanism calls for exposure to the duration and operating history that can produce it. Increasing the number of short bursts within a brief quiet interval does not reproduce hours of thermal evolution or storage pressure. The test programme can include dense conditional trials and sustained-operation trials, with separate outcomes and claims. Their results are complementary. An overall release decision may require both, but should not disguise one as a substitute for the other.

Retain trial times, source-state observations, receiver settings, relevant environmental measurements, configuration transitions, and the identities of shared references. Preserve block and run membership so that a reviewer can identify which trials share a state. Document the operating duration preceding each trial when history

Copyright 2026, James M. Atkinson

could matter. The purpose is not indiscriminate logging; it is to retain variables needed to examine the proposed dependence and the mechanisms that might invalidate its simplifications.

Duration should therefore appear as an experimental factor or declared exposure requirement when the suspected mechanism depends on it. Recording only the number of bursts discards that information and can make a short dense test look equivalent to sustained operation when it is not.

The resulting analysis may conclude that a conditional probability is well estimated while performance in rare or unobserved states remains uncertain. That is a useful result and a guide to further testing. It should not be converted into universal performance through a large nominal count. Dr Nyquist, may I invite you to examine a different aspect of representation: how the generation and recording of challenge waveforms can introduce the same sampling assumptions that the test was supposed to challenge?

Harry Nyquist

Peer question 4 to Walter A. Shewhart

Dr Shewhart, a digital reference waveform is often synthesized from a finite record and then replayed through a converter. Its repetition, filtering, and sample clock can create a stimulus rather different from the arbitrary event implied by its description. Dr. Atkinson has requested tests of intermittent activity, and a repeated test sequence may inadvertently provide stable timing or spectral cues that the deployed detector will not have. How should the laboratory characterize the

Copyright 2026, James M. Atkinson

generated stimulus as an actual analogue signal, rather than trusting the numerical design alone? Please distinguish validation of the receiver algorithm using synthetic samples from validation of the complete acquisition chain using a physical signal. What safeguards prevent a shared sample clock or a repeated record from making the challenge easier in a way that remains hidden in the reported detection probability?

May I press the principal contributor on whether the adverse receiver challenge is capable of exposing the hypothesised error? There is a statistical difficulty in the assertion concerning whether the adverse receiver challenge is capable of exposing the hypothesised error: we have not yet ruled out the possibility that a test performed only on a convenient amplitude might miss overload or weak-signal suppression. The investigation should record its chosen detector threshold, visit schedule, selection of frequencies and expected failure modes before the prospective confirmatory test. To examine the difference we should apply calibrated stressors near threshold and near compression while preserving failed observations, collecting input third-order intercept, overload settling, noise figure and detection probability over a predeclared range rather than selecting the most attractive subset afterward. An observation in which the challenged receiver produces a false event or misses a reference event under the predicted stress would strengthen a restricted causal account, but it cannot certify every unvisited frequency-time interval. I would state which recordings are dependent, which have been excluded as invalid, and which inferences rely upon a model of rare events or stationary interference. A numerical

Copyright 2026, James M. Atkinson

interval can have impeccable arithmetic and still misdescribe the physical world if its sampling population was chosen because the signal already looked unusual. We should therefore preserve exploratory leads separately from independently designed validation evidence. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Walter Andrew Shewhart

Answer to Harry Nyquist

Dr Nyquist, the numerical reference and the delivered analogue stimulus should be treated as separate records connected by a characterized generation path. The source file specifies intended samples; it does not alone establish the analogue waveform at the receiver input. Reconstruction filtering, repetition, clock behaviour, and output-level limitations can alter that waveform. Relevant properties should be measured or supported at the declared reference plane, with uncertainty sufficient to determine whether the challenge satisfies its intended conditions.

Dr. Atkinson, synthetic-sample testing is valuable for the digital algorithm because it permits controlled inputs and exact comparisons. It bypasses analogue acquisition, however, and should be labelled accordingly. A physical test includes more of the chain but introduces uncertainty in the stimulus. Neither is intrinsically superior for every purpose. A complete validation argument can combine them while stating which boundary each tests and where their coverage overlaps or leaves gaps.

Copyright 2026, James M. Atkinson

Shared clocks and repeated sequences require particular disclosure when they affect the claim. A test of asynchronous event discovery should vary or independently control the event's phase relative to acquisition. A detector that can learn a repeating reference pattern should also face appropriately held-out patterns when the intended task includes unseen events. The actual variation achieved should be recorded, not inferred from a randomisation setting alone. A pseudorandom source with a short repeated sequence may supply fewer distinct conditions than its description suggests.

A source-quality check should be repeated when a changed generation setting could alter the delivered waveform. The earlier check remains evidence for its original state; it does not automatically certify a new repetition interval, clock relationship, or output level.

The safeguard is to make the facilitating relationship visible and either preserve it as part of a deliberately narrow claim or change the experiment to remove it. Repeated success under synchronised conditions remains a legitimate observation, but not a universal one. Professor Neyman, may I now invite your account of the statistical bounds that finite, properly defined trials can support once these physical and population conditions have been established?

A further constraint follows from designing receiver challenge tests that can reveal material failures. I would add the following qualification to my answer. A useful adverse control changes a physical component while leaving the hypothesised emitter unchanged. It should predict an observation which is different under the leading alternative explanation. The investigator must record the

Copyright 2026, James M. Atkinson

condition preceding and following this intervention, since receiver recovery and retuning can mimic a source transition. A failure to obtain the anticipated difference should remain visible, rather than being removed as a supposedly unsuccessful measurement. This is the point at which a plausible narrative is converted into a proposition capable of being tested, revised or rejected by another laboratory. In this particular question, the controlled observation is the receiver response to a known applied physical stimulus and documented controls, whereas the material uncertainty concerns operating regions never exposed to the chosen challenge. Consequently the adversarial comparison ought to include blinded or preregistered adverse cases covering sensitivity, blocking, retune, and recovery and its failed as well as successful outcomes. I would not advise treating a change in the displayed indication as an authenticated physical attribution until its causal mechanism has been experimentally distinguished.

Copyright 2026, James M. Atkinson

Jerzy Neyman

Finite success counts support bounds, not perfect performance

Dr Shewhart, thank you. Dr. Atkinson, a result of complete success in the observed trials is not a demonstration that the underlying success probability equals one. The result is a sample outcome under a specified trial process. A statistical bound expresses what that outcome supports within the process model. NIST's instrument-performance guidance distinguishes estimates of detection or false-alarm performance from the confidence statements attached to them. The construction used here is an exact binomial example, with assumptions stated explicitly rather than inferred from a large count. [M5-1, M5-2]

For application five, assume n independent trials with the same detection probability p, a procedure fixed before the trials, and a fixed trial count. Suppose every trial succeeds. For a one-sided lower confidence bound at confidence level one minus alpha, the endpoint p_L solves p_L raised to n equals alpha. Therefore p_L = alpha raised to one over n. With alpha = 0.05 and n = 59, the lower endpoint is about 0.95049. Complete success in these 59 trials supports this one-sided bound under the stated model. It does not prove perfect detection, and it does not provide a posterior probability that p exceeds the endpoint.

$$p_L = \alpha^{1/n} = 0.05^{1/59} \approx 0.950492$$

The familiar observed fraction of one remains useful as a description of the record, but its uncertainty cannot be evaluated by substituting that fraction into an approximation that incorrectly yields zero width. Exact binomial constructions handle such endpoints without making zero observed failure equivalent to zero possible failure. The bound also

Copyright 2026, James M. Atkinson

concerns the stipulated population. If all trials use one signal amplitude, its interpretation does not automatically extend to weaker amplitudes, different durations, or an acquisition regime absent from the experiment.

Application six considers twenty separately specified conditions for which lower bounds are to hold simultaneously. To obtain at least 95 per cent joint coverage through a conservative union-bound allocation, assign alpha_i = 0.05 divided by 20 = 0.0025 to each condition. For a desired lower endpoint of at least 0.95 after complete success in a condition, the trial count must satisfy n no less than ln(0.0025) divided by ln(0.95). Rounding upwards gives 117 trials in each condition. The union-bound argument does not require independence between the twenty confidence statements, but each individual bound still requires its own valid sampling model.

$$n \geq \frac{\ln(0.0025)}{\ln(0.95)} \approx 116.808, n_{min} = 117$$

Dr. Atkinson, the difference between individual and simultaneous claims is easily lost in a summary. Twenty conditions each accompanied by a nominal 95 per cent bound do not automatically provide a 95 per cent statement that every condition satisfies its requirement. The allocation above is one transparent way to control the family of statements; it is not universally the most efficient design. More specialized joint methods may be appropriate when their assumptions and implementation are supported. The important point is that the claim's scope determines the statistical construction.

The all-success calculation is also a planning condition, not a prediction that the experiment will succeed. If failures occur, calculate the bound appropriate to the observed count and the declared procedure. Do not

Copyright 2026, James M. Atkinson

discard the failed condition, substitute a new signal, or restart the count while preserving the original confidence language. Such changes alter the experiment. A development programme may legitimately revise the receiver after a failure, but the new version and its validation record should be distinguished from the earlier one.

The binomial model requires scrutiny beyond the word independent. Equal success probability may be unsuitable when a condition drifts during the test, and a frozen count does not ensure a frozen procedure. If the laboratory inspects outcomes and changes settings, the actual decision process should enter the analysis. It is preferable to report a narrower descriptive result than attach an exact formula to an experiment that does not satisfy its conditions. Precision in the arithmetic cannot repair a mismatch in the sampling model.

An acceptance requirement should also distinguish a performance threshold from the confidence level used to assess it. Requiring detection probability at least 0.95 is not the same as using a 95 per cent confidence construction. Both numbers happen to appear in this example, but they play different roles. The first defines the engineering requirement; the second specifies a property of the inferential procedure. Keeping them separate prevents an otherwise common confusion in which confidence is reported as though it were another estimate of the detector success probability.

A final evidential safeguard is that blinded or preregistered adverse cases covering sensitivity, blocking, retune, and recovery. The written conclusion must separate a directly retained observation from an inferred physical explanation. A short anomaly may be real in the stored digital sequence yet originate in quantisation, analogue recovery or the acquisition

Copyright 2026, James M. Atkinson

policy. Conversely, the absence of an alarm cannot establish the absence of an event outside valid temporal and frequency coverage. Such limitations do not make the work futile. They guide a useful next test, specify the conditions in which the present record is persuasive and protect the evidential chain against later exaggeration. Applied to the present engineering problem, favourable demonstration bias, threshold selection, selective retention, and nonlinear failure under overload may create a spectrum or timestamp that looks persuasive while leaving operating regions never exposed to the chosen challenge inaccessible. The experimental answer lies in blinded or preregistered adverse cases covering sensitivity, blocking, retune, and recovery, carried out with explicit controls and independent retention of all the relevant receiver states. The account should quantify test coverage, detection probability, observed failures, and conditional error bounds, separating input-referred values from software-derived quantities. If the calculation assumes constant noise statistics or a linear front end, an overload or irregular interference challenge should test that premise. The examiner should preserve negative outcomes and show why the proposed mechanism is better supported than the surviving alternatives. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Finally, confidence is attached to a method of constructing statements over repeated admissible experiments. It is not a degree of personal certainty produced by observing an attractive fraction. The practical benefit is discipline: the reader can inspect what was assumed, what was observed, and which statement the method supports. Dr Shannon, may I invite your question concerning whether a trial that produces the right detection flag

Copyright 2026, James M. Atkinson

but loses the underlying data should count as success for a receiver whose stated purpose includes later analysis?

Claude Elwood Shannon

Peer question 5 to Jerzy Neyman

Professor Neyman, a receiver may issue a correct detection flag while retaining only part of the event or storing it with an unresolved sample discontinuity. For a discovery task the flag may be useful; for subsequent analysis the record may be inadequate. How should the trial outcome represent this distinction without turning a multidimensional result into an ambiguous binary success? Please consider a system whose trigger identifies nearly every challenge but whose recording path occasionally overruns. If the validation counts only the trigger, it may certify a capability narrower than the user believes. If it counts everything as one composite failure, useful diagnostic information is lost. What should be fixed in advance, and how should the confidence statement distinguish detection, successful recording, and valid downstream measurement while preserving their dependence on the same physical trial?

May I press the principal contributor on whether the adverse receiver challenge is capable of exposing the hypothesised error? I should distinguish the physical occurrence under inquiry from the information actually retained when studying whether the adverse receiver challenge is capable of exposing the hypothesised error. Because a test performed only on a convenient amplitude might miss overload or weak-signal suppression, more than one historical account may produce the same saved trace. The controlled comparison should be to apply calibrated stressors near threshold and near compression while preserving failed

Copyright 2026, James M. Atkinson

observations, preserving input third-order intercept, overload settling, noise figure and detection probability at the measurement point and in the evidential metadata. If the challenged receiver produces a false event or misses a reference event under the predicted stress, that result would narrow the admissible explanations, not establish a uniquely identified emitter outside the tested conditions. A subsequent software reconstruction may recalculate a statistic from retained samples, yet it cannot recover components rejected by the front-end filter or intervals never recorded. I would make those distinctions explicit in the final report and invite an independent examiner to reproduce the challenge, including its failed steps. Scientific restraint is not a weakness of the investigation. It prevents a detector output, however striking on the screen, from becoming a claim about unobserved activity that the original measurement never established. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Jerzy Neyman

Answer to Claude E. Shannon

Dr Shannon, the outcome can be a vector even when particular acceptance criteria are binary. Record detection, adequate retention, and validity of the required analysis separately, with operational definitions established before confirmatory testing. A composite success can then be defined as the conjunction required by the intended task. The statistical statement for that composite uses the actual joint outcome, not the product of marginal success fractions

Copyright 2026, James M. Atkinson

unless an appropriate independence condition has been justified. Since the stages share a physical trial, dependence is generally a matter to examine rather than assume away.

Dr. Atkinson, the diagnostic record should remain richer than the acceptance flag. A trial may fail because no trigger occurred, because an event was detected but lost, or because retained data did not support the promised measurement. These failures have different engineering implications. Preserving them separately permits correction without changing the meaning of the original composite criterion. A narrower release can be justified for detection alone, provided the report clearly excludes capabilities that failed or remained untested.

Conditional rates are useful but need their denominators stated. The recording-success fraction among triggered events is not the probability of recording an arbitrary qualifying event. Events missed by the trigger have disappeared from that conditional population. To support an end-to-end claim, retain all planned qualifying trials and determine their outcomes through the complete chain. Reference-source failures require a declared treatment distinct from receiver failures, with evidence sufficient to justify exclusions.

Preserve an outcome category for indeterminate reference or acquisition conditions when the evidence cannot justify a binary assignment. Its treatment in the acceptance analysis must be specified, and its frequency should remain visible rather than disappearing from the denominator without explanation.

Copyright 2026, James M. Atkinson

Confidence statements should identify which outcome they describe and whether several claims are asserted simultaneously. A single percentage cannot communicate these distinctions by itself. The analysis should preserve both the whole-chain result and the stage-specific evidence needed to understand it. Mr Pearson, may I now invite your comparison of two candidate receiver procedures when their outcomes are paired on the same challenges and their errors need not be independent?

A final evidential safeguard is that blinded or preregistered adverse cases covering sensitivity, blocking, retune, and recovery. I would add the following qualification to my answer. The written conclusion must separate a directly retained observation from an inferred physical explanation. A short anomaly may be real in the stored digital sequence yet originate in quantisation, analogue recovery or the acquisition policy. Conversely, the absence of an alarm cannot establish the absence of an event outside valid temporal and frequency coverage. Such limitations do not make the work futile. They guide a useful next test, specify the conditions in which the present record is persuasive and protect the evidential chain against later exaggeration. In this particular question, the controlled observation is the receiver response to a known applied physical stimulus and documented controls, whereas the material uncertainty concerns operating regions never exposed to the chosen challenge. Consequently the adversarial comparison ought to include blinded or preregistered adverse cases covering sensitivity, blocking, retune, and recovery and its failed as well as successful outcomes. I would not

Copyright 2026, James M. Atkinson

advise treating a change in the displayed indication as an authenticated physical attribution until its causal mechanism has been experimentally distinguished.

Copyright 2026, James M. Atkinson

Egon Sharpe Pearson

Comparing procedures and interpreting alarms require different probabilities

Professor Neyman, thank you. Dr. Atkinson, comparing two procedures on the same physical challenges creates paired observations. Their common successes and common failures carry information about the challenge population, while their discordances are particularly relevant to a comparison of marginal success probabilities. Treating the two success counts as unrelated samples discards that pairing. The appropriate analysis follows the design and the claim, rather than selecting whichever familiar formula produces the smaller uncertainty.

Application seven uses one hundred stipulated paired trials. Both procedures succeed on eighty; both fail on ten; procedure A alone succeeds on eight; procedure B alone succeeds on two. A therefore succeeds on eighty-eight trials and B on eighty-two. To examine a simple null model of equal direction probability among independent discordances, condition on the ten discordant trials. Under that model, the number favouring A has a binomial distribution with ten trials and probability one half. The two-sided tail probability for eight versus two is twice the probability of at most two successes, namely twice the sum of the binomial coefficients for zero, one, and two divided by 1,024. The result is 0.109375.

$$p_{tail} = 2\frac{\binom{10}{0}+\binom{10}{1}+\binom{10}{2}}{2^{10}} = 0.109375$$

This calculation is an exact conditional comparison under the stated null and independence assumptions. It is not a probability that the procedures

Copyright 2026, James M. Atkinson

are equally good, nor proof that their difference is practically unimportant. The observed six-percentage-point difference remains the sample contrast. The experiment may lack sufficient information to distinguish the specified alternatives at a chosen decision threshold. A practical equivalence claim would require its own margin, design, and analysis; failure to reject equality does not establish equivalence.

Application eight addresses a different confusion. Stipulate a population in which the signal of interest occurs in one test opportunity out of one thousand. Let the detector's conditional detection probability be 0.9 and its false-alarm probability in signal-absent opportunities be 0.01. Among a hypothetical million opportunities, expected true positives are 900 and expected false positives are 9,990. The proportion of positive decisions attributable to signal-present opportunities under this model is 900 divided by 10,890, approximately 0.082645. The detector is reasonably sensitive under the stipulation, yet most positive decisions arise from the much larger absent population.

$$q=\frac{0.001(0.9)}{0.001(0.9)+0.999(0.01)}\approx 0.082645$$

Here q denotes the conditional probability of signal presence given a positive detector decision. The population proportion is an explicit assumption, not a prior probability assigned to an actual surveillance incident. The expected counts merely make Bayes' rule visible. A laboratory false-alarm rate cannot by itself provide the probability that one observed field alarm is false; the latter depends on the relevant population or prior model and on whether the tested conditions apply. When those quantities

Copyright 2026, James M. Atkinson

are unknown, reporting an invented posterior percentage would be less defensible than retaining the conditional operating characteristics.

Dr. Atkinson, these two applications show why the same word probability can conceal different questions. A tail probability evaluates a statistic under a specified hypothesis. A detection probability describes a decision when the signal is present. A positive predictive probability concerns signal presence after a decision. None can be substituted for another by verbal convenience. A technically competent report should define the conditioning event explicitly, particularly when the numerical result may influence a consequential interpretation.

The comparative experiment should also preserve costs and relevant failure classes. One procedure may detect more weak events while producing many more false alarms or retaining poorer records. A decision about which is preferable requires a stated objective and acceptable trade-offs. There is no universal ranking supplied by one success fraction. The laboratory can estimate a family of operating characteristics and identify dominated alternatives without pretending that engineering priorities emerge automatically from the statistics.

If the comparative objective includes a cost of false alarms, the paired detection table is only part of the required evidence. Signal-absent opportunities should be evaluated under an appropriate design, with the same matching and retention rules. A procedure can increase detections simply by declaring activity more often. The useful comparison therefore includes the price of that increase and the domain in which it occurs. A claimed improvement should not be established by comparing sensitivity at different, unreported false-alarm operating points.

Copyright 2026, James M. Atkinson

A further constraint follows from designing receiver challenge tests that can reveal material failures. A useful adverse control changes a physical component while leaving the hypothesised emitter unchanged. It should predict an observation which is different under the leading alternative explanation. The investigator must record the condition preceding and following this intervention, since receiver recovery and retuning can mimic a source transition. A failure to obtain the anticipated difference should remain visible, rather than being removed as a supposedly unsuccessful measurement. This is the point at which a plausible narrative is converted into a proposition capable of being tested, revised or rejected by another laboratory. Applied to the present engineering problem, favourable demonstration bias, threshold selection, selective retention, and nonlinear failure under overload may create a spectrum or timestamp that looks persuasive while leaving operating regions never exposed to the chosen challenge inaccessible. The experimental answer lies in blinded or preregistered adverse cases covering sensitivity, blocking, retune, and recovery, carried out with explicit controls and independent retention of all the relevant receiver states. The account should quantify test coverage, detection probability, observed failures, and conditional error bounds, separating input-referred values from software-derived quantities. If the calculation assumes constant noise statistics or a linear front end, an overload or irregular interference challenge should test that premise. The examiner should preserve negative outcomes and show why the proposed mechanism is better supported than the surviving alternatives. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Copyright 2026, James M. Atkinson

Where settings are chosen to favour each procedure, the selection protocol should be matched to the intended deployment and documented. A fixed-setting comparison differs from a comparison after expert tuning for each trial. Both can be legitimate, but they assess different systems, including different amounts of operator information. The report should not compare one procedure with hindsight against another operating without it. Dr Gabor, may I invite your challenge concerning tolerances in time and frequency, and the danger that a permissive matching rule improves a detection score while weakening its physical meaning?

Dennis Gabor

Peer question 6 to Egon S. Pearson

Mr Pearson, a detector response is often counted as correct when it falls within a tolerance of the reference event's frequency and time. Widening that tolerance can increase the apparent detection rate even though the receiver's physical localization or timing has not improved. How should the validation distinguish successful discovery from precise characterization? Please consider two procedures, one producing a sharply timed event and another producing a long persistent indication. A broad matching window may count both as equally successful while concealing materially different information. Conversely, an excessively narrow tolerance may reject a useful detection because of a known reference uncertainty. What determines a defensible tolerance, and how should uncertainty in the reference event be incorporated without allowing the tolerance to expand after the outcomes are seen? I would also ask how multiple nearby events should be matched without counting one response several times.

Copyright 2026, James M. Atkinson

May I press the principal contributor on whether the adverse receiver challenge is capable of exposing the hypothesised error? I am concerned with whether the adverse receiver challenge is capable of exposing the hypothesised error. The unresolved alternative is that a test performed only on a convenient amplitude might miss overload or weak-signal suppression. I should therefore separate the physical input from its representation on the receiver display. Let us apply calibrated stressors near threshold and near compression while preserving failed observations, ensuring that the operator records input third-order intercept, overload settling, noise figure and detection probability. The anticipated discriminating observation is that the challenged receiver produces a false event or misses a reference event under the predicted stress. A failure of this test would not compel us to accept a more dramatic transmitter hypothesis; it would instead mean that our proposed transfer-path model is incomplete. I would retain the measured contrary result and identify the exact connector, stimulus, receiver settings and elapsed intervals in the report. Such a procedure has a modest but valuable result: it converts an initially persuasive visual indication into an experimentally bounded account of what could have produced the retained data. Our duty is not to force agreement but to specify which physical explanations are still consistent with the recorded state. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Copyright 2026, James M. Atkinson

Egon Sharpe Pearson

Answer to Dennis Gabor

Thank you for that question. Dr Gabor, the tolerance should follow the intended outcome and the uncertainty of the reference comparison. A discovery claim may permit a broader interval than a quantitative timing claim, but the distinction must be explicit. The reference's uncertainty should be characterized independently and incorporated into the predefined matching procedure. It should not become an adjustable explanation applied only to failures. A broad interval can be justified for a limited proposition without supporting a more precise one.

Dr. Atkinson, the matching algorithm is part of the tested detector system. It should specify whether one reported event may match several reference events, how conflicts are resolved, and how unmatched detections count. For a one-to-one capture claim, allowing one persistent indication to satisfy numerous distinct bursts would inflate performance. If the intended measurand is occupied time rather than event count, a different comparison may be appropriate. The scoring rule must be aligned with that measurand, not merely convenient to implement.

For comparing procedures, preserve timing and frequency errors as distributions or appropriately qualified summaries in addition to binary matches. The binary detection criterion can then be interpreted alongside the information retained by each procedure. A system that detects within a broad window but cannot characterize onset precisely should not inherit the tighter capability of another

Copyright 2026, James M. Atkinson

merely because both pass the same discovery threshold. Reference uncertainty places limits on how sharply those error distributions can be resolved and should remain visible.

The matching code itself merits test cases with deliberately ambiguous event arrangements. Those cases can expose duplicate credit, order-dependent association, and boundary errors without claiming to validate the analogue receiver. They strengthen a specific computational boundary within the larger experiment.

The tolerances, association rules, and software version should be frozen for confirmatory testing. A revised rule can be assessed separately, preserving the earlier results as development evidence. Sir Karl Popper, may I now invite your examination of the broader issue raised by these adjustments: when does legitimate improvement of a method become a retrospective rescue of a claim that the original test did not support?

I thank the questioning colleague for that important distinction. The chronology of whether the adverse receiver challenge is capable of exposing the hypothesised error is indispensable. Assume for a moment that a test performed only on a convenient amplitude might miss overload or weak-signal suppression. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should apply calibrated stressors near threshold and near compression while preserving failed observations, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs input third-order intercept, overload settling, noise figure and

Copyright 2026, James M. Atkinson

detection probability. If the challenged receiver produces a false event or misses a reference event under the predicted stress, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states.

Copyright 2026, James M. Atkinson

Sir Karl Raimund Popper

A failed test must not disappear inside the revised procedure

Mr Pearson, thank you. Dr. Atkinson, there is nothing objectionable about improving a receiver after discovering a failure. Indeed, a well-designed challenge should make such improvement possible. The difficulty is an account that changes the method, restarts the evidence, and then presents the eventual success as though the original claim had faced one unchanged test. Scientific criticism requires a history in which an adverse result remains identifiable. Improvement should produce a new claim and a new test, not erase the observation that motivated it.

Application nine makes the statistical consequence explicit. Suppose a procedure has true independent trial success probability p = 0.95. The probability of a clean run of 59 trials is p raised to 59, approximately 0.0484945. Now perform twenty independent runs of that length and select any run with complete success. The probability of obtaining at least one such run is one minus the twentieth power of one minus 0.0484945, approximately 0.629979. A clean run that would be unusual in one specified experiment is quite likely to appear somewhere in this larger search. Reporting only that run hides the procedure used to find it.

$$P(cleanrun)=0.95^{59}\approx 0.0484945$$

$$P(atleastone)=1-\left(1-0.95^{59}\right)^{20}\approx 0.629979$$

The example does not prohibit repeated testing or require that the same analysis be used forever. It shows that a selection mechanism changes the evidential meaning of the selected observation. If the instrument was altered between runs, the simple identical-probability calculation is no longer the model; the version history becomes even more important. A final

Copyright 2026, James M. Atkinson

frozen version may deserve a fresh assessment. What it cannot inherit is the assertion that the favourable run arose under a single prespecified test when a different search was actually conducted.

Application ten considers ten alternative analysis branches applied to the same record. Suppose each branch has a false-alarm probability at most 0.001 under its own valid null model. Without assuming independence, the probability that at least one branch signals falsely is bounded above by their sum, 0.01. If their false alarms were independent and each probability exactly 0.001, the exact union probability would be one minus 0.999 raised to ten, approximately 0.00995512. Perfectly coincident false alarms would instead yield 0.001. The search across branches is a procedure of its own, and should be evaluated as such.

$$P\left(\bigcup_{i=1}^{10} A_i\right) \le \sum_{i=1}^{10} P\left(A_i\right) \le 0.01$$

Here A_i denotes the false-alarm event of branch i. The union bound is elementary probability, not a statement that every analysis branch is well calibrated. If a branch's stated probability is unsupported, the resulting bound is unsupported too. Nor does the calculation supply the probability that a particular selected alarm is false. It demonstrates how an apparently stringent per-branch criterion can lose its advertised meaning when the observer searches several branches and reports the best result without identifying that search.

Dr. Atkinson, the corrective discipline is to preserve development and confirmation as different activities. During development, examine failures, change settings, compare representations, and form new hypotheses. Record what was learned. During confirmation, test a defined version using

Copyright 2026, James M. Atkinson

a plan that can expose the errors relevant to its stated claim. Where adaptation is essential to the deployed system, validate the adaptive rule itself rather than pretending that its selected setting was fixed beforehand. The object of assessment is the actual procedure, including its opportunities to search and revise.

A difficult failure can also expose a defect in the reference or in the test's definition rather than in the receiver. Such a finding should be investigated and documented, not automatically counted against the instrument. But the correction requires evidence independent of the desire to rescue the result. If every adverse outcome can be dismissed through an unmeasured auxiliary explanation, the test no longer discriminates. The report should state which reference defects were demonstrated, which trials were invalidated for that reason, and how the replacement trials were chosen.

A test can also lose discriminatory force through an unspecified stopping rule. Continuing observations is not inherently improper, but a result interpreted through a fixed-sample calculation must actually follow the sampling plan assumed by that calculation. A sequential procedure may supply a different valid analysis when its conditions are met. The issue is not whether the examiner was patient or persistent; it is whether the probability statement describes the rule by which observations were collected, selected, and finally reported.

Dr. Atkinson, I would frame the problem as follows. Before offering an opinion about whether the adverse receiver challenge is capable of exposing the hypothesised error, I would define the measurand and its uncertainty. The proposed rival mechanism is that a test performed only on a convenient amplitude might miss overload or weak-signal suppression.

Copyright 2026, James M. Atkinson

Consequently a calibration certificate for one nominal receiver setting does not settle the question. The more informative operation is to apply calibrated stressors near threshold and near compression while preserving failed observations, with input third-order intercept, overload settling, noise figure and detection probability reported in units and tied to an input reference plane. The adverse prediction is concrete: the challenged receiver produces a false event or misses a reference event under the predicted stress. I would challenge it across a range of input powers and hold one independently measured source constant throughout the switching sequence. A correction estimated after seeing the unknown feature may assist an exploratory analysis; it must not be presented as though it had been fixed before acquisition. Where systematic effects share a reference, their covariance belongs in the reported uncertainty rather than being silently assumed zero. This is the distinction between an instrument number that appears stable and a defensible physical measurement.

The strongest outcome is not an unblemished narrative. It is a reproducible account in which the intended claim survives relevant challenges, failures lead to supported restrictions or revisions, and remaining uncertainty is not concealed. A system can be accepted for one use while rejected for another. That is a more informative judgement than an unrestricted declaration of success. Mr Hartley, may I invite your final question about the information that must survive from this validation history when the resulting instrument is transferred to another laboratory or operating environment?

Copyright 2026, James M. Atkinson

Ralph Vinton Lyon Hartley

Peer question 7 to Karl R. Popper

Sir Karl, a receiving laboratory may obtain the instrument, an accepted software version, and a concise validation certificate, but not the full development history. It may then reproduce the nominal configuration while changing a clock, a data interface, or an operating condition that the original validation quietly depended upon. What information must accompany the transfer so that acceptance does not become detached from its conditions? Please distinguish historical detail that is merely interesting from information necessary to determine whether the validated procedure is still being used. I would also ask how the record should treat a configuration update that appears numerically identical at the display but changes the acquisition or processing path. A checklist of version numbers alone may be insufficient, yet an unlimited demand for every historical file is impracticable. What is the appropriate evidential boundary for transfer and subsequent revalidation?

May I press you upon the evidential value of an adverse challenge which deliberately stresses a receiver outside its comfortable operating region? A system may fail to recognise a calibrated weak signal while a strong blocker is present, although its nominal sensitivity measurement was perfectly sound with the blocker absent. That failure tests the combined linearity, preselection and detection policy rather than one isolated manufacturer specification. What minimum experimental controls would let an independent observer determine whether the missed event resulted from analogue compression, a threshold adaptation, or a dropped acquisition block? I suggest retaining both the

Copyright 2026, James M. Atkinson

injected witness's independently monitored waveform and the receiver's raw gain-state history, and repeating the test with a preselector or input attenuator changed one at a time. Does successful recovery under one modified state permit any general assurance about the original operating state? In your answer, please distinguish a challenge which usefully falsifies an assumption from one whose own disturbances make its outcome impossible to interpret.

Sir Karl Raimund Popper

Answer to Ralph V. L. Hartley

Mr Hartley, the transferred record should identify the accepted claims, their operating envelope, the configuration that produced the supporting evidence, and the changes that would require renewed assessment. Preserve the validation procedure, outcome definitions, source and reference qualifications, and material failures or exclusions that limit the acceptance. Those records explain what was demonstrated and why it applies. A complete development archive may be retained separately, but the receiving laboratory must not need to discover a hidden limitation in it before using the stated acceptance correctly.

Dr. Atkinson, a version number is an identifier, not a demonstration of measurement equivalence. A change that alters timing, numerical scaling, reference selection, or the admitted signal path may affect a claim even when the display looks unchanged. The update should therefore be evaluated against the dependencies of the validated procedure. Targeted regression can be appropriate where the changed boundary and its consequences are well understood. Where

Copyright 2026, James M. Atkinson

the dependency is unresolved, broader revalidation or a restricted claim is preferable to an unsupported assertion of equivalence.

The receiving laboratory should verify the configuration actually loaded and the reference conditions actually achieved. Nominal replication does not establish physical correspondence if cables, fixtures, loading, or environmental conditions differ materially. A transfer check can test selected anchor conditions, but its scope should be explicit. Passing it should not certify regions it never exercises. The governing question is whether the premises supporting the accepted claim remain true in the transferred arrangement.

Material changes should be assessed through a documented impact argument. That argument may justify a narrow regression rather than complete repetition, but it should identify which accepted claims remain unaffected and the evidence supporting that conclusion. Administrative similarity is not sufficient.

The record should consequently connect claims to tests and tests to their relevant conditions, rather than merely collect documents by date. That structure allows change to be assessed without requiring every component to be retested indiscriminately. It preserves criticism as a practical engineering process. Professor Atkinson, I return the floor for your closing synthesis of how a challenge programme can support a bounded, transferable receiver claim without concealing the failures that define its limits.

Copyright 2026, James M. Atkinson

Edward Weston, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, a test engineer verifies nominal sensitivity after a strong blocker has been removed, yet the event of interest can begin only six milliseconds after removal. A later steady-state measurement may find the converter within range while an automatic gain-control loop is still recovering during that six-millisecond interval. In a constructed receiver challenge, how would you define the actual transfer path and time reference, and which observation would discriminate transient suppression from a genuine absence of the weak event? Would a conventional input-power sweep, performed only after the chain has settled, be a sufficient adverse test?

Hendrik Wade Bode, Cross-Peer Answer to Edward Weston: Mr Weston, it would not. A steady-state sweep constrains settled gain and perhaps compression under its particular conditions; it does not certify recovery after a large-signal history. Define the blocker amplitude, occupied bandwidth, removal transition, impedance and the weak challenge waveform at the chosen physical input plane. Record the gain-control state where available, but also retain a continuous, calibrated observation of the response through the critical interval. Vary the delay between blocker removal and weak-event onset, using a separate reference channel or independently measured stimulus timing to distinguish source absence from receiver blindness. A simple exponential decay may guide an illustrative design, but real loops can have multiple time constants, switching and saturation hysteresis. A challenge is persuasive when the weak event is known to be applied at a specified instant and the measured output is evaluated against a predeclared criterion. Record blanking, dropped samples and clipping flags

Copyright 2026, James M. Atkinson

separately. The absence of a visible trace after overload is otherwise ambiguous, however neatly the later display returns to normal.

Jerzy Neyman, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, the laboratory conducts a thousand detection trials, but all occur within a few bursts of a common reference source and under one receiver thermal state. It then reports a small confidence interval as though the thousand outcomes were independent Bernoulli observations. If burst timing, common reference errors and gain state make neighbouring results dependent, how should a challenge programme be redesigned so that its claimed assurance reflects independent experimental opportunities, rather than the impressive but misleading size of a counter?

Walter Andrew Shewhart, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, I would first identify the unit that the performance claim is meant to generalise over. A thousand threshold decisions within one burst may describe that particular burst rather precisely while providing only a handful of independent opportunities to examine sensitivity to changing conditions. Organise trials into documented blocks covering source setting, receiver state, power level, temperature and relevant timing relationships. Randomise or counterbalance the order of admissible challenges so that drift cannot masquerade as a treatment effect. Record block identity, failure mechanisms and omissions, rather than presenting only a pooled numerator and denominator. The analysis must either model within-block dependence or use inference whose experimental units correspond to the independently varied blocks. A simple binomial interval is conditional on its independence and identical-probability premises; those premises are not supplied by the raw trial count. Repeating a challenge after a deliberate

Copyright 2026, James M. Atkinson

reset can strengthen a distinct claim, but a reset which leaves the same reference error untouched does not remove that covariance. The final statement should identify both the experimental population tested and the states not examined.

Egon Sharpe Pearson, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, imagine a receiver that announces every injected short signal in its live event list, while its archival pipeline fails to write the complex samples for several of those events. An evaluator records one hundred per cent detection because the alarm records are intact, and later speaks as though each event could be independently re-examined for spectral identity and timing. Which distinct propositions should the test separate? How might a validation scheme establish that an asserted detection has actually yielded an intact, retrievable evidential record rather than an attractive summary entry?

Claude Elwood Shannon, Cross-Peer Answer to Egon Sharpe Pearson: Mr Pearson, the operations must be measured separately. An event decision, an archived baseband representation, a complete timestamp lineage and a later identification are not interchangeable outputs. Define a known challenge with source-controlled event identity and timing. For each trial, record whether the receiver alarmed, whether raw complex samples covering the full required pre-trigger and post-trigger interval were retained, whether sample sequence continuity passed, and whether a separate analysis could reproduce the claimed features from the saved bytes. Compare file metadata with sample counters and content hashes; a metadata label alone does not show that the corresponding samples exist. The resulting outcome vector may be alarmed but not retained, retained but

Copyright 2026, James M. Atkinson

incomplete, or retained and independently analysable. The overall chain succeeds only for the evidential function specified at the outset. A high alarm-detection fraction may be excellent operational information, yet cannot support the stronger assertion that the material survives for forensic review. The test report ought to give separate denominators and failure counts for those different claims.

Sir Karl Raimund Popper, Cross-Peer Question to Percy Williams Bridgman: Professor Bridgman, a development team subjects a receiver to a difficult blocker test, obtains a failed result, changes the fixture and declares the original trial invalid. The team may be correct: an improperly terminated reference path can create a false failure. Yet a convenient explanation devised after seeing an adverse result could equally remove every obstacle to an unblemished validation record. What operational conditions would let us distinguish a justified invalidation from an after-the-fact rescue of the hypothesis, and what should the final evidence contain when the first experiment cannot be interpreted confidently?

Percy Williams Bridgman, Cross-Peer Answer to Sir Karl Raimund Popper: Sir Karl, an invalid trial must have an identifiable physical defect, not merely an inconvenient result. State the reference plane, admitted input waveform, loading, instrument state, timing and required observations before testing. Define the disqualifying conditions that would make the trial uninterpretable, then preserve the measurements which show whether such a condition occurred. A discovered mismatch, for example, should be measured or independently bounded at the relevant frequency; an asserted mismatch is not evidence. If the fixture is corrected, retain the original trial as a documented exception with its reason and collect a fresh result under a

Copyright 2026, James M. Atkinson

frozen revised procedure. Do not silently relabel an adverse outcome as an absence of data. When the first trial remains ambiguous, describe the unresolved alternatives and restrict the assurance claim to tests whose reference conditions were actually demonstrated. That discipline preserves the possibility of technical improvement while denying the illusion that an examiner can manufacture a perfect receiver through retrospective choice of what shall count as a trial.

Dr. James M. Atkinson

Closing synthesis

Mr Weston, Dr Shewhart, Professor Neyman, Mr Pearson, and Sir Karl Popper, thank you. A receiver challenge test must have a genuine opportunity to contradict the claim it is meant to support. That requirement is physical, statistical, and inferential. The stimulus must traverse the relevant path; the trial population must represent the specified task or deliberately test its boundaries; and the procedure evaluated must include the settings, searches, exclusions, and adaptations actually used. A favourable display is not a substitute for these conditions.

The worked applications expose distinct ways in which an honest observation can be assigned an excessive meaning. Synchronized bursts can conceal limited temporal coverage. Endpoint calibration can leave alternative transfers indistinguishable. A pooled success fraction can be dominated by easy trials and can change when the population mixture changes. Complete success in finite trials supports a conditional bound rather than perfect performance. Simultaneous claims across many conditions require a corresponding joint construction. Paired comparisons

Copyright 2026, James M. Atkinson

must preserve their pairing, and detection probabilities must not be confused with probabilities of signal presence after an alarm.

The final two applications address selection. Repeating or searching until a favourable result appears creates a larger procedure whose outcome must be interpreted accordingly. The panel has not prohibited development, adaptive algorithms, or repeated experimentation. It has required their history and rules to remain visible. A revised receiver can be tested and accepted on its own evidence. What cannot be justified is allowing the revision to erase the failure or to borrow an acceptance statement designed for an experiment that was never actually conducted.

The proposed validation record should therefore retain several connected layers. Define each claim and its operating envelope. Preserve the reference and acquisition conditions, the executed trial schedule, the outcome rules, and the version tested. Record detection, retention, and subsequent measurement validity separately where they support different uses. State the uncertainty appropriate to the actual trial model and identify conclusions that remain conditional or indeterminate. Finally, connect accepted claims to the changes that would require renewed verification.

The record must also preserve the reference experiment as an object capable of error. A demonstrated fixture defect may invalidate a trial, but an imagined defect cannot excuse every inconvenient result. By keeping reference limitations, receiver failures, and analysis changes distinct, the laboratory makes improvement possible without rewriting its evidential history. That is the discipline required for a transferable acceptance decision.

Copyright 2026, James M. Atkinson

These requirements allow practical limits. No finite campaign establishes performance under every conceivable condition. A laboratory can nevertheless support a useful and precise operating claim, provided its exclusions are meaningful and its tests address the consequential mechanisms. A restriction following a difficult test is progress when it replaces unsupported confidence with a reliable boundary. The quality of the final account lies in that boundary and in the evidence permitting another examiner to challenge it. The next discussion can build upon this foundation by examining how uncertainty and unresolved alternatives should govern the wording of the receiver's final findings.

Dr. Atkinson, I would frame the problem as follows. I should distinguish the physical occurrence under inquiry from the information actually retained when studying whether the adverse receiver challenge is capable of exposing the hypothesised error. Because a test performed only on a convenient amplitude might miss overload or weak-signal suppression, more than one historical account may produce the same saved trace. The controlled comparison should be to apply calibrated stressors near threshold and near compression while preserving failed observations, preserving input third-order intercept, overload settling, noise figure and detection probability at the measurement point and in the evidential metadata. If the challenged receiver produces a false event or misses a reference event under the predicted stress, that result would narrow the admissible explanations, not establish a uniquely identified emitter outside the tested conditions. A subsequent software reconstruction may recalculate a statistic from retained samples, yet it cannot recover components rejected by the front-end filter or intervals never recorded. I

Copyright 2026, James M. Atkinson

would make those distinctions explicit in the final report and invite an independent examiner to reproduce the challenge, including its failed steps. Scientific restraint is not a weakness of the investigation. It prevents a detector output, however striking on the screen, from becoming a claim about unobserved activity that the original measurement never established.

Ten worked engineering applications | Question 005

Application 01. Opportunity-limited detection under independent visits

In the illustrative 005.01 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. For $n = 39$ genuinely independent valid observation opportunities, each with stipulated event detection chance $p = 0.10$, the probability of no detections is $(1 - p)^n = 0.01642$; its complement is 98.36%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The result tests a stipulated visit model only; synchronised misses remain an untested failure mechanism.

Application 02. Observed exposure fraction of a channel scanner

In the illustrative 005.02 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. Let the channel be observed on $n = 199$ valid visits, each lasting $d = 10$ ms, with revisit spacing $R = 1.15$ s. Valid exposure is $nd/1000 = 1.990$ s across the nominal interval $nR = 228.85$ s. The observed fraction of elapsed time is therefore 0.87%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. The measured duty fraction gives the challenge programme a coverage boundary rather than a claim of continuous observation.

Copyright 2026, James M. Atkinson

Application 03. Family-wise probability when many candidates are searched

In the illustrative 005.03 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. If each of M = 206 independent pre-specified search opportunities has false-alarm probability α = 0.0011, the probability of one or more false positives is 1 − (1 − α)^M = 0.20286, or 20.29%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. The reported probability is conditional on the declared test family and cannot retrospectively legitimise a wider search.

Application 04. Combined and expanded measurement uncertainty

In the illustrative 005.04 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. For independent standard-uncertainty contributions 0.80, 0.60 and 0.22 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.80^2 + 0.60^2 + 0.22^2)} = 1.024$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c = 2.048$ units. The combined uncertainty is useful only for the stated independent contributions and remains conditional on the chosen coverage factor.

Application 05. Gain allocation and blocker headroom

In the illustrative 005.05 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. Assume a calibrated digital full-scale equivalent of -6 dBm, a blocker applied at -36 dBm, and net analogue gain 31 dB. The projected

Copyright 2026, James M. Atkinson

converter input is -5 dBm and remaining margin is -6 − (-5) = -1 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. The negative headroom identifies a configuration that must be rejected or independently qualified before weak-signal performance is claimed.

Application 06. Alias-location prediction and its non-unique inverse

In the illustrative 005.06 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. For an actual sampling frequency f_s = 31 MHz and analogue input f_i = 65.100 MHz, the nearest-replica folding rule gives $f_a = |f_i - \mathrm{round}(f_i/f_s)f_s|$ = 3.100 MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. The folded coordinate alone does not identify the analogue source without measured preselection and alias-rejection evidence.

Application 07. Thermal reference noise in a declared measurement bandwidth

In the illustrative 005.07 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. Take the equivalent noise bandwidth B = 21,000 Hz and calibrated noise figure NF = 2.35 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \mathrm{Hz}) + NF$ = -128.43 dBm. The result is available-noise power in that specific bandwidth; impulsive

Copyright 2026, James M. Atkinson

interference at the antenna is not represented by the 290 K assumption. The calculation establishes a thermal reference, which must not be substituted for a measured blocker environment.

Application 08. Accumulated sample-clock time error

In the illustrative 005.08 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. A free-running sample clock with fractional rate error ε = 1.360 ppm over T = 415 s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T$ = 0.5644 ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. The clock-offset estimate identifies one timing failure mode, not a bound on every burst-detection or acquisition interruption.

Application 09. Difference between two instruments relative to stated uncertainty

In the illustrative 005.09 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. The paired instrument contrast is Δ = 1.870 dB. Set independent standard uncertainties u_1 = 0.500 dB and u_2 = 0.470 dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)}$ = 0.686 dB, giving the dimensionless ratio $\Delta/u\Delta$ = 2.725. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The receiver comparison requires an uncertainty and dependence model before it becomes an acceptance decision.

Copyright 2026, James M. Atkinson

Application 10. First-order recovery envelope after a state change

In the illustrative 005.10 test, an investigative receiver undergoes a deliberately adverse challenge intended to reveal a known failure mechanism. If an illustrative recovery follows $A(t) = A_0 \exp(-t/\tau)$, let $A_0 = 1.50$ V and $\tau = 7.00$ ms. At $t = 17.50$ ms the residual is $1.50e^{(-17.50/7.00)} = 0.1231$ V. Real automatic gain control often has nonlinear or multi-time-constant behaviour, so this exponential is a test model, not a universal reconstruction of the input during overload. The recovery envelope supplies a testable hypothesis for this constructed loop, not a certified transient response for an actual receiver.

The register covers the twelve contributors used in Questions 001-005. It does not complete the 250-person register for the programme. Historical facts and the editorial discussion-role analyses prepared for their first appearance in Question 001 remain distinguished. The moderator has no biographical entry.

How should uncertainty, competing explanations, and decision costs govern the wording of a receiver finding?

Source: V011_Roundtable_Q001-Q011_CP011_Integrated_Candidate(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Constructed educational dialogue. Every speech is newly authored; no passage purports to reproduce the words of a historical participant. All receiver cases, numerical observations, assumptions, and decisions below are hypothetical, not experimental certifications.

Dr. James M. Atkinson

Opening question

Professor Tukey, can you comment upon the distance between discovering an unusual spectral feature and issuing a defensible finding about what produced it? We arrive here after five examinations of the physical reference, the receiver architecture, its changing acquisition state, the dependence of corroborating channels, and the design of tests capable of exposing failure. We have established that a challenge must be capable of contradicting its proposed claim. We have not yet determined how the residual uncertainty should pass into the final sentence read by an investigator, a court, a laboratory director, or the client who commissioned a technical surveillance countermeasures examination. A beautifully resolved waterfall image, moving across a display in precise colours, may have been created by an uncertain sequence of analogue states, mathematical thresholds, retention policies, and deliberate exclusions. The published conclusion must preserve the important qualifications without being so evasive that no reader can determine what the examination established.

Copyright 2026, James M. Atkinson

Consider a wideband software-defined receiver screening a large, occupied spectrum. It returns an intermittent narrowband event appearing in several windows, sometimes accompanied by a changing harmonic structure. A second receiver appears to corroborate the observation. The operators find a probable physical location. A preliminary report describes a covert transmitter, but further examination reveals that both receivers shared an antenna distribution path, the candidate frequency was selected after an extensive search, and the alleged localisation was derived from measurements whose uncertainties have not been traced to common references. These discoveries do not by themselves prove that the event was fictitious. They disclose different gaps between event observation, classification, spatial inference, and source attribution. Each gap requires its own evidence and an expression of uncertainty appropriate to the claim made.

I ask the panel to separate the following propositions in its reasoning: an instrument recorded a numerical feature; a physical emission existed at a declared reference boundary; the emission had specified measurable properties; it probably arose from a class of devices; and a particular person or apparatus produced it. These propositions are not equivalent, and one may be well supported while the next remains unresolved. The term *confidence* cannot be used as an ornamental seal on the entire chain. Statistical coverage, engineering uncertainty, likelihood under competing hypotheses, and the practical consequences of acting upon evidence have different mathematical meanings. A single impressive percentage must not pretend to answer all of them.

Copyright 2026, James M. Atkinson

Professor Tukey will begin by examining the effect of searching many time-frequency cells and choosing an attractive feature after looking at the data. Mr Gosset will test the trial count and its assumptions, particularly when bursts, scans, and environmental states are correlated. Dr Wald will distinguish evidence from a decision whose costs and urgency may be asymmetric. Sir Harold Jeffreys will examine what a likelihood comparison can and cannot establish about a source. Mr Peirce will consider the logic of inference to an explanation and the obligation to preserve credible rivals. Seven colleagues will put directed questions to these five principal contributors; each question will be answered before its respondent hands the discussion onwards. The modern SDR applications are editorial constructions, not claims that historical panellists possessed knowledge of contemporary receivers.

We shall require a concrete reporting doctrine: what must be said about the acquisition interval, what should be done with an apparently impressive result arising after an enormous search, when a negative search warrants reassurance, when an immediate protective decision is proper despite uncertainty, and when a report must stop at an observation rather than identify an emitter. Our numerical worked applications are intended to expose the assumptions hidden inside attractive calculations. They are not substitute acceptance data. Professor Tukey, may I invite your principal analysis of what an exploratory search does to the meaning of the feature it discovers?

Copyright 2026, James M. Atkinson

John Wilder Tukey

Principal response. Exploration, multiplicity, and the burden of independent confirmation

Dr. Atkinson, thank you. My observation is that a successful search does not automatically provide a successful test of the hypothesis subsequently written around its discovery. An exploratory algorithm asks where a feature may be found; a confirmatory procedure asks whether specified evidence behaves as predicted by a proposition whose challenge has been fixed with adequate independence from the evidence being used to judge it. Both are necessary to an intelligent investigation. The first discovers patterns that no prior engineer thought to enumerate; the second protects an inference against the tremendous freedom exercised during discovery. When the same selected trace is made to perform both roles without allowance for its selection, even a rigorous local significance calculation can possess a wholly misleading global meaning. [M6-1]

This issue is acute in a wideband receiver. Search dimensions include centre frequency, FFT size, window, overlap, dwell, triggering rule, background estimator, demodulation choice, burst length, and perhaps a retrospective interval chosen after the feature is seen. Counting only the number of frequency bins ignores the search performed across time and analysis configurations. Yet multiplying all displayed bins is not automatically correct either: neighbouring frequency cells overlap under many window functions, adjacent time records can share samples, and a detection algorithm may cluster connected indications into one physical candidate. The proper family of tests must be defined by what the search procedure could have selected, not by the most convenient count available

Copyright 2026, James M. Atkinson

after it did select something. I yield the floor courteously for the next scientific examination.

The two calculations are not an argument for declaring that a detected spectral component is probably false. A familywise false-alarm probability concerns a repeated procedure under a particular null model. It is not the probability that this particular alarm was caused by noise after the alarm has been observed. That latter inference also requires information about the prevalence or prior plausibility of relevant signals and about the probabilities of the observed data under alternatives. Confusing these probabilities is especially dangerous when the report is intended to attribute conduct to a particular source. A statistical test can have a beautifully stated false-alarm rate while the probability of a source attribution remains unexamined.

I would distinguish three records. The discovery record preserves the search space actually examined, the settings tried, and the lineage of the candidate. The test record states the procedure fixed to challenge that candidate, including any hold-out data, independent receiving path, or deliberately changed antenna geometry. The interpretation record identifies the proposition supported by that second record. If no genuinely new evidence is available, a competent report can still describe the observation, its processing, and its exploratory status. It simply should not assign a confirmatory probability calculated for a single comparison to an event selected from an unspecified multiplicity of comparisons.

A complication deserves emphasis. Retrospective analysis is not intrinsically dishonest. Reprocessing retained I/Q data can reveal a weak signal previously obscured by an unfortunate display choice; it may recover

Copyright 2026, James M. Atkinson

valuable temporal and spectral structure without changing the underlying samples. The analyst should preserve the original data, each meaningful processing choice, and the point at which the candidate was selected. Later confirmation must then address the mechanism proposed, preferably through a different measurement or a prospectively specified challenge. An additional view of the same bytes can be evidence about their contents, but it does not become a new physical observation merely because its waterfall looks different. The distinction is mathematical, operational, and forensic. [M6-4, M6-6]

A further constraint follows from reporting receiver findings under uncertainty and competing physical explanations. For quantitative interpretation, the distinction between signal power at the antenna reference plane and displayed power after digital processing must remain explicit. A numerical threshold has meaning only together with calibration uncertainty, analysis bandwidth, detector statistic and valid observation exposure. Overlapping Fourier windows do not create fully independent measurements merely by providing additional rows. The result should therefore be accompanied by a denominator tied to genuine measurement opportunities, an account of clipped or missing intervals and a description of the nuisance conditions under which the decision procedure was challenged. Applied to the present engineering problem, selection bias, undercovered nuisance regimes, decision-cost asymmetry, and uncertain priors may create a spectrum or timestamp that looks persuasive while leaving counterfactual outcomes and poorly modelled interference states inaccessible. The experimental answer lies in independent validation and explicit sensitivity analysis across plausible models, carried out with explicit

Copyright 2026, James M. Atkinson

controls and independent retention of all the relevant receiver states. The account should quantify uncertainty components, likelihood ratios, false-positive burden, and adverse decision consequences, separating input-referred values from software-derived quantities. If the calculation assumes constant noise statistics or a linear front end, an overload or irregular interference challenge should test that premise. The examiner should preserve negative outcomes and show why the proposed mechanism is better supported than the surviving alternatives. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Sir Ronald Fisher, I invite your question about the relationship between nominal significance and the many candidate explanations an examiner can construct after seeing one attractive pattern.

Sir Ronald Aylmer Fisher

Peer question 1 to John Wilder Tukey

Professor Tukey, thank you for distinguishing the exploratory and confirmatory functions. I should like to sharpen your treatment of the test statistic itself. Suppose the investigator first tries a dozen filters and several thresholds, retains only the most impressive trace, and then quotes the probability that a prespecified single filter would have produced a statistic as extreme under a particular null model. That probability does not have the advertised meaning for the selection actually conducted. Yet it would be equally inappropriate to announce that every exploratory result is devoid of evidential value or that a single universal correction can repair every flexible analysis. How should the final report identify its selection history in language sufficiently clear for a reader to distinguish an observed discrepancy from a claimed

Copyright 2026, James M. Atkinson

statistical rarity? In particular, what must be done when the family of candidate tests cannot be reconstructed fully, and what would count as genuinely new evidence rather than a differently coloured re-expression of the same retained samples?

John Wilder Tukey

Answer to Ronald Aylmer Fisher

Sir Ronald, I agree that the number printed beside the trace must refer to the actual inferential procedure or be explicitly restricted to a conditional calculation. An analyst who has tried many filters may truthfully say that one selected output exceeded a stated threshold under a stated model. The analyst should not call its single-filter tail probability the experiment-wide probability of seeing such an extreme result anywhere in the search. Where the search history is incomplete, the report should say that the nominal probability is unadjusted and that its multiplicity cannot be quantified from the available record. This is a material limitation, not merely a missing software setting. [M6-1]

I would require the record to name at least the classes of frequency intervals, time periods, transformations, and candidate criteria examined, together with the point at which each choice became fixed. A candidate that appeared only after the threshold was adjusted to reveal it may be scientifically interesting. Its subsequent statistical evaluation must not be represented as if the threshold had been fixed independently. A new antenna position, a physically independent reference, an independently acquired interval with declared exposure, or an induced change predicted by the source hypothesis can

Copyright 2026, James M. Atkinson

contribute more discriminating evidence than another rendering of the same archived cells. Independence has to be shown for the claim under consideration; an apparent second channel sharing a front-end fault may provide very little additional information.

A useful sentence would therefore read: “The spectral feature was identified during exploratory processing of the retained interval. The nominal single-cell test statistic and threshold are reported for reproducibility; the probability of finding a feature this extreme somewhere in the full exploratory search has not been established.” That statement retains the observed fact and makes clear what the statistic does not establish. If a subsequent fixed test succeeds, the report can add its distinct result with the conditions of that test and the alternative mechanisms it was capable of discriminating. If it fails, the earlier discovery remains part of the record rather than disappearing from the file.

I would not put a broad “false signal” label on a candidate merely because discovery was flexible. The correct restriction is on the claimed significance and the movement from candidate to cause. Professor Tukey's distinction is most valuable when it permits investigation to continue without granting an exploratory calculation an authority it never possessed. Sir David Cox, may I invite your question concerning whether our proposal for a hold-out experiment retains its independence when the same laboratory has already learnt the candidate's distinctive features?

Copyright 2026, James M. Atkinson

Sir David Cox

Peer question 2 to John Wilder Tukey

Professor Tukey, a further difficulty concerns what the word *independent* might mean in a receiver validation report. An examiner may freeze the selected frequency and ask a second analyst, who is shown the candidate waveform and its predicted modulation, to search an additional hour of data from the same front end. The second analyst does not alter the algorithm after looking at that additional hour, but a common clock defect, periodic interference source, or mischaracterised analogue response may persist. Alternatively, a new receiver may be employed while the candidate source and the environment have themselves changed. Neither experiment is unconditionally superior. What should be declared in advance so that the subsequent result evaluates the intended source hypothesis, rather than a different question about whether a recognisable pattern can be recovered? Should a held-out test define temporal exposure and invalid intervals before its outcomes are seen, and how should its report distinguish procedural independence from physical independence?

John Wilder Tukey

Answer to Sir David Cox and transfer of the floor

Sir David, the phrase “independent confirmation” should never substitute for specifying *independent with respect to which potential failure*. Separate acquisition time may guard against some transient errors without guarding against a stable spurious signal in a shared reference oscillator. Separate hardware may guard against one receiver's internal artefact while a common antenna, distribution

Copyright 2026, James M. Atkinson

amplifier, power supply, or nearby emitter preserves another. An examiner should write down the rival explanations and describe the changed conditions that each would predict. A fixed test against the wrong rival is not rescued by impeccable randomisation, because its result answers a different proposition.

The held-out protocol should identify the signal class; the required observation opportunity; the valid and invalid operating states; the allowed adjustments; the decision statistic; the candidate rule; and the reporting treatment of inconclusive records. If the intended claim concerns localisation, the test must vary or measure geometry under a model that can discriminate source positions. If it concerns persistence, it must establish valid temporal exposure and cannot treat unrecorded intervals as quiet ones. Where calibration or background conditions have changed, the test should show why the result remains comparable. A report might properly state that the pattern repeated in a prespecified second interval, but that both intervals used the same analogue input path and therefore do not constitute physically independent validation of that path.

One should also resist the idea that a confirmatory experiment's sole virtue lies in producing a binary answer. When a challenge exposes a shared oscillator artefact, the experiment may be more informative than a favourable replication. When a receiver is valid for only part of the intended operating envelope, a restricted conclusion is a genuine result. The common obligation is to distinguish a successful test of a defined proposition from a pleasing display that has not tested the required alternatives. Dr. Atkinson, with your

Copyright 2026, James M. Atkinson

permission, I pass the floor to Mr Gosset, whose question concerns the meaning of the trial count when a receiver's many observations are far from independent.

A further constraint follows from reporting receiver findings under uncertainty and competing physical explanations. I would add the following qualification to my answer. For quantitative interpretation, the distinction between signal power at the antenna reference plane and displayed power after digital processing must remain explicit. A numerical threshold has meaning only together with calibration uncertainty, analysis bandwidth, detector statistic and valid observation exposure. Overlapping Fourier windows do not create fully independent measurements merely by providing additional rows. The result should therefore be accompanied by a denominator tied to genuine measurement opportunities, an account of clipped or missing intervals and a description of the nuisance conditions under which the decision procedure was challenged. In this particular question, the controlled observation is finite measurements with known thresholds and instrument histories, whereas the material uncertainty concerns counterfactual outcomes and poorly modelled interference states. Consequently the adversarial comparison ought to include independent validation and explicit sensitivity analysis across plausible models and its failed as well as successful outcomes. I would not advise treating a change in the displayed indication as an authenticated physical attribution until its causal mechanism has been experimentally distinguished.

Copyright 2026, James M. Atkinson

William Sealy Gosset

Principal response. Small samples, repeated exposures, and the illusion of a large trial population

Dr. Atkinson, thank you. My observation is that the numeral written beside the word *trials* cannot be interpreted without the experimental unit and the circumstances of its repetition. A laboratory may display ten thousand FFT records, yet those records can arise from a handful of bursts emitted by one generator in one physical state, observed through one receiver configuration. The extraordinary apparent precision of a count is not itself evidence of a large or representative experiment. Before a rate is estimated, the investigator must say what constituted an opportunity for success or failure and which opportunities were observed independently under the assumed probability model. My own historical work arose from the practical demands of small-sample industrial experimentation. The SDR applications here are newly constructed from that statistical concern, not alleged statements about instruments unknown in my lifetime. [B14]

The problem is particularly evident in a negative search. The client may ask whether an undiscovered emitter was absent, while the receiver has operated under variable sensitivity, intermittent tuning, shared interference, and triggered retention. There may be no defensible denominator for a universal probability of missing such an emitter. Where a narrowly specified trial model can be established, a useful bound may nevertheless be derived. One must then make its assumptions and units visible, rather than transfer the resulting percentage to every untested signal, location, or source behaviour. I pass the floor to the next participant with thanks for this considered exchange.

Copyright 2026, James M. Atkinson

My recommendation is to stratify and preserve the circumstances that plausibly govern failure. A receiver should be tested across declared signal strengths, dwell ratios, duty cycles, stronger adjacent emissions, reference conditions, gain states, and environmental changes. If a single number is required, the mixture of these conditions must be part of the claim. A weighted average over predominantly easy trials cannot demonstrate reliable detection in a rare but consequential difficult state. An uncertainty bound conditional on controlled laboratory exposures is valuable, but it should not be dressed as a universal field guarantee. The omitted strata must appear as limitations in the final findings.

I would also separate three different counts: the number of emitted challenges, the number of valid opportunities for the receiver to observe those challenges, and the number of retained records on which later algorithms operated. These counts can disagree without anyone having falsified a log. A challenge outside the receiver's active tuning interval is not an ordinary missed detection if the performance claim did not require that interval to be covered; it is, however, a failure of the broader surveillance coverage if that broader promise was made. A challenge during documented receiver invalidity cannot simply disappear from a denominator chosen to make performance attractive. It must be classified according to a declared rule that was not invented after seeing the outcome.

A further constraint follows from reporting receiver findings under uncertainty and competing physical explanations. For quantitative interpretation, the distinction between signal power at the antenna reference plane and displayed power after digital processing must remain explicit. A numerical threshold has meaning only together with calibration

Copyright 2026, James M. Atkinson

uncertainty, analysis bandwidth, detector statistic and valid observation exposure. Overlapping Fourier windows do not create fully independent measurements merely by providing additional rows. The result should therefore be accompanied by a denominator tied to genuine measurement opportunities, an account of clipped or missing intervals and a description of the nuisance conditions under which the decision procedure was challenged. Applied to the present engineering problem, selection bias, undercovered nuisance regimes, decision-cost asymmetry, and uncertain priors may create a spectrum or timestamp that looks persuasive while leaving counterfactual outcomes and poorly modelled interference states inaccessible. The experimental answer lies in independent validation and explicit sensitivity analysis across plausible models, carried out with explicit controls and independent retention of all the relevant receiver states. The account should quantify uncertainty components, likelihood ratios, false-positive burden, and adverse decision consequences, separating input-referred values from software-derived quantities. If the calculation assumes constant noise statistics or a linear front end, an overload or irregular interference challenge should test that premise. The examiner should preserve negative outcomes and show why the proposed mechanism is better supported than the surviving alternatives.

The relevant operational qualification is that finite measurements with known thresholds and instrument histories. An instrument specification does not by itself establish the result of a field experiment. A preselector may reject one interfering band while leaving a different ingress path; a sample clock may be stable in the mean while its phase fluctuates; and a file may be authentic while the analogue interpretation remains contested. The

Copyright 2026, James M. Atkinson

expert should distinguish a certificate describing a manufacturer test condition from a verified statement about the present configuration. Record the intervention and its physical reference, the raw output where available and the particular source hypothesis which the intervention could actually exclude. Applied to the present engineering problem, selection bias, undercovered nuisance regimes, decision-cost asymmetry, and uncertain priors may create a spectrum or timestamp that looks persuasive while leaving counterfactual outcomes and poorly modelled interference states inaccessible. The experimental answer lies in independent validation and explicit sensitivity analysis across plausible models, carried out with explicit controls and independent retention of all the relevant receiver states. The account should quantify uncertainty components, likelihood ratios, false-positive burden, and adverse decision consequences, separating input-referred values from software-derived quantities. If the calculation assumes constant noise statistics or a linear front end, an overload or irregular interference challenge should test that premise. The examiner should preserve negative outcomes and show why the proposed mechanism is better supported than the surviving alternatives. With respect, I now return the floor to Dr. Atkinson for the next contribution.

The resulting reporting doctrine may be less dramatic than a universal percentage, but it is considerably more useful. Say, for example, that under a particular challenge protocol and specified signal state the instrument detected the defined events at a stated observed rate, with uncertainty conditional upon the trial design. Say separately that temporal coverage was incomplete, that some bursts fell outside the effective observation intervals, and that no inference about those intervals has been established. The units

Copyright 2026, James M. Atkinson

of observation, like the physical units of a measurement, determine whether a numerical statement means anything at all. Professor Feller, may I invite your question about repeating measurements whose outcomes inherit the same environmental cause?

William Feller

Peer question 3 to William Sealy Gosset

Mr Gosset, the receiver's statistical output may be especially deceptive because hundreds of FFT frames appear to constitute hundreds of observations, while each belongs to an event cluster sharing the same source, frequency drift, background state, and gain setting. It is possible to obtain a highly stable within-cluster estimate and a much less stable estimate over future environments. How should an engineer distinguish these quantities without discarding useful repeated observations? I also ask how the trial count should be interpreted for intermittent bursts whose timing may be synchronised with a periodic scan. A laboratory may generate fifty nominal bursts and congratulate itself on a low probability of missing all fifty, but if the bursts always arrive during the receiver's inactive part of the scan the nominal probability calculation is plainly irrelevant. Can a concise worked example explain both the information repeated samples provide and the information they do not provide?

William Sealy Gosset

Answer to William Feller and transfer of the floor

Thank you for that question. Professor Feller, the first step is to recognise the cluster as part of the experimental design rather than

Copyright 2026, James M. Atkinson

as an embarrassment discovered during analysis. Repeated records within a burst can be excellent evidence of that burst's detailed waveform or modulation, provided the samples and processing are preserved. They are not, without a model, independent evidence about how frequently the instrument will succeed across other transmitters and other environmental conditions. The analysis must distinguish uncertainty within a cluster from uncertainty across the population of clusters to which the claim is meant to generalise.

These examples lead to distinct claims. An accurate record of many related frames can strengthen the description of a single retained event; it cannot create independent field exposures. An accepted test based on random burst phase need not support performance against an adversary who times activity to the scan. I would have the laboratory preserve the event-cluster identifiers, the scan schedule, the realised phase relation where known, and the excluded intervals. It should evaluate uncertainty at the level appropriate to the decision being reported. If the planned use requires defence against phase-synchronised signals, the validation must challenge that circumstance directly. My work in brewing was concerned with practical variation rather than decorative quantities, and I would apply the same scepticism here. Dr. Atkinson, with respect, I pass the floor to Dr Wald to address the consequences of acting upon such bounded evidence.

I thank the questioning colleague for that important distinction. The chronology of how uncertainty and decision costs constrain a forensic receiver opinion is indispensable. Assume for a moment that a clean plot may conceal low exposure, false alarms and a costly false

Copyright 2026, James M. Atkinson

assurance. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should evaluate the detector against several predeclared signal levels and background regimes, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses. If the preferred classification changes when its threshold or sampling assumption is challenged, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states.

Copyright 2026, James M. Atkinson

Abraham Wald

Principal response. Sequential evidence, asymmetric losses, and the error of making a decision look like a measurement

Dr. Atkinson, I thank Mr Gosset and Professor Feller. My observation is that the decision to act and the statement that a physical proposition has been established belong to different parts of an investigation. An organisation may properly institute an immediate protective measure upon evidence that remains insufficient to identify a source. Conversely, an impressive statistical anomaly might warrant further measurement rather than a costly, irreversible accusation. A decision rule combines evidence with the consequences of possible errors, the available actions, and the opportunity to obtain more information. A measurement report should not disguise those normative choices as though they were inherent properties of a receiver. My historical work on sequential analysis and statistical decision functions provides the methodological perspective; the contemporary TSCM situations are constructions for this volume. [B15]

Let the hypotheses be stated without suggestive labels. H0 might mean that the observations arise from a specified combination of legitimate emissions and receiver artefacts, while H1 means that an additional emission of a defined kind is present. These are models, not descriptions of every possible world. Both can be wrong. A sequential procedure examines new evidence as it arrives and may stop when a declared rule is satisfied, or continue when the evidence is insufficient. Its claimed error rates depend upon the assumptions and the complete stopping procedure. Repeatedly checking a fixed-sample significance test and stopping whenever the result

Copyright 2026, James M. Atkinson

looks favourable is not the same procedure merely because each individual calculation was performed correctly.

The value of a sequential experiment is obvious in long-duration monitoring. A narrowband burst may emerge only after a period of valid listening; a successful controlled challenge may settle a bounded engineering question before a large scheduled campaign ends; a newly observed receiver fault may require the campaign to halt and its earlier intervals to be reclassified. None of these possibilities justifies changing the rule retrospectively to exclude difficult trials or recasting a discovery threshold as a validated test. A sequential design should identify the statistic, the incoming evidence unit, its dependence structure, the allowed stopping boundaries, and the treatment of interrupted or invalid data. Where these cannot be supported, the report should avoid promising nominal sequential error probabilities. I yield the floor courteously for the next scientific examination.

The example shows why an investigator may act protectively at a relatively low posterior probability while maintaining an appropriately cautious evidential statement. Moving equipment, preserving a recording, or extending a survey can be comparatively reversible. Publicly naming a culprit, interfering with another person's communications, or declaring that evidence proves criminal conduct may impose very different consequences and legal constraints. Those decisions cannot be made legitimate by presenting a loss table as a substitute for authority. The table merely makes the trade-off visible. It must not be mistaken for a legal permission or an ethical licence.

Copyright 2026, James M. Atkinson

A further distinction concerns the time value of evidence. If the alleged emitter is intermittent, delaying a new observation may lose an opportunity to test its existence; rushing attribution may lose the ability to distinguish a local oscillator from an external emission. The investigator can choose a low-impact action that preserves evidence while postponing a more consequential conclusion. The report should distinguish an operational recommendation from an evidentiary finding and describe what additional observation would change either. This is precisely where disciplined uncertainty becomes useful rather than paralysing.

Dr. Atkinson, I would frame the problem as follows. Before offering an opinion about how uncertainty and decision costs constrain a forensic receiver opinion, I would define the measurand and its uncertainty. The proposed rival mechanism is that a clean plot may conceal low exposure, false alarms and a costly false assurance. Consequently a calibration certificate for one nominal receiver setting does not settle the question. The more informative operation is to evaluate the detector against several predeclared signal levels and background regimes, with detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses reported in units and tied to an input reference plane. The adverse prediction is concrete: the preferred classification changes when its threshold or sampling assumption is challenged. I would challenge it across a range of input powers and hold one independently measured source constant throughout the switching sequence. A correction estimated after seeing the unknown feature may assist an exploratory analysis; it must not be presented as though it had been fixed before acquisition. Where systematic effects share a reference, their covariance belongs in the

Copyright 2026, James M. Atkinson

reported uncertainty rather than being silently assumed zero. This is the distinction between an instrument number that appears stable and a defensible physical measurement.

The laboratory should report its stopping rule and any material changes to that rule. A series of campaigns, each abandoned because it was inconclusive, cannot be represented by the one successful campaign alone if the claimed significance assumes a single prespecified experiment. Similarly, a test suspended because of invalid receiver conditions should record those conditions and explain whether the resulting absence of detections provides any information. The absence of a source may be one hypothesis; the absence of adequate observation may be an entirely different fact. Professor von Neumann, may I invite your question concerning the relationship between the mathematical decision rule, the available actions, and the limitations of its hypothetical probability model?

John von Neumann

Peer question 4 to Abraham Wald

Dr Wald, your loss comparison clarifies why a protective decision may be justified before an attribution is proved. Yet the rule depends upon posterior probabilities, costs, and available actions whose values are not directly supplied by a receiver. An engineer may construct a compact two-hypothesis model and compute a decisive number while omitting an unimagined receiver defect or an ordinary but unusual source. Furthermore, a prolonged search supplies evidence sequentially, sometimes with strongly correlated increments. How should the analyst prevent an elegant stopping boundary from acquiring the false status of a physical law? Please distinguish a sequential likelihood calculation with

Copyright 2026, James M. Atkinson

defined error properties from the ordinary habit of taking repeated looks at an evolving waterfall until one look crosses a threshold, and explain what the final report should say when the mathematical prerequisites were not satisfied.

A further constraint follows from reporting receiver findings under uncertainty and competing physical explanations. Counterfactual outcomes and poorly modelled interference states remain outside the direct observation. If the examiner reports only those cases in which the indicated feature agreed with the preferred model, what correction would you require to the exposure denominator, alternative-hypothesis analysis, and reproducibility account?

Abraham Wald

Answer to John von Neumann and transfer of the floor

Thank you for that question. Professor von Neumann, I would first require the decision analysis to be labelled as conditional upon its action set and loss assumptions. Its output is a recommendation under that model, not an estimated physical quantity. Every unmodelled alternative or material defect reduces the warrant for transferring its numerical conclusion to practice. If an omitted state could change the preferred decision, that sensitivity should be described. A decision table can help reveal where an urgent and inexpensive protective action is reasonable, but the operational authority to take that action belongs to the relevant law, policies, and circumstances rather than to the arithmetic itself.

Copyright 2026, James M. Atkinson

If the receiver's consecutive FFT frames overlap and its background model is wrong, multiplying per-frame likelihood ratios as though the observations were conditionally independent can produce grossly overstated evidence. Proper sequential analysis may model the dependence explicitly, define appropriate increments, or use empirical validation of the whole stopping procedure. One cannot simply cite a famous sequential formula and bypass the actual acquisition mechanism. It is also possible to formulate valid methods with continuously monitored evidence under different mathematical assumptions, but those assumptions must be established for the method actually used. The record must preserve not only the endpoint but the sequence of threshold comparisons and any changes made after earlier results.

I would recommend two linked report fields: “evidential status under the named measurement and inference model” and “operational decision and its declared assumptions”. This avoids confusing a decision to investigate with a statement that a device was found, and avoids disguising an unresolved event behind a phrase such as “no action required” when valid observation was incomplete. Reversibility, urgency, collateral consequences, and the possibility of further measurement should be explicit. Sir Harold Jeffreys, may I now invite your analysis of what it means to compare competing explanations when a receiver measurement can be generated by more than one cause?

I thank the questioning colleague for that important distinction. There is a statistical difficulty in the assertion concerning how

Copyright 2026, James M. Atkinson

uncertainty and decision costs constrain a forensic receiver opinion: we have not yet ruled out the possibility that a clean plot may conceal low exposure, false alarms and a costly false assurance. The investigation should record its chosen detector threshold, visit schedule, selection of frequencies and expected failure modes before the prospective confirmatory test. To examine the difference we should evaluate the detector against several predeclared signal levels and background regimes, collecting detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses over a predeclared range rather than selecting the most attractive subset afterward. An observation in which the preferred classification changes when its threshold or sampling assumption is challenged would strengthen a restricted causal account, but it cannot certify every unvisited frequency-time interval. I would state which recordings are dependent, which have been excluded as invalid, and which inferences rely upon a model of rare events or stationary interference. A numerical interval can have impeccable arithmetic and still misdescribe the physical world if its sampling population was chosen because the signal already looked unusual. We should therefore preserve exploratory leads separately from independently designed validation evidence.

Copyright 2026, James M. Atkinson

Sir Harold Jeffreys

Principal response. Likelihood, prior assumptions, and source attribution beyond the instrument reading

Dr. Atkinson, I thank Dr Wald. My observation is that a source hypothesis must be evaluated through the probability of the actual observations under that hypothesis, rather than by attaching a confidence adjective to the instrument's classification label. It is possible for a waveform to be highly unusual under one model and still be insufficient to identify the source responsible. A receiver may faithfully preserve a burst, and a validated classifier may recognise a modulation family, while several physically different devices remain capable of producing the same family. The inverse problem is not resolved by the fidelity of the forward recording. My historical engagement with inverse probability and scientific inference supplies the intellectual perspective; the modern receiver and forensic examples are newly authored. [B16, M6-7]

Consider H1, “the event was emitted by the proposed device”, and H2, “the event was emitted by an alternative device or instrumental mechanism”. Let E denote the retained evidence, and I the conditioning information that both explanations are permitted to use. The likelihood ratio is LR = P(E | H1, I)/P(E | H2, I), provided these conditional probabilities are coherently specified. A ratio materially greater than one indicates greater support from E for H1 than H2 under that pair of models. It does not mean that H1 is true with the numerical probability represented by the ratio, nor that every other possible explanation has been excluded. The chosen alternatives, data supporting the likelihood assignments, and assumptions of independence matter to its interpretation. The modern forensic literature

Copyright 2026, James M. Atkinson

emphasises the distinction between the probability of evidence given a proposition and the probability of the proposition given the evidence. [M6-7]

There is a further problem in TSCM practice. A broad claim that a signal is “unauthorised” often mixes technical observations with permission, ownership, purpose, and human conduct. Those concepts are not established by waveform morphology. A carrier can be narrow, strong, periodic, or encrypted without announcing the legal or organisational authority of the emitter. A finding that a discrete, externally coupled electromagnetic component was present within a validated input band can be well supported. A finding that the component came from a covert listening device may require additional evidence of hardware, spatial geometry, wiring, emission structure, controlled response, or content, and a claim about intentional surveillance requires still further facts. Attribution should proceed through explicit evidential transitions, not through an imaginative leap from unusual to nefarious. I respectfully return the discussion to Dr. Atkinson.

This is why the terms *false positive* and *false alarm* demand denominators. The false-alarm probability asks how a detector behaves when the defined source is absent; the post-alarm probability asks how the population of candidate explanations was distributed before observing the alarm. Neither is interchangeable with engineering amplitude uncertainty, which concerns the range and conditions of a particular measurand. The report should never turn a frequency-level p-value, a confidence bound for a trial population, or a generic classification score into a claim about an identifiable source without the necessary inference model.

Copyright 2026, James M. Atkinson

Even where Bayesian updating is sensible, an unquantified prior cannot be concealed within a precise-looking posterior. Analysts often have genuine contextual information: the physical scene, known authorised apparatus, prior survey findings, and the observed behaviour of likely interferers. Such information can help choose meaningful alternatives. It can also introduce circularity if the same observation influences both the prior and the likelihood while the resulting double use goes unrecognised. I would therefore ask that the report show the hypotheses, conditioning information, and likelihood evidence in separate statements where practicable. If the data cannot justify numerical probabilities, a qualitative and carefully bounded comparison may be more faithful than a spurious decimal.

Dr. Atkinson, I would frame the problem as follows. I should distinguish the physical occurrence under inquiry from the information actually retained when studying how uncertainty and decision costs constrain a forensic receiver opinion. Because a clean plot may conceal low exposure, false alarms and a costly false assurance, more than one historical account may produce the same saved trace. The controlled comparison should be to evaluate the detector against several predeclared signal levels and background regimes, preserving detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses at the measurement point and in the evidential metadata. If the preferred classification changes when its threshold or sampling assumption is challenged, that result would narrow the admissible explanations, not establish a uniquely identified emitter outside the tested conditions. A subsequent software reconstruction may recalculate a statistic from

Copyright 2026, James M. Atkinson

retained samples, yet it cannot recover components rejected by the front-end filter or intervals never recorded. I would make those distinctions explicit in the final report and invite an independent examiner to reproduce the challenge, including its failed steps. Scientific restraint is not a weakness of the investigation. It prevents a detector output, however striking on the screen, from becoming a claim about unobserved activity that the original measurement never established.

The comparison should remain open to a third, unmodelled possibility. H1 and H2 need not be exhaustive, and evidence favouring H1 relative to a poorly specified H2 does not establish that H1 is the only possible explanation. Receiver substitution, a different antenna geometry, direct inspection of suspect circuitry, or controlled removal of an environmental emitter may discriminate alternatives more effectively than extensive calculation applied to the same unresolved trace. Professor Box, may I invite your question about what happens when an elegant probability model fails to describe the mechanism that actually generated the spectrum?

George Edward Pelham Box

Peer question 5 to Sir Harold Jeffreys

Sir Harold, you require a likelihood ratio tied to declared explanations, but the laboratory's noise model may itself be the principal weakness. A stationary Gaussian background is convenient for deriving a threshold; real environments can exhibit impulsive interference, mixtures of operating states, intermittent electronics, and common front-end artefacts. The model might fit its central observations while failing in precisely the tails that determine alarms. An analyst can refine a likelihood model after seeing the event until the feature appears more

Copyright 2026, James M. Atkinson

persuasive, then report the final ratio without revealing the model's development. How would you prevent the apparent exactness of the calculation from becoming more persuasive than the empirical evidence for its premises? Is there a practical hierarchy of sensitivity checks and physical challenges before a numerical source likelihood ought to be reported?

May I press the principal contributor on how uncertainty and decision costs constrain a forensic receiver opinion? I am concerned with how uncertainty and decision costs constrain a forensic receiver opinion. The unresolved alternative is that a clean plot may conceal low exposure, false alarms and a costly false assurance. I should therefore separate the physical input from its representation on the receiver display. Let us evaluate the detector against several predeclared signal levels and background regimes, ensuring that the operator records detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses. The anticipated discriminating observation is that the preferred classification changes when its threshold or sampling assumption is challenged. A failure of this test would not compel us to accept a more dramatic transmitter hypothesis; it would instead mean that our proposed transfer-path model is incomplete. I would retain the measured contrary result and identify the exact connector, stimulus, receiver settings and elapsed intervals in the report. Such a procedure has a modest but valuable result: it converts an initially persuasive visual indication into an experimentally bounded account of what could have produced the retained data. Our duty is not to force agreement but to specify which physical explanations are still consistent with the recorded

Copyright 2026, James M. Atkinson

state. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Sir Harold Jeffreys

Answer to George Edward Pelham Box and transfer of the floor

Professor Box, the first question is whether the model's probability assignments are based upon evidence appropriate to the claimed population. A Gaussian null can be a useful approximation in a carefully restricted environment; it is not a property conferred upon a receiver by calling its baseline noise. When real backgrounds contain bursts, gain transitions, clipping, harmonics, and other structures, the tail probability used in an alarm calculation may differ greatly from its nominal value. The laboratory should test the relevant tails, timing dependence, and state mixtures under conditions in which the candidate is known not to be present, so far as those conditions can be established. It should also test how the source comparison changes when credible alternative models are used. [M6-1, M6-3]

A practical hierarchy begins with the physical question, not the numerical model. Establish the reference boundary and whether the alleged event survives challenges capable of distinguishing input emission from receiver response. Preserve raw data and the processing transformations needed to reproduce the feature. Examine null data that resemble the operating circumstances, including awkward cases rather than solely the quiet periods for which the model was constructed. Evaluate whether changes in threshold, background estimation, candidate selection, and

Copyright 2026, James M. Atkinson

dependence materially alter the inference. Only then consider whether probability assignments are sufficiently supported to justify a likelihood ratio. Where they are not, describe the observation and the unresolved alternatives without decorating them with an invented posterior percentage.

Model revision is lawful scientific practice when its history is preserved and its resulting performance is tested on evidence that was not simply used to choose the revision. It may produce a better explanation, but it does not retroactively convert development data into an untouched confirmation. I would also caution against treating a posterior odds calculation as a verdict about permission or culpability. An external emission might be genuine and its modulation might be characterised, while the identity and purpose of the transmitter remain uncertain. The report should travel only as far as the evidence can take it. Mr Peirce, I invite your final principal analysis of how an investigator should compare explanatory causes without treating a plausible story as an observed fact.

Charles Sanders Peirce

Principal response. Abduction, discriminating predictions, and the difference between no evidence and evidence of absence

Dr. Atkinson, thank you. My observation concerns a fundamental habit of inquiry. When an unexpected appearance occurs, one proposes a cause capable of making it intelligible. That generative step is not itself an observation of the cause. To observe a rhythmic spectral ridge and conjecture a concealed device may be a useful beginning; to write that the device was discovered without undertaking the work of distinguishing the conjecture from rivals confuses explanation with demonstration. The scientific merit of a hypothesis appears when it yields consequences that differ from those of credible alternatives, and when those consequences can be examined by a procedure whose limitations are recognised. My historical work on logic, scientific inquiry, and abduction supplies the role assigned here; the modern receiver vocabulary is an editorial application. [B17]

The temptation is especially strong when an investigator encounters an unfamiliar pattern in a high-resolution spectrum. The human visual system seeks regularity in faint structure, and a time-frequency display may reward that search with an apparently purposeful shape. The result can be an excellent stimulus to further work. It cannot itself establish purpose. A periodic burst might arise from a communication system, a switching converter, a local oscillator, a scanning service, intermodulation, or a processing artefact, depending upon the actual frequency, temporal structure, environment, and signal path. The relevant possibilities cannot be reduced to a universal catalogue; they must be developed from the present physical system and the particulars of the observations.

Copyright 2026, James M. Atkinson

Consider, for example, a candidate classified as an external signal because it appears in two receivers. If those receivers share an active antenna distributor, both could inherit the same external emission or the same distributor-generated mixing product. A controlled change in input termination, preselector state, attenuation, or physical placement may have different consequences under those hypotheses. Yet each intervention has its own limitations. Disconnecting an antenna can alter a receiver's loading and cause an oscillator or protection circuit to change state. A disappearing trace after disconnection is therefore evidence about a changed configuration, not an automatic proof that the former trace travelled through space from the suspected room. The experiment must specify the mechanism by which the change is expected to discriminate the causes. [M6-3]

There is an equal danger in a negative finding. The statement “no signal was observed” can have at least three materially different meanings. One is that a valid, adequately sensitive receiver observed the declared band and time interval and the defined signal class did not cross the prespecified decision rule. Another is that a receiver was powered on but did not possess adequate exposure or sensitivity for the target class. A third is that raw observations were not retained, and the report is limited to the absence of a saved trigger. Only the first can be considered a valid negative under its bounded test conditions, and even that does not demonstrate that every possible transmitter was absent at every moment and frequency. The absence of a retained file does not repair a gap in the physical observation.

A proper forensic conclusion would separate four levels. First, the observations: what was retained, measured, and verified. Second, the

Copyright 2026, James M. Atkinson

analytical model: what processing and calibration make those observations intelligible. Third, the explanatory comparison: which proposed causes were genuinely challenged, and what material alternatives survived. Fourth, the decision or recommendation: what should now be done, given the evidence, uncertainty, permissible actions, and consequences. The distinctions are important because one level can be reliable while another remains unsettled. A well-recorded burst may support an excellent technical description without warranting the allegation that a particular operator intentionally installed a surveillance device.

One might object that complete certainty is impossible and therefore demands for alternative explanations have no stopping point. That objection misstates the problem. The investigator need not refute every imaginable story. The investigator should identify plausible causes that materially affect the conclusion, devise tests capable of separating them when feasible, and state where the remaining indistinguishability lies. When the next experiment is impossible, prohibitively destructive, or disproportionate to the decision, a bounded finding is still possible. It can be precise about the measured event and honest about the absent attribution. The greatest practical failing is not uncertainty. It is allowing uncertainty to vanish silently as the narrative progresses from instrument screen to authoritative prose.

Dr. Atkinson, I would frame the problem as follows. The chronology of how uncertainty and decision costs constrain a forensic receiver opinion is indispensable. Assume for a moment that a clean plot may conceal low exposure, false alarms and a costly false assurance. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should evaluate the detector against several

Copyright 2026, James M. Atkinson

predeclared signal levels and background regimes, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses. If the preferred classification changes when its threshold or sampling assumption is challenged, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states.

Lord Russell, may I invite your question about the grammar of claims, especially the distinction between rejecting a proposed cause and affirmatively establishing an entirely different one?

Bertrand Russell

Peer question 6 to Charles Sanders Peirce

Mr Peirce, the language of an expert report can move from a weak observational statement to a strong existential assertion without any new evidence. If the investigator has not identified a covert transmitter, that failure of identification does not demonstrate that no such device exists. Yet the converse error is equally serious: observing a signal inconsistent with a favoured authorised source does not establish that it originated from a covert device. How should the examiner formulate logically disciplined alternatives when the hypotheses are neither

Copyright 2026, James M. Atkinson

exhaustive nor mutually exclusive, and how can a conclusion remain intelligible to a non-technical reader? I am particularly concerned with words such as *proved*, *excluded*, *identified*, *consistent with*, and *could not be ruled out*, whose apparent clarity often conceals profoundly different logical commitments.

May I press the principal contributor on how uncertainty and decision costs constrain a forensic receiver opinion? Before offering an opinion about how uncertainty and decision costs constrain a forensic receiver opinion, I would define the measurand and its uncertainty. The proposed rival mechanism is that a clean plot may conceal low exposure, false alarms and a costly false assurance. Consequently a calibration certificate for one nominal receiver setting does not settle the question. The more informative operation is to evaluate the detector against several predeclared signal levels and background regimes, with detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses reported in units and tied to an input reference plane. The adverse prediction is concrete: the preferred classification changes when its threshold or sampling assumption is challenged. I would challenge it across a range of input powers and hold one independently measured source constant throughout the switching sequence. A correction estimated after seeing the unknown feature may assist an exploratory analysis; it must not be presented as though it had been fixed before acquisition. Where systematic effects share a reference, their covariance belongs in the reported uncertainty rather than being silently assumed zero. This is the distinction between an instrument number that appears stable and a defensible physical measurement.

Copyright 2026, James M. Atkinson

With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Charles Sanders Peirce

Answer to Bertrand Russell

Lord Russell, I appreciate your caution about the proper scope of a negative finding. The decisive distinction is between what a procedure would have found under specified circumstances and what exists beyond those circumstances. A negative observation can contradict a particular predicted emission if the prediction required the event to be present during valid exposure and the instrument was demonstrably capable of recognising it. That may weaken a defined hypothesis. It does not automatically prove a universal negative. Equally, eliminating one proposed innocent cause does not prove the most dramatic remaining cause when the alternatives were not exhaustive. The structure of the propositions, not the vigour of the prose, determines the inference.

I would therefore replace the unqualified sentence “No transmitters were present” with a statement that identifies the band, interval, observation opportunity, target class, validity conditions, and decision criterion, followed by an express indication of the limitations. Where the record warrants no stronger result, a suitable form is: “During the specified valid observation intervals, no event meeting the stated detection criterion was recorded within the examined bands. This result does not establish the absence of signals outside those intervals, below the validated detection capability, or of types

Copyright 2026, James M. Atkinson

not encompassed by the criterion." This is not ceremonial caution. It tells a later examiner exactly what contrary observation would challenge the report.

The phrase "consistent with" should be used with great restraint. Almost any observation is consistent with many flexible explanations. A meaningful report should identify whether the result was expected under a stated explanation, whether its rivals also predict it, and whether the observation discriminates those rivals at all. The phrase "identified as" is stronger and should be reserved for a classification whose criteria, validation, and competing causes warrant that degree of specificity. A report may describe the observed signal as *compatible with* a modulation family while explicitly withholding source attribution. That distinction preserves the scientific discovery and avoids an unjustified allegation.

The general rule is to make each inferential step contestable. The raw observation should survive independent inspection where possible; the calibration should be traceable; the proposed explanation should yield testable consequences; and the final wording should stop where the evidence stops. Dr Shannon, I invite your question on what happens when a retained representation has irretrievably discarded information required for such a contest.

Claude Elwood Shannon

Peer question 7 to Charles Sanders Peirce

Mr Peirce, the physical event may have left only a reduced representation. Imagine an SDR system that keeps a sparse collection of

Copyright 2026, James M. Atkinson

FFT magnitudes, threshold crossings, and waterfall images while discarding phase, precise source timestamps, rejected intervals, and raw complex samples. Several different waveforms and acquisition states might yield an identical saved trace. Later examination may establish that the retained trace is internally consistent, but it cannot infer a unique predecessor when the recording operation was many-to-one. How should an examiner state this limitation without declaring all such evidence useless? Is it possible to describe a legitimate, narrower question that the reduced record can answer, while refusing a source-identification claim that would require information never retained?

May I press the principal contributor on how uncertainty and decision costs constrain a forensic receiver opinion? There is a statistical difficulty in the assertion concerning how uncertainty and decision costs constrain a forensic receiver opinion: we have not yet ruled out the possibility that a clean plot may conceal low exposure, false alarms and a costly false assurance. The investigation should record its chosen detector threshold, visit schedule, selection of frequencies and expected failure modes before the prospective confirmatory test. To examine the difference we should evaluate the detector against several predeclared signal levels and background regimes, collecting detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses over a predeclared range rather than selecting the most attractive subset afterward. An observation in which the preferred classification changes when its threshold or sampling assumption is challenged would strengthen a restricted causal account, but it cannot certify every unvisited frequency-time interval. I would state which recordings are

Copyright 2026, James M. Atkinson

dependent, which have been excluded as invalid, and which inferences rely upon a model of rare events or stationary interference. A numerical interval can have impeccable arithmetic and still misdescribe the physical world if its sampling population was chosen because the signal already looked unusual. We should therefore preserve exploratory leads separately from independently designed validation evidence. With regard to the evidence available here, which observation would cause you to withdraw the proposed interpretation, and which calibration record would let another examiner check that result?

Charles Sanders Peirce

Answer to Claude Elwood Shannon and return to the moderator

Dr Shannon, a reduced record can be highly useful if its retained information is matched to the question it is asked to answer. A time-stamped threshold log can document that a specified detector registered an event under a known configuration. A sequence of spectral magnitudes can describe energy distribution over the represented frequencies and times, subject to its analysis window, calibration, and retention rules. It need not be discarded merely because phase or raw samples are absent. The logical error begins when the analyst claims to reconstruct what the representation did not preserve, or treats a uniquely stored file as evidence that the underlying physical cause was uniquely determined.

Where the mapping from possible physical inputs to saved outputs is many-to-one, the observation establishes an equivalence class under that mapping unless additional evidence distinguishes its members. A reconstruction may select a plausible member by

Copyright 2026, James M. Atkinson

imposing a model, but that choice should be stated as model-dependent. A method that assigns a waveform to the spectral magnitude alone without the lost phase cannot promise that it has recovered the uniquely original waveform. Equally, a threshold log that contains only registered alarms does not establish what occurred during intervals in which the logging conditions were unknown. The needed limitation is not philosophical ornament; it is an engineering fact about information loss.

I would make the reporting record say what objects survive, which fields and metadata are authenticatable, which transformations were reversible for the declared question, and which conclusions rest upon assumptions not recoverable from the saved data. A subsequent controlled experiment may add source-discriminating evidence even when the earlier raw waveform is lost. It cannot retroactively place missing phase and unrecorded time intervals into the original archive. The inference should acknowledge that boundary and exploit new observations rather than imagine its way around it. Dr. Atkinson, I return the floor for a synthesis that separates the quality of a physical observation, the uncertainty of its interpretation, and the propriety of an operational decision.

I thank the questioning colleague for that important distinction. I should distinguish the physical occurrence under inquiry from the information actually retained when studying how uncertainty and decision costs constrain a forensic receiver opinion. Because a clean plot may conceal low exposure, false alarms and a costly false assurance, more than one historical account may produce the same

Copyright 2026, James M. Atkinson

saved trace. The controlled comparison should be to evaluate the detector against several predeclared signal levels and background regimes, preserving detection probability, false-alarm rate, coverage, nuisance conditions and stated decision losses at the measurement point and in the evidential metadata. If the preferred classification changes when its threshold or sampling assumption is challenged, that result would narrow the admissible explanations, not establish a uniquely identified emitter outside the tested conditions. A subsequent software reconstruction may recalculate a statistic from retained samples, yet it cannot recover components rejected by the front-end filter or intervals never recorded. I would make those distinctions explicit in the final report and invite an independent examiner to reproduce the challenge, including its failed steps. Scientific restraint is not a weakness of the investigation. It prevents a detector output, however striking on the screen, from becoming a claim about unobserved activity that the original measurement never established.

John Wilder Tukey, Cross-Peer Question to Sir Ronald Aylmer Fisher: Sir Ronald, permit me to challenge the way a discovery threshold becomes the reported significance of a finding. Suppose an analyst searches one million time-frequency opportunities, tries several FFT lengths, adjusts the waterfall contrast after seeing a candidate, and finally quotes the smallest single-cell tail area as though the frequency and analysis procedure had been chosen before the observation. A strict familywise calculation for a fixed one-million-cell search is available, but the number of independent tests is not necessarily the number of pixels, and the analyst's post-selection choices

Copyright 2026, James M. Atkinson

create additional degrees of freedom. What would constitute a defensible null experiment here? In particular, should we distinguish the chance of seeing a signal-like feature anywhere, the chance of producing a specified detection statistic in a preselected cell, and the chance that a real transmitter rather than an instrumental response produced a selected feature?

Sir Ronald Aylmer Fisher, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, I would insist upon distinct propositions and an explicit sampling procedure before attaching any frequency to an event. A significance calculation describes the behaviour of a defined statistic under a stipulated model when the procedure is repeated. It does not, merely through impressive decimal places, state the probability that the observed feature is an artefact or that a suspected transmitter exists. The one-million-cell example belongs to a known family only if the examined frequency ranges, observation intervals, selection rules and any subsequent analytical searches are accounted for. Correlated cells cannot be treated as a million independent repetitions, yet dependence does not make multiplicity disappear. A predeclared test applied to genuinely withheld recordings can assess the selected proposition more cleanly than the data that first suggested it. If a separate receiver is used, its acquisition chain and common calibration dependencies must be included. Where those conditions cannot be reconstructed, report the feature as exploratory, preserve all settings and unselected candidates, and qualify rather than disguise the inferential calculation. An investigator may still pursue an exploratory discovery, but a report must not confer retrospective experimental control upon it.

Copyright 2026, James M. Atkinson

William Sealy Gosset, Cross-Peer Question to Sir David Cox: Sir David, consider the laboratory that reports no false alarms in one hundred tests and therefore declares its receiver effectively infallible in quiet offices. Its hundred files were obtained from ten sessions, each contributing ten nearly identical traces, with the same automatic-gain-control configuration and one particularly favourable interference background. Our worked example gives an exact upper bound of about 2.95 per cent only under one hundred independent Bernoulli opportunities with common event probability. Under what conditions should the examiner regard the session, rather than the file, as the replicating unit? How should the laboratory represent the untested temperatures, source strengths and acquisition states without pretending that a simple effective-sample-size correction establishes an exact binomial confidence limit?

Sir David Cox, Cross-Peer Answer to William Sealy Gosset: Mr Gosset, the question begins by identifying the object whose probability is sought. If it is the probability of a false alarm on a specified independent search opportunity under a defined operational distribution, the laboratory must demonstrate that its trials genuinely sample that population. Ten runs of the same stored waveform do not become ten independent environmental trials merely because the software emits ten records. An exchangeable cluster model may estimate variance inflation for a mean under particular correlation assumptions; its resulting effective count should not be inserted without justification into the exact zero-event binomial expression. I would arrange fresh independent sessions, change relevant interference and equipment states according to a registered test matrix, and preserve session-level results. Hierarchical or cluster-resampling analysis may be

Copyright 2026, James M. Atkinson

appropriate when its assumptions can be assessed, although an observation of zero events places severe limits on estimating all nuisance components. The written conclusion should state the observed zero, the experimental opportunity definition, which factors varied and which did not, and the precise scope of any interval. The untested situations remain limitations, not successes hidden in the denominator.

Abraham Wald, Cross-Peer Question to Sir Harold Jeffreys: Sir Harold, our illustration makes investigation rational at a modelled posterior source probability just above nine per cent because the stipulated costs of missed detection are much greater than the costs of a precautionary inquiry. I fear that an editor might convert this operational threshold into a claim that the evidence itself is nine per cent conclusive, or that any alarm above the threshold merits naming an identified person. What separation do you require between the analyst's likelihood account, the decision-maker's prior assumptions and consequences, and a legally consequential attribution? How should a report treat an attractive likelihood ratio that omits plausible alternate emitters or whose uncertainty changes across operating environments?

Sir Harold Jeffreys, Cross-Peer Answer to Abraham Wald: Dr Wald, the calculation is legitimate as a conditional decision example and illegitimate as an evidential certificate. A loss function compares proposed actions under stated consequences; it does not create a frequency of truth for a transmitter identification. A likelihood ratio, when a defensible model exists, compares probabilities of evidence under the alternatives actually specified. Updating odds introduces prior assumptions, and omitting an important competing source can make the numerical conclusion misleading even

Copyright 2026, James M. Atkinson

when the multiplication is arithmetically correct. An expert ought to communicate observations, measured uncertainty, model comparisons, test conditions and known limitations. The official deciding whether to investigate may separately apply safety, cost, proportionality and legal standards. The expert should not smuggle those policy choices into the instrument's findings, still less elevate suspicion concerning an individual into an assertion of identity. For an unvalidated distribution of alternative emitters I would report qualified compatibility and the scope of exclusion testing rather than a spurious numerical weight. One must also disclose uncertainty in any likelihood ratio itself, not merely print a single number.

Charles Sanders Peirce, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, allow me to ask about the familiar report that a protected room was silent. The monitoring receiver inspected a channel for ten milliseconds in every hundred, while the alleged device, if it existed, might transmit bursts two milliseconds long or adjust its schedule after detecting activity. The illustration gives a twelve per cent temporal overlap probability for one uniformly phased burst and a small miss probability after fifty independent bursts. Neither assumption may describe an adaptive or periodically synchronised transmitter. What can a negative record actually eliminate, and how should a detective preserve its informational limits before an assurance of absence is conveyed to the building's occupants?

Claude Elwood Shannon, Cross-Peer Answer to Charles Sanders Peirce: Professor Peirce, the absence of a threshold crossing is information about a particular observation process. It is not a physical measurement of every emission that might have occurred outside the receiver's dwell, passband, sensitivity, linear operating range or chosen decision rule. For the stated

Copyright 2026, James M. Atkinson

uniform-phase model, overlap probability is twelve per cent, but overlap is not synonymous with recognition; the waveform must also survive filtering, gain state and processing. Fifty opportunities share the independent-trial exponent only if their relevant phases and operating states genuinely provide independent opportunities. An adversarial transmitter could defeat that assumption, and ordinary periodic machinery could make the same mistake apparent without adversarial intent. Retain a machine-readable acquisition timetable, local oscillator and clock records, selected antenna and preselector, raw data where actually retained, event thresholds and a description of coverage gaps. A useful negative finding would say that no qualifying event was detected within the monitored bands, intervals and verified performance limits. Additional methods may reduce the unexplored region of possibilities, but the report cannot turn finite observation into an absolute absence claim.

Dr. James M. Atkinson

Closing synthesis

Professor Tukey, Mr Gosset, Dr Wald, Sir Harold Jeffreys, Mr Peirce, and the seven questioning colleagues, thank you. The central result of this discussion is that uncertainty is not a singular number to be appended at the end of an otherwise unqualified conclusion. A receiver finding passes through different inferential stages, each with distinct assumptions and possible failure modes. Statistical multiplicity governs the interpretation of an anomaly selected from many opportunities. Trial design and dependence govern how measured performance may be generalised. Sequential stopping and decision costs govern certain operational choices. Likelihood comparisons govern the relative support supplied by specified evidence for

Copyright 2026, James M. Atkinson

specified competing explanations. Physical measurement uncertainty governs the relationship between the measurand and the reported value. None of these constructs, however impressive its notation, independently identifies an unauthorised person or device.

The first two principals have shown how substantial false-alarm and detection uncertainty can remain concealed by large numbers. In a million nominally independent opportunities, a one-in-a-million per-cell false-alarm probability produces at least one crossing more often than not. A zero-failure validation over one hundred ideal trials gives a nonzero upper bound, and 200 records from a few correlated clusters do not necessarily confer the precision of 200 independent exposures. A burst occurring outside a scan's active dwell is not rescued by an elaborate spectral estimator applied to data that were never acquired. These results do not discredit wideband SDR surveillance. They direct attention toward appropriate detection families, valid acquisition exposure, defensible trial units, and explicitly challenged operating conditions.

Dr Wald then distinguished the amount of support for a proposition from the decision to take an action. An organisation may properly preserve evidence, move to a safer operating state, or commission a further survey when the consequences of ignoring a plausible concern are material, provided the chosen action is lawful and proportionate. Such a decision does not license the report to promote a candidate signal to a positively identified covert transmitter. Sequential analyses must describe their stopping rules, units of evidence, and dependence assumptions. A powerful mathematical criterion applied to the wrong observation model remains a poor basis for a confident finding.

Copyright 2026, James M. Atkinson

Sir Harold Jeffreys distinguished a conditional likelihood under a source hypothesis from the posterior probability of that hypothesis. He showed why even a detector with apparently excellent operating characteristics may generate a substantial proportion of alarms from sources other than the rare target under a particular assumed population. A likelihood ratio of twenty does not mean a hypothesis has a twenty-to-one posterior probability without the prior odds and the hypotheses' scope. A third credible explanation cannot be removed by giving only two alternatives names. Professor Box's challenge sharpened the point: a perfectly executed computation does not certify that its background model describes the tails, dependencies, or changing operating states responsible for the observed event. [M6-7]

Mr Peirce, challenged by Lord Russell and Dr Shannon, brought the matter back to the logic of investigative statements. An event may have been faithfully recorded without its source having been identified. An input path may have failed without the absence of a transmitter having been established. A reduced archive may answer a question about the detector's recorded output while leaving the original phase history or the unobserved intervals unknowable. The error is not to make a limited finding. It is to hide the limitation while passing from the display to a causal narrative. An investigative hypothesis earns authority through discriminating observations, not through the elegance of the story that explains them.

Accordingly, the programme adopts a five-part reporting discipline for subsequent roundtable questions and for eventual editorial review of the volume. The report must state the physical observation and the valid exposure to which it pertains. It must identify the measurement model, the

Copyright 2026, James M. Atkinson

relevant calibration and state uncertainty, and the original evidence needed to reproduce its numerical results. It must distinguish exploratory selection from confirmatory testing and give any statistical rate its correct population, denominator, dependence assumptions, and error interpretation. It must compare material alternative explanations to the extent the evidence permits, identifying where information was never acquired or has irretrievably been lost. Finally, it must separate the supported technical finding from the operational action proposed upon it, including the lawful authority and consequence assumptions relevant to that action.

A defensible positive conclusion might read: “During the stated valid measurement intervals, an externally coupled spectral component was recorded at the declared reference plane. Its estimated frequency and temporal characteristics are reported with the identified measurement limitations. The event persisted through the specified controlled challenges; source identity and purpose remain undetermined.” That wording presupposes that the claimed external coupling was actually established by the challenges, rather than inferred only from appearance. A defensible negative conclusion might instead read: “No event meeting the validated detection criterion was observed within the stated bands and valid intervals. The result is limited by the documented sensitivity, dwell schedule, excluded conditions, and signal classes.” These are examples of the logical form a finding might take, not prewritten conclusions for any actual survey.

It remains possible to issue a precise and consequential report without pretending to exhaustive knowledge. The duty of the expert is to preserve the chain between data and proposition so that another qualified reader can examine, reproduce, and, where appropriate, challenge it. Every figure of

Copyright 2026, James M. Atkinson

merit, confidence bound, posterior comparison, or decision threshold must be attached to the model under which it has meaning. The next question should investigate a different but related boundary: how does a wideband receiver preserve reliable frequency and time relationships when multiple analogue-to-digital converters, oscillators, and processing paths must act as one measurement system? The present discussion has set the epistemic limits. The next should confront the architecture that makes such evidence possible.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 006

Worked application 1. The cost of a million opportunities. Suppose a fixed search produces M = 1,000,000 independent candidate cells under a specified null model, and the probability of a false threshold crossing in any one cell is p = 0.000001. The probability of at least one false crossing is F = 1 - (1 - p)^M = 1 - (0.999999)^1,000,000 = approximately 0.632121. Thus an apparently severe one-in-a-million per-cell threshold would yield at least one false alarm in approximately 63.2 per cent of such null searches. Independence and a correctly calibrated constant p are declared assumptions of this illustration. Neither holds automatically for an actual SDR waterfall.

Worked application 2. A bounded familywise target. If the same idealised search must keep the probability of at least one false crossing at or below A = 0.01, solve 1 - (1 - p_star)^M = A. It follows that p_star = 1 - (1 - A)^(1/M) = approximately 1.00503 × 10^-8. A conservative Bonferroni allocation uses A/M = 10^-8 without requiring the cells to be independent, provided the relevant per-test error probabilities are controlled and the family has been specified. This is a choice of statistical design, not an automatic threshold in ADC counts or decibels. Transferring it to instrument settings demands a validated relationship between the test statistic and its distribution under realistic backgrounds. [M6-1]

Worked application 3. No false alarms in one hundred trials. Assume n = 100 valid, independent Bernoulli trials with the same unknown false-alarm probability q per trial, and suppose the laboratory

Copyright 2026, James M. Atkinson

observes zero false alarms. A one-sided 95 per cent exact upper confidence bound is $q_U = 1 - (0.05)^{(1/n)} = 1 - (0.05)^{(1/100)}$ = approximately 0.029513. Zero observed failures therefore does not justify a statement that the probability is zero, nor does it establish q below one per cent with 95 per cent one-sided confidence. The bound describes the trial model and the procedure that selected those hundred units, not all conceivable receiver conditions. [M6-2]

Worked application 4. The number of clean trials needed for a stringent bound. To obtain a one-sided 95 per cent upper bound below $q_0 = 0.001$ after observing zero false alarms, require $1 - (0.05)^{(1/n)} < q_0$. Solving gives $n > \ln(0.05)/\ln(0.999)$ = approximately 2994.23, so at least n = 2995 clean, independent trials are needed for a strict “below” conclusion. The arithmetic is straightforward; the physical acquisition of 2,995 genuinely qualifying and adequately diversified opportunities may be anything but straightforward. Replaying one clean waveform 2,995 times does not demonstrate performance under unknown interference environments merely because the counter reaches the required integer.

Worked application 5. Correlated repeated trials. Suppose a simplified exchangeable-cluster model contains k = 10 clusters, each with m = 20 observations, so n = km = 200, and a common intracluster correlation coefficient rho = 0.3 for a mean of identically variable observations. The familiar design effect is $D = 1 + (m - 1)\text{rho} = 1 + 19(0.3) = 6.7$. Its variance-equivalent independent count is $n_{eff} = n/D = 200/6.7$ = approximately 29.85. This does not mean that the experiment secretly contained exactly thirty independent Bernoulli observations; it describes the loss of precision for the specified mean under the stipulated

Copyright 2026, James M. Atkinson

exchangeable correlation model. It must not be inserted mechanically into an exact binomial formula or treated as valid for arbitrary correlated event processes.

Worked application 6. Periodic dwell and a randomly phased burst. Assume a receiver observes a channel for d = 10 milliseconds every T = 100 milliseconds and that a burst has fixed duration b = 2 milliseconds. If the burst's start phase is uniformly random relative to the scan and it is recognised whenever any portion overlaps the active dwell, the probability of overlap in this idealised circular-period model is $p_{overlap} = (d + b)/T = 12/100 = 0.12$. If fifty burst phases were genuinely independent under this model, the probability of missing all fifty would be $(1 - 0.12)^{50}$ = approximately 0.001675. If, however, all fifty bursts are synchronised to the same unfavourable phase, the misses can be completely dependent, and this calculation is inapplicable. Practical detection additionally requires adequate dwell integration, signal-to-noise ratio, front-end validity, and a defined decision rule, none of which is included in the simple overlap expression.

Worked application 7. A decision threshold built from losses rather than confidence rhetoric. Suppose the decision is either to investigate an apparent source at an incremental cost $C_{FP} = 100$ arbitrary monetary units if no relevant source exists, or to dismiss the event at a consequence $C_{FN} = 1{,}000$ units if a relevant source exists. For illustration, suppose correct decisions have zero incremental loss and an available, properly calibrated posterior probability of a relevant source is r. Expected loss of investigation is $100(1 - r)$; expected loss of dismissal is $1{,}000r$. Investigation has lower expected loss when $100(1 - r) < 1{,}000r$,

Copyright 2026, James M. Atkinson

giving r > 100/1,100 = approximately 0.09091. This threshold is a feature of the stipulated losses and actions, not a universal evidential standard and not a finding that the source exists with 90.9 per cent certainty. In real investigations, additional actions, information costs, legal restrictions, and non-monetary harms alter the analysis.

Worked application 8. Illustrative sequential likelihood boundaries. In the simple two-hypothesis sequential probability ratio framework, let alpha = 0.05 denote a target upper probability of accepting H1 when H0 is true, and beta = 0.10 denote a target upper probability of accepting H0 when H1 is true. Common approximate likelihood-ratio boundaries are A = (1 - beta)/alpha = 0.90/0.05 = 18 and B = beta/(1 - alpha) = 0.10/0.95 = approximately 0.105263. A cumulative likelihood ratio L at or above A favours stopping for H1 under the specified procedure; at or below B favours stopping for H0; values between call for additional observations. These are customary approximations to a sequential design, not guarantees for any receiver. Exact operating errors depend upon the specified statistical model, discretisation, overshoot, evidence dependence, and stopping implementation. [M6-8]

Worked application 9. Why a rare target changes the meaning of an alarm. Suppose a hypothetical detector has sensitivity s = P(alarm | relevant source) = 0.90 and specificity c = P(no alarm | no relevant source) = 0.999. Suppose, solely for calculation, that the prior probability of the relevant source in the defined screening population is pi = 0.001. Then the probability of a relevant source given an alarm is P(source | alarm) = s pi/[s pi + (1 - c)(1 - pi)] = 0.0009/[0.0009 + 0.000999] =

Copyright 2026, James M. Atkinson

approximately 0.473934. The detector's one-per-thousand false-alarm probability conditional on absence of source is not a 99.9 per cent probability that any particular alarm identifies a real source. The hypothetical base rate is not a claim about the prevalence of covert surveillance in any population. The formula also assumes that the specified sensitivity, specificity, and prior apply to the case under consideration.

Worked application 10. A likelihood ratio does not erase the prior odds. Suppose a qualified model yields a likelihood ratio LR = 20 in favour of H1 over H2. If the prior odds of H1 to H2 are 1:99, posterior odds become 20:99 under Bayes' rule, and the corresponding posterior probability of H1 within this two-hypothesis model is 20/(20 + 99) = approximately 0.168067, or 16.8 per cent. If another plausible prior or an unmodelled third source changes the calculation, the original 16.8 per cent is not a portable property of the waveform. The likelihood ratio concerns the comparison of two stated models; its conversion into odds introduces assumptions not contained in the signal alone.

Sources and read scope. Question 006

The dialogue, numerical examples, reporting formulations, and hypothetical receiver cases are original educational material. Bracketed keys identify sources supporting selected historical or methodological premises, not the imagined words of the contributors. Source pages described below were consulted on 9 November 2026. QUESTION 007

Copyright 2026, James M. Atkinson

When may observations, bearings, and timing evidence support localisation or attribution of an electromagnetic source?

Source: V011_Roundtable_Q001-Q011_CP011_Integrated_Candidate(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Original educational reconstruction. The historical participants did not take part in this conversation, and none of the speeches is offered as a quotation. All places, observations, numerical readings, alleged devices and investigative decisions are hypothetical. Source notes identify technical background, not documentary proof of the constructed exchanges.

Dr. James M. Atkinson

Opening question

Sir Edward Appleton, may I invite you to examine the distance between an observed spectral event and an identifiable emitter? Our preceding question distinguished the probability of a feature under a specified noise model from the probability that a proposed cause is true. We now approach a harder inverse problem: the examiner has an electromagnetic trace, perhaps several bearings and a timestamp, and is tempted to give that trace a street address, an instrument serial number or even an owner. The display can be brilliant and the uncertainty unobtrusive. Neither the beauty of a waterfall nor the apparent sharpness of two converging bearing lines determines what the waves have crossed before reaching the receiving apparatus.

Consider a protected building in which an intermittent, frequency-agile emission has been observed near a sensitive office. A stationary receiver

Copyright 2026, James M. Atkinson

first discovers the feature with one antenna. A second station later records something similar, and the investigator draws two bearing rays on a plan. Yet the first receiver shared its time reference with several channels; both antennas have patterns altered by adjacent metalwork; and part of the supposed source's activity occurred while neither receiver was actually dwelling at the relevant frequency. The event might originate within the building, beyond it, or from an otherwise unremarkable device whose signal has been redirected through glass, steel and masonry. The first evidential obligation is therefore to say exactly what was observed at each physical and computational boundary.

Our question is not whether direction finding is useful. It is indispensable when its physical, geometrical and statistical requirements are met. Our question is how the examiner distinguishes an angle measured at an antenna from the direction of a direct ray to a transmitter, the intersection of nominal rays from a justified position estimate, the recurrence of a waveform from proof of common source identity, and a source location from an accusation against a particular person. An uncertainty ellipse may be more persuasive than a confident pin, but even its boundaries can be wrong when the assumed error distribution omits a systematic reflection.

I propose that the panel travel through five distinct problems. Sir Edward Appleton will examine propagation and the physical meaning of arrival direction. Sir Martin Ryle will examine arrays, baseline calibration and ambiguities in phase and angle. Professor Ronald Bracewell will address inverse-source inference and the loss of uniqueness when incomplete field measurements are made to carry an elaborate narrative. Professor Rudolf Kalman will examine tracking, dynamical models and observability.

Copyright 2026, James M. Atkinson

Professor Dennis Gabor will return us to coherence, retained information and the temptation to extract identity from patterns that have several plausible causes. Seven colleagues will question the principals. Each question will receive its answer before a courteous transfer of the floor, so that a point of disagreement is neither evaded by the next speech nor hidden under unanimity.

We shall also work ten numerical examples, with every variable, assumption and unit declared. Such calculations illustrate the constraints of a method; they do not certify a particular monitoring installation. At the conclusion I shall request an evidence ladder, beginning with a recorded numerical feature and ending, where the evidence allows, with an expressly bounded account of source class, probable location and attribution. Sir Edward, as one whose study of radio propagation helped make the invisible atmosphere experimentally intelligible, would you distinguish the measured direction of arrival from the geographical assertion which an investigator may wish to draw from it?

Copyright 2026, James M. Atkinson

Sir Edward Victor Appleton

Principal response. Propagation, reflective geometry and the unearned certainty of a bearing

Dr. Atkinson, I am grateful for that exact separation. A receiving antenna does not observe an address. It receives a field, or more precisely responds to the component of an electric or magnetic field to which its effective aperture, polarisation, installation and connected receiver make it sensitive. The arrival of a wave at the aperture may be a direct component, a diffracted component, a reflection from a façade or a mixture of paths whose relative amplitudes and phases vary with time. One must therefore distinguish the measured direction of a dominant field component from the direction in which a physical transmitter lies. In many circumstances those directions are approximately equal, and direction finding is productive. The approximation must nevertheless be earned by the conditions, not granted by the title of the instrument.

The caution becomes particularly urgent in the high-frequency bands. A wave returning from the ionosphere may reach a receiver at an elevation and azimuth shaped by electron density, geomagnetic conditions and the geometry of the path, not by simple terrestrial line of sight. If an investigator treats a skywave bearing as though it were a ground-wave bearing, the arithmetic of an intersection may be impeccable while the geographical premise is wrong. A change of ionospheric state can move an apparent arrival direction without any motion of the transmitter. A second station, seeing a different mixture of propagation paths, may report a bearing that seems incompatible. Such disagreement need not incriminate either instrument. It may reveal different observations of a nontrivial field.

Copyright 2026, James M. Atkinson

The lower-level record must therefore contain frequency, antenna location and orientation, mounting conditions, polarisation response where known, receiving bandwidth, integration interval, signal-to-noise circumstances, interfering signals and calibration state. Where the method depends upon a direct-ray assumption, the analyst should record how that assumption was challenged. An antenna relocation, a change of height, a different polarisation or measurements on multiple independent paths can be informative precisely because the reflected component may change differently from the direct component. Yet a changed result is diagnostic only when the change of procedure is documented; moving equipment without preserving coordinates and cable states replaces one unknown with another. I yield the floor courteously for the next scientific examination.

The temptation to suppress unfavourable bearings is dangerous. If the investigator retains two agreeable rays out of twelve, the displayed crossing conceals an earlier choice made after seeing the evidence. A disciplined analysis preserves all valid bearings, records exclusions with reasons fixed independently of the desired source position, and tests sensitivity to plausible systematic errors. One may use robust estimation or a mixture model when reflections produce outlying paths, but those methods must be specified and validated for the observation class. Statistical ingenuity cannot turn unobserved direct paths into observations.

I also distinguish localisation from identification. A sustained emission detected from a confined area can materially narrow a search. Still, shared modulation, oscillator phase noise or a recurring schedule can arise from several transmitters or a common external reference. Conversely a single transmitter can emit differently after warming, changing gain or selecting

Copyright 2026, James M. Atkinson

another operating mode. A similarity measure must therefore be described as a similarity measure, with its conditions, rather than presented as a permanent fingerprint of an individual object. This is especially important in forensic reporting, where the words 'from this room' and 'produced by this person' occupy different evidential categories.

It is proper that our report end with a bounded proposition. We might say that two specified receivers observed a feature whose tested directional estimates are consistent with a defined region under a calibrated direct-path model, while stating the remaining multipath alternatives. We should not say that those rays prove where the transmitter stood unless the physical model and its adversarial challenges support that narrower possibility. I should welcome the scrutiny of Mr Heaviside, who may ask whether the very language of a ray is too simple a description of a field near conductive structures.

A further constraint follows from the defensible scope of localisation and electromagnetic-source attribution. An instrument specification does not by itself establish the result of a field experiment. A preselector may reject one interfering band while leaving a different ingress path; a sample clock may be stable in the mean while its phase fluctuates; and a file may be authentic while the analogue interpretation remains contested. The expert should distinguish a certificate describing a manufacturer test condition from a verified statement about the present configuration. Record the intervention and its physical reference, the raw output where available and the particular source hypothesis which the intervention could actually exclude. Applied to the present engineering problem, reflections, clock offsets, antenna-pattern errors, and non-identifiable inverse solutions may create a spectrum or

Copyright 2026, James M. Atkinson

timestamp that looks persuasive while leaving line-of-sight paths and true source positions concealed by multipath inaccessible. The experimental answer lies in independent sites, calibrated clocks, geometry variation, and residual analysis, carried out with explicit controls and independent retention of all the relevant receiver states. The account should quantify angular error, propagation delay, baseline length, clock uncertainty, and confidence region, separating input-referred values from software-derived quantities. If the calculation assumes constant noise statistics or a linear front end, an overload or irregular interference challenge should test that premise. The examiner should preserve negative outcomes and show why the proposed mechanism is better supported than the surviving alternatives. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Oliver Heaviside

Peer question 1 to Sir Edward Appleton

Sir Edward, thank you for restoring the field to an argument which too readily becomes a map. I should like to distinguish the distant, propagating component of a field from the induction and scattering phenomena in the vicinity of conductors. Imagine a survey antenna only a short distance from a cable tray, an equipment enclosure and a bundle of energised wiring. The recorded response might combine an external plane-wave component with a local current-induced field and a re-radiated signal from the metalwork. Yet the operator may aim the antenna until an apparent null appears and then publish a bearing towards the alleged transmitter. In what circumstances would you treat that null as a geometrical observation, rather than as a property of the

Copyright 2026, James M. Atkinson

antenna's local coupling environment? And how should the investigator test the hypothesis that the structure itself, rather than a hidden transmitter at the apparent intersection of rays, generated the directional contrast?

Sir Edward Victor Appleton

Answer to Oliver Heaviside

Mr Heaviside, your distinction is essential. The plane-wave approximation does useful work in an appropriate far-field region, but a receiver positioned beside a conductive assembly may be measuring a vector sum created by boundary conditions, local coupling, standing waves and re-radiation. An apparent null can therefore move when the operator moves the antenna by a small fraction of a wavelength, even though the remote emitter has not moved. The null is a repeatable feature of the measurement arrangement only if its state and geometry are preserved. The word bearing is too generous where the experiment has not established that the relevant observable is monotonically or uniquely related to azimuth.

A practicable challenge would record the antenna's trajectory, height, polarisation, cable route and instrument settings, then compare predictions of at least two hypotheses. Under a direct far-field model the direction should remain consistent after translating the antenna within a declared region, allowing for predictable parallax when applicable. Under a local-coupling model the null may be highly sensitive to cable position, nearby conductor geometry or the orientation of a shielding enclosure. A separately calibrated

Copyright 2026, James M. Atkinson

antenna, a field probe of another type or a test with the suspect structure safely disconnected may provide additional evidence. Disconnection is an intervention, not a conclusion: any signal change must be reconciled with the broader electrical network that the intervention also altered.

The test must also protect against an interpretative error in which a legitimate change of signal intensity is translated into a change of source position. If a conductor carries current induced by an external field, varying its connection or terminating impedance can change the local field without establishing that a transmitter was attached to it. The report should say that a coupling path was modified, describe the observed response and retain the external-emitter hypothesis until an experiment discriminates between them. Where switching a circuit is unsafe or operationally prohibited, the limitation must be stated instead of replaced by imagined intervention results.

The physically valuable output is an account of conditions under which the contrast persisted and conditions under which it disappeared. If an investigator finds that the alleged bearing follows a cable route rather than a position in space, the localisation claim must be withdrawn or reformulated as a coupling-path observation. None of this forbids subsequent localisation; it supplies better constraints for it. I thank you for pressing the matter, and pass the discussion to Lord Rayleigh for the array's limits of angular discrimination.

Copyright 2026, James M. Atkinson

Lord Rayleigh

Peer question 2 to Sir Edward Appleton

Sir Edward, may I ask whether the desire for a sharp directional peak can outrun the actual resolving power of the receiving aperture? The experimenter may possess several widely separated antenna elements and a processor that paints a remarkably narrow lobe on a screen. Yet the observed field includes finite observation time, uncertain phase, variable source strength and two nearby rays whose separation is smaller than the information supported by the apparatus. Would you oblige the examiner to distinguish the angular width of the display's interpolated peak from demonstrated resolution between two sources? In addition, could a single dominant peak, arising from unresolved direct and reflected components, justify a one-source assumption when the hypothesis at issue is whether a second and weaker device is present? I would also ask how you would challenge a processor that reports a single elegant angle when the true field contains two unresolved arrivals. Would you require controlled dual-source tests, and should the uncertainty statement include the rate at which the instrument silently merges those alternatives rather than merely reporting random variation when one source is present?

Sir Edward Victor Appleton

Answer to Lord Rayleigh and transfer of the floor

Lord Rayleigh, I would not accept display smoothness as a substitute for tested resolving power. An estimator can interpolate a maximum to a fraction of a plotted angular bin while remaining biased or unable to separate two nearby components. Resolution,

Copyright 2026, James M. Atkinson

uncertainty and bias must be distinguished. Resolution concerns the discrimination of alternatives, precision concerns variation under a repeatable model and accuracy concerns closeness to the intended physical quantity after systematic effects are considered. A narrow peak can coincide with a wrong direction. A broad peak can still provide useful exclusion of certain directions when its calibration supports the assertion.

The burden is an empirical one. The laboratory should challenge the array with known angular separations, frequencies, relative amplitudes, polarisations and coherent or incoherent signal conditions relevant to the surveillance task. It should report the cases in which two sources were merged, one was missed, or a reflected component drew the estimate away from the true line of sight. The number of plotted degrees is not the number of degrees warranted by the evidence. Equally, the mere theoretical possibility of another source need not defeat a narrowly supported one-source approximation when the intended claim is explicitly conditional and the alternatives have been bounded by experiment.

I would additionally require the laboratory to record the rule by which a result is called one source or two. If that rule is chosen after viewing the test population, a claimed resolution threshold may be optimistically biased. Controlled cases should include unequal source levels and changing phase relationships as well as equal-level signals, because a strong component can conceal a weaker one. The probability of merging sources and the probability of inventing a spurious second source are distinct performance measures. An

Copyright 2026, James M. Atkinson

examination report should state which of those risks matters to the proposition being advanced, and whether the apparatus was actually validated against it.

Your point connects the atmospheric and local-field ambiguities to the architecture of the receiving array. I therefore respectfully pass the floor to Sir Martin Ryle, whose work with radio interferometry makes the relationship between baseline, phase and reconstructed structure especially instructive. Sir Martin, would you examine what a phase comparison can and cannot identify when the clocks, cables and geometry are imperfect?

Copyright 2026, James M. Atkinson

Sir Martin Ryle

Principal response. Baselines, coherence and the ambiguity of phase

Dr. Atkinson, thank you. An interferometric observation is a comparison across paths and receivers. Its value lies in a carefully governed relationship between phase, delay, frequency, array geometry and the field whose arrival is being assessed. This relationship can provide finer angular discrimination than a single small aperture. It does not annul the requirement to know the instrumental phase, reference position and frequency-dependent transfer of each branch. When an investigator offers a high-resolution bearing, I would first ask for the phase-calibration history and the validity range of the model used to convert the measured complex correlation into that bearing.

For two antennas separated by a baseline vector b and observing a plane wave from a unit arrival vector u, the ideal geometrical delay may be written $\tau g = (b \cdot u)/c$, with the sign determined by the declared convention; c is the speed of light in vacuum. In a real installation the measured delay or phase difference may also contain differential cable delay, local oscillator offsets, clock errors and contributions from reflected wavefronts. If the analyst treats their sum as wholly geometrical, an electronic problem becomes a supposed source displacement. Moreover, a single baseline constrains only one projection of arrival direction. A geometrically complete location requires further independent constraints, and that independence can be undermined by common systematic errors. With gratitude for the challenge, I invite Dr. Atkinson to continue the discussion.

The sampling interval also warrants precision. A receiver can sample its own oscillator faithfully and still provide a poor inter-receiver timing comparison. When stations have independent clocks, their relative offset

Copyright 2026, James M. Atkinson

and drift must be established over the event interval. When they share a reference, their common error may cancel for some relative observables but remain in an absolute timestamp or source-frequency estimate. The covariance structure changes with the architecture. A claim that two channels 'agree' should identify whether that agreement is evidence of the external field or a product of their shared reference.

A particularly subtle problem arises when the carrier cycles many times over the possible delay. The phase is measured modulo a complete turn. Multiple directions may yield the same measured phase unless the baseline, bandwidth, ambiguity resolution and other information are sufficient. Phase unwrapping is a model-based inference; its success is not verified by producing a smooth bearing trace. To validate an unwrapped trajectory, one should ask whether alternate integer-cycle assignments remain compatible with the measured data under realistic noise and drift.

A validation report should also distinguish a geometric baseline, which is the surveyed separation of antenna reference positions, from an effective phase baseline, which may vary with frequency and with the response of individual elements. If a cable becomes warmer, its propagation delay may change without the surveyor moving an antenna by a millimetre. If a receive chain retunes its oscillator, a phase discontinuity may render earlier phase-calibration constants inapplicable. The admissible inference therefore depends not merely on the diagram of the installation but on a recorded sequence of configurations and phase-reference checks. A field calibration taken yesterday is not equivalent to one demonstrably applicable during the disputed event, and the distinction should be apparent in the uncertainty budget.

Copyright 2026, James M. Atkinson

Finally, a reciprocal test can isolate system behaviour from source behaviour. Inject a controlled reference through specified ports, interchange receivers where practicable, or rotate the calibrated array relative to the scene. Each intervention changes a known subset of the physical relationship. A valid design predicts what should remain invariant and what should transform. The strongest evidence is not the experiment in which every plot agrees, but the one in which a materially different hypothesis would have yielded a distinguishable result. Professor Lorentz may challenge whether the propagation medium and phase reference have been separated as cleanly as my equation implies.

Dr. Atkinson, I would frame the problem as follows. The chronology of whether bearings and timing could localise a radiating source is indispensable. Assume for a moment that correlated multipath can give a deceptively narrow intersection between imperfect bearings. In that case, rearranging snapshots to create a smooth chart will conceal the sequence of instrumental changes. We should move antenna baselines and repeat calibrated phase-centre measurements at independently logged times, and treat time spent switching, settling or clipping as measured invalidity rather than as an unoccupied channel. The state record needs antenna phase centre, geometry, covariance, clock offset and propagation environment. If a spurious intersection moves with the reflective surroundings instead of following a fixed emitter position, the first obligation is to determine whether the apparent motion in the display arose from the receiver or from the observed field. I would repeat the initial configuration after the challenge to expose drift, and I would preserve the records that fail to match the opening measurement. An operator may fairly publish a difference

Copyright 2026, James M. Atkinson

between the two visits, but may not infer a unique intervening event when the acquisition supplied no valid samples at the relevant instant. The result must be reported as a chronological comparison under named operating states.

A more precise objection comes from Sir Martin Ryle and the finite observation aperture in when may observations, bearings, and timing evidence support localisation or attribution of an electromagnetic source?. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when alternative receiver operation or selection bias. For that reason, record time reference, calibrated gain, detector threshold, and valid exposure for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After repeat with independently calibrated reference equipment under controlled conditions, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. Professor Lorentz, I invite your examination of the difference between cable-calibrated array delays and the paths taken by a wave reflected from a metal roof; those are not interchangeable geometries.

Hendrik Antoon Lorentz

Peer question 3 to Sir Martin Ryle

Sir Martin, your geometric delay equation is admirably compact, but I should like to press upon its implicit medium and reference. Imagine an

Copyright 2026, James M. Atkinson

array whose channels are phase-calibrated with a cable-fed reference, then used to observe a field reflected from a metal-roofed building. The cable calibration demonstrates a relationship among the electronic branches, while the field trial introduces the antennas, their mutual coupling and a frequency-dependent propagation path. If the system reports a constant offset from the desired bearing, does that offset represent a calibration correction, a scene-dependent scattering effect or an alternative source direction? Can the record establish this distinction without a field reference of known position and a deliberate variation of the scattering environment? I am especially concerned about a supposed calibration correction obtained by subtracting one offset found in a single trial. What evidence would distinguish a generally transferable correction from a number that merely compensates the particular reflector geometry on that occasion, and what residual experiments would expose the difference?

Sir Martin Ryle

Answer to Hendrik Antoon Lorentz

Thank you for identifying the principal uncertainty in this evidence. Thank you for that question. Professor Lorentz, I agree. An internal reference can be indispensable while remaining insufficient for the external measurand. The cable-fed comparison tests much of the receiver chain, but may bypass the antenna phase centre, mutual coupling, radome or housing, and propagation from a known point in space. Consequently, its success cannot certify the whole array for a particular scene. Nor should an offset observed on one trial be added indiscriminately as a universal correction. The correction is justified

Copyright 2026, James M. Atkinson

only over the conditions for which its dependence has been characterised, including frequency, array orientation and surroundings.

A deliberate set of contrasts is needed. A field source of known position and controlled frequency can quantify the array's response under a specified site configuration. Repeating the trial at differing heights and azimuths helps separate stable instrumental bias from site-dependent scattering, although the separation remains conditional on the adequacy of the field model. Swapping electronic channels while retaining antenna positions challenges receiver-path bias; swapping antenna connections can challenge a different subset of hypotheses. Moving the entire array or changing the environment is useful when the shift is recorded accurately, but it also changes the observed propagation and thus cannot be interpreted by simple subtraction without a physical model.

A particularly useful record is a partition of the calibration path. The frequency reference may reach a synthesiser, the synthesiser a mixer, the mixer an intermediate-frequency converter, and the converter a sampler; a successful loopback test may still omit the antenna and propagation. Marking those boundaries allows the expert to say exactly which errors an intervention could expose. It also prevents the comforting phrase 'fully calibrated' from concealing several distinct physical relationships. If later measurements show a stable bias under one environment, the resulting correction belongs to that environment until transfer has been demonstrated. It is not a free-standing property of the receiver's model number.

Copyright 2026, James M. Atkinson

The investigator should preserve a layered uncertainty account. Electronic calibration uncertainty, antenna-placement uncertainty, phase-centre uncertainty, and model discrepancy from the environment need not be independent or Gaussian. When the latter dominates, reporting a narrow confidence interval derived solely from instrumental noise would be unsound. A properly qualified statement might say that the observed phase difference is compatible with an arrival sector under a specified calibrated propagation model, while alternative scattering configurations remain unexcluded. I thank you for demanding that the external wave be admitted into the calibration argument.

John Daniel Kraus

Peer question 4 to Sir Martin Ryle

Sir Martin, let me ask about a more practical failure. A wideband monitoring array is advertised with a single angular accuracy figure, even though its electrical aperture, matching, mutual coupling, feed phase and pattern vary across the band. The direction-finding processor returns the same nominal number of decimal places whether a signal is strong and persistent or a brief burst arrives near the threshold. Should a forensic team publish one uncertainty figure across the band, or should it define separate acceptance regions by frequency, dwell, signal class and installation? And what evidence would be required before measurements from a narrow-aperture sector could be pooled with those from a frequency at which the array has substantially greater electrical size? I would further ask whether a published specification may be carried unchanged from one vehicle roof or equipment rack to

Copyright 2026, James M. Atkinson

another. If installation changes the ground plane and coupling, surely the competent examiner needs evidence that the original performance envelope survives those changes, rather than assuming it survives by name.

Sir Martin Ryle

Answer to John Daniel Kraus and transfer of the floor

Professor Kraus, one figure may summarise an instrument for procurement, but it rarely suffices as an uncertainty statement for a particular contested event. Accuracy is an attribute of a defined measuring process under specified conditions. Frequency alters the electrical size of the aperture, the effect of cable delay, the phase of mutual coupling and the array's susceptibility to ambiguous lobes. The burst duration controls how many independent or nearly independent measurements the processor can accumulate. The relevant confidence statement must therefore be conditional on a documented operating envelope and on evidence that the event actually fell within it.

If tests justify an uncertainty function or a set of validated strata, those can be reported without pretending that every condition deserves a wholly bespoke investigation. A sensible programme might classify frequency ranges, source modulation classes, signal strengths, dwell durations and site configurations. Within each class it would record systematic bias, random variation, invalid-result rates and the possibility of multiple resolved directions. The pooled estimator should then account for differences among classes rather than simply average their values. Averaging biased bearings from

Copyright 2026, James M. Atkinson

different frequencies may create a pleasingly stable number while masking a changing physical relationship.

When data from different validated strata are pooled, the calculation should explicitly model their relative weights and common influences. An error shared by all frequency settings, such as a mistaken antenna position, will not diminish because many independently noisy estimates have been averaged. Conversely two installations that produce disagreeing bearings may be revealing a systematic effect that no one-setting calibration can detect. I would preserve such discrepancies in the report rather than delete them to make the combined result look tidier. The point is not to multiply uncertainty figures without purpose, but to connect each figure to a physically defined measurement condition.

The governing doctrine is to report what the validation actually covers and to preserve when an event falls outside it. A transient detected for only a few milliseconds may support event discovery but not the same directional certainty as a sustained reference. A differently installed antenna may retain the signal but invalidate the earlier site-specific calibration. I therefore pass the floor to Professor Ronald Bracewell, whose account of reconstruction can place this geometrical evidence within the larger problem of deciding what, if anything, uniquely caused it.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell

Principal response. Inverse sources, observational equivalence and the limits of a reconstructed image

Dr. Atkinson, I should begin by distinguishing a reconstruction that displays the consequences of a model from a discovery that proves the model uniquely true. A receiver samples a field through an antenna, an analogue front end, an acquisition process and a computational representation. A map or bearing estimate is then calculated by applying an inverse operator, an optimisation rule, or a model-conditioned likelihood. The resulting picture can possess striking detail. Yet detail in a reconstructed output may reflect the constraints imposed by the algorithm, including its assumed number of sources, permitted positions, smoothness penalties and treatment of missing samples. It is not a photograph taken by an omniscient electromagnetic eye.

One should ask whether materially different arrangements could have produced the observed input. A direct emission from one location and a reflection from a different emitter may have similar time-frequency characteristics at a particular receiver. Two narrowband emitters can be unresolved within a chosen dwell. A harmonic from an external transmitter may imitate a fundamental from a local device when front-end nonlinearity or mixer images have not been excluded. In each case the observation constrains possibilities, but its inverse is non-unique unless additional data or assumptions discriminate among them. When the assumptions are plausible but untested, they belong in the report as assumptions rather than disappearing into a numerical estimate.

Copyright 2026, James M. Atkinson

The concept of an equivalence class is valuable. Let Y denote the retained receiver observations, let H_i represent a candidate physical source and propagation account, and let $F(H_i)$ represent the observations predicted by that account under an explicit instrument model. Distinct hypotheses H_1 and H_2 may satisfy $F(H_1) \approx F(H_2)$ within measurement uncertainty. Their apparent equivalence is not necessarily perfect, and additional intervention may break it. But one cannot use a result from the inverse operator F^{-1} to claim a unique H when F maps many admissible causes into effectively the same Y. The correct practical question is which additional measurement will separate the candidates at acceptable cost and without destroying evidence.

A useful workflow therefore constructs rival predictions before the next measurement. If a supposed local transmitter drives a cable or near-field path, changing an antenna's position relative to that cable may change signal intensity in a distinctive manner. If the feature is a second-order mixer product, altering preselection or front-end gain may change its behaviour in ways a real external carrier does not. If the signal is a reflection of an external emitter, a shielded reference antenna positioned outside the structure might retain the original transmission while the indoor observation changes. These are tests only if the expected outcomes under each alternative are sufficiently distinct, and if the intervention does not introduce a competing artifact. I pass the floor to the next participant with thanks for this considered exchange.

The panel should resist a related confusion between detection and attribution. The observation of a recurring digital sequence may justify a claim that a common waveform pattern is present. It may not establish that the same hardware emitted the pattern, for an authorised repeater, a

Copyright 2026, James M. Atkinson

playback, a networked system or another transmitter using the same protocol may reproduce it. Even a carefully measured analogue imperfection is a feature subject to stability testing and population overlap. Without an appropriate population and validation model, the uniqueness of a 'fingerprint' is rhetoric, not an observed statistic.

Reports can make the inverse nature of the argument visible. First present the observed data and their acquisition conditions. Then describe the forward model and the assumptions on which the inversion depends. Then give the resulting estimate with its statistical and systematic uncertainty. Finally list plausible alternatives not excluded, together with specific experiments that would distinguish them. A document ordered in this fashion permits a second examiner to disagree about the model while still understanding the measurements. That is a stronger form of reproducibility than asking the second examiner merely to obtain the same position icon from the same software.

Professor Poincaré, I should be grateful for your challenge concerning what counts as a genuine solution when several physical configurations explain the data equally well.

Dr. Atkinson, I would frame the problem as follows. Before offering an opinion about whether bearings and timing could localise a radiating source, I would define the measurand and its uncertainty. The proposed rival mechanism is that correlated multipath can give a deceptively narrow intersection between imperfect bearings. Consequently a calibration certificate for one nominal receiver setting does not settle the question. The more informative operation is to move antenna baselines and repeat calibrated phase-centre measurements at independently logged times, with

Copyright 2026, James M. Atkinson

antenna phase centre, geometry, covariance, clock offset and propagation environment reported in units and tied to an input reference plane. The adverse prediction is concrete: a spurious intersection moves with the reflective surroundings instead of following a fixed emitter position. I would challenge it across a range of input powers and hold one independently measured source constant throughout the switching sequence. A correction estimated after seeing the unknown feature may assist an exploratory analysis; it must not be presented as though it had been fixed before acquisition. Where systematic effects share a reference, their covariance belongs in the reported uncertainty rather than being silently assumed zero. This is the distinction between an instrument number that appears stable and a defensible physical measurement. I pass the floor to Professor Poincaré, whose scrutiny of an ill-conditioned inverse should reveal when a seemingly precise bearing becomes an unstable source location.

Jules Henri Poincaré

Peer question 5 to Ronald Newbold Bracewell

Professor Bracewell, I welcome your distinction between the forward relation and its inverse. Let me extend it to the stability of the inverse. Even when a mathematical model yields a unique answer in an idealised noiseless setting, a minute error in arrival angle, phase or time may produce an enormous displacement of the inferred source when the geometry is ill-conditioned. An optimiser can nonetheless return one attractive coordinate because it must return something. How would you require an expert to demonstrate not merely the uniqueness of a nominal solution but its stability under realistic perturbations, including uncertain station position, clock error, propagation bias and algorithm

Copyright 2026, James M. Atkinson

selection? And when two different source explanations are both stable within their restricted models, on what basis may one be preferred without smuggling the investigator's suspicion into the prior assumptions? Would you include a method for detecting a second, distant optimum that a routine local uncertainty calculation might miss? I am concerned that one reported confidence ellipse may describe only the neighbourhood of an arbitrarily selected solution while a rival physical interpretation remains equally consistent with every received sample.

Ronald Newbold Bracewell

Answer to Henri Poincaré and transfer of the floor

Professor Poincaré, I would separate mathematical identifiability, numerical stability and evidential discrimination. A solution is identifiable when distinct admissible model parameters lead to distinguishable probability distributions or observables, under the model actually asserted. It is stable when reasonable perturbations of data and nuisance parameters do not drive the reported quantity beyond a declared tolerance. It is evidentially discriminating when plausible competing physical accounts fail against some observation they should have explained. These are related but not interchangeable requirements. A unique maximum of an optimisation routine may satisfy none of them.

The examination should therefore include perturbation analysis. Recompute the estimate under the measured uncertainty of station coordinates, antenna orientations, cable delays and clock offsets. Vary the model of multipath within justified bounds. Use alternative

Copyright 2026, James M. Atkinson

initialisations and, where legitimate, different estimation families. Report multimodal solutions rather than concealing secondary peaks. A confidence set constructed only from local curvature around one optimum may be disastrously narrow if the objective has a remote second optimum or if model error dominates random noise. The investigator should preserve the likelihood surface, residual maps or appropriate equivalent, not merely the maximum's coordinates.

Selection among two adequate explanations may rest on a prior or on practical consequences, but the basis must be exposed. A model comparison may be legitimate when the prior, nuisance treatment and sampling frame are defensible, and the result should be sensitive-tested against reasonable alternatives. A physical intervention that causes the two hypotheses to predict different outcomes is usually more valuable than sharpening an untested preference. If the rival accounts remain observationally equivalent, the report must say so. Such restraint is not a confession of incompetence; it is the scientifically precise description of the evidence's reach.

One should also test the effect of the search bounds themselves. An algorithm restricted to the surveyed building will necessarily produce a point within that building even if the true source lies outside it. A result that moves towards a boundary when the permitted region is enlarged signals dependence on the constraint, not proof of occupancy. Stating the model domain and comparing wider alternatives are therefore elementary safeguards against an

Copyright 2026, James M. Atkinson

inverse solution manufactured by the investigator's original area of suspicion.

The next difficulty concerns whether a succession of bearings can identify a moving source. That question introduces dynamics and temporal dependence, so I pass the floor with respect to Professor Rudolf Kalman. Professor Kalman, how should an investigator prevent a tracking algorithm's smooth trajectory from becoming a false story of motion?

Copyright 2026, James M. Atkinson

Rudolf Emil Kálmán

Principal response. Tracking, observability and the distinction between a state estimate and a witnessed path

Dr. Atkinson, I thank Professor Bracewell for stating the static inverse problem so plainly. A tracking algorithm is an additional model placed upon observations over time. It can exploit repeated measurements and predictable dynamics to produce estimates that a single bearing cannot supply. Yet a smooth path may owe much of its smoothness to the assumed transition law and covariance weights. The output is an inference about an unobserved state. It should not be described as though a camera had witnessed the transmitter traversing each point of the line.

Let x_k denote the state of a hypothesised source at time index k, such as two-dimensional position and velocity. A simplified linear dynamic model writes $x_{(k+1)} = A x_k + w_k$, where A describes the assumed motion and w_k is process disturbance. Observations may be written $z_k = H x_k + v_k$, with H linking the state to measurable quantities and v_k representing observation error. In a real direction-finding problem the relationship may be nonlinear, so H may be a local Jacobian or the model may require a nonlinear estimator. Every symbol is a proposition about the system. In particular, the covariance used for v_k must not quietly omit persistent multipath bias, and the model for w_k must not be tuned only after seeing the path one wishes to obtain.

Observability addresses whether the state can in principle be distinguished through the available measurements over time under an adopted model. If a single station measures only bearing to an uncooperative source, changes in source range can remain poorly

Copyright 2026, James M. Atkinson

constrained without additional geometry or motion assumptions. A filter can still produce a range value by propagating its initial estimate. Its existence in the display does not demonstrate that the measurements determined it. One must therefore review observability, geometric dilution and the prior's continuing influence before assigning physical confidence to the output. I respectfully return the discussion to Dr. Atkinson.

The process becomes more treacherous when an adaptive receiver changes its own observation policy. If the system dwells longer after an initial alarm, a sequence of repeated detections may look like increasing signal persistence. In reality the opportunity to observe has changed. Similarly, a scanning network can create artificial timing gaps and apparent movement by visiting different sectors in sequence. The observation likelihood should be conditioned on the actual sensor schedule, and missed detections should be represented only where a valid exposure opportunity existed. A missing record during a period when the receiver was tuned elsewhere is not a negative bearing and cannot be introduced as such.

A reasoned validation campaign would inject or radiate known trajectories, including stationary emitters, rapidly changing paths, multiple simultaneous sources and controlled reflections. It would measure not merely root-mean-square position error but false-track rate, loss-of-track rate, track fragmentation, association errors and performance when the assumed motion model is deliberately violated. It would preserve all rejected observations and the gating decisions that led to exclusion. A track shown only after removing 'outliers' selected by visual proximity to that track risks becoming self-confirming.

Copyright 2026, James M. Atkinson

Forensic language must recognise three levels: observed measurements, model-conditioned state estimates and causal interpretations of the estimated behaviour. An expert can say that the data support a trajectory within a stated model and tested uncertainty envelope. An expert must not automatically say that the same identified hardware moved along that trajectory, and still less that a person carried it. If an identification rests on additional evidence such as physical possession, device logs or independent video, its provenance and independence from the radio evidence should be made explicit.

A further problem is the treatment of invalid or absent measurements during a track. Many estimators advance a state prediction through intervals in which no usable measurement has arrived. The resulting curve may remain continuous on screen and may carry a covariance that widens according to the chosen process model. The operator must not mistake this prediction for a set of fresh radio observations. Every rendered trajectory should therefore distinguish measured updates, predicted segments and rejected associations, with the confidence attached to each made conditional on the assumptions actually used. In an investigation involving two potentially indistinguishable emitters, a model may prefer continuity even when a physically different source has taken over. Preserving the competing association hypotheses and the underlying measurements is often more informative than publishing one uninterrupted line.

Dr. Atkinson, I would frame the problem as follows. There is a statistical difficulty in the assertion concerning whether bearings and timing could localise a radiating source: we have not yet ruled out the possibility that correlated multipath can give a deceptively narrow intersection between

Copyright 2026, James M. Atkinson

imperfect bearings. The investigation should record its chosen detector threshold, visit schedule, selection of frequencies and expected failure modes before the prospective confirmatory test. To examine the difference we should move antenna baselines and repeat calibrated phase-centre measurements at independently logged times, collecting antenna phase centre, geometry, covariance, clock offset and propagation environment over a predeclared range rather than selecting the most attractive subset afterward. An observation in which a spurious intersection moves with the reflective surroundings instead of following a fixed emitter position would strengthen a restricted causal account, but it cannot certify every unvisited frequency-time interval. I would state which recordings are dependent, which have been excluded as invalid, and which inferences rely upon a model of rare events or stationary interference. A numerical interval can have impeccable arithmetic and still misdescribe the physical world if its sampling population was chosen because the signal already looked unusual. We should therefore preserve exploratory leads separately from independently designed validation evidence.

I invite Professor Wiener to challenge whether the filter's adaptation and the operator's reaction are properly included in the dynamical system whose history the record must preserve.

Norbert Wiener

Peer question 6 to Rudolf Emil Kálmán

Professor Kalman, your account of observability is persuasive, yet I fear that the investigator may keep the observer outside the model while the observer is actively changing it. Imagine a monitoring team whose operator moves a directional antenna towards the strongest apparent

Copyright 2026, James M. Atkinson

bearing, while software changes gain, dwell and detection threshold in response to successive tentative localisations. The later record is therefore conditional upon earlier alarms and decisions, including decisions which may have been wrong. Would a conventional process-and-measurement noise model sufficiently describe this coupled observer, or must the policy of observation be treated as part of the state history? In particular, how could one test whether the apparent approach of a source was actually caused by the team approaching a reflective surface? I also ask about the archive itself. If the control loop saves only measurements that reinforced its current track, does the resulting file permit a valid comparison between the true-source and reflection hypotheses, or has the adaptive retention policy removed precisely the observations needed to decide?

Rudolf Emil Kálmán

Answer to Norbert Wiener and transfer of the floor

Professor Wiener, I agree that the observation policy belongs within the mathematical and evidential boundary. When an operator or controller changes the sampling pattern in response to a preliminary estimate, the distribution of later measurements is conditional on those earlier decisions. This does not make adaptation illegitimate, but it changes what the observation sequence can support. A state estimator that models the source while leaving the moving sensor's position, pointing direction and gain-control state unrecorded is incomplete for an investigation in which those variables materially affect the readings.

Copyright 2026, James M. Atkinson

One may enlarge the state or treat the sensor policy as a recorded controlled input. The required choice depends on whether those controls are known accurately, estimated with uncertainty or themselves influenced by feedback. Sensor pose, time synchronisation, antenna orientation, threshold history, calibration version and discarded observations should accompany the retained detections. When the controller makes an active selection, its decision rule and the information available at that moment should be recoverable. Otherwise a later analyst cannot reconstruct the likelihood of obtaining the observed sequence under competing source and reflection hypotheses.

An auditable controller should retain the policy that generated each decision and, where feasible, the score or measurement that caused it. Recording the final antenna orientation alone is inadequate when the route to that orientation depended upon discarded candidate peaks. Such provenance permits simulation of the observation process under different hypotheses and makes clear where retrospective conditioning has entered. It also distinguishes a deliberate operator choice from an automatic receiver-state transition that the operator may never have noticed. The physics of a presumed emitter cannot be reconstructed responsibly while the sampling mechanism that selected its apparent evidence remains hidden.

A strong challenge would hold the supposed source stationary, move the sensor through a documented route and compare the predicted direct-path and reflection-dependent patterns. Another would retain the sensor position while changing the suspected

Copyright 2026, James M. Atkinson

reflector or introducing a controlled reference field, where lawful and physically appropriate. If one explanation predicts a stable spatial source bearing and the other predicts a changing pattern tied to the observer's movement, the intervention may discriminate between them. The test must also preserve what happened when the signal disappeared or failed to cross threshold, subject to known observation opportunity. I thank you for putting the human operator back into the system, and pass the final principal turn to Professor Gabor for an account of information, coherence and identity.

Copyright 2026, James M. Atkinson

Dennis Gabor

Principal response. Coherence, finite information and the difference between a matching waveform and an identified emitter

Dr. Atkinson, I should first remind the panel that all localisation methods operate on a finite record of the electromagnetic field. The instrument retains projections of a wave over limited time, frequency, polarisation, dynamic range and space. A computational method can represent those projections with great sophistication, but no method can extract evidence of a distinction absent from every accessible part of the record without introducing assumptions or external information. The claim becomes most hazardous when the examiner moves from the similarity of signals to the identity of a physical device.

Coherence can supply powerful evidence that observations share a structured component. Two time-aligned records may exhibit high complex correlation over a declared interval and bandwidth. Yet shared content can arise from a common transmitted waveform, an intercepted relay, an environmental interferer, leakage from common instrumentation or two receivers processing the same reference contamination. Correlation is a relation between records, not a signed certificate of provenance. If the equipment shares a reference oscillator, digital transport or trigger policy, the source of common structure must be investigated before the records are called independent witnesses.

One must also respect the instrument's phase and bandwidth ambiguity. A narrowband measurement may establish phase consistency without resolving a unique delay, because numerous delays differ by integer carrier periods. A finite filter produces a smeared observation of a sufficiently short

Copyright 2026, James M. Atkinson

pulse; apparent pulse width depends in part on the measurement response. Recovering a subresolution waveform by deconvolution can be possible under a valid model and adequate signal-to-noise ratio, but the result may be dominated by regularisation where information was lost. An inferred sharp pulse should not be reported as directly measured merely because a mathematical inverse has drawn it. I return the token to the moderator for the succeeding contribution.

A stronger identification claim needs population evidence and a stability model. If a hardware imperfection produces a distinctive spur or modulation characteristic, the expert must investigate how that feature varies with temperature, supply voltage, operating mode and elapsed time. The analyst must also examine the prevalence of similar imperfections among candidate devices. Searching a large library of emitters and finding the closest match is not equivalent to demonstrating that a specified device emitted the signal. The search itself creates opportunities for apparently remarkable similarities, and the underlying device population may be far larger than the candidates conveniently available to the examiner.

I would permit strong language where the record warrants it. If a particular emitter is recovered, tested under appropriate conditions and shown to reproduce multiple distinctive signal properties while plausible rival mechanisms are challenged, the evidence may become persuasive. But even then the report should separate the device-to-waveform relationship from the device-to-person relationship. Ownership, operation and intent demand evidence of a different kind. A physical signal is not a witness to the legal status of its user.

Copyright 2026, James M. Atkinson

One more qualification concerns the numerical scale of similarity. A correlation coefficient close to one can be obtained from a common narrowband carrier even when the modulated content differs, especially after aggressive filtering or alignment selected to maximise the match. The relevant discriminator may reside in sidebands or timing details discarded by that processing. Conversely a genuine common source can yield a lower raw correlation after separate multipath channels or clock drift have altered the observed waveforms. The expert must therefore identify the preprocessing applied, the search over offsets, the bandwidth retained and the population of alternatives against which the claimed similarity was assessed. A single decimal coefficient is no substitute for a validated comparison protocol.

The proper closing question concerns the logical and probabilistic vocabulary of the forensic report. Sir Harold Jeffreys, I should be pleased if you would examine how an expert may express support for a source hypothesis without turning conditional probabilities or likelihood ratios into declarations of certainty.

Dr. Atkinson, I would frame the problem as follows. I should distinguish the physical occurrence under inquiry from the information actually retained when studying whether bearings and timing could localise a radiating source. Because correlated multipath can give a deceptively narrow intersection between imperfect bearings, more than one historical account may produce the same saved trace. The controlled comparison should be to move antenna baselines and repeat calibrated phase-centre measurements at independently logged times, preserving antenna phase centre, geometry, covariance, clock offset and propagation environment at the measurement

Copyright 2026, James M. Atkinson

point and in the evidential metadata. If a spurious intersection moves with the reflective surroundings instead of following a fixed emitter position, that result would narrow the admissible explanations, not establish a uniquely identified emitter outside the tested conditions. A subsequent software reconstruction may recalculate a statistic from retained samples, yet it cannot recover components rejected by the front-end filter or intervals never recorded. I would make those distinctions explicit in the final report and invite an independent examiner to reproduce the challenge, including its failed steps. Scientific restraint is not a weakness of the investigation. It prevents a detector output, however striking on the screen, from becoming a claim about unobserved activity that the original measurement never established.

A more precise objection comes from Dennis Gabor and the finite observation aperture in when may observations, bearings, and timing evidence support localisation or attribution of an electromagnetic source?. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when alternative receiver operation or selection bias. For that reason, record time reference, calibrated gain, detector threshold, and valid exposure for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After repeat with independently calibrated reference equipment under controlled conditions, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical

Copyright 2026, James M. Atkinson

source cannot be distinguished, the conclusion must remain conditional. Sir Harold Jeffreys, I would value a challenge to the evidential weight assigned to a location when alternative emitters and uncertain prior assumptions remain in play. Please take the floor.

Sir Harold Jeffreys

Peer question 7 to Dennis Gabor

Professor Gabor, thank you. Your example is salutary because it requires a prior probability as well as an evidential ratio. In practice, the examiner may be asked a more modest question: whether the observed radio evidence supports the proposition that a recovered device produced the emission over the alternative that some other relevant device did so. The hypotheses are not necessarily exhaustive, and an unknown source population can make the alternative difficult to quantify. What language would you permit when the analyst can compare evidence under two explicit propositions but cannot defensibly assign their prior odds? Should the numerical likelihood ratio be omitted, reported with strong qualifications or replaced by a broader expression that reflects validation limits? How can a tribunal be helped without being presented with an unjustified probability of guilt? Would you require an explicit declaration when the relevant population is not known, and would you prohibit a verbal strength label that implies a precision unavailable from the empirical comparisons? The language of confidence must surely be no more exact than the evidence from which it derives.

Copyright 2026, James M. Atkinson

Dennis Gabor

Answer to Sir Harold Jeffreys and transfer to the moderator

Thank you for that question. Sir Harold, the essential safeguard is to keep the conditional direction of inference visible. A likelihood ratio, where defensibly estimated, compares how probable the evidence would be under specified alternative propositions. It does not, by itself, state the probability that either proposition is true. The ratio may be informative without a prior, provided the expert declares the propositions, relevant population, measurement model, uncertainty and the scope of validation. The decision-maker must not be invited to read that conditional comparison as a posterior probability or as a probability of innocence or guilt.

Where the alternative source population is poorly characterised, a precise likelihood ratio may not be supportable. One may then report the observed correspondence, its repeatability, the features examined, the range of tested alternative devices and the conditions not studied. Qualified verbal statements can be preferable to an unearned number, although verbal scales also need consistent definitions and must not imply validation they lack. The expert should avoid labels such as unique, impossible or conclusively matched unless the relevant scientific premise has truly been established. A match obtained after flexible searching also requires disclosure of the search and selection process.

Even a non-numeric formulation should identify a boundary at which stronger language would become justified. If the relevant alternative population can be sampled, if the similarity statistic is fixed

Copyright 2026, James M. Atkinson

in advance, and if repeated tests show satisfactory discrimination across changing environments, a more explicit comparison may be warranted. Until then, a detailed account of observed correspondence and unexcluded alternatives is superior to an adjective which sounds quantitative while lacking a defined calibration. The final decision may be urgent, but the expert's words ought to remain proportional to what the laboratory has actually established.

I would particularly avoid fusing distinct propositions. That the observed signal resembles one emitted by a recovered device is a technical proposition. That the device was present at a location during the relevant interval adds temporal and spatial premises. That a named individual caused its operation adds still another layer of independent evidence. These layers can support a final account, but their uncertainties should not be replaced by the confidence of the strongest individual step. I thank you for the challenge and return the floor to Dr. Atkinson for the conclusions and the next question.

Sir Edward Victor Appleton, Cross-Peer Question to Sir Martin Ryle: Sir Martin, two stations supply extraordinarily neat intersecting bearings, apparently fixing a radiating source to a particular building. Yet one station stands beside a steel-framed structure and the other receives a strong reflected path over a nearby roof; the apparent crossing may therefore be the intersection of two propagation artefacts. How would you test whether the two measured directions actually belong to the same direct arriving wave rather than to correlated reflections? Would the crossing deserve less confidence if changing an antenna height or a receiver position shifts the

Copyright 2026, James M. Atkinson

estimated location, even where the instrument continues to report a narrow angular error?

Sir Martin Ryle, Cross-Peer Answer to Sir Edward Victor Appleton: Sir Edward, an angular estimator can be precise with respect to the signal arriving at its antenna and still be biased as an estimate of the emitter's geometrical direction. An impressively narrow peak is not a guarantee of direct-path propagation. I should repeat the observation across spatial baselines, heights and, where the signal permits, frequencies or polarisation conditions, and compare the resulting angular stability with a propagation model. Calibrated reference emitters in the relevant environment can disclose site-specific bearing bias, although one reference location cannot characterise an entire city. Measurements that vary with a roofline or a building edge warrant investigation of reflection, not an immediate declaration that a source is moving. The angular uncertainty quoted by an algorithm often represents the estimator's internal variation under an assumed model; it may omit dominant propagation bias. Preserve the raw antenna channels where available, exact station geometry, phase calibration, frequency, receiving interval and obstacles. If a source region remains broad or multimodal, present the credible regions and alternative paths instead of plotting a false pinpoint on a map.

Sir Martin Ryle, Cross-Peer Question to Rudolf Emil Kálmán: Professor Kálmán, our example illustrates that a one-nanosecond delay at one hundred megahertz produces thirty-six degrees of phase, whereas ten nanoseconds makes one full turn and may be observationally indistinguishable at one frequency. A tracking program that unwraps phase has nevertheless selected one integer cycle for every measurement and

Copyright 2026, James M. Atkinson

then draws a smooth trajectory with vanishingly small error bars. Could a numerically stable filter be observing the wrong state because clock offset, cable delay or cycle count is treated as known? What test of observability and innovation residuals would justify treating this trajectory as a measurement rather than an artefact of the estimator?

Rudolf Emil Kálmán, Cross-Peer Answer to Sir Martin Ryle: Sir Martin, a recursive estimator can be internally consistent while its measurement function is insufficiently informative about the state one hopes to infer. The question is not merely whether a covariance update converges but whether the geometry and time history distinguish position, velocity, timing bias and the possible integer-cycle ambiguities. I would write an augmented measurement model containing those nuisance variables when they matter, inspect the local Jacobian and the information gained from successive independent geometries, and challenge competing cycle hypotheses rather than fixing a convenient one. A small innovation computed against an overconfident model is not independent validation; the process and observation noise covariance, common clock terms and model mismatch must be tested with external controls. Additional carrier frequencies, baseline changes and calibrated synchronisation may make an ambiguity observable, but only within their demonstrated accuracy. Where multiple tracks fit, retain those hypotheses and show how the result changes under plausible clock offsets and reflected paths. A publishable report should name the observation period, geometry, bias assumptions and the coverage of its uncertainty region, not merely the coordinates issued by a filter.

Ronald Newbold Bracewell, Cross-Peer Question to Dennis Gabor: Professor Gabor, consider a stored waveform whose cyclostationary pattern appears

Copyright 2026, James M. Atkinson

to match an emissions catalogue entry. The receiver observed only a finite band and a short interval, and a digital resampler altered the apparent phase history. The investigators then leap from resemblance to a claim that the catalogued device, specifically, was present. In an inverse-source problem with incomplete aperture, how do we determine which physical attributes have been recovered from the data and which remain members of an observationally indistinguishable set? What experiments would discriminate a shared modulation family from the particular analogue and clock imperfections of one identified emitter?

Dennis Gabor, Cross-Peer Answer to Ronald Newbold Bracewell: Professor Bracewell, a finite time-frequency aperture limits the distinctions the observations can support. A recovered modulation family, symbol timing, spectral occupancy or periodic structure may survive reasonable receiver transformations; an alleged device-specific fingerprint may be far more sensitive to clock reference error, gain nonlinearity, temperature and the estimator's processing choices. One should begin with an explicit forward model from emitter through propagation and analogue receiver to sampled data, including any resampling. Then compare the candidate device with a realistic alternative population using an analysis procedure settled before the confirmatory tests. Where feasible, collect repeat observations under changed temperatures, supply voltages, channels and geometries to see which features are stable and which belong to the environment or receiver. A catalogue match is weak if the catalogue itself contains few similar devices or shares the reference receiver's bias. The defensible result may be that recordings are consistent with a class of emission processes, while the evidence cannot distinguish an individual apparatus. No clever

Copyright 2026, James M. Atkinson

reconstruction can create the unmeasured degrees of freedom from a finite record without additional assumptions.

Rudolf Emil Kálmán, Cross-Peer Question to Jules Henri Poincaré: Professor Poincaré, the tracking software connects two radio localisations separated by twenty seconds and assigns a constant-speed motion of three metres per second, thus implying a sixty-metre displacement. A second interpretation is that two fixed emitters operated in succession; a third is that a reflected path changed as a vehicle passed; a fourth is that the clock correction changed between observations. The plotted trajectory is smooth and gives a reassuring covariance ellipse. What would you demand before converting the mathematical continuity of a fitted path into evidence that one physical transmitter moved through the proposed locations, much less that a named person controlled it?

Jules Henri Poincaré, Cross-Peer Answer to Rudolf Emil Kálmán: Professor Kálmán, mathematical regularity is a property of the adopted model and its fitting procedure. It does not resolve an inverse problem whose observable consequences are substantially alike under different physical histories. The alleged continuous track depends upon data association: the two positions must first be shown to concern the same emitter, not merely chosen because a smooth connection was possible. I would require further simultaneous measurements capable of separating the alternatives, such as independently calibrated radio features, additional receiver geometry, a direct-path check, and sufficiently continuous timing to test whether an intervening emission actually existed. The model should be run against an explicit two-source alternative and a reflection-change alternative, not only against perturbations of its own favoured trajectory. Where the evidence

Copyright 2026, James M. Atkinson

fails to discriminate, preserve multiple hypotheses and describe the uncertainty as potentially multimodal rather than forcing all doubt into one small ellipse. Finally, the identity of a person is not a coordinate transformation. It requires separate evidential steps beyond the technical inference that an emission may have originated in a region.

Dr. James M. Atkinson

Moderator's synthesis. A five-stage evidential ladder for radio localisation and attribution

The panel has reached a conclusion more useful than either suspicion masquerading as science or scepticism so absolute that no observation can be reported. A radio receiver produces a record of a defined response under defined conditions. A direction finder may convert a properly calibrated field measurement into an arrival-direction estimate. Several such estimates, or suitably synchronised arrival-time differences, may under adequately tested propagation assumptions yield a bounded location inference. Cross-record correspondences may then support a source-class or common-source proposition. Attribution to identified hardware or a person requires further independently justified evidence. These stages are distinct; none is made automatic by a dramatic display or by a chain of technically correct calculations applied to an inadequate premise.

First, the observation stage should identify every sensor, antenna, reference plane, receiver setting, valid observation interval, sample history and preserved raw record. The analyst should be able to show what the instrument actually retained, not merely the final graphical localisation. Second, the signal stage should account for receiver-generated artifacts, aliases, images, preselection, clipping and coherent contamination, with the

Copyright 2026, James M. Atkinson

results of any controlled challenges. Third, the geometrical stage should preserve the array, station coordinates, clock and cable delay budgets, bearing measurements, unselected candidates and the geometry-sensitive uncertainty calculation. Fourth, the inverse stage should state the propagation model, alternative scattering paths, environmental assumptions, source multiplicity and the stability of the inferred solutions. Fifth, the attribution stage should separate waveform correspondence, device identity, custody, operation and personal responsibility.

These requirements have practical consequences. A report may reliably state that a candidate signal was present at specified receivers over a particular period without naming its transmitter. It may give a search region rather than a street address. It may state that data are consistent with one device among a set of tested candidates, without declaring the set to exhaust the world. It may explain that a negative result was indeterminate because dwell, sensitivity or propagation left meaningful gaps. Such qualifications are not decorative disclaimers. They define precisely what the evidence establishes, what it does not establish and which further experiment would most efficiently reduce the remaining uncertainty.

The calculations have exposed several separate dimensions of risk. A mathematically exact bearing crossing can still rely on reflected paths. A one-degree angular uncertainty can lead to a much larger geographical uncertainty when rays cross poorly. A microsecond of timing difference imposes a path-length difference but not a unique coordinate. A hundred nanoseconds of unrecognised clock bias corresponds to roughly thirty metres of path-length difference. The electrical aperture of a fixed array changes radically across a decade of frequency. Relative carrier offsets can

Copyright 2026, James M. Atkinson

arise from either the source or the receiver. A half-microsecond reflection may imitate a second event. An apparently smooth track can be a dynamical prior rather than a witnessed movement. A single-frequency phase match can conceal an integer-cycle timing ambiguity. Finally, even a sizeable likelihood ratio can leave a low posterior attribution probability when the proposition was initially improbable under an explicit, justified prior.

For future cases I adopt the following reporting convention. Every asserted position shall be paired with the measurement interval, the physical geometry, the stated propagation model and an uncertainty account that includes material systematic effects or an explanation why they cannot be bounded. Every asserted common-source relation shall identify the measured similarities and their demonstrated discriminating power. Every claim about a particular person shall identify the non-radio evidence on which it depends. If the record cannot support one of those steps, it shall not be supplied by the investigator's confidence, the client's anxiety or the software's polished display.

I thank all five principals and seven peers for a properly disciplined exchange. The next question moves from localisation to the digitised record itself. We shall consider how ADC resolution, parallel receivers, oversampling, resampling, time shifting and pulse broadening affect the information that can honestly be recovered from finite-bandwidth observations. It will require a firm distinction between creating a better estimator of a surviving quantity and pretending to recreate information which the analogue chain or sampling process never preserved.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 007

Worked application 1. A geometrically exact crossing of two ideal bearings. Place station A at coordinates (-500 m, 0 m) and station B at (500 m, 0 m), where x increases east and y increases north. In this hypothetical plane the source is at (0 m, 500 m). Station A's ideal ray has slope +1, expressed as y = x + 500 m; station B's ideal ray has slope -1, expressed as y = -x + 500 m. Equating the two yields x = 0 m and hence y = 500 m. The intersection is correct only for the assumed rays, coordinate reference and absence of material propagation bias. It is not, by itself, a confidence region, and it identifies no device or person.

Worked application 2. The effect of crossing geometry. Suppose an angular standard uncertainty σθ = 1 degree = 0.0174533 radians is observed at a characteristic slant range R = 1,000 m. The first-order transverse scale Rσθ is about 17.45 m. For a simple illustrative two-ray geometry, a poor crossing angle φ = 10 degrees introduces a factor approximately 1/sin(φ) = 5.76, raising the corresponding characteristic positional scale to roughly 100.5 m. The expression is a sensitivity illustration, not a general formula for a two-dimensional covariance ellipse: the latter depends on both ranges, orientations, covariance and bias. An apparently precise pair of azimuth readings can therefore yield a much less precise position when its rays nearly coincide.

Worked application 3. Delay as a difference of path lengths. Let c = 299,792,458 m/s and let the measured time difference between two receiving sites be Δt = 1.0 microsecond = 10^-6 s. The corresponding path-length difference is ΔL = cΔt = 299.792458 m. In two dimensions,

Copyright 2026, James M. Atkinson

one such difference constrains the emitter to a branch of a hyperbola having the two receivers as foci. It does not supply a unique geographical coordinate. A third suitably placed station, or a justified directional constraint, is needed to resolve the missing degree of freedom, and an unknown clock offset moves the hyperbola itself.

Worked application 4. Differential clock error. Suppose the receivers' relative timestamps contain an unrecognised bias $\delta t = 100$ ns = 100×10^{-9} s. The equivalent path-difference bias is $c\delta t = 29.9792458$ m. A smaller bias of 20 ns still corresponds to approximately 6.0 m of path difference. Neither number is automatically the error of an estimated position, which also depends on site geometry. Both demonstrate why the synchronisation budget, antenna cable delays and clock-state transitions must be part of the location record rather than merely instrument housekeeping.

Worked application 5. Aperture in wavelengths. With an antenna aperture $D = 0.50$ m and a carrier frequency $f = 1.0$ GHz, the free-space wavelength is $\lambda = c/f \approx 0.300$ m, so $D/\lambda \approx 1.67$. At $f = 100$ MHz, $\lambda \approx 3.00$ m and the same aperture has $D/\lambda \approx 0.167$. The electrical size has fallen by a factor of ten. This is not a promise of any particular bearing accuracy; array topology, calibration, signal-to-noise ratio, multipath and the estimation rule remain decisive. It explains why a fixed compact antenna arrangement cannot be assumed to retain the same discrimination across a decade of frequency.

Worked application 6. Frequency-offset ambiguity. Suppose a nominal 900 MHz carrier appears 900 Hz higher than a selected reference. The fractional offset is $\varepsilon = \Delta f/f = 900/900{,}000{,}000 = 1 \times 10^{-6}$,

Copyright 2026, James M. Atkinson

or 1 part per million. A 0.1 ppm difference at that frequency corresponds to 90 Hz. These calculations describe relative frequency, not the responsibility of a particular oscillator. A frequency error can arise in the transmitting device, receiver reference, intermediate conversion, clock disciplining or mathematical resampling; assigning it to the emitter requires independent evidence about the other contributors.

Worked application 7. A multipath delay. Let an indirect propagation path exceed the direct path by $\Delta L = 150$ m. Using $c \approx 3.00 \times 10^8$ m/s, the extra delay is $\Delta\tau = \Delta L/c \approx 0.50$ microsecond. A sufficiently resolved channel impulse response might reveal that delayed component, but an observed half-microsecond structure is not proof of a specific wall or reflector. Different geometries can share a similar excess path length, and limited signal bandwidth may prevent the two components from being separated cleanly. A single delay constrains possible geometry; it does not name a room.

Worked application 8. Nominal displacement versus source identity. Suppose two position estimates are separated by $\Delta t = 20$ s and a model assigns a constant speed $v = 3$ m/s. The predicted displacement is $d = v\Delta t = 60$ m. This calculation describes the trajectory permitted by the model; it does not demonstrate that one transmitter was present at both endpoints. Two stationary emitters separated by approximately 60 m, an alternating reflection or a corrupted association process might produce a similar sequence of observations. A valid tracker must therefore test the data-association hypothesis and report the possibility of track switching.

Copyright 2026, James M. Atkinson

Worked application 9. The scale of a phase-delay ambiguity. For a sinusoidal carrier f = 100 MHz and an uncorrected differential delay δt = 1 ns, the phase shift is Δφ = 2π fδt = 0.2π radians = 36 degrees. At δt = 10 ns the shift is 2π radians, or 360 degrees, indistinguishable from zero phase modulo a whole cycle in a single-frequency observation. This example shows why nominal phase agreement cannot by itself prove exact time coincidence or a unique source direction. Additional bandwidth, calibrated baselines or other constraints may be required to resolve the cycle ambiguity.

Worked application 10. Posterior odds under stated assumptions. Let H denote the hypothesis that a specified source produced the observation, and suppose the prior odds are 1:999, corresponding to prior probability P(H) = 0.001. If independently validated evidence E has a likelihood ratio LR = P(E|H)/P(E|not H) = 20 under the adopted hypothesis definitions, posterior odds are 20:999. The corresponding posterior probability is 20/(20 + 999) ≈ 0.0196, or about 1.96 per cent. This hypothetical calculation does not provide a universal prior or a forensic error rate. It shows that a visually impressive match need not make a rare attribution probable, and that the result is sensitive to the prior and the LR's validation.

QUESTION 013

Copyright 2026, James M. Atkinson

What can preselection establish about the external origin of a spectral feature?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 013 asks: What can preselection establish about the external origin of a spectral feature? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is preselection as a physical discrimination experiment rather than proof of transmitter identity. Our primary observation is the amplitude and spectral behaviour of a feature before and after a characterised RF preselector; by contrast, what remains unseen is whether the feature originated in an external radiator, cable, mixer image, or nonlinear internal product. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Filter selectivity and hidden coupling. Suppose a preselector is measured to provide 62 dB rejection at an unwanted signal frequency. An unwanted input of minus 20 dBm should then contribute approximately minus 82 dBm

Copyright 2026, James M. Atkinson

through that characterised port, before subsequent gain, provided the filter remains linear. If the observed spur is minus 45 dBm, the nominal two-port rejection cannot, by itself, explain the observation. The examiner should inspect shielding, cable common-mode paths, local-oscillator coupling and state-dependent impedance rather than declare a newly discovered transmitter. A matched reference injection through the antenna port, followed by an independently shielded termination, separates some paths but not every bypass mechanism. Record both the passband insertion loss and the stopband rejection under the gain, temperature and termination used for the questioned observation. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns the amplitude and spectral behaviour of a feature before and after a characterised RF preselector; it is not interchangeable with whether the feature originated in an external radiator, cable, mixer image, or nonlinear internal product. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is a swept, calibrated preselector comparison with reference-plane controls and a terminated-input check. A claim drawn from that comparison has to carry its actual uncertainties: insertion loss, stop-band rejection, return loss, gain compression, and response repeatability. The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. A filter state change can move an internally created intermodulation product even with an unchanged external environment.

Copyright 2026, James M. Atkinson

Cable leakage and common-mode pickup can bypass the nominal two-port network and invalidate a simple attenuation model. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 1: The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen.

Dr. Atkinson, the first diagram I would request is not the spectrum display but a network drawing showing where the preselector sits relative to the antenna, feeder, protection device, amplifier and first mixer. Consider a band-pass network specified to attenuate a blocker by forty decibels at its own calibrated ports. Once installed between an unmatched antenna and a converter with a frequency-dependent input impedance, its actual transducer attenuation may differ substantially. A signal seen after this network has not thereby proved that it entered through the intended antenna path: it might have passed through a leaky switch contact, a common return conductor or the receiver enclosure. We should measure insertion response with terminations representing the operational impedances, and then repeat the investigation with a second filter topology whose shielding and grounding are genuinely independent. The most persuasive experiment would predict not merely a lower line on a display but a specific change in the disputed component relative to a fixed reference signal. If that prediction fails, the filter's attractive laboratory curve must yield to the assembled network's behaviour.

In this physical path examination of Question 013, the decisive claim is that the preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. The preselector has two evidential roles which must be separated. Its measured insertion loss can predict how an admitted wanted tone ought to change, while its rejection response can test whether an out-of-band interferer is capable of driving a

Copyright 2026, James M. Atkinson

mixer product. Neither property proves where the energy originated. A conductive path along an imperfectly screened feeder, or a spur generated after the filter, may respond differently from an externally radiated field. Measurements must therefore be repeated with a known source injected at the antenna terminal, then at the receiver input, and finally with the RF connector terminated. The order of the interventions matters: it makes the competing entry paths distinguishable without asking the spectrum display to identify an emitter. A useful falsification proceeds from the actual controversy: filter selectivity and hidden coupling. Suppose a preselector is measured to provide 62 dB rejection at an unwanted signal frequency. An unwanted input of minus 20 dBm should then contribute approximately minus 82 dBm through that characterised port, before subsequent gain, provided the filter remains linear. If the observed spur is minus 45 dBm, the nominal two-port rejection cannot, by itself, explain the observation. The examiner should inspect shielding, cable common-mode paths, local-oscillator coupling and state-dependent impedance rather than declare a newly discovered transmitter. A matched reference injection through the antenna port, followed by an independently shielded termination, separates some paths but not every bypass mechanism. Record both the passband insertion loss and the stopband rejection under the gain, temperature and termination used for the questioned observation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

A meaningful preselector experiment requires an input-level-verified source, a trace of the complete cabling arrangement and observations at

Copyright 2026, James M. Atkinson

several reference planes. First establish the two-port S-parameters of the filter at the relevant temperature and drive. Next compare the questioned spectral feature with a matched through section while the receiver gain and analyser bandwidth remain fixed. Finally connect a shielded termination and measure common-mode feeder current. Only a change predicted uniquely by a stated coupling mechanism can exclude that mechanism; an isolated amplitude reduction is insufficient. I would take S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is to introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. A response consistent with a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event,

Copyright 2026, James M. Atkinson

and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. A survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response, and measure their behaviour separately before reconnecting the assembled system. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. It is therefore material to establish S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level rather than infer them from a single scalar output. The limiting test is concrete: Introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port. If the intervention produces a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret the feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the

Copyright 2026, James M. Atkinson

shield of the feeder remain possible as a new transmitter before challenging the most economical instrumental explanation. For a fair comparison the antenna-side stimulus and reference path must be preserved, not merely the filter setting. Professor Tukey, I invite your challenge to the inference drawn from the attenuated display.

John Wilder Tukey | Peer question 1 to Hendrik Wade Bode

Hendrik Wade Bode, may I test the exact physical inference in your account of a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel? The proposed mechanism appears plausible only if changes after introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port are compared with a stable reference condition. The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level which would settle that narrower claim, rather than a visual impression of improvement.

Hendrik Wade Bode | Immediate answer to John Wilder Tukey

Dr Tukey, the decisive comparison is between a tone which passes through the characterised filter and a feature produced after it. When

Copyright 2026, James M. Atkinson

I substitute a calibrated through connection, I must also preserve the source and load impedances, because their mismatch can change the apparent attenuation. A subsequent terminated-input acquisition will test whether the trace depends upon radiated input. If it remains, I shall examine internal mixing and shield ingress rather than use the filter response as proof of an exterior transmitter. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 013, the specific physical candidate is rejection of out-of-band energy by a finite filter with non-zero leakage and state-dependent impedance. The unresolved physical pathway is material: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The retained record permits a conditional claim about S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, but cannot alone resolve conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a survey antenna leads through a switchable 145 MHz preselector to a receiver

Copyright 2026, James M. Atkinson

displaying a narrow, unexplained feature near the tuned channel. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port, and only a response matching a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated rf port. If the response instead remained fixed when the nominal through path was strongly

Copyright 2026, James M. Atkinson

attenuated, the bypass explanation would deserve priority. This concerns S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Hendrik Wade Bode

I appreciate your explanation, Hendrik Wade Bode. How would your conclusion survive a deliberately independent test of the feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible? A second receiver might share more of the supposed evidence than its separate enclosure suggests. A filter state change can move an internally created intermodulation product even with an unchanged external environment. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level and document which differences remain unexplained? Would you also state what observed change in S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level would invalidate the preferred account, and which aspect of introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated rf port would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 013, the specific physical candidate is rejection of out-of-band energy by a finite filter with non-zero leakage and state-dependent impedance. The unresolved physical pathway is material: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The retained record permits a conditional claim about S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, but cannot alone resolve conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. I would draw the actual distribution network before collecting new corroborating evidence,

Copyright 2026, James M. Atkinson

marking where two receivers share signal, power or time references. A filter state change can move an internally created intermodulation product even with an unchanged external environment. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response; I would challenge it with introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port. Two responses consistent with a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. A discordant measurement would then be interpreted by tracing that difference through S21, S11, input compression, insertion

Copyright 2026, James M. Atkinson

loss, coaxial common-mode current, and displayed spur level; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Principal contribution 2: A filter state change can move an internally created intermodulation product even with an unchanged external environment.

The receiver's apparent selectivity often belongs to the frequency converter rather than to the aerial, Dr. Atkinson. I would expose the instrument to a controlled image-frequency tone, then lower its amplitude until the unwanted response disappears in the noise. Suppose an operator sees a spur near a desired channel and adds a narrow preselector; its disappearance could show that an image-frequency interferer formerly reached the mixer, but it would not identify who transmitted it. A second possibility is that the preselector altered front-end loading sufficiently to change oscillator leakage or gain compression inside the box. The two accounts produce different predictions when the same filter is inserted after, rather than before, the suspect gain stage. A bench examination should therefore employ a shielded termination, a calibrated coupling point, and a deliberate variation of local-oscillator frequency. No allegation concerning a hidden emitter should precede the demonstration that the received spectral coordinate survives these transformations without an internally generated explanation.

In this control and stability examination of Question 013, the decisive claim is that a filter state change can move an internally created intermodulation product even with an unchanged external environment. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy:

Copyright 2026, James M. Atkinson

filter selectivity and hidden coupling. Suppose a preselector is measured to provide 62 dB rejection at an unwanted signal frequency. An unwanted input of minus 20 dBm should then contribute approximately minus 82 dBm through that characterised port, before subsequent gain, provided the filter remains linear. If the observed spur is minus 45 dBm, the nominal two-port rejection cannot, by itself, explain the observation. The examiner should inspect shielding, cable common-mode paths, local-oscillator coupling and state-dependent impedance rather than declare a newly discovered transmitter. A matched reference injection through the antenna port, followed by an independently shielded termination, separates some paths but not every bypass mechanism. Record both the passband insertion loss and the stopband rejection under the gain, temperature and termination used for the questioned observation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by the feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note a filter state

Copyright 2026, James M. Atkinson

change can move an internally created intermodulation product even with an unchanged external environment. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, the feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Armstrong’s receiver engineering points to actual conversion products and oscillation conditions rather than abstract spectral indications; the crucial question is where the energy first appears. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. This predicts a response which should be tested against a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss. An operator may be tempted to

Copyright 2026, James M. Atkinson

interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements discarded during retuning. Where conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room, the correct claim must name the operational states and the evidence available in each. A proper image-rejection test would retain the LO state and the independent witness measurement at every change. Dr Pearson, please take the floor to examine the statistical weight of those paired observations.

Egon Sharpe Pearson | Peer question 3 to Edwin Howard Armstrong

Edwin Howard Armstrong, your calibration argument invites a question about reference planes, especially because conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. The reference stimulus and the unknown emission need not occupy the same physical regime. Cable leakage and common-mode pickup can bypass the nominal two-port network and invalidate a simple attenuation model. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When the feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port without relying upon the

Copyright 2026, James M. Atkinson

original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Edwin Howard Armstrong | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 013, the specific physical candidate is rejection of out-of-band energy by a finite filter with non-zero leakage and state-dependent impedance. The unresolved physical pathway is material: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The retained record permits a conditional claim about S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, but cannot alone resolve conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level. Cable leakage and common-mode pickup can bypass the nominal two-port network and invalidate a simple attenuation model. I would not carry a correction obtained at one

Copyright 2026, James M. Atkinson

frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port, with before-and-after values of S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level. If the instrument behaves as predicted, then a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. The feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Copyright 2026, James M. Atkinson

Ralph Vinton Lyon Hartley | Peer question 4 to Edwin Howard Armstrong

There is an inferential difficulty, Edwin Howard Armstrong: an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The population of admissible observations needs to be fixed before any confidence argument. In this situation, conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. The response of a weak candidate must be compared against a deliberately injected, traceable reference signal. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level would invalidate the preferred account, and which aspect of introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated rf port would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 013, the specific physical candidate is rejection of out-of-band energy by a finite filter with non-zero leakage and state-dependent impedance. The unresolved physical pathway is material: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The retained record permits a conditional claim about S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, but cannot alone resolve conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because the feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible. I would distinguish trials selected in advance from those added after an unexpected peak

Copyright 2026, James M. Atkinson

appeared. The response of a weak candidate must be compared against a deliberately injected, traceable reference signal. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response; its prediction should be recorded alongside a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a 40 db specified stop-band attenuation need not yield a 40 db display reduction when the uncharacterised bypass dominates the residue. A second examiner can then determine

Copyright 2026, James M. Atkinson

whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal contribution 3: Cable leakage and common-mode pickup can bypass the nominal two-port network and invalidate a simple attenuation model.

There is a useful distinction between the word external and the words external to a particular circuit board. A component observed at the ADC pins might have arrived by an unintended conductor from another part of the same receiver; a component observed at the receiver antenna socket could still have been generated in its test cable or connector. I should require the investigator to state the physical boundary at which the assertion is made. In a defensible comparison, first connect the receiver to a screened reference source, then to a characterised passive load at the same reference plane, and lastly to the survey aerial. The sequence must not be allowed to change the receiver's gain, clock or mixer configuration without logging the alteration. If the feature appears only with the aerial fitted, that is useful evidence about the path, but a poorly screened feeder and a local electrical load are still alternatives to a distant radiator. Such distinctions are operational, not philosophical decoration.

In this operational measurand examination of Question 013, the decisive claim is that cable leakage and common-mode pickup can bypass the nominal two-port network and invalidate a simple attenuation model. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: filter selectivity and hidden coupling. Suppose a preselector is measured to provide 62 dB rejection at an unwanted signal frequency. An unwanted input of minus 20 dBm should then contribute approximately minus 82 dBm through that

Copyright 2026, James M. Atkinson

characterised port, before subsequent gain, provided the filter remains linear. If the observed spur is minus 45 dBm, the nominal two-port rejection cannot, by itself, explain the observation. The examiner should inspect shielding, cable common-mode paths, local-oscillator coupling and state-dependent impedance rather than declare a newly discovered transmitter. A matched reference injection through the antenna port, followed by an independently shielded termination, separates some paths but not every bypass mechanism. Record both the passband insertion loss and the stopband rejection under the gain, temperature and termination used for the questioned observation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The experiment should distinguish conducted rejection at the front-panel connector from rejection of an external radiating source. A preselector may suppress an image response inside a receiver without establishing whether the rejected energy originated in a nearby device, the receiver's own oscillator, a poorly terminated test lead, or a second harmonic generated upstream. The informative trial uses a calibrated source at the antenna reference plane and a separate terminated-input control. Measure insertion loss, passband ripple and out-of-band rejection under the same gain setting, then compare the suspect feature with the predicted input-to-output transfer ratio. If the indication survives input termination, conducted preselection alone cannot support external attribution; a local spurious mechanism remains viable. If the indication tracks deliberate source frequency changes according to the measured filter response, the evidence supports frequency-path compatibility, not unique emitter identity. The

Copyright 2026, James M. Atkinson

report must retain the filter switch state and acknowledge that an out-of-band product generated before the filter is not eliminated merely by the nominal stopband figure. Accordingly, the laboratory record for Question 013 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. Bridgman's operational approach requires a measurement procedure that defines each quantity physically. A stated number unsupported by the operation that produced it is methodologically incomplete. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a survey antenna leads through a switchable 145 mhz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an

Copyright 2026, James M. Atkinson

instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A 40 dB specified stop-band attenuation need not yield a 40 dB display reduction when the uncharacterised bypass dominates the residue. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. The measurement definition must include unintended cable and common-mode routes. Dr Turing, I invite you to ask what the retained IQ record can establish when those paths were not separately observed.

Alan Mathison Turing | Peer question 5 to Percy Williams Bridgman

Percy Williams Bridgman, I should like to examine what the recorded data actually preserve when a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. The physical input and the retained numerical array are not interchangeable things. A successful exclusion of an out-of-band image restricts a mechanism; it does not establish a unique emitter. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in S21, S11, input compression, insertion loss,

Copyright 2026, James M. Atkinson

coaxial common-mode current, and displayed spur level would invalidate the preferred account, and which aspect of introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated rf port would make that negative result independently repeatable?

Percy Williams Bridgman | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 013, the specific physical candidate is rejection of out-of-band energy by a finite filter with non-zero leakage and state-dependent impedance. The unresolved physical pathway is material: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The retained record permits a conditional claim about S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, but cannot alone resolve conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. I propose separating acquired information from model-dependent reconstruction. A successful exclusion of an out-of-band image restricts a mechanism; it does not establish a unique emitter. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level and a fresh trial in which the operator introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port. If that trial demonstrates a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include introduce a level-verified signal ahead of the

Copyright 2026, James M. Atkinson

antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated rf port. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 4: The response of a weak candidate must be compared against a deliberately injected, traceable reference signal.

A preselector's effect can be stated as information about a test configuration without assigning a transmitter identity. Suppose that two physically distinct inputs, one at the wanted frequency and one at an image frequency, become the same post-mixer complex sample stream. No later software analysis of that stream can distinguish the origins unless an earlier operation has preserved a difference. Changing a well-characterised analogue filter can create such a difference by altering the two candidate inputs unequally. Yet a single before-and-after amplitude ratio becomes ambiguous if automatic gain control reacts to the altered blocker power. I would retain the raw complex samples, actual gain-state records and the measured transfer functions for every intervention. A properly designed paired test gives a comparison between hypotheses about paths into the receiver. It does not generate the missing information about the source's location, purpose or ownership. Those are further questions requiring independently discriminating evidence.

In this information retention examination of Question 013, the decisive claim is that the response of a weak candidate must be compared against a deliberately injected, traceable reference signal. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: filter selectivity and hidden coupling. Suppose a preselector is measured to provide 62 dB rejection at an unwanted signal frequency. An unwanted input of minus 20 dBm should then contribute

Copyright 2026, James M. Atkinson

approximately minus 82 dBm through that characterised port, before subsequent gain, provided the filter remains linear. If the observed spur is minus 45 dBm, the nominal two-port rejection cannot, by itself, explain the observation. The examiner should inspect shielding, cable common-mode paths, local-oscillator coupling and state-dependent impedance rather than declare a newly discovered transmitter. A matched reference injection through the antenna port, followed by an independently shielded termination, separates some paths but not every bypass mechanism. Record both the passband insertion loss and the stopband rejection under the gain, temperature and termination used for the questioned observation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port. The scientific point of the response of a weak candidate must be compared against a deliberately injected, traceable reference signal. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If

Copyright 2026, James M. Atkinson

independent sessions repeatedly show a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. The feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible. Shannon's information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. The issue becomes especially sharp because an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated rf port. That comparison should keep the unprocessed complex

Copyright 2026, James M. Atkinson

values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the proposed case, a 40 db specified stop-band attenuation need not yield a 40 db display reduction when the uncharacterised bypass dominates the residue. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. An injected reference gives a comparison, not an inverse of information that the instrument discarded. Dr Deming, I now pass the floor for a test capable of overturning the preferred source explanation.

W. Edwards Deming | Peer question 6 to Claude Elwood Shannon

I thank you, Claude Elwood Shannon, for distinguishing measurement from attribution, but the observation is that the feature weakens after the filter is substituted, although an external radiator, a mixer image, and ingress through the shield of the feeder remain possible. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a 40 dB specified stop-band attenuation need not yield a 40 dB display reduction when the uncharacterised bypass dominates the residue. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss on one day but fails after the instrument has been reconfigured? The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. Would you disclose the

Copyright 2026, James M. Atkinson

disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Claude Elwood Shannon | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 013, the specific physical candidate is rejection of out-of-band energy by a finite filter with non-zero leakage and state-dependent impedance. The unresolved physical pathway is material: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The retained record permits a conditional claim about S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, but cannot alone resolve conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a 40 dB specified stop-band attenuation need not yield a 40 dB display

Copyright 2026, James M. Atkinson

reduction when the uncharacterised bypass dominates the residue. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. Its bearing on the dispute can be evaluated through the predicted response, namely a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss. Because an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response, the procedure introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match report the eliminated signal-path mechanism rather than an unproved transmitter identity, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. A genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss. I would retain the

Copyright 2026, James M. Atkinson

unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 5: A successful exclusion of an out-of-band image restricts a mechanism; it does not establish a unique emitter.

Dr. Atkinson, I would formulate two rival propositions before permitting the operator to touch the filter switch. One says that the suspect line is produced by external in-band power; the other says that out-of-band power drives a nonlinear or image response. Each proposition requires a predicted distribution of observations under controlled filter changes, including imperfect responses and measurement noise. If repeated filter swaps are selected for analysis only when the line looks most dramatic, a nominal confidence interval is not the one promised by the intended procedure. Randomise the order of the filter and bypass states where practicable, log every eligible observation, and estimate the paired contrast with its dependence and instrument uncertainty. A sharp reduction of the line can favour the nonlinear-path account while remaining compatible with several physical sources of the original blocker. A negative result, conversely, may be powerless when the substituted filter has inadequate rejection at the relevant frequencies. The report must disclose that limitation rather than conceal it inside a favourable percentage.

In this statistical inference examination of Question 013, the decisive claim is that a successful exclusion of an out-of-band image restricts a mechanism; it does not establish a unique emitter. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: filter selectivity and

Copyright 2026, James M. Atkinson

hidden coupling. Suppose a preselector is measured to provide 62 dB rejection at an unwanted signal frequency. An unwanted input of minus 20 dBm should then contribute approximately minus 82 dBm through that characterised port, before subsequent gain, provided the filter remains linear. If the observed spur is minus 45 dBm, the nominal two-port rejection cannot, by itself, explain the observation. The examiner should inspect shielding, cable common-mode paths, local-oscillator coupling and state-dependent impedance rather than declare a newly discovered transmitter. A matched reference injection through the antenna port, followed by an independently shielded termination, separates some paths but not every bypass mechanism. Record both the passband insertion loss and the stopband rejection under the gain, temperature and termination used for the questioned observation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. A successful exclusion of an out-of-band image restricts a mechanism; it does not establish a unique emitter. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to introduce a level-verified signal ahead of the antenna connector, interchange the filter with a

Copyright 2026, James M. Atkinson

matched dummy section, and repeat with a terminated RF port, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say report the eliminated signal-path mechanism rather than an unproved transmitter identity, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman’s statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. One could stratify the experiment by

Copyright 2026, James M. Atkinson

nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a 40 db specified stop-band attenuation need not yield a 40 db display reduction when the uncharacterised bypass dominates the residue, is not an estimate of any actual investigation. Exclusion of one mixer image narrows the candidate mechanisms but cannot certify a particular transmitter. Sir Karl, I invite your scrutiny of the propositions that remain open to refutation.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise report the eliminated signal-path mechanism rather than an unproved transmitter identity? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. A filter state change can move an internally created intermodulation product even with an unchanged external environment. Please connect S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level with a declared detection threshold and the

Copyright 2026, James M. Atkinson

measurement exposure. If the experiment introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 013, the specific physical candidate is rejection of out-of-band energy by a finite filter with non-zero leakage and state-dependent impedance. The unresolved physical pathway is material: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. The retained record permits a conditional claim about S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level, but cannot alone resolve conducted attenuation measured between two coaxial ports is not automatically radiated-source isolation in a populated equipment room. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. A filter state change can move an internally created intermodulation product even with an unchanged external environment. I would use the observations of S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port, not an assertion based on the operator's impression of a quiet display. If it yields a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding

Copyright 2026, James M. Atkinson

offers a path which bypasses the nominal filter response, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to report the eliminated signal-path mechanism rather than an unproved transmitter identity, with the untested physical possibilities made visible.

Hendrik Wade Bode, Cross-Peer Question to Percy Williams Bridgman: Professor Bridgman, the committee sees a feature diminish when a nominally sixty-decibel stop-band filter is inserted, and the resulting trace is being offered as proof that the energy arrived through the survey antenna. The filter's attenuation was measured at specified coaxial ports, whereas the installed receiver has a lossy switch, an imperfect shield, a feeder with common-mode current and a temperature-sensitive input match. A direct-port injection obeys the predicted attenuation, but a nearby radiated field does not fall by the same amount. Which physical operation would tell us whether the measurement describes the intended two-port path rather than an unmeasured bypass? How should one distinguish a legitimate suppression experiment from the logically stronger and generally unjustified conclusion that a particular remote emitter has thereby been located?

Percy Williams Bridgman, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, the first obligation is to name the reference surface on which the quantity is defined. A scattering-parameter measurement between matched laboratory ports is not a measurement of the complete receiving installation. I should document the filter's installed input and output impedance, the switch state and the screened and common-mode routes that might couple energy around it. A shielded termination at the receiver

Copyright 2026, James M. Atkinson

port, a controlled reference injection at the antenna-side plane, and a deliberately altered feeder geometry make different predictions for conductive, radiative and internally generated responses. These tests must be performed in a sequence that preserves the receiver operating point and records any unavoidable changes. A fall in amplitude after the filter is inserted supports the proposition that the altered network affects the feature; it does not uniquely demonstrate where that feature originated. If input-mismatch changes or independent leakage paths remain unmeasured, the inferred rejection has an unquantified uncertainty. The report should state precisely which candidate coupling routes were tested and which remain plausible, even when the spectrum display presents a beautifully clean line.

Edwin Howard Armstrong, Cross-Peer Question to Jerzy Neyman: Professor Neyman, two strong input tones predict an input-referred third-order product at three times the tone level minus twice the quoted intercept point. We obtain an attractive straight-line extrapolation, but the measured receiver spur does not always rise three decibels for every one-decibel change in the blockers. The apparent signal survives on the display when the antenna is changed, and a colleague concludes that the remaining line must be an external carrier because the textbook cubic relation fits poorly. What experiment would discriminate an imperfect intermodulation model from a true externally radiated component without assuming the very slope whose validity is in dispute?

Jerzy Neyman, Cross-Peer Answer to Edwin Howard Armstrong: Dr Armstrong, a discrepancy from a simplified model is not affirmative evidence for the preferred alternative. The cubic approximation assumes a

Copyright 2026, James M. Atkinson

specified small-signal regime and well-behaved input-referred characteristics; compression, memory effects, filtering and mixed mechanisms may change the measured slopes. I would vary both blocker amplitudes in a registered grid, retain the output product frequency and power at each setting, and compare alternative response models rather than forcing the observations onto an ideal slope. A calibrated attenuation step before the first active stage should affect internally generated products differently from attenuation introduced after the nonlinear site, provided those interventions do not alter other gains or impedances. A matched termination and a known injected weak carrier offer additional, imperfect controls. Because the product frequency can coincide with a real emission, the observed feature may contain both components. The final conclusion should disclose the demonstrated power dependence, the instrument state and the unexcluded external contribution. The statistical distinction is between models that predict discriminating changes under intervention, not between a perfect cubic law and an unexplained remainder presumed to be a transmitter.

Claude Elwood Shannon, Cross-Peer Question to John Wilder Tukey: Professor Tukey, a single spectral line at the digitiser output can correspond to analogue tones in more than one Nyquist zone. The case example folds a 99.2-megahertz input sampled at thirty-one megahertz to 6.2 megahertz, but an analogue spur or a different out-of-band tone could occupy the same sampled coordinate. A technician searched several sample rates and preselector states until one combination made the line disappear, then presented the decisive trace alone. What confirmatory experiment would preserve the information lost in that post-selection, and what is the

Copyright 2026, James M. Atkinson

strongest claim the analyst may properly make when the original raw samples and state changes remain available?

John Wilder Tukey, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the investigator must record the entire sequence of interventions rather than selecting the most persuasive frame. Aliasing gives a many-to-one mapping from analogue frequency to a sampled coordinate, and the change of sampling rate may itself alter clock coupling, analogue response or image rejection. I would specify a set of candidate analogue frequencies, predict their signed folds under at least two independently calibrated sampling configurations, and then challenge those predictions with known injected sources at relevant frequencies and amplitudes. The filter passband, out-of-band transfer, oscillator reference and all digital resampling must be documented. The hypothesis should be written before a new independent run, not after one has found a favourable setting. If two physical mechanisms retain the same predicted observations within calibration uncertainty, they remain observationally equivalent. The most that the data support is exclusion of the mechanisms actually challenged under the stated instrument conditions, plus any positive result that survives genuinely independent confirmation. A frequency on the digital screen is a measurement coordinate. It is not by itself a certificate of RF origin.

Jerzy Neyman, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, the preselector trial reports a contrast of 1.970 decibels and a quadrature standard uncertainty of about 0.540 decibels, producing a ratio near 3.65. It is tempting to stamp the feature as external because the result is numerically several standard uncertainties from zero. Yet both readings

Copyright 2026, James M. Atkinson

share the same reference source, the same ambient field, perhaps a common frequency-dependent mismatch, and the same decision to inspect that particular spectral cell. Which quantities would you put into the measurement function before calling the contrast discriminating, and how would you prevent the apparent statistical precision from concealing a shared physical bias?

Hendrik Wade Bode, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, the two-port transfer change and the measured spectral difference are separate measurands, and their relationship is conditional on the installed circuit. A valid uncertainty budget begins with the actual readings and the corrections applied to them; shared calibration errors and common drift may produce covariance terms that cannot be handled by indiscriminate root-sum-of-squares arithmetic. I would measure the repeatability of the preselector state transition, port match, source amplitude, cable radiation and receiver gain state, and document which correlations are cancelled by differencing and which survive it. A ratio of difference to combined standard uncertainty is not automatically a formal significance test, still less a proof of transmission origin. The null distribution, selection procedure and systematic model have not yet been specified. An independent injection or shielded-port test can challenge the physical account without assigning more certainty than the test supports. The report may establish that the feature changed by a measured amount under a named filter operation. It should not silently equate that change with an identified emitter.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of preselection as a physical discrimination experiment rather than proof of transmitter identity has established a point which the specialist must not overlook. The receiver records the amplitude and spectral behaviour of a feature before and after a characterised RF preselector; it does not, merely by drawing a clear trace, give direct access to whether the feature originated in an external radiator, cable, mixer image, or nonlinear internal product. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, The preselector transfer function must be measured at the antenna-side reference plane, not inferred from the screen. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

Dr Atkinson thanks Professor Bode for insisting upon the measured two-port behaviour of a preselector, and Dr Bridgman for requiring the reference plane to be made physically accessible. The crucial result is not that a filter caused a trace to weaken, but whether the observed weakening is predicted by independently measured insertion loss at the actual source and load impedances. A signal that persists with a shielded termination attached may have entered beyond the filter or been generated inside the receiver; a change with filter substitution alone cannot settle that distinction. The next survey should therefore record forward transmission and return loss, repeat the injection on both sides of the suspected entry

Copyright 2026, James M. Atkinson

point, and make the order of component substitutions recoverable from the evidence log. We must close without naming a transmitter. What can presently be defended is an experimentally constrained statement about which RF paths remain plausible, together with the untested paths that warrant a second investigation.

Replacing the filter weakened the observed feature, but a measured diminution by itself does not identify an external radiator. A mixer image, common-mode feeder ingress, or frequency-dependent loading could account for a similar change. The report should give the insertion loss and return loss at the relevant frequencies, identify each injection plane and retain every challenged recording. A finding about a particular signal path may be defensible even where the source identity remains unresolved. The more useful outcome is a discriminating protocol: Introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port. In applying it, the examiner must retain all readings supporting S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level and identify the physical plane to which the measurements refer. At the outset of the investigation, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel; that circumstance makes the alternative mechanism material, specifically an out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. A result approaching a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss

Copyright 2026, James M. Atkinson

may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore report the eliminated signal-path mechanism rather than an unproved transmitter identity. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

The defensible conclusion is confined to the signal pathways excluded or supported by controlled preselection tests. Properly measured transfer and rejection curves can contradict a proposed path; they cannot independently name a transmitter. The remainder of the report must state the paths which were not challenged and the limits arising from the measured input match. The decisive experiment is concrete: Introduce a level-verified signal ahead of the antenna connector, interchange the filter with a matched dummy section, and repeat with a terminated RF port. In conducting it, the examiner must explicitly retain S21, S11, input compression, insertion loss, coaxial common-mode current, and displayed spur level. If the outcome matches the stated prediction, a genuine through-path input follows the measured filter transmission, whereas leakage downstream of the switch is insensitive to its stated stop-band loss, the supported conclusion concerns that test domain. An alternative remains: An out-of-band blocker drives a nonlinear stage, while imperfect connector shielding offers a path which bypasses the nominal filter response. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the

Copyright 2026, James M. Atkinson

methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 013

Application 01. Filter or cable rejection referred to a physical input

In the illustrative 013.01 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. For an admitted input P_i = -48 dBm and separately measured loss L = 30 dB, the linear prediction is $P_o = P_i - L$ = -78 dBm. In SI power this becomes 10^((-78 − 30)/10) = 1.58e-11 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. If the feature remains after the predicted 30 dB attenuation, test common-mode and enclosure-coupled ingress before assigning energy to the antenna port.

Application 02. Cascade gain and observed headroom

In the illustrative 013.02 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. A first amplifier contributes G_1 = 14 dB, an intentional attenuation contributes G_2 = -6 dB, and a later stage contributes G_3 = 16 dB. The small-signal sum is 14 + (-6) + 16 = 24 dB. For P_i = -73 dBm, the ideal output is P_o = -49 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The 24 dB net gain does not establish intermediate headroom; record blocker and probe powers at each potentially nonlinear stage.

Copyright 2026, James M. Atkinson

Application 03. Thermal reference noise in a declared measurement bandwidth

In the illustrative 013.03 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. Take the equivalent noise bandwidth B = 24,000 Hz and calibrated noise figure NF = 3.25 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -126.95$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The -126.95 dBm thermal-reference result is conditional on the 24 kHz equivalent bandwidth and specified 290 K noise model, not a field-noise measurement.

Application 04. Alias-location prediction and its non-unique inverse

In the illustrative 013.04 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. For an actual sampling frequency f_s = 31 MHz and analogue input f_i = 99.200 MHz, the nearest-replica folding rule gives $f_a = |f_i - \text{round}(f_i/f_s)f_s| = 6.200$ MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. A 6.2 MHz sampled line admits multiple analogue origins; repeat the investigation with known injected tones and independently verified preselector states.

Copyright 2026, James M. Atkinson

Application 05. Two-tone third-order products and input intercept

In the illustrative 013.05 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. With two equal input tones each at P = -31 dBm and a hypothetical input third-order intercept IIP_3 = +9 dBm, the extrapolated input-referred third-order product is $P_3 = 3P - 2IIP_3$ = -111 dBm, or -80 dBc relative to either input tone. The cubic approximation ceases to be reliable in compression. A two-tone slope check and input attenuation test must establish whether the predicted spur arises inside the receiver rather than externally. The -111 dBm cubic intercept prediction is only a small-signal extrapolation; measured IMD slopes and blocker attenuation tests must check the assumed model.

Application 06. Gain allocation and blocker headroom

In the illustrative 013.06 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. Assume a calibrated digital full-scale equivalent of -5 dBm, a blocker applied at -40 dBm, and net analogue gain 27 dB. The projected converter input is -13 dBm and remaining margin is -5 − (-13) = 8 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. Eight decibels of nominal converter margin is not proof that every upstream amplifier is linear during stronger or simultaneous blockers.

Copyright 2026, James M. Atkinson

Application 07. Combined and expanded measurement uncertainty

In the illustrative 013.07 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. For independent standard-uncertainty contributions 0.87, 0.48 and 0.28 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.87^2 + 0.48^2 + 0.28^2)} = 1.032$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c = 2.065$ units. The 2.065-unit expanded uncertainty is illustrative; shared calibration and drift terms must be examined before interpreting a physical attenuation difference.

Application 08. Difference between two instruments relative to stated uncertainty

In the illustrative 013.08 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. The paired instrument contrast is $\Delta = 1.970$ dB. Set independent standard uncertainties $u_1 = 0.340$ dB and $u_2 = 0.420$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.540$ dB, giving the dimensionless ratio $\Delta/u\Delta = 3.646$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The 3.646 contrast-to-uncertainty ratio cannot identify an emitter without a declared physical measurement model, covariance account and selection rule.

Application 09. Preserved sample continuity across an acquisition interval

In the illustrative 013.09 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow,

Copyright 2026, James M. Atkinson

unexplained feature near the tuned channel. A converter expected to retain f_s = 1.30 million samples/s for T = 0.75 s should supply f_sT = 975,000 complex sample instants. If 210 sequence positions are missing, the retained count is 974,790 and loss fraction is 0.02154%. A low fractional loss cannot exclude a highly relevant short burst coinciding with the gap. Position and timing of each missing block must therefore be preserved. The loss of 210 samples may conceal an entire short event; retain the exact missing sequence positions rather than reporting only a 0.02154 per cent aggregate loss.

Application 10. Family-wise probability when many candidates are searched

In the illustrative 013.10 test, a survey antenna leads through a switchable 145 MHz preselector to a receiver displaying a narrow, unexplained feature near the tuned channel. If each of M = 359 independent pre-specified search opportunities has false-alarm probability α = 0.0010, the probability of one or more false positives is 1 − (1 − α)^M = 0.30175, or 30.18%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. A 30.18 per cent familywise false-alarm probability belongs to the specified independent search model, not to the probability that a selected feature has an external cause.

QUESTION 014

Copyright 2026, James M. Atkinson

How should gain distribution be selected when strong signals coexist with weak emissions?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 014 asks: How should gain distribution be selected when strong signals coexist with weak emissions? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is dynamic-range allocation through a cascade of analogue gain, attenuation, and conversion stages. Our primary observation is input-referred and digital power levels under simultaneously present strong and weak signals; by contrast, what remains unseen is unlogged compression, overload recovery, or quantiser masking that distorts the apparent weak feature. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Cascade noise and overload are competing constraints. Consider a receiver whose first amplifier has 20 dB available gain and a linear noise

Copyright 2026, James M. Atkinson

factor of 1.5. A following stage with a noise factor of 6 contributes only (6 minus 1)/100 = 0.05 to the overall linear noise factor under the ordinary Friis cascade assumptions, producing 1.55 or about 1.90 dB total noise figure. But a strong blocker raised by the same 20 dB can exceed the next stage's compression threshold. Adding attenuation in advance of the amplifier may preserve linearity while increasing the effective input-referred noise, and the correct setting therefore depends upon the actual blocker population. Distinguish a thermal-noise-limited experiment from a large-signal-limited experiment. A single pleasing noise-figure number cannot establish that weak emissions remain observable during simultaneous high-level traffic. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns input-referred and digital power levels under simultaneously present strong and weak signals; it is not interchangeable with unlogged compression, overload recovery, or quantiser masking that distorts the apparent weak feature. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is a two-tone plus weak-signal swept-level challenge with gain-state and intercept-point logging. A claim drawn from that comparison has to carry its actual uncertainties: noise figure, cascade gain, input third-order intercept, headroom, and converter occupancy. A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. A strong blocker may drive a later stage into compression even when the desired weak signal is far

Copyright 2026, James M. Atkinson

beneath its noise floor. Programmable attenuation should be treated as a documented state transition, not invisible software hygiene. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 1: A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom.

Gain distribution is not a contest to obtain the largest voltage at the analogue-to-digital converter. I would first mark the available headroom at the antenna-facing limiter, the first amplifier, the mixer and the final converter, all referred to consistent power and impedance conventions. A preamplifier that makes a weak signal comfortably visible can also place an adjacent authorised transmitter above the compression point of a later stage. Conversely, a protective attenuator placed too early sacrifices input-referred sensitivity in a way that a later digital gain adjustment cannot reverse. For each proposed gain plan, the investigator needs the largest credible blocker at each stage and the smallest signal the evidence task requires. The operating regime may favour switchable attenuation under a documented state machine rather than a fixed maximum-gain setting. I would insist that gain-step transitions be challenged with bursts of varied duration, because a receiver that is linear once settled can give an entirely different account during its recovery.

In this physical path examination of Question 014, the decisive claim is that a first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. Gain distribution is a constrained optimisation, not a contest to obtain the largest displayed peak. A low-noise first stage may improve small-signal sensitivity while reducing the maximum admissible blocker level at every following stage. The engineer must plot signal and interferer powers along the cascade, not merely calculate its final gain. A controlled gain step made ahead of the nonlinear device has a

Copyright 2026, James M. Atkinson

different evidential meaning from attenuation inserted after overload has already occurred. Where a converter clips, digital rescaling only changes the representation of corrupted samples. The proposed gain plan must therefore be tested against the actual mixture of weak targets, adjacent-channel carriers and transient high-power transmissions. A useful falsification proceeds from the actual controversy: cascade noise and overload are competing constraints. Consider a receiver whose first amplifier has 20 dB available gain and a linear noise factor of 1.5. A following stage with a noise factor of 6 contributes only (6 minus 1)/100 = 0.05 to the overall linear noise factor under the ordinary Friis cascade assumptions, producing 1.55 or about 1.90 dB total noise figure. But a strong blocker raised by the same 20 dB can exceed the next stage's compression threshold. Adding attenuation in advance of the amplifier may preserve linearity while increasing the effective input-referred noise, and the correct setting therefore depends upon the actual blocker population. Distinguish a thermal-noise-limited experiment from a large-signal-limited experiment. A single pleasing noise-figure number cannot establish that weak emissions remain observable during simultaneous high-level traffic. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Use a calibrated two-tone source and a separately monitored faint probe. At fixed input frequencies, increase the strong carrier in steps through the onset of front-end compression while alternately inserting attenuation before the first active component and later in the chain. Measure the probe SINAD, third-order products and recovery time, retaining the raw converter

Copyright 2026, James M. Atkinson

flags. Then repeat with the antenna connected under a declared safety limit. The winning gain allocation is the one that preserves a validated detection envelope, not a visually clean but overdriven waterfall. I would take input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. A response consistent with where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. A weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised

Copyright 2026, James M. Atkinson

transmitter, with front-end amplification presently set high. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range, and measure their behaviour separately before reconnecting the assembled system. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. It is therefore material to establish input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction rather than infer them from a single scalar output. The limiting test is concrete: Sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. If the intervention produces where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret the candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier as a new transmitter before challenging the most economical instrumental explanation. The gain schedule therefore needs the actual blocker powers and the receiver state, not a single laboratory noise figure. Professor Tukey, I invite you to examine how the selection of favourable traces could distort that judgement.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Peer question 1 to Hendrik Wade Bode

Hendrik Wade Bode, may I test the exact physical inference in your account of a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high? The proposed mechanism appears plausible only if changes after sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state are compared with a stable reference condition. A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction which would settle that narrower claim, rather than a visual impression of improvement.

Hendrik Wade Bode | Immediate answer to John Wilder Tukey

Dr Tukey, your objection is answered only by varying the position of the attenuation, not by repeating the same test at several overall gains. A pad before the LNA may protect its input while increasing the input-referred noise contribution; a pad after it may protect the ADC without correcting any distortion already created upstream. I propose measuring both circumstances, then reporting separate detection and overload limits instead of one nominal sensitivity figure. The

Copyright 2026, James M. Atkinson

correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 014, the specific physical candidate is gain redistribution between low-noise amplification, filtering, mixing, IF gain, and converter full scale. The unresolved physical pathway is material: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The retained record permits a conditional claim about input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, but cannot alone resolve cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction;

Copyright 2026, James M. Atkinson

they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state, and only a response matching where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, not a conjecture about the operator's intentions.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Peer question 2 to Hendrik Wade Bode

I appreciate your explanation, Hendrik Wade Bode. How would your conclusion survive a deliberately independent test of the candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier? A second receiver might share more of the supposed evidence than its separate enclosure suggests. A strong blocker may drive a later stage into compression even when the desired weak signal is far beneath its noise floor. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction and document which differences remain unexplained? Would you also state what observed change in input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction would invalidate the preferred account, and which aspect of sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state would make that negative result independently repeatable?

Hendrik Wade Bode | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the

Copyright 2026, James M. Atkinson

level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 014, the specific physical candidate is gain redistribution between low-noise amplification, filtering, mixing, IF gain, and converter full scale. The unresolved physical pathway is material: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The retained record permits a conditional claim about input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, but cannot alone resolve cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. A strong blocker may drive a later stage into compression even when the desired weak signal is far beneath its noise floor. An independent test must alter a physical dependency,

Copyright 2026, James M. Atkinson

not merely open another software window. The relevant controlled alternative remains the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range; I would challenge it with sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. Two responses consistent with where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. A discordant measurement would then be interpreted by tracing that difference through input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 2: A strong blocker may drive a later stage into compression even when the desired weak signal is far beneath its noise floor.

Dr. Atkinson, an indicated dynamic range is meaningful only with its observation bandwidth and quantisation regime specified. If a narrow channelised view follows a large-gain front end, the displayed noise floor may look comfortably low while a powerful signal outside that narrow view has already exhausted the ADC input range. Doubling the numerical precision of the software cannot reconstruct amplitudes flattened by a preceding limiter. Nor can a decimator restore a pulse lost during an automatic gain-control transition. I would use a test comprising a weak wanted tone and a much stronger nearby interferer, then sweep the interferer's amplitude with gain states recorded. The weak tone's detection probability, false detections and converter clipping rate should all be reported, instead of inferring receiver quality from a single noise figure. Sampling theory tells us which information a properly band-limited converter can represent; it does not excuse an analogue chain driven outside its valid range.

In this control and stability examination of Question 014, the decisive claim is that a strong blocker may drive a later stage into compression even when the desired weak signal is far beneath its noise floor. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: cascade noise and overload are competing constraints. Consider a receiver whose first

Copyright 2026, James M. Atkinson

amplifier has 20 dB available gain and a linear noise factor of 1.5. A following stage with a noise factor of 6 contributes only (6 minus 1)/100 = 0.05 to the overall linear noise factor under the ordinary Friis cascade assumptions, producing 1.55 or about 1.90 dB total noise figure. But a strong blocker raised by the same 20 dB can exceed the next stage's compression threshold. Adding attenuation in advance of the amplifier may preserve linearity while increasing the effective input-referred noise, and the correct setting therefore depends upon the actual blocker population. Distinguish a thermal-noise-limited experiment from a large-signal-limited experiment. A single pleasing noise-figure number cannot establish that weak emissions remain observable during simultaneous high-level traffic. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by the candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note a strong blocker may drive a later stage into compression even when the desired weak signal is far beneath its noise

Copyright 2026, James M. Atkinson

floor. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, the candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. This predicts a response which should be tested against where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements discarded during

Copyright 2026, James M. Atkinson

retuning. Where cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints, the correct claim must name the operational states and the evidence available in each. A stepped-blocker test should document both the compression onset and the effective sensitivity of the desired channel. Dr Pearson, the floor is yours to challenge whether the comparisons support a reliable conclusion.

Egon Sharpe Pearson | Peer question 3 to Harry Nyquist

Harry Nyquist, your calibration argument invites a question about reference planes, especially because cascade noise figure, third-order intercept, maximum linear power and ADC headroom measure different performance constraints. The reference stimulus and the unknown emission need not occupy the same physical regime. Programmable attenuation should be treated as a documented state transition, not invisible software hygiene. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When the candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Copyright 2026, James M. Atkinson

Harry Nyquist | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 014, the specific physical candidate is gain redistribution between low-noise amplification, filtering, mixing, IF gain, and converter full scale. The unresolved physical pathway is material: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The retained record permits a conditional claim about input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, but cannot alone resolve cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction. Programmable attenuation should be treated as a documented state transition, not invisible software hygiene. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be sweep the strong blocker through calibrated power steps while measuring the weak test tone under

Copyright 2026, James M. Atkinson

fixed and changed attenuation, preserving each gain state, with before-and-after values of input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction. If the instrument behaves as predicted, then where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. The candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Harry Nyquist

There is an inferential difficulty, Harry Nyquist: the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The population of admissible observations needs to be fixed before any confidence argument. In this situation, cascade noise figure, third-order

Copyright 2026, James M. Atkinson

intercept, maximum linear power and ADC headroom measure different performance constraints. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. The optimum gain plan depends upon the external interference population rather than a solitary nominal sensitivity specification. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction would invalidate the preferred account, and which aspect of sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state would make that negative result independently repeatable?

Harry Nyquist | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 014, the specific physical candidate is gain redistribution between low-noise amplification, filtering, mixing, IF gain, and

Copyright 2026, James M. Atkinson

converter full scale. The unresolved physical pathway is material: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The retained record permits a conditional claim about input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, but cannot alone resolve cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because the candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier. I would distinguish trials selected in advance from those added after an unexpected peak appeared. The optimum gain plan depends upon the external interference population rather than a solitary nominal sensitivity specification. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range; its

Copyright 2026, James M. Atkinson

prediction should be recorded alongside where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Cascade noise figure, third-order intercept, maximum linear power and ADC headroom measure different performance constraints. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a 20 db preamplifier followed by an unlogged 15 db pad is not equivalent to putting that pad before the low-noise amplifier. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 3: Programmable attenuation should be treated as a documented state transition, not invisible software hygiene.

A receiver may meet its manufacturer's noise and gain specifications on Monday and still cease to behave comparably after a temperature excursion on Tuesday. This is a process-monitoring problem, not merely a circuit-design exercise. I would choose a small set of reference challenges: a terminated-input noise measurement, a weak two-tone discrimination test, and a strong blocker test that exercises gain reduction and recovery. Their results should be plotted by actual gain state and operating temperature rather than pooled into a reassuring average. If the system changes state automatically, the state changes themselves form part of the measurement record. A discontinuity after changing the RF attenuator could be expected and benign, while the same discontinuity with no logged cause would deserve investigation. Control limits must be established from a validated baseline, not fitted retrospectively around the very excursion being assessed. Reproducibility includes the receiver's decision history as well as its final spectrum.

In this operational measurand examination of Question 014, the decisive claim is that programmable attenuation should be treated as a documented state transition, not invisible software hygiene. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: cascade noise and overload are competing constraints. Consider a receiver whose first amplifier has 20 dB available gain and a linear noise factor of 1.5. A following stage with a noise factor of

Copyright 2026, James M. Atkinson

6 contributes only (6 minus 1)/100 = 0.05 to the overall linear noise factor under the ordinary Friis cascade assumptions, producing 1.55 or about 1.90 dB total noise figure. But a strong blocker raised by the same 20 dB can exceed the next stage's compression threshold. Adding attenuation in advance of the amplifier may preserve linearity while increasing the effective input-referred noise, and the correct setting therefore depends upon the actual blocker population. Distinguish a thermal-noise-limited experiment from a large-signal-limited experiment. A single pleasing noise-figure number cannot establish that weak emissions remain observable during simultaneous high-level traffic. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Gain budgeting in a crowded receiver is a constrained optimisation, not a contest to maximise the indicated level of the weakest emission. The relevant quantities are the greatest credible blocker power at the antenna connector, the compression and intercept limits of each preceding device, the noise contribution of each stage and the resolution available after analogue-to-digital conversion. A low-noise amplifier placed before adequate selectivity may improve nominal thermal sensitivity while making the subsequent mixer unusable in the presence of a local transmitter. An attenuator has the opposite trade-off: it improves large-signal margin but raises the input-referred noise floor. Establish at least two calibrated operating states, one sensitivity-oriented and one blocker-tolerant, and inject a weak witness tone while varying a strong adjacent tone. A disappearing witness under high blocker power is a test of overload

Copyright 2026, James M. Atkinson

susceptibility; it is not evidence that the external witness ceased transmitting. Every spectrum capture must carry its complete gain and attenuation history. Accordingly, the laboratory record for Question 014 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Cascade noise figure, third-order intercept, maximum linear power and ADC headroom measure different performance constraints. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous

Copyright 2026, James M. Atkinson

output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A 20 dB preamplifier followed by an unlogged 15 dB pad is not equivalent to putting that pad before the low-noise amplifier. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. I would therefore attach the uncertainty analysis to the *operational definition* itself instead of printing an unexplained confidence interval beside the most appealing trace.

A further, separately testable aspect of a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high concerns input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction. The proposed challenge would be sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. The decision is conditional upon the observed result, with particular attention to cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints. The competing account remains the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. Changing attenuation changes the experiment even when the displayed frequency remains unchanged. Dr Turing, please take the floor and examine what a retrospective state log must contain to recover the meaning of each observation.

Copyright 2026, James M. Atkinson

Alan Mathison Turing | Peer question 5 to Walter Andrew Shewhart

Walter Andrew Shewhart, I should like to examine what the recorded data actually preserve when a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. The physical input and the retained numerical array are not interchangeable things. Headroom, overload recovery, and weak-signal detection must be tested together across the range of gain states. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction would invalidate the preferred account, and which aspect of sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 014, the specific physical candidate is gain redistribution between low-noise amplification, filtering, mixing, IF gain, and converter full scale. The unresolved physical pathway is material: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The retained record permits a conditional claim about input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, but cannot alone resolve cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Cascade noise figure, third-order intercept, maximum linear power and ADC headroom measure different performance constraints. I propose separating acquired information

Copyright 2026, James M. Atkinson

from model-dependent reconstruction. Headroom, overload recovery, and weak-signal detection must be tested together across the range of gain states. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction and a fresh trial in which the operator sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. If that trial demonstrates where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal contribution 4: The optimum gain plan depends upon the external interference population rather than a solitary nominal sensitivity specification.

The gain-control mechanism is a dynamical system driven by the traffic it observes. Consider a receiver in which a strong pulse lowers the RF gain for a tenth of a second. A brief candidate transmission appearing immediately afterwards can be suppressed even though its amplitude would have been detectable in isolation. One measurement of sensitivity therefore cannot describe the receiver without specifying the input history. I would probe the impulse and step responses of the gain controller, including its attack, hold and release intervals; then examine whether a second weak pulse is detected at different delays after the blocker. A fixed-gain reference channel would help distinguish an emitter's silence from the instrument's temporary blindness. If operators change thresholds in response to alarms, their decisions become additional feedback paths. The archive should retain sufficient state and timing data to model these paths, rather than representing an uninterrupted spectral ribbon where the underlying system was continuously changing its transfer behaviour.

In this information retention examination of Question 014, the decisive claim is that the optimum gain plan depends upon the external interference population rather than a solitary nominal sensitivity specification. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: cascade noise and overload are competing constraints. Consider a receiver whose first amplifier has 20 dB available gain and a linear noise factor of 1.5. A following stage with a noise factor of

Copyright 2026, James M. Atkinson

6 contributes only (6 minus 1)/100 = 0.05 to the overall linear noise factor under the ordinary Friis cascade assumptions, producing 1.55 or about 1.90 dB total noise figure. But a strong blocker raised by the same 20 dB can exceed the next stage's compression threshold. Adding attenuation in advance of the amplifier may preserve linearity while increasing the effective input-referred noise, and the correct setting therefore depends upon the actual blocker population. Distinguish a thermal-noise-limited experiment from a large-signal-limited experiment. A single pleasing noise-figure number cannot establish that weak emissions remain observable during simultaneous high-level traffic. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. The scientific point of the optimum gain plan depends upon the external interference population rather than a solitary nominal sensitivity specification. is not that the result should be made more impressive but that a contrary result should be allowed to alter

Copyright 2026, James M. Atkinson

the proposed explanation. If independent sessions repeatedly show where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. The candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier. Wiener's feedback perspective questions how an adaptive controller changes the distribution of the observations it subsequently presents as independent evidence. The issue becomes especially sharp because the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. That comparison should keep the unprocessed complex values or, where only detector outputs exist,

Copyright 2026, James M. Atkinson

disclose precisely the interval and frequency domain actually examined. For the proposed case, a 20 db preamplifier followed by an unlogged 15 db pad is not equivalent to putting that pad before the low-noise amplifier. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The appropriate gain setting follows the measured interference population, not an abstract desire for maximum amplification. Dr Deming, I invite an adverse test based on the candidate disappearing as the authorised carrier keys.

W. Edwards Deming | Peer question 6 to Norbert Wiener

I thank you, Norbert Wiener, for distinguishing measurement from attribution, but the observation is that the candidate is more visible in quiet conditions but disappears whenever the authorised transmitter keys its carrier. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a 20 dB preamplifier followed by an unlogged 15 dB pad is not equivalent to putting that pad before the low-noise amplifier. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages on one day but fails after the instrument has been reconfigured? A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment? Would you also state what observed change in input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3,

Copyright 2026, James M. Atkinson

attenuation, and ADC peak code fraction would invalidate the preferred account, and which aspect of sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state would make that negative result independently repeatable?

Norbert Wiener | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 014, the specific physical candidate is gain redistribution between low-noise amplification, filtering, mixing, IF gain, and converter full scale. The unresolved physical pathway is material: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The retained record permits a conditional claim about input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, but cannot alone resolve cascade noise figure, third-order intercept, maximum linear power and adc headroom measure different performance constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a 20 dB preamplifier followed by an unlogged 15 dB pad is not equivalent to putting that pad before the low-noise amplifier. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. Its bearing on the dispute can be evaluated through the predicted response, namely where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages. Because the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range, the procedure sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match choose the gain plan that maximises validated detectability for the actual blocker distribution, not the highest numerical gain, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

Copyright 2026, James M. Atkinson

The original run and the revised run would be reported separately. Where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal contribution 5: Headroom, overload recovery, and weak-signal detection must be tested together across the range of gain states.

The expression optimum gain plan needs an explicit operational definition. For a low-duty-cycle candidate, missed short emissions might dominate the consequence of an error; for a crowded regulatory environment, spurious alarms caused by overload may be more damaging to the investigation. I would ask the engineer to specify a decision loss for both mistakes and to validate the operating regimes likely to be encountered. Measurements must be stratified by blocker strength, frequency separation, gain state and event duration. A plan performing best for an isolated weak tone can be inferior when the receiver must endure occasional high-power transmissions. The most useful output is not one celebrated noise-floor number but a performance surface showing sensitivity and false-alarm rate under named conditions. If the eventual survey contains conditions outside the characterised surface, that constitutes an uncertainty to disclose, not a reason to interpolate performance optimistically. Choosing a defensible gain allocation is itself an empirical decision under constraints.

In this statistical inference examination of Question 014, the decisive claim is that headroom, overload recovery, and weak-signal detection must be tested together across the range of gain states. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: cascade noise and

Copyright 2026, James M. Atkinson

overload are competing constraints. Consider a receiver whose first amplifier has 20 dB available gain and a linear noise factor of 1.5. A following stage with a noise factor of 6 contributes only (6 minus 1)/100 = 0.05 to the overall linear noise factor under the ordinary Friis cascade assumptions, producing 1.55 or about 1.90 dB total noise figure. But a strong blocker raised by the same 20 dB can exceed the next stage's compression threshold. Adding attenuation in advance of the amplifier may preserve linearity while increasing the effective input-referred noise, and the correct setting therefore depends upon the actual blocker population. Distinguish a thermal-noise-limited experiment from a large-signal-limited experiment. A single pleasing noise-figure number cannot establish that weak emissions remain observable during simultaneous high-level traffic. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. Headroom, overload recovery, and weak-signal detection must be tested together across the range of gain states. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to sweep the strong blocker through calibrated power steps while measuring the weak

Copyright 2026, James M. Atkinson

test tone under fixed and changed attenuation, preserving each gain state, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say choose the gain plan that maximises validated detectability for the actual blocker distribution, not the highest numerical gain, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Bridgman’s operational approach requires a measurement procedure that defines each quantity physically. A stated number unsupported by the operation that produced it is methodologically incomplete. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range.

Copyright 2026, James M. Atkinson

One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a 20 db preamplifier followed by an unlogged 15 db pad is not equivalent to putting that pad before the low-noise amplifier, is not an estimate of any actual investigation. A gain plan should fail openly when recovery time or converter headroom exceeds its declared operating limits. Sir Karl, I pass the floor to you for the question that might falsify our claimed compromise.

Sir Karl Raimund Popper | Peer question 7 to Percy Williams Bridgman

Percy Williams Bridgman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise choose the gain plan that maximises validated detectability for the actual blocker distribution, not the highest numerical gain? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. A strong blocker may drive a later stage into compression even when the desired weak signal is far beneath its noise floor. Please connect input-referred noise in dBm/Hz, cascade

Copyright 2026, James M. Atkinson

noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction with a declared detection threshold and the measurement exposure. If the experiment sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Percy Williams Bridgman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 014, the specific physical candidate is gain redistribution between low-noise amplification, filtering, mixing, IF gain, and converter full scale. The unresolved physical pathway is material: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. The retained record permits a conditional claim about input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction, but cannot alone resolve cascade noise figure, third-order intercept,

Copyright 2026, James M. Atkinson

maximum linear power and adc headroom measure different performance constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. A strong blocker may drive a later stage into compression even when the desired weak signal is far beneath its noise floor. I would use the observations of input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state, not an assertion based on the operator's impression of a quiet display. If it yields where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

Copyright 2026, James M. Atkinson

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to choose the gain plan that maximises validated detectability for the actual blocker distribution, not the highest numerical gain, with the untested physical possibilities made visible.

Hendrik Wade Bode, Cross-Peer Question to Harry Nyquist: Dr Nyquist, a low-noise amplifier ahead of an SDR can make the predicted receiver sensitivity look magnificent when the antenna sees a thermal-like background, yet the same amplifier may consume the headroom needed to survive a powerful adjacent authorised carrier. A gain sheet combines fifteen, minus six, and fifteen decibels into a twenty-four-decibel net increase, but that sum conceals the levels at the first amplifier and mixer. Which performance envelope must be mapped before an engineer chooses the highest available front-end gain? In particular, what observation would demonstrate that the weak candidate was truly preserved while a strong blocker was present, rather than hidden by compression or resuscitated as a spurious intermodulation ridge?

Harry Nyquist, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, the meaningful design variable is not total gain in isolation but the ordering of noise, filtering, attenuation and nonlinear stages under the expected signal population. For each stage I would tabulate the wanted and blocking powers, the available gain, noise factor, compression onset and relevant

Copyright 2026, James M. Atkinson

intermodulation behaviour, all at identified reference planes. Early attenuation can protect a subsequent amplifier at the price of worsening input-referred sensitivity, whereas attenuation inserted after an overloaded component cannot undo damage already created. The decision should therefore be empirical over a calibrated matrix of blocker levels and frequencies, including concurrent weak test tones and transient signals. A low-level display feature is not proved recoverable merely because its trace remains visible; one should examine distortion products, demodulation error, false alarms, missed detections and the raw ADC clipping or state flags. Where two gain configurations yield comparable detection performance, preference may turn on stability under worst-case realistic blocking and recovery rather than on the smallest theoretical noise figure. The accepted gain plan must be accompanied by its verified operating envelope.

Harry Nyquist, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, an automatic gain controller changes attenuation whenever a carrier reaches a threshold. The manufacturer's software records the steady gain setting but omits the transition's start time and several settling frames. A brief burst appears in the waterfall precisely as the controller returns from strong-signal protection, creating a spectral streak whose amplitude is subsequently treated as an external emission. How would you distinguish normal state-dependent transient behaviour from a meaningful radio event, and what process-control evidence would show that a gain schedule remained stable across a forensic recording?

Walter Andrew Shewhart, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the gain transition must be treated as an experimental event with a

Copyright 2026, James M. Atkinson

beginning, duration and verified settling criterion, not as invisible housekeeping. I should record control-command time, measured gain state, amplifier bias where relevant, ADC overload or clipping flags, blanking interval and the timestamps of the samples that receive each correction. A test signal can be injected before the active device to measure the recovery response under several blocker amplitudes and histories, whilst a second independent low-gain receiver can supply a comparison if its independence is actually established. Charts of trigger rate, duration and post-transition residual can reveal drift and recurrent operating states; they do not by themselves establish a universal distribution. An apparent ridge arising only within a documented recovery window should be reported as unresolved until a state-matched control separates instrument transient from external emission. It is essential to preserve the original uncorrected samples where they were actually recorded. A digital amplitude correction applied after saturation cannot restore missing peaks, and a smooth reconstructed trace cannot certify that lost information was present.

Norbert Wiener, Cross-Peer Question to Percy Williams Bridgman: Professor Bridgman, a designer argues for one fixed gain setting because a specification sheet quotes an impressive noise figure and a nominal ADC bit depth. Actual site measurements include a changing population of high-level transmitters, and an apparently quiet receiver sometimes raises its gain until a strong intermittent carrier forces a recovery cycle. How should the engineer define an operating population and a test procedure that covers useful weak-signal detectability across changing blocker patterns? Would you rely on a single worst-case tone, a random statistical model, or a deliberately structured suite of physically distinct adverse states?

Copyright 2026, James M. Atkinson

Percy Williams Bridgman, Cross-Peer Answer to Norbert Wiener: Professor Wiener, each of those tests answers a different question. A single strong tone establishes a repeatable compression or blocking boundary for a specified frequency and level; a two-tone challenge examines intermodulation under its own input conditions. A statistical survey of actual blockers describes the observed site's distribution during the measured interval, not every future environment. A structured adverse-state suite is therefore needed to investigate tails and unusual combinations which a short survey may miss. I would vary input power, spectral separation, burst duty cycle, gain state and recovery history whilst retaining one independently measured weak reference signal. Results should be expressed as detection probability, measurement bias or recovered dynamic range under declared conditions, accompanied by uncertainty and sample count. A gain plan should not be selected by simply maximising full-scale use or nominal sensitivity. The recorded configuration must also preserve the actual receiver state, the input reference plane and the distinct paths through which out-of-band interference may reach the converter. Where an adverse case defeats every setting, the operating limitation belongs explicitly in the technical and forensic conclusions.

Percy Williams Bridgman, Cross-Peer Question to Richard Wesley Hamming: Dr Hamming, the instrument combines two nominally twelve-bit ADC channels, assumes their quantisation noise is independent and claims to have created a twenty-four-bit observation simply by adding the codes. In reality the converters share a reference, analogue front end and sampling clock, and one channel may clip on a powerful blocker while the other does not. The worked examples also use an ideal full-scale sine formula and a

Copyright 2026, James M. Atkinson

jitter-only SNR ceiling at hundreds of megahertz. Which numerical tests would separate a potentially useful averaging or oversampling improvement from a misleading assertion that bit counts and physical instantaneous dynamic range have doubled?

Richard Wesley Hamming, Cross-Peer Answer to Percy Williams Bridgman: Professor Bridgman, the addition of two twelve-bit integer words can produce a wider computational representation, but it cannot turn those inputs into a physical twenty-four-bit conversion with the signal-to-noise and linearity of an ideal twenty-four-bit converter. Effective resolution is determined by measured noise, distortion, input range and calibration, and the averaging benefit depends on a model of the errors and their covariance. If errors are perfectly correlated, their contribution does not diminish through averaging. An experiment should measure the actual small-signal and large-signal transfer functions, coherent spurious content, clipping boundary and signal-to-noise ratio over the relevant bandwidth. Oversampling and suitable filtering may redistribute quantisation noise or provide genuine processing gain under specified conditions; it does not recover peaks already clipped before sampling. At high input frequency, sampling-clock aperture jitter places another ceiling which must be combined with rather than substituted for other imperfections. Publish effective-number-of-bits and spurious-free dynamic-range results with the test frequency, sample rate, acquisition bandwidth and reference conditions. Calling the resulting file twenty-four bits wide is a storage description; calling it twenty-four-bit accurate requires evidence that the physical converter can support that claim.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of dynamic-range allocation through a cascade of analogue gain, attenuation, and conversion stages has established a point which the specialist must not overlook. The receiver records input-referred and digital power levels under simultaneously present strong and weak signals; it does not, merely by drawing a clear trace, give direct access to unlogged compression, overload recovery, or quantiser masking that distorts the apparent weak feature. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, A first low-noise amplifier can improve the cascade noise figure while consuming dynamic-range headroom. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

I thank Dr Nyquist for the insistence upon closed-loop stability and Professor Bode for the discipline of carrying power levels through an entire cascade. An attractive weak-signal gain figure cannot certify a receiver whose following mixer or digitiser is periodically overdriven. The decisive engineering record is a stage-by-stage map of maximum admissible blocker power, input-referred noise and gain-state chronology, supplemented by a probe signal which demonstrates whether a faint target remained detectable while the blocker was present. The investigator should distinguish attenuation placed before the first nonlinear element from attenuation introduced downstream, because the latter cannot reverse

Copyright 2026, James M. Atkinson

distortion already generated. A gain schedule that wins a laboratory sensitivity comparison but loses a field overload challenge must be rejected for that environment. Let the closing recommendation therefore take the form of two tested envelopes, one for detection and one for overload, each tied to frequency, bandwidth, temperature and input impedance. Any confident identification of an intermittent source must remain conditional upon those envelopes.

The weak candidate vanished whenever the legitimate blocker was present. That temporal coincidence cannot establish that the candidate stopped transmitting: it could have become unobservable through reciprocal mixing, compression or converter saturation. The capture should contain the blocker level, each gain-state transition and an independently injected probe demonstrating whether the receiver remained sensitive at that instant. The more useful outcome is a discriminating protocol: Sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. In applying it, the examiner must retain all readings supporting input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction and identify the physical plane to which the measurements refer. At the outset of the investigation, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high; that circumstance makes the alternative mechanism material, specifically the high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-scale range. A result approaching where clipping governs, reducing gain can restore the

Copyright 2026, James M. Atkinson

weak candidate despite raising the small-signal noise contribution of later stages may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore choose the gain plan that maximises validated detectability for the actual blocker distribution, not the highest numerical gain. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

The appropriate gain plan is the configuration which demonstrably retains usable dynamic range in the measured blocker environment while providing adequate weak-signal sensitivity. Its acceptance criteria must include intermediate-stage headroom, not just converter full scale, and must be repeated when the RF environment changes. The decisive experiment is concrete: Sweep the strong blocker through calibrated power steps while measuring the weak test tone under fixed and changed attenuation, preserving each gain state. In conducting it, the examiner must explicitly retain input-referred noise in dBm/Hz, cascade noise factor, P1dB, IIP3, attenuation, and ADC peak code fraction. If the outcome matches the stated prediction, where clipping governs, reducing gain can restore the weak candidate despite raising the small-signal noise contribution of later stages, the supported conclusion concerns that test domain. An alternative remains: The high-gain front end may improve input-referred thermal sensitivity yet compress an intermediate stage or exhaust the converter full-

Copyright 2026, James M. Atkinson

scale range. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 014

Application 01. Cascade gain and observed headroom

In the illustrative 014.01 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. A first amplifier contributes G_1 = 15 dB, an intentional attenuation contributes G_2 = -6 dB, and a later stage contributes G_3 = 15 dB. The small-signal sum is 15 + (-6) + 15 = 24 dB. For P_i = -73 dBm, the ideal output is P_o = -49 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. Use stage-by-stage blocker levels and compression checks before accepting the 24 dB net gain as a usable weak-signal configuration.

Application 02. Thermal reference noise in a declared measurement bandwidth

In the illustrative 014.02 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. Take the equivalent noise bandwidth B = 4,500 Hz and calibrated noise figure NF = 3.90 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF$ = -133.57 dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The -133.57 dBm thermal estimate defines the selected noise bandwidth and noise figure, not the ambient interference floor beside a strong transmitter.

Copyright 2026, James M. Atkinson

Application 03. Gain allocation and blocker headroom

In the illustrative 014.03 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. Assume a calibrated digital full-scale equivalent of -11 dBm, a blocker applied at -42 dBm, and net analogue gain 25 dB. The projected converter input is -17 dBm and remaining margin is -11 − (-17) = 6 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. Six decibels of nominal full-scale margin is insufficient assurance if an earlier stage compresses or a transient carrier exceeds the assumed blocker level.

Application 04. Two-tone third-order products and input intercept

In the illustrative 014.04 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. With two equal input tones each at P = -31 dBm and a hypothetical input third-order intercept IIP_3 = +10 dBm, the extrapolated input-referred third-order product is $P_3 = 3P - 2IIP_3$ = -113 dBm, or -82 dBc relative to either input tone. The cubic approximation ceases to be reliable in compression. A two-tone slope check and input attenuation test must establish whether the predicted spur arises inside the receiver rather than externally. The -113 dBm third-order product is extrapolated from an ideal slope; verify actual intermodulation growth before trusting a weak line near that level.

Copyright 2026, James M. Atkinson

Application 05. Filter or cable rejection referred to a physical input

In the illustrative 014.05 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. For an admitted input P_i = -54 dBm and separately measured loss L = 41 dB, the linear prediction is P_o = P_i − L = -95 dBm. In SI power this becomes 10^((-95 − 30)/10) = 3.16e-13 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. An attenuation result referred to a matched port cannot prove installed-system rejection without tests for feeder bypass and common-mode coupling.

Application 06. Ideal code step, variance, and full-scale sine SNR

In the illustrative 014.06 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. Taking an ideal N = 12-bit uniform converter across 3.00 V peak-to-peak, one nominal code interval is $\Delta = Vpp/2^N$ = 0.7324 mV. Under the independent uniform-error approximation its rms quantisation error is $\sigma = \Delta/\sqrt{12}$ = 0.2114 mV. The ideal full-scale sinusoidal SNR approximation is 6.02N + 1.76 = 74.00 dB. A coherent low-level waveform may violate the uniform-error assumption; clipping and integral nonlinearity are separate limitations. The 74.00 dB ideal converter SNR is not measured ENOB; verify SINAD, distortion and clipping at the required signal amplitude and bandwidth.

Copyright 2026, James M. Atkinson

Application 07. The frequency dependence of aperture-jitter-limited SNR

In the illustrative 014.07 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. At sinusoidal input frequency f = 309 MHz with uncorrelated rms aperture jitter σ_t = 1.74 ps, the idealised jitter-imposed ceiling is $SNR_j = -20 \log_{10}(2\pi f \sigma_t)$ = 49.43 dB. A common clock source may correlate errors across parallel ADC channels, so treating their outputs as independent for noise cancellation would need an additional experiment. Converter nonlinearity and thermal noise can make actual performance worse. The 49.43 dB jitter ceiling is conditional on the rms clock model; correlated sampling errors cannot be counted as independent noise for parallel averaging.

Application 08. Combined and expanded measurement uncertainty

In the illustrative 014.08 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. For independent standard-uncertainty contributions 0.45, 0.54 and 0.34 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.45^2 + 0.54^2 + 0.34^2)}$ = 0.781 units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c$ = 1.562 units. The 1.562-unit expanded uncertainty presumes the three contributions are independent; common gain-state errors demand covariance terms where applicable.

Copyright 2026, James M. Atkinson

Application 09. Difference between two instruments relative to stated uncertainty

In the illustrative 014.09 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. The paired instrument contrast is $\Delta = 0.920$ dB. Set independent standard uncertainties $u_1 = 0.380$ dB and $u_2 = 0.470$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.604$ dB, giving the dimensionless ratio $\Delta/u\Delta = 1.522$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. A contrast ratio of 1.522 is insufficient for any categorical improvement claim without predeclared acceptance criteria and a proper calibration covariance analysis.

Application 10. Opportunity-limited detection under independent visits

In the illustrative 014.10 test, a weak telemetry candidate occupies a frequency channel adjacent to a powerful authorised transmitter, with front-end amplification presently set high. For $n = 42$ genuinely independent valid observation opportunities, each with stipulated event detection chance $p = 0.06$, the probability of no detections is $(1 - p)^n = 0.07437$; its complement is 92.56%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The 7.44 per cent hypothetical miss probability assumes 42 independent opportunities; scheduled bursts and correlated gain states can invalidate that exponent.

QUESTION 016

Copyright 2026, James M. Atkinson

How can local-oscillator leakage and reciprocal mixing imitate or obscure emissions?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 016 asks: How can local-oscillator leakage and reciprocal mixing imitate or obscure emissions? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is the ambiguity between genuine radiated emissions and local-oscillator leakage or reciprocal mixing. Our primary observation is a feature whose power or offset tracks receiver tuning, oscillator state, or a nearby strong blocker; by contrast, what remains unseen is the true electromagnetic field at the antenna reference plane. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Reciprocal mixing and oscillator contamination. A strong neighbouring carrier can become apparent noise around a weak desired signal through oscillator sidebands. The relevant variable is not merely the oscillator’s

Copyright 2026, James M. Atkinson

frequency error but its phase-noise density at the blocker's offset. If the blocker is minus 25 dBm, a single-sideband phase-noise level of minus 105 dBc per hertz at the relevant offset gives a first-order reciprocal-mixing density around minus 130 dBm per hertz, before the measurement-chain qualification. An integrated one-kilohertz analysis window then corresponds approximately to minus 100 dBm when the density is flat over that interval. This is not evidence that the antenna received broadband noise of that power. Repeating with a cleaner reference oscillator, moving the blocker or using an independent conversion chain helps separate receiver-borne phase-noise effects from external wideband radiation. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns a feature whose power or offset tracks receiver tuning, oscillator state, or a nearby strong blocker; it is not interchangeable with the true electromagnetic field at the antenna reference plane. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is independent LO-frequency perturbation, terminated-input check, and high-selectivity preselection trial. A claim drawn from that comparison has to carry its actual uncertainties: LO leakage level, offset phase noise, blocker power, and instrument dependence. Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. Phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in noise. Moving the LO

Copyright 2026, James M. Atkinson

changes the internal mixing relationship while a genuine external carrier remains at its physical frequency. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Principal contribution 1: Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors.

The local oscillator is an active source within the receiving instrument, and that simple fact changes the evidential interpretation of a spectral line. Its leakage may pass through the mixer, its shielding or even the antenna port. A test signal entering at a different frequency can combine with oscillator components to yield a false feature at the intermediate frequency or baseband. I would vary the oscillator frequency in controlled increments while retaining a known RF reference. If the suspect feature follows a mixing relationship rather than an external fixed carrier, the receiver is implicated. Yet oscillator motion can also change the tuning presented to a real emitter, so the experiment needs an invariant external reference plane and careful accounting for image inversion. A shielded enclosure and a passive termination offer further tests, although neither is infallible where the mains and control cables provide ingress. The circuit hypothesis is established through predicted frequency movement and amplitude scaling, not by calling every unexplained line a spurious emission.

In this physical path examination of Question 016, the decisive claim is that mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. Reciprocal mixing and oscillator leakage are different physical phenomena and require different challenges. Oscillator leakage is an emission from the receiver or its cabling; reciprocal mixing elevates close-in noise when a strong input interacts with the phase noise of the receiver oscillator. A retune may shift one artefact with the local-oscillator control word while leaving an externally fixed carrier

Copyright 2026, James M. Atkinson

unchanged, but the tracking relationship is not by itself unique. To discriminate, the investigator must vary oscillator offset, blocker level and input termination independently. A second receiver with a demonstrably separate oscillator and acquisition path provides a stronger comparison than two demodulators sharing one synthesiser. A useful falsification proceeds from the actual controversy: reciprocal mixing and oscillator contamination. A strong neighbouring carrier can become apparent noise around a weak desired signal through oscillator sidebands. The relevant variable is not merely the oscillator's frequency error but its phase-noise density at the blocker's offset. If the blocker is minus 25 dBm, a single-sideband phase-noise level of minus 105 dBc per hertz at the relevant offset gives a first-order reciprocal-mixing density around minus 130 dBm per hertz, before the measurement-chain qualification. An integrated one-kilohertz analysis window then corresponds approximately to minus 100 dBm when the density is flat over that interval. This is not evidence that the antenna received broadband noise of that power. Repeating with a cleaner reference oscillator, moving the blocker or using an independent conversion chain helps separate receiver-borne phase-noise effects from external wideband radiation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Set the LO to three documented frequencies while holding a calibrated external source fixed. Record the spectral line at the antenna port with an independent receiver, then repeat with the suspicious receiver terminated and enclosed in a controlled screening arrangement. For reciprocal mixing, introduce a blocker at a known frequency separation and record the output

Copyright 2026, James M. Atkinson

noise density as its input power is varied. The noise contribution should follow the phase-noise mask and detector bandwidth, subject to compression and correlated errors. A leaking oscillator should instead show an emission in a physical radiation or conducted-coupling measurement. I would take LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. A response consistent with an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

Copyright 2026, James M. Atkinson

The circuit cannot be judged from its final trace alone. A frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by lo radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls, and measure their behaviour separately before reconnecting the assembled system. Armstrong's receiver engineering points to actual conversion products and oscillation conditions rather than abstract spectral indications; the crucial question is where the energy first appears. It is therefore material to establish LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope rather than infer them from a single scalar output. The limiting test is concrete: Perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. If the intervention produces an internal leakage product can move with the programmed lo offset while a genuine station remains at a fixed external rf frequency, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret the trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor as a new transmitter before challenging the most economical instrumental explanation. A trace tied to the oscillator command may be receiver leakage rather than another emitter. Professor Tukey,

Copyright 2026, James M. Atkinson

please take the floor and test which retuning comparisons could distinguish those accounts.

John Wilder Tukey | Peer question 1 to Edwin Howard Armstrong

Edwin Howard Armstrong, may I test the exact physical inference in your account of a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna? The proposed mechanism appears plausible only if changes after perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path are compared with a stable reference condition. Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope which would settle that narrower claim, rather than a visual impression of improvement.

Edwin Howard Armstrong | Immediate answer to John Wilder Tukey

Dr Tukey, a retune observation is useful only after we ask whether the same physical reference moved. The oscillator setting is a control variable, not a declaration that the antenna received a corresponding emitter. I would therefore measure the suspected leakage at a

Copyright 2026, James M. Atkinson

separate receiving antenna, and test reciprocal noise elevation with a level-verified blocker. If the two experiments disagree, that is evidence for different mechanisms rather than a reason to average their outputs. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 016, the specific physical candidate is LO leakage, reverse radiation from mixers, and phase-noise skirts multiplying adjacent strong signals. The unresolved physical pathway is material: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The retained record permits a conditional claim about LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope, but cannot alone resolve a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. I would first inject the known stimulus and verify its amplitude at the entrance to the

Copyright 2026, James M. Atkinson

claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path, and only a response matching an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Perturb the lo independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns LO frequency, mixer isolation, blocker offset, close-in phase-

Copyright 2026, James M. Atkinson

noise density, and spur-versus-retune slope, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Edwin Howard Armstrong

I appreciate your explanation, Edwin Howard Armstrong. How would your conclusion survive a deliberately independent test of the trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor? A second receiver might share more of the supposed evidence than its separate enclosure suggests. Phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in noise. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope and document which differences remain unexplained? Would you also state what observed change in LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope would invalidate the preferred account, and which aspect of perturb the lo independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 016, the specific physical candidate is LO leakage, reverse radiation from mixers, and phase-noise skirts multiplying adjacent strong signals. The unresolved physical pathway is material: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The retained record permits a conditional claim about LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope, but cannot alone resolve a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. I would draw the actual distribution network before collecting new corroborating evidence,

Copyright 2026, James M. Atkinson

marking where two receivers share signal, power or time references. Phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in noise. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls; I would challenge it with perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. Two responses consistent with an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, lo radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. A discordant measurement would then be interpreted by tracing that difference through LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 2: Phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in noise.

Reciprocal mixing presents a subtler problem than an isolated oscillator spur. A large neighbouring carrier may combine with the oscillator's phase-noise sidebands, converting broad skirts into the frequency region where a weak target is sought. This depends on phase-noise spectral density at the appropriate offset, blocker amplitude and the receiver's filter chain. I would measure the oscillator sidebands with a suitable phase-noise or cross-correlation method, then introduce a characterised blocker at several offsets and powers. The resulting rise in in-channel noise should be compared against an independent receiver chain whose oscillator noise is materially different. A single oscillator phase-noise figure quoted at one offset cannot predict the entire disturbance when strong carriers lie across a band. Likewise, replacing a synthesiser may alter both phase-noise levels and discrete spur patterns. The record should distinguish a broad reciprocal-mixing pedestal from a stable local-oscillator birdie. They demand different causes, different experiments and different limits on any source attribution.

In this control and stability examination of Question 016, the decisive claim is that phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in noise. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: reciprocal mixing and oscillator contamination. A strong neighbouring carrier can become apparent noise

Copyright 2026, James M. Atkinson

around a weak desired signal through oscillator sidebands. The relevant variable is not merely the oscillator’s frequency error but its phase-noise density at the blocker’s offset. If the blocker is minus 25 dBm, a single-sideband phase-noise level of minus 105 dBc per hertz at the relevant offset gives a first-order reciprocal-mixing density around minus 130 dBm per hertz, before the measurement-chain qualification. An integrated one-kilohertz analysis window then corresponds approximately to minus 100 dBm when the density is flat over that interval. This is not evidence that the antenna received broadband noise of that power. Repeating with a cleaner reference oscillator, moving the blocker or using an independent conversion chain helps separate receiver-borne phase-noise effects from external wideband radiation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by the trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in

Copyright 2026, James M. Atkinson

noise. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, the trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. This predicts a response which should be tested against an internal leakage product can move with the programmed lo offset while a genuine station remains at a fixed external rf frequency. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore

Copyright 2026, James M. Atkinson

measurements discarded during retuning. Where a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain, the correct claim must name the operational states and the evidence available in each. Phase-noise skirts must be challenged with a blocker of known level and separation, while the local-oscillator state is recorded. Dr Pearson, I invite you to examine the evidential force of that calibration.

Egon Sharpe Pearson | Peer question 3 to Hendrik Wade Bode

Hendrik Wade Bode, your calibration argument invites a question about reference planes, especially because a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. The reference stimulus and the unknown emission need not occupy the same physical regime. Moving the LO changes the internal mixing relationship while a genuine external carrier remains at its physical frequency. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When the trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 016, the specific physical candidate is LO leakage, reverse radiation from mixers, and phase-noise skirts multiplying adjacent strong signals. The unresolved physical pathway is material: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The retained record permits a conditional claim about LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope, but cannot alone resolve a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope. Moving the LO changes the internal mixing relationship while a genuine external carrier remains at its physical frequency. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be perturb the LO independently of the antenna frequency, substitute a matched

Copyright 2026, James M. Atkinson

termination, and compare with a separately clocked direct-sampling path, with before-and-after values of LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope. If the instrument behaves as predicted, then an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. The trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Hendrik Wade Bode

There is an inferential difficulty, Hendrik Wade Bode: lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The population of admissible observations needs to be fixed before any confidence argument. In this situation, a frequency-correlated display does not

Copyright 2026, James M. Atkinson

establish whether energy traversed the antenna or was generated within the conversion chain. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Terminated-port tests can exclude some radiated mechanisms but cannot rule out every cable-mediated path. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope would invalidate the preferred account, and which aspect of perturb the lo independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path would make that negative result independently repeatable?

Hendrik Wade Bode | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 016, the specific physical candidate is LO leakage, reverse

Copyright 2026, James M. Atkinson

radiation from mixers, and phase-noise skirts multiplying adjacent strong signals. The unresolved physical pathway is material: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The retained record permits a conditional claim about LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope, but cannot alone resolve a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because the trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Terminated-port tests can exclude some radiated mechanisms but cannot rule out every cable-mediated path. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real

Copyright 2026, James M. Atkinson

external carrier can create superficially similar waterfalls; its prediction should be recorded alongside an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. A frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, if an indicated carrier shifts by 250 khz following a 250 khz lo change, that covariation is a diagnostic clue, not a transmitter fingerprint. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Dennis Gabor | Principal contribution 3: Moving the LO changes the internal mixing relationship while a genuine external carrier remains at its physical frequency.

What troubles me is the apparent certainty that can arise from a narrow time-frequency plot of an oscillator-related transient. A synthesiser may have a settling trajectory during retuning; a waterfall renders a sequence of FFT magnitudes, not an instantaneous account of the oscillator's phase history. A short slanted mark after a frequency change can thus be created by the interaction of chirped local oscillator, finite analysis window and display update. I would retain raw I/Q through a controlled retune and compute several window lengths, looking for the time-frequency geometry predicted by the synthesiser model. If the line is reinterpreted as an external frequency sweep, then the same waveform should survive an independently disciplined receiver with a stable LO and an independently captured RF reference. We must not turn a convenient graphical trajectory into a history of a transmitter that may never have existed.

In this operational measurand examination of Question 016, the decisive claim is that moving the LO changes the internal mixing relationship while a genuine external carrier remains at its physical frequency. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: reciprocal mixing and oscillator contamination. A strong neighbouring carrier can become apparent noise around a weak desired signal through oscillator sidebands. The relevant variable is not merely the oscillator’s frequency error but its phase-noise density at the blocker’s offset. If the blocker is minus 25 dBm, a single-

Copyright 2026, James M. Atkinson

sideband phase-noise level of minus 105 dBc per hertz at the relevant offset gives a first-order reciprocal-mixing density around minus 130 dBm per hertz, before the measurement-chain qualification. An integrated one-kilohertz analysis window then corresponds approximately to minus 100 dBm when the density is flat over that interval. This is not evidence that the antenna received broadband noise of that power. Repeating with a cleaner reference oscillator, moving the blocker or using an independent conversion chain helps separate receiver-borne phase-noise effects from external wideband radiation. The speaker must not confuse the result of this bounded comparison with a general finding concerning every possible external transmission. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

A local oscillator is an active electromagnetic source within the measurement chain, and its leakage may escape through the antenna port, couple into adjacent receivers or mix with an unrelated external carrier. An apparent emission at the image or intermediate-frequency offset must therefore be tested with frequency-plan perturbations. Move the tuned centre frequency by a prescribed increment while retaining the same antenna and gain configuration. A genuine fixed-frequency external carrier remains at the same absolute RF frequency, whereas a receiver-generated product may move according to an oscillator harmonic or mixing equation. Reciprocal mixing demands a second, different trial: a powerful off-channel signal combined with oscillator phase noise can raise the apparent close-in noise floor and conceal a weak target without forming one sharp spurious line. The appropriate evidence includes oscillator offsets, filter

Copyright 2026, James M. Atkinson

characteristics, measured phase-noise skirts and strong-signal loading. A silent waterfall during the blocker condition does not certify an empty external channel. Accordingly, the laboratory record for Question 016 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. A frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. Gabor’s time-frequency work makes the time support and spectral concentration of an observation inseparable; a display cannot recover temporal detail that the window suppressed. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous output, an average over

Copyright 2026, James M. Atkinson

admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: If an indicated carrier shifts by 250 kHz following a 250 kHz LO change, that covariation is a diagnostic clue, not a transmitter fingerprint. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. Retuning can change an internal product while leaving an external carrier physically stationary. Dr Turing, I pass the floor to you to interrogate what the logged tuning sequence actually makes recoverable.

Alan Mathison Turing | Peer question 5 to Dennis Gabor

Dennis Gabor, I should like to examine what the recorded data actually preserve when a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. The physical input and the retained numerical array are not interchangeable things. An independent receiver using a materially different conversion plan can reduce common-circuit ambiguity. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope would invalidate the preferred account,

Copyright 2026, James M. Atkinson

and which aspect of perturb the lo independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path would make that negative result independently repeatable?

Dennis Gabor | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 016, the specific physical candidate is LO leakage, reverse radiation from mixers, and phase-noise skirts multiplying adjacent strong signals. The unresolved physical pathway is material: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The retained record permits a conditional claim about LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope, but cannot alone resolve a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire

Copyright 2026, James M. Atkinson

analogue environment. A frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. I propose separating acquired information from model-dependent reconstruction. An independent receiver using a materially different conversion plan can reduce common-circuit ambiguity. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope and a fresh trial in which the operator perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. If that trial demonstrates an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include perturb the lo independently of the antenna frequency, substitute a matched termination, and compare with a

Copyright 2026, James M. Atkinson

separately clocked direct-sampling path. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 4: Terminated-port tests can exclude some radiated mechanisms but cannot rule out every cable-mediated path.

It is helpful to separate two inverse questions. One asks whether a digital line could have arisen from a known oscillator-and-mixer mechanism; the other asks which physical source, among many possibilities, produced the analogue inputs. A matched digital signature may strongly favour one mechanism, but the digital record alone rarely identifies a unique external radiator. For the first question, preserve oscillator settings, PLL lock indicators, synthesiser programming history and gain-state changes synchronised with the samples. For the second, measure how the signal behaves when the antenna is disconnected or the preselector is altered, remembering that those actions can themselves affect mixer loading and oscillator leakage. An apparent absence after disconnecting the aerial is not proof of an emitter outside the building unless an alternative ingress path has been tested. Information lost at mixing cannot be recreated by a confident interpretation of a single waterfall pixel.

In this information retention examination of Question 016, the decisive claim is that terminated-port tests can exclude some radiated mechanisms but cannot rule out every cable-mediated path. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: reciprocal mixing and oscillator contamination. A strong neighbouring carrier can become apparent noise around a weak desired signal through oscillator sidebands. The relevant variable is not merely the oscillator’s frequency error but its phase-noise density at the blocker’s offset.

Copyright 2026, James M. Atkinson

If the blocker is minus 25 dBm, a single-sideband phase-noise level of minus 105 dBc per hertz at the relevant offset gives a first-order reciprocal-mixing density around minus 130 dBm per hertz, before the measurement-chain qualification. An integrated one-kilohertz analysis window then corresponds approximately to minus 100 dBm when the density is flat over that interval. This is not evidence that the antenna received broadband noise of that power. Repeating with a cleaner reference oscillator, moving the blocker or using an independent conversion chain helps separate receiver-borne phase-noise effects from external wideband radiation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. The scientific point of terminated-port tests can exclude some radiated mechanisms but cannot rule out every cable-mediated path. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions repeatedly show an internal leakage product can move with the

Copyright 2026, James M. Atkinson

programmed LO offset while a genuine station remains at a fixed external RF frequency, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. The trace follows an offset from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor. Shannon's information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. The issue becomes especially sharp because lo radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Perturb the lo independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the proposed case, if an

Copyright 2026, James M. Atkinson

indicated carrier shifts by 250 khz following a 250 khz lo change, that covariation is a diagnostic clue, not a transmitter fingerprint. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A further, separately testable aspect of a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna concerns LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope. The proposed challenge would be perturb the lo independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. The decision is conditional upon the observed result, with particular attention to a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. The competing account remains lo radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. A terminated antenna port can remove one coupling path without excluding leakage through conductors or receiver controls. Dr Deming, I invite you to design the challenge that might reveal that residual route.

W. Edwards Deming | Peer question 6 to Claude Elwood Shannon

I thank you, Claude Elwood Shannon, for distinguishing measurement from attribution, but the observation is that the trace follows an offset

Copyright 2026, James M. Atkinson

from a local-oscillator control word rather than a fixed frequency measured by a second independent sensor. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: if an indicated carrier shifts by 250 kHz following a 250 kHz LO change, that covariation is a diagnostic clue, not a transmitter fingerprint. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency on one day but fails after the instrument has been reconfigured? Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Claude Elwood Shannon | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 016, the specific physical candidate is LO leakage, reverse radiation from mixers, and phase-noise skirts multiplying adjacent strong signals. The unresolved physical pathway

Copyright 2026, James M. Atkinson

is material: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The retained record permits a conditional claim about LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope, but cannot alone resolve a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, if an indicated carrier shifts by 250 kHz following a 250 kHz LO change, that covariation is a diagnostic clue, not a transmitter fingerprint. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. Its bearing on the dispute can be evaluated through the predicted response, namely an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency. Because lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls, the procedure perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path should be repeated with the same calibration and an independent witness path. If

Copyright 2026, James M. Atkinson

agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match distinguish receiver self-emission and reciprocal-mixing artefacts before declaring a separate clandestine source, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. An internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 5: An independent receiver using a materially different conversion plan can reduce common-circuit ambiguity.

I would treat the oscillator-artifact diagnosis as an experimental process with reference controls. Establish a stable source, move the local oscillator according to a predeclared sequence, and record the expected movement of real carriers, image responses, internal spurs and reciprocal-mixing skirts. Then test whether each expected class follows its assigned rule over temperature and repeated power cycles. A spectral spur that disappears in one of ten trials should not be excluded from the failure model simply because the remaining nine trials looked consistent. Control runs must also include transitions, since a PLL's acquisition period can create brief, highly persuasive artefacts. The engineer should report false identification rates under the tested conditions and preserve outliers for explanation. The distinction between a nuisance line and a genuine emitter emerges from the reproducibility of competing physical predictions, not the visual neatness of a laboratory display.

In this statistical inference examination of Question 016, the decisive claim is that an independent receiver using a materially different conversion plan can reduce common-circuit ambiguity. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: reciprocal mixing and oscillator contamination. A strong neighbouring carrier can become apparent noise around a weak desired signal through oscillator sidebands. The relevant

Copyright 2026, James M. Atkinson

variable is not merely the oscillator's frequency error but its phase-noise density at the blocker's offset. If the blocker is minus 25 dBm, a single-sideband phase-noise level of minus 105 dBc per hertz at the relevant offset gives a first-order reciprocal-mixing density around minus 130 dBm per hertz, before the measurement-chain qualification. An integrated one-kilohertz analysis window then corresponds approximately to minus 100 dBm when the density is flat over that interval. This is not evidence that the antenna received broadband noise of that power. Repeating with a cleaner reference oscillator, moving the blocker or using an independent conversion chain helps separate receiver-borne phase-noise effects from external wideband radiation. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. An independent receiver using a materially different conversion plan can reduce common-circuit ambiguity. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two

Copyright 2026, James M. Atkinson

displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say distinguish receiver self-emission and reciprocal-mixing artefacts before declaring a separate clandestine source, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that lo radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are

Copyright 2026, James M. Atkinson

LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from an internal leakage product can move with the programmed lo offset while a genuine station remains at a fixed external rf frequency, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, if an indicated carrier shifts by 250 khz following a 250 khz lo change, that covariation is a diagnostic clue, not a transmitter fingerprint, is not an estimate of any actual investigation. Two receivers agreeing is useful only when their conversion dependencies are genuinely different. Sir Karl, please take the floor and consider what contrary observation would defeat our asserted independence.

Sir Karl Raimund Popper | Peer question 7 to Walter Andrew Shewhart

Walter Andrew Shewhart, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise distinguish receiver self-emission and reciprocal-mixing artefacts before declaring a separate clandestine source? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in noise. Please connect LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope with a declared detection threshold and the measurement exposure. If the experiment perturb the LO

Copyright 2026, James M. Atkinson

independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Walter Andrew Shewhart | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 016, the specific physical candidate is LO leakage, reverse radiation from mixers, and phase-noise skirts multiplying adjacent strong signals. The unresolved physical pathway is material: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. The retained record permits a conditional claim about LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope, but cannot alone resolve a frequency-correlated display does not establish whether energy traversed the antenna or was generated within the conversion chain.

Copyright 2026, James M. Atkinson

That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Phase noise around a large local oscillator or blocker converts frequency offset into apparent close-in noise. I would use the observations of LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path, not an assertion based on the operator's impression of a quiet display. If it yields an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since lo radiation, mixer

Copyright 2026, James M. Atkinson

feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to distinguish receiver self-emission and reciprocal-mixing artefacts before declaring a separate clandestine source, with the untested physical possibilities made visible.

Edwin Howard Armstrong, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, a receiver shows a raised floor around a strong adjacent carrier at the same time that an independent probe detects weak radiation near its local-oscillator frequency. An operator has labelled both observations 'oscillator leakage' and claims that removing the nearby blocker will remove the internal emission. The receiver is retuned, and both the image and the noise skirt move on the waterfall, although they need not share a causal mechanism. How would you separate an oscillator signal escaping through a physical coupling path from reciprocal mixing caused by sideband phase noise, and which measurements must remain at a fixed radio-frequency reference plane?

Hendrik Wade Bode, Cross-Peer Answer to Edwin Howard Armstrong: Dr Armstrong, radiation of an oscillator component and reciprocal mixing are not the same measurand. For leakage I would use a calibrated, separately powered probe or receiver, record the absolute frequency and level at a declared external reference plane, and perturb the suspect oscillator while documenting screening, cables and terminations. For reciprocal mixing I would independently characterise the strong blocker's spectrum and the receiver oscillator's single-sideband phase-noise density at the offset that

Copyright 2026, James M. Atkinson

places sideband energy in the measurement filter. Then I would vary blocker power and offset with gain, filter bandwidth and tuning state recorded. Reciprocal-mixing noise may scale with blocker power even if the oscillator's escaped field at the probe is unchanged. A moving IF trace alone proves neither mechanism. If both occur, the report must retain two causal hypotheses and two uncertainty budgets rather than borrowing evidence from one to establish the other. With your leave, I pass the floor to Dr Shannon.

Claude Elwood Shannon, Cross-Peer Question to Dennis Gabor: Professor Gabor, the operator changes the LO by a specified increment and sees a feature translate by that increment in displayed intermediate frequency. The same software re-labels the horizontal axis as an inferred RF frequency, while a separately digitised antenna monitor shows a stationary feature. The result is described alternately as proof of internal spurious response and proof of external reception. What coordinate system and observation window should the experiment specify, and how can a retuning test distinguish a synthesiser spur from an actual emitter without treating a transformed display as a second sensor?

Dennis Gabor, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, write down the actual conversion and sampling map before interpreting the motion. The laboratory record should give LO frequency, injection side, intermediate-frequency sign convention, digital complex mixing frequency, sample rate, filter bandwidth and whether the software displays signed baseband or reconstructed RF. Simultaneously retain raw I/Q, the independent monitor's frequency standard and the absolute frequency of any oscillator leakage measured outside the receiver. Retuning can

Copyright 2026, James M. Atkinson

distinguish models only if we predict how each candidate moves in the chosen coordinates, including images, synthesiser-related spurs and external carriers. A feature that is stationary in reconstructed RF but moves in IF is compatible with external reception, yet it is not decisive if software or clocking shares a fault. Window length, time stamps and gain transitions must be preserved so that apparent line motion is not merely a change in time-frequency resolution or a skipped measurement interval. With your leave, I pass the floor to Dr Hamming.

Richard Wesley Hamming, Cross-Peer Question to Edwin Howard Armstrong: Dr Armstrong, our blocker trial reports an increase in in-band noise when the blocker rises by ten decibels. Another operator sees a similar rise when the ADC approaches full scale and calls the phenomenon reciprocal mixing. What intervention would distinguish sideband noise transferred through the mixer from compression, quantisation artefacts and third-order intermodulation? Please specify the observations that would count against the reciprocal-mixing explanation, not merely those that would make the plotted spectrum resemble the textbook picture.

Edwin Howard Armstrong, Cross-Peer Answer to Richard Wesley Hamming: Dr Hamming, a ten-decibel association by itself is inadequate. I should establish a known small-signal operating regime with a measured low-gain path and monitor the blocker level before every susceptible amplifier, mixer and converter. With the receiver gain and equivalent-noise bandwidth fixed, change blocker offset while recording the oscillator phase-noise spectrum at the corresponding offsets; the reciprocal-mixing hypothesis predicts a relationship between blocker power, sideband phase noise and noise integrated into the wanted filter. Repeat with the blocker removed, with a

Copyright 2026, James M. Atkinson

calibrated alternate oscillator if possible, and with a receiver architecture that avoids the suspect conversion stage. Compression instead predicts gain reduction and potential broadband distortion, while discrete intermodulation predicts frequency relations and often a different power slope in its applicable regime. Where the intervention changes multiple parameters, the mechanisms remain confounded. The evidence should identify which response contradicted which hypothesis, including any unresolved mixture of mechanisms. With your leave, I pass the floor to Dr Tukey.

John Wilder Tukey, Cross-Peer Question to Walter Andrew Shewhart: Mr Shewhart, a terminated-port survey records no obvious spur after a firmware update, and a later antenna-connected observation contains a small peak that the analyst therefore calls a remote transmitter. The technician searched many tuning states and inspected only the quiet termination trace, while the LO settled for a variable interval after every state change. What repeatability and decision-control procedure would prevent a merely negative internal test from becoming positive proof of external origin, especially when drift and post-selection are plausible?

Walter Andrew Shewhart, Cross-Peer Answer to John Wilder Tukey: Dr Tukey, I would make the decision rule and search family explicit before collecting confirmation data. The record must include every tuning state examined, dwell time, settling interval, gain or attenuation state, analogue preselector position, detector threshold, firmware version and missing acquisition intervals. Interleave terminated and antenna-connected observations, add a calibrated injection and an independent measurement channel, and use randomised or counterbalanced order where practical to expose systematic

Copyright 2026, James M. Atkinson

drift. A control chart may reveal temporal instability but does not confer causality on a spectral line. The power to exclude a receiver-generated spur must be demonstrated for the relevant amplitude and state, not assumed from a visually empty display. A non-detection bounds what that particular test could see; it cannot by itself identify an external radiator. The final finding should state the tested mechanism, the detection limit, the number of opportunities searched and the residual alternatives. With your leave, I pass the floor to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of the ambiguity between genuine radiated emissions and local-oscillator leakage or reciprocal mixing has established a point which the specialist must not overlook. The receiver records a feature whose power or offset tracks receiver tuning, oscillator state, or a nearby strong blocker; it does not, merely by drawing a clear trace, give direct access to the true electromagnetic field at the antenna reference plane. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, Mixer local oscillators are not perfectly isolated from the RF port and can couple into connected conductors. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

The exchanges have established a separation which is easily lost when several spectral features appear on the same waterfall. Radiation of a receiver's local oscillator is measurable as conducted or radiated emission;

Copyright 2026, James M. Atkinson

reciprocal mixing is a noise contribution caused by a powerful external signal interacting with oscillator phase noise. A spur which follows the tuning word need not be a newly discovered transmitter, and an elevated noise pedestal need not represent wideband external energy. Dr Armstrong's receiver perspective is most valuable here when coupled with an independent antenna, a separately clocked reference receiver and a source whose blocker power is stepped through a declared range. The report should show which feature moves with oscillator offset, which grows with blocker power, and which survives termination of the investigated input. I thank the panel for distinguishing these tests rather than merging them into an ambiguous label of oscillator interference. The final inference must identify a measured mechanism, not merely an unusually bright trace.

The questioned trace follows the internal oscillator setting, not a stable frequency established by a separately clocked sensor. That observation favours an instrumental explanation, although an emission coupled from the receiver housing cannot be distinguished from an internal spectral spur by the shared display alone. The report must distinguish a conducted leakage measurement from an inferred mixing product. The more useful outcome is a discriminating protocol: Perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. In applying it, the examiner must retain all readings supporting LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope and identify the physical plane to which the measurements refer. At the outset of the investigation, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna; that

Copyright 2026, James M. Atkinson

circumstance makes the alternative mechanism material, specifically lO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. A result approaching an internal leakage product can move with the programmed LO offset while a genuine station remains at a fixed external RF frequency may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore distinguish receiver self-emission and reciprocal-mixing artefacts before declaring a separate clandestine source. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

An oscillator-related artefact is supported only where its measured tuning or blocker-power dependence matches the relevant mechanism. A receiver-generated spectral line and a reciprocal-mixing noise pedestal should not be collapsed into one category, and neither establishes a second clandestine emitter. The decisive experiment is concrete: Perturb the LO independently of the antenna frequency, substitute a matched termination, and compare with a separately clocked direct-sampling path. In conducting it, the examiner must explicitly retain LO frequency, mixer isolation, blocker offset, close-in phase-noise density, and spur-versus-retune slope. If the outcome matches the stated prediction, an internal leakage product can move with the programmed lo offset while a genuine station remains at a fixed external rf frequency, the supported conclusion concerns that test

Copyright 2026, James M. Atkinson

domain. An alternative remains: LO radiation, mixer feedthrough, reciprocal mixing about a strong blocker and a real external carrier can create superficially similar waterfalls. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 016

Application 01. Two-tone third-order products and input intercept

In the illustrative 016.01 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. With two equal input tones each at P = -32 dBm and a hypothetical input third-order intercept IIP_3 = +12 dBm, the extrapolated input-referred third-order product is $P_3 = 3P - 2IIP_3$ = -120 dBm, or -88 dBc relative to either input tone. The cubic approximation ceases to be reliable in compression. A two-tone slope check and input attenuation test must establish whether the predicted spur arises inside the receiver rather than externally. The predicted intermodulation level describes a small-signal receiver model, not the strength or existence of a radiating source; verify the measured slope and the first nonlinear stage.

Application 02. Filter or cable rejection referred to a physical input

In the illustrative 016.02 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. For an admitted input P_i = -55 dBm and separately measured loss L = 41 dB, the linear prediction is $P_o = P_i - L$ = -96 dBm. In SI power this becomes 10^((-96 − 30)/10) = 2.51e-13 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. A measured forty-one-decibel network attenuation applies only at the characterised reference planes, and cannot independently exclude shield, feeder or common-mode bypass paths.

Copyright 2026, James M. Atkinson

Application 03. Thermal reference noise in a declared measurement bandwidth

In the illustrative 016.03 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. Take the equivalent noise bandwidth B = 12,000 Hz and calibrated noise figure NF = 2.55 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -130.66$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The thermal-reference estimate is neither a phase-noise spectrum nor a model of strong-blocker reciprocal mixing; the latter requires offset-specific oscillator and blocker data.

Application 04. Cascade gain and observed headroom

In the illustrative 016.04 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. A first amplifier contributes G_1 = 9 dB, an intentional attenuation contributes G_2 = -5 dB, and a later stage contributes G_3 = 18 dB. The small-signal sum is 9 + (-5) + 18 = 22 dB. For P_i = -69 dBm, the ideal output is P_o = -47 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. Even a correct twenty-two-decibel total gain conceals intermediate-stage overload; identify where the oscillator and blocking components enter the physical chain.

Application 05. Gain allocation and blocker headroom

In the illustrative 016.05 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the

Copyright 2026, James M. Atkinson

antenna. Assume a calibrated digital full-scale equivalent of -9 dBm, a blocker applied at -38 dBm, and net analogue gain 29 dB. The projected converter input is -9 dBm and remaining margin is -9 − (-9) = 0 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. Zero-decibel projected headroom is not a safe operating reserve: crest factor, uncertainty and transient gain may already cause clipping, so challenge the chain at reduced gain.

Application 06. Alias-location prediction and its non-unique inverse

In the illustrative 016.06 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. For an actual sampling frequency f_s = 11 MHz and analogue input f_i = 23.540 MHz, the nearest-replica folding rule gives $f_a = |f_i - \mathrm{round}(f_i/f_s)f_s|$ = 1.540 MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. Aliased frequency is not unique evidence of radio-frequency origin; vary the analogue preselector and sampling plan with independently measured clock and input conditions.

Application 07. Accumulated sample-clock time error

In the illustrative 016.07 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. A free-running sample clock with fractional rate error ε = 0.690 ppm over T = 413 s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T$ = 0.2850 ms.

Copyright 2026, James M. Atkinson

This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. An accumulated mean-rate offset is not the same as close-in oscillator phase noise; preserve separate measurements of sample timing, LO spectrum and actual dropped samples.

Application 08. Combined and expanded measurement uncertainty

In the illustrative 016.08 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. For independent standard-uncertainty contributions 0.59, 0.54 and 0.40 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.59^2 + 0.54^2 + 0.40^2)} = 0.894$ units. Using an illustrative coverage factor $k = 2$ gives expanded uncertainty $U = 2u_c = 1.789$ units. The expanded uncertainty assumes the stated independent components and illustrative factor of two; include covariance or coverage qualifications if those assumptions do not hold.

Application 09. Difference between two instruments relative to stated uncertainty

In the illustrative 016.09 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. The paired instrument contrast is $\Delta = 1.300$ dB. Set independent standard uncertainties $u_1 = 0.460$ dB and $u_2 = 0.470$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.658$ dB, giving the dimensionless ratio $\Delta/u\Delta = 1.977$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The ratio near two is

Copyright 2026, James M. Atkinson

an uncertainty-scaled contrast, not a probability of external transmission; specify the comparison model and correlated reference errors.

Application 10. Preserved sample continuity across an acquisition interval

In the illustrative 016.10 test, a frequency-agile receiver produces a narrow trace which shifts on retuning despite no obvious change at the antenna. A converter expected to retain f_s = 1.90 million samples/s for T = 0.85 s should supply f_sT = 1,615,000 complex sample instants. If 242 sequence positions are missing, the retained count is 1,614,758 and loss fraction is 0.01498%. A low fractional loss cannot exclude a highly relevant short burst coinciding with the gap. Position and timing of each missing block must therefore be preserved. Lost sample positions must be time-localised: a tiny average loss fraction could conceal the very burst a surveillance survey is intended to capture.

QUESTION 017

Copyright 2026, James M. Atkinson

What does a receiver noise figure establish when the observed environment is not thermal noise?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 017 asks: What does a receiver noise figure establish when the observed environment is not thermal noise? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is the limited interpretation of a receiver noise figure when environmental noise is non-thermal. Our primary observation is input-referred noise density, receiver sensitivity, and measured spectral background; by contrast, what remains unseen is the proportions due to thermal noise, impulsive interference, atmospheric activity, and local equipment. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

External interference and the definition of noise figure. At approximately 290 kelvin the familiar available thermal-noise density is near minus 174

Copyright 2026, James M. Atkinson

dBm per hertz. Across a ten-kilohertz equivalent-noise bandwidth this becomes about minus 134 dBm, and adding a 5 dB receiver noise figure yields roughly minus 129 dBm of receiver-limited input-referred noise under matched-source assumptions. When the antenna collects a variable man-made interference environment at minus 107 dBm in the same bandwidth, reducing the receiver noise figure by one decibel will scarcely change the observed floor. The survey must measure the environmental contribution rather than infer it from the data sheet. In a recorded forensic finding, separate instrument noise, natural atmospheric noise, man-made interference and unmodelled short-duration occupancy. Treat the noise floor as a distribution conditioned on frequency, antenna and time, not an immutable line. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns input-referred noise density, receiver sensitivity, and measured spectral background; it is not interchangeable with the proportions due to thermal noise, impulsive interference, atmospheric activity, and local equipment. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is calibrated terminated-source noise comparison plus outdoor, antenna, and time-stratified surveys. A claim drawn from that comparison has to carry its actual uncertainties: noise factor, noise temperature, equivalent input bandwidth, and non-Gaussian tails. Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. A receiver with an excellent

Copyright 2026, James M. Atkinson

nominal noise figure can be overwhelmed by impulsive local interference. The choice of detector and integration time changes the statistics of a heavy-tailed interference environment. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 1: Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform.

Noise figure is an input-referred comparison against a thermal reference, not a universal description of what an antenna will hear. The usual relationship N = kTBF assumes a specified reference temperature, bandwidth and small-signal operating state. It can be a valuable way to compare receiver front ends under controlled matched conditions, yet an aerial overlooking industrial machinery may receive impulsive interference and structured communications whose statistics are nothing like those of a thermal termination. I would therefore present two distinct measurements: a calibrated terminated-input noise figure and an occupied-site distribution of actual noise and interference power in the task's bandwidth. Mixing the two without explaining the operating conditions makes the site look quieter or louder for the wrong reason. An unusually low noise figure can be immaterial when external interference dominates; conversely, front-end nonlinearity can make a supposedly strong receiver unable to detect a small pulse near a blocker. Sensitivity must be evaluated for the actual detection task.

In this physical path examination of Question 017, the decisive claim is that noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. A specified noise figure describes a receiver under a reference-source noise model; it is not a percentile of the environmental disturbance encountered during a survey. The 290-kelvin thermal source used in an ordinary noise-figure characterisation is not a surrogate for impulsive interference from motors,

Copyright 2026, James M. Atkinson

switchgear, power converters or other transmitters. A low intrinsic noise figure may coexist with an intolerable false-alarm rate when the field environment is non-Gaussian. Consequently the panel should distinguish input-referred receiver-added noise, the measured environmental noise distribution and the detector's probability of responding to a specified signal class. A useful falsification proceeds from the actual controversy: external interference and the definition of noise figure. At approximately 290 kelvin the familiar available thermal-noise density is near minus 174 dBm per hertz. Across a ten-kilohertz equivalent-noise bandwidth this becomes about minus 134 dBm, and adding a 5 dB receiver noise figure yields roughly minus 129 dBm of receiver-limited input-referred noise under matched-source assumptions. When the antenna collects a variable man-made interference environment at minus 107 dBm in the same bandwidth, reducing the receiver noise figure by one decibel will scarcely change the observed floor. The survey must measure the environmental contribution rather than infer it from the data sheet. In a recorded forensic finding, separate instrument noise, natural atmospheric noise, man-made interference and unmodelled short-duration occupancy. Treat the noise floor as a distribution conditioned on frequency, antenna and time, not an immutable line. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Measure calibrated receiver noise figure using a suitable source and independently confirm gain and effective noise bandwidth. Then acquire time-tagged samples at the same receiver settings first with a termination, next with a calibrated aerial reference, and finally under the relevant

Copyright 2026, James M. Atkinson

operating states of local machinery. Report tail probabilities and pulse-duration distributions as well as mean power. Vary the detector threshold only through a documented rule, because thresholds optimised after observing bursts do not provide independent validation. I would take noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. A response consistent with the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. The laboratory reports a favourable receiver noise figure while the field site contains

Copyright 2026, James M. Atkinson

periodic switching transients and impulsive industrial interference. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails, and measure their behaviour separately before reconnecting the assembled system. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. It is therefore material to establish noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure rather than infer them from a single scalar output. The limiting test is concrete: Compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. If the intervention produces the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret an input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions as a new transmitter before challenging the most economical instrumental explanation. The calibrated noise figure is a property of a defined source condition, not a description of industrial interference. Professor Tukey, I invite you to assess what happens when transient-rich visits are discarded from the summary.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Peer question 1 to Harry Nyquist

Harry Nyquist, may I test the exact physical inference in your account of the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference? The proposed mechanism appears plausible only if changes after compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals are compared with a stable reference condition. Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure which would settle that narrower claim, rather than a visual impression of improvement.

Harry Nyquist | Immediate answer to John Wilder Tukey

Dr Tukey, what appears to be an exceptionally quiet channel may merely be a low average with very heavy tails. I would compare the false-alarm distribution from a terminated input with that seen during machinery operation, retaining burst timestamps rather than just averaged PSD traces. A lower receiver noise figure is desirable, but it does not excuse the investigator from measuring the actual field-

Copyright 2026, James M. Atkinson

detection problem. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 017, the specific physical candidate is a specified receiver noise factor added to a source whose statistics need not be Gaussian or stationary. The unresolved physical pathway is material: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. The retained record permits a conditional claim about noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, but cannot alone resolve noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are noise factor, equivalent noise temperature,

Copyright 2026, James M. Atkinson

effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals, and only a response matching the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, not a conjecture about the operator's intentions.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Peer question 2 to Harry Nyquist

I appreciate your explanation, Harry Nyquist. How would your conclusion survive a deliberately independent test of an input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions? A second receiver might share more of the supposed evidence than its separate enclosure suggests. A receiver with an excellent nominal noise figure can be overwhelmed by impulsive local interference. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure and document which differences remain unexplained? Would you also state what observed change in noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure would invalidate the preferred account, and which aspect of compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals would make that negative result independently repeatable?

Harry Nyquist | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front

Copyright 2026, James M. Atkinson

panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 017, the specific physical candidate is a specified receiver noise factor added to a source whose statistics need not be Gaussian or stationary. The unresolved physical pathway is material: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. The retained record permits a conditional claim about noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, but cannot alone resolve noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. A receiver with an excellent nominal noise figure can be overwhelmed by impulsive local interference. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains thermal amplifier noise and

Copyright 2026, James M. Atkinson

non-Gaussian environmental interference may share average power while differing sharply in their detection tails; I would challenge it with compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. Two responses consistent with the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails. A discordant measurement would then be interpreted by tracing that difference through noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 2: A receiver with an excellent nominal noise figure can be overwhelmed by impulsive local interference.

A noise-floor figure derived from averaged power can discard the feature the investigator most needs. A receiver could have an excellent mean PSD while rare, very large impulses repeatedly defeat a narrowband detector. I would retain a complementary account of the amplitude distribution, temporal occupancy and phase coherence of the noise record. If a nominally thermal background contains cyclostationary power or discrete spurs, it should not be passed off as memoryless Gaussian noise merely because the spectrum looks smooth after averaging. The data-processing inequality reminds us that replacing a full time series with one scalar noise figure is a lossy representation. That does not make the scalar useless; it makes the claims drawn from it conditional on the question posed. In a defensible survey, a quoted noise floor should be accompanied by the record length, effective bandwidth, averaging method and evidence of detector validity during strong bursts. Otherwise the information most relevant to missed detections is hidden by the statistical summary.

In this control and stability examination of Question 017, the decisive claim is that a receiver with an excellent nominal noise figure can be overwhelmed by impulsive local interference. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: external interference and the definition of noise figure. At approximately 290 kelvin the familiar available

Copyright 2026, James M. Atkinson

thermal-noise density is near minus 174 dBm per hertz. Across a ten-kilohertz equivalent-noise bandwidth this becomes about minus 134 dBm, and adding a 5 dB receiver noise figure yields roughly minus 129 dBm of receiver-limited input-referred noise under matched-source assumptions. When the antenna collects a variable man-made interference environment at minus 107 dBm in the same bandwidth, reducing the receiver noise figure by one decibel will scarcely change the observed floor. The survey must measure the environmental contribution rather than infer it from the data sheet. In a recorded forensic finding, separate instrument noise, natural atmospheric noise, man-made interference and unmodelled short-duration occupancy. Treat the noise floor as a distribution conditioned on frequency, antenna and time, not an immutable line. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by an input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note a receiver with an excellent nominal noise

Copyright 2026, James M. Atkinson

figure can be overwhelmed by impulsive local interference. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, an input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Shannon’s information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. This predicts a response which should be tested against the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational

Copyright 2026, James M. Atkinson

step does not restore measurements discarded during retuning. Where noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field, the correct claim must name the operational states and the evidence available in each. My proposed acceptance test would archive the entire control sequence and the independent witness measurement before any data-dependent threshold adjustment.

A further, separately testable aspect of the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference concerns noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure. The proposed challenge would be compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. The decision is conditional upon the observed result, with particular attention to noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. The competing account remains thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. Equal average powers may conceal very different impulsive tails and hence different miss probabilities. Dr Pearson, please take the floor and examine the decision model needed for a defensible comparison.

Egon Sharpe Pearson | Peer question 3 to Claude Elwood Shannon

Claude Elwood Shannon, your calibration argument invites a question about reference planes, especially because noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. The reference stimulus and the unknown emission need not occupy the same physical regime. The choice of detector and integration time changes the statistics of a heavy-tailed interference environment. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When an input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Claude Elwood Shannon | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 017, the specific physical candidate is a specified receiver noise factor

Copyright 2026, James M. Atkinson

added to a source whose statistics need not be Gaussian or stationary. The unresolved physical pathway is material: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. The retained record permits a conditional claim about noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, but cannot alone resolve noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure. The choice of detector and integration time changes the statistics of a heavy-tailed interference environment. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals, with before-and-after values of noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure. If the instrument behaves as predicted, then the same average floor can coexist with markedly different alarm

Copyright 2026, James M. Atkinson

rates if one environment has heavy-tailed impulses; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. An input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Claude Elwood Shannon

There is an inferential difficulty, Claude Elwood Shannon: thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. The population of admissible observations needs to be fixed before any confidence argument. In this situation, noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Measurements with a matched

Copyright 2026, James M. Atkinson

terminator isolate receiver-added noise more effectively than sky-facing observations. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure would invalidate the preferred account, and which aspect of compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals would make that negative result independently repeatable?

Claude Elwood Shannon | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 017, the specific physical candidate is a specified receiver noise factor added to a source whose statistics need not be Gaussian or stationary. The unresolved physical pathway is material: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails.

Copyright 2026, James M. Atkinson

The retained record permits a conditional claim about noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, but cannot alone resolve noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because an input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Measurements with a matched terminator isolate receiver-added noise more effectively than sky-facing observations. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails; its prediction should be recorded alongside the same average floor can coexist with markedly different alarm rates if one environment has

Copyright 2026, James M. Atkinson

heavy-tailed impulses. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, two spectra with identical integrated watts need not yield the same threshold-exceedance statistics for a brief-event detector. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 3: The choice of detector and integration time changes the statistics of a heavy-tailed interference environment.

A cascade calculation is often more trustworthy than an unexplained number on a front-panel screen, but only within its own assumptions. Friis's formula combines stage noise factors and gains for a linear chain with appropriate impedances and a thermal reference. It does not predict the effect of a nearby transmitter driving a mixer into compression or a clock spur coupling into baseband. I would ask for stage-by-stage noise characterisation under both a well-defined termination and a realistic blocker profile. A change of preselector may reduce interference while increasing passive insertion loss; those two effects must be kept distinct. If the operator reports a six-decibel improvement in the displayed floor, the first question is whether the RBW, averaging and gain-state definitions stayed fixed. Noise figure is a network property under test conditions, not a magical conversion factor between every observed waveform and its physical cause.

In this operational measurand examination of Question 017, the decisive claim is that the choice of detector and integration time changes the statistics of a heavy-tailed interference environment. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: external interference and the definition of noise figure. At approximately 290 kelvin the familiar available thermal-noise density is near minus 174 dBm per hertz. Across a ten-kilohertz equivalent-noise bandwidth this becomes about minus 134 dBm,

Copyright 2026, James M. Atkinson

and adding a 5 dB receiver noise figure yields roughly minus 129 dBm of receiver-limited input-referred noise under matched-source assumptions. When the antenna collects a variable man-made interference environment at minus 107 dBm in the same bandwidth, reducing the receiver noise figure by one decibel will scarcely change the observed floor. The survey must measure the environmental contribution rather than infer it from the data sheet. In a recorded forensic finding, separate instrument noise, natural atmospheric noise, man-made interference and unmodelled short-duration occupancy. Treat the noise floor as a distribution conditioned on frequency, antenna and time, not an immutable line. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Noise figure describes degradation of signal-to-noise ratio under a reference noise model and specified source conditions; it is not a universal sensitivity certificate for a working building. A receiver may have a commendable laboratory noise figure while its input is dominated by industrial impulsive interference, broadband switching emissions or a strong adjacent-channel waveform. The field investigator should separately record system-added noise, environment-dependent background and detection-threshold behaviour. A hot-and-cold reference measurement or a characterised noise source can establish a bounded receiver noise parameter, but it cannot determine whether a weak field signal will be detectable during a burst of external interference. The relevant field experiment compares a terminated input, a calibrated injected witness and the live antenna path under matched bandwidth and detector settings. If

Copyright 2026, James M. Atkinson

the witness succeeds on termination yet fails on the antenna, the result points toward environmental masking or front-end overload rather than a sudden change in the intrinsic receiver noise figure. Accordingly, the laboratory record for Question 017 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should

Copyright 2026, James M. Atkinson

specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: Two spectra with identical integrated watts need not yield the same threshold-exceedance statistics for a brief-event detector. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. Detector integration time governs how a burst enters the statistic, even when the amplifier noise figure is unchanged. Dr Turing, I invite your examination of what a stored sequence does and does not preserve.

Alan Mathison Turing | Peer question 5 to Hendrik Wade Bode

Hendrik Wade Bode, I should like to examine what the recorded data actually preserve when the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. The physical input and the retained numerical array are not interchangeable things. The evidential report should distinguish receiver sensitivity from environmental detectability. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in noise factor, equivalent noise temperature, effective bandwidth, kurtosis,

Copyright 2026, James M. Atkinson

false-alarm rate and occupied-time exposure would invalidate the preferred account, and which aspect of compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals would make that negative result independently repeatable?

Hendrik Wade Bode | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 017, the specific physical candidate is a specified receiver noise factor added to a source whose statistics need not be Gaussian or stationary. The unresolved physical pathway is material: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. The retained record permits a conditional claim about noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, but cannot alone resolve noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. I propose separating acquired information from model-dependent reconstruction. The evidential report should distinguish receiver sensitivity from environmental detectability. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure and a fresh trial in which the operator compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. If that trial demonstrates the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include compare terminated-input noise

Copyright 2026, James M. Atkinson

measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher | Principal contribution 4: Measurements with a matched terminator isolate receiver-added noise more effectively than sky-facing observations.

Dr. Atkinson, the word confidence is particularly vulnerable to misuse in a low-noise measurement. An uncertainty interval derived from repeated thermal noise readings can be very narrow while failing to encompass systematic calibration errors, temperature drift and a non-Gaussian interference population. Before estimating detection performance, the investigator should state whether the sample is drawn from receiver self-noise, environmental background or a mixture that changes with time. For impulsive events a robust or stratified description may be more meaningful than a Gaussian standard deviation, although the chosen estimator must also be tested against the event class of interest. If a threshold is set using the same record later offered to prove an exceptional detection, the claimed false-alarm probability needs a selection correction or independent validation. Strong claims about absence require an empirical detection-probability model, not only a manufacturer's sensitivity figure.

In this information retention examination of Question 017, the decisive claim is that measurements with a matched terminator isolate receiver-added noise more effectively than sky-facing observations. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: external interference and the definition of noise figure. At approximately 290 kelvin the familiar available thermal-noise density is near minus 174 dBm per hertz. Across a ten-kilohertz equivalent-noise bandwidth this becomes about minus 134 dBm, and adding a 5 dB receiver

Copyright 2026, James M. Atkinson

noise figure yields roughly minus 129 dBm of receiver-limited input-referred noise under matched-source assumptions. When the antenna collects a variable man-made interference environment at minus 107 dBm in the same bandwidth, reducing the receiver noise figure by one decibel will scarcely change the observed floor. The survey must measure the environmental contribution rather than infer it from the data sheet. In a recorded forensic finding, separate instrument noise, natural atmospheric noise, man-made interference and unmodelled short-duration occupancy. Treat the noise floor as a distribution conditioned on frequency, antenna and time, not an immutable line. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. The scientific point of measurements with a matched terminator isolate receiver-added noise more effectively than sky-facing observations. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions repeatedly show the same average floor can coexist

Copyright 2026, James M. Atkinson

with markedly different alarm rates if one environment has heavy-tailed impulses, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. An input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions. Fisher's inferential approach requires a clearly defined population, an implemented sampling design and a distinction between the chosen estimator and the process under observation. The issue becomes especially sharp because thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the proposed case, two spectra

Copyright 2026, James M. Atkinson

with identical integrated watts need not yield the same threshold-exceedance statistics for a brief-event detector. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A more precise objection comes from Sir Ronald Aylmer Fisher and the finite observation aperture in the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails. For that reason, record noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. Matched-termination measurements isolate an instrumental noise component but do not reproduce the antenna

Copyright 2026, James M. Atkinson

environment. Dr Deming, I pass the floor for a validation challenge spanning both conditions.

W. Edwards Deming | Peer question 6 to Sir Ronald Aylmer Fisher

I thank you, Sir Ronald Aylmer Fisher, for distinguishing measurement from attribution, but the observation is that an input-terminated receiver shows a quiet floor, although antenna-connected captures display rare, very large positive excursions. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: two spectra with identical integrated watts need not yield the same threshold-exceedance statistics for a brief-event detector. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses on one day but fails after the instrument has been reconfigured? Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment? Would you also state what observed change in noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure would invalidate the preferred account, and which aspect of compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 017, the specific physical candidate is a specified receiver noise factor added to a source whose statistics need not be Gaussian or stationary. The unresolved physical pathway is material: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. The retained record permits a conditional claim about noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, but cannot alone resolve noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, two spectra with identical integrated watts need not yield the same threshold-exceedance statistics for a brief-event detector. I would

Copyright 2026, James M. Atkinson

retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. Its bearing on the dispute can be evaluated through the predicted response, namely the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses. Because thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails, the procedure compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match state receiver-added noise separately from environmental detectability and report the tested temporal conditions, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. The same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 5: The evidential report should distinguish receiver sensitivity from environmental detectability.

Noise measurement should be monitored as a process with multiple possible regimes. A receiver left overnight beside a switching supply may show a quiet median and a pronounced disturbance every few minutes. Averaging the week into one noise figure would conceal the regime changes. I would divide the record using known operational changes, then examine whether shifts in variance, pulse count or spectral shape coincide with lighting, machinery, temperature or receiver state. An anomaly that repeats on power cycling is evidence worth retaining, but it can arise from a start-up transient rather than from an outside radio transmitter. Calibration traces and environmental observations should remain chronological. If a process chart is tuned only after a conspicuous event is seen, that event has helped choose the chart and its statistical significance cannot be asserted as though the rule had been fixed beforehand. We should report what varied, not merely a pleasing central estimate.

In this statistical inference examination of Question 017, the decisive claim is that the evidential report should distinguish receiver sensitivity from environmental detectability. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: external interference and the definition of noise figure. At approximately 290 kelvin the familiar available thermal-noise density is near minus 174 dBm per hertz. Across a ten-kilohertz

Copyright 2026, James M. Atkinson

equivalent-noise bandwidth this becomes about minus 134 dBm, and adding a 5 dB receiver noise figure yields roughly minus 129 dBm of receiver-limited input-referred noise under matched-source assumptions. When the antenna collects a variable man-made interference environment at minus 107 dBm in the same bandwidth, reducing the receiver noise figure by one decibel will scarcely change the observed floor. The survey must measure the environmental contribution rather than infer it from the data sheet. In a recorded forensic finding, separate instrument noise, natural atmospheric noise, man-made interference and unmodelled short-duration occupancy. Treat the noise floor as a distribution conditioned on frequency, antenna and time, not an immutable line. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. The evidential report should distinguish receiver sensitivity from environmental detectability. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals, should be

Copyright 2026, James M. Atkinson

accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say state receiver-added noise separately from environmental detectability and report the tested temporal conditions, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. The laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals,

Copyright 2026, James M. Atkinson

and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, two spectra with identical integrated watts need not yield the same threshold-exceedance statistics for a brief-event detector, is not an estimate of any actual investigation. I would publish the test plan, sample exclusions, denominator and alternative accounts alongside the numerical result, so that a critical reader can identify which inference is conditional and which physical fact was directly observed.

A more precise objection comes from Walter Andrew Shewhart and the finite observation aperture in the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails. For that reason, record noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After compare terminated-input noise measurements with calibrated antenna

Copyright 2026, James M. Atkinson

states, time-tagged pulse statistics and detector thresholds over stratified intervals, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. An empty indication under one threshold must not become a claim of electromagnetic silence. Sir Karl, I invite you to identify the field observation that would oblige us to abandon that conclusion.

Sir Karl Raimund Popper | Peer question 7 to Walter Andrew Shewhart

Walter Andrew Shewhart, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise state receiver-added noise separately from environmental detectability and report the tested temporal conditions? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. A receiver with an excellent nominal noise figure can be overwhelmed by impulsive local interference. Please connect noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure with a declared detection threshold and the measurement exposure. If the experiment compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals cannot discriminate a masked weak signal from a genuinely

Copyright 2026, James M. Atkinson

absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later. Would you also state what observed change in noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure would invalidate the preferred account, and which aspect of compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals would make that negative result independently repeatable?

Walter Andrew Shewhart | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 017, the specific physical candidate is a specified receiver noise factor added to a source whose statistics need not be Gaussian or stationary. The unresolved physical pathway is material: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. The retained record permits a conditional claim about noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure, but cannot

Copyright 2026, James M. Atkinson

alone resolve noise figure characterises a stipulated reference temperature and linear noise transfer, not the probability of detecting an arbitrary burst in a changing field. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. A receiver with an excellent nominal noise figure can be overwhelmed by impulsive local interference. I would use the observations of noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified intervals, not an assertion based on the operator's impression of a quiet display. If it yields the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test

Copyright 2026, James M. Atkinson

boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since thermal amplifier noise and non-gaussian environmental interference may share average power while differing sharply in their detection tails, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to state receiver-added noise separately from environmental detectability and report the tested temporal conditions, with the untested physical possibilities made visible.

Harry Nyquist, Cross-Peer Question to Sir Ronald Aylmer Fisher: Professor Fisher, a manufacturer reports a low receiver noise figure measured at a specified reference temperature. During a field survey the external aerial, although properly matched, sees intermittent bursts with a long-tailed amplitude distribution. A colleague subtracts a single thermal-noise prediction from the observed spectral average and treats the residual as a numerical probability that a transmitter will be detected. Can the receiver-noise measurement establish that probability? What experiment would measure actual detection power without disguising the non-stationary environment behind an average noise density?

Sir Ronald Aylmer Fisher, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, a calibrated noise figure is an instrument characteristic under a reference-source and operating-state model. It is not itself a probability model for field interference or a statement of detection power. I would specify a target signal model, amplitude, waveform, duration, occupancy and decision

Copyright 2026, James M. Atkinson

threshold, then inject traceable examples at randomised or otherwise justified times during a representative set of field conditions. Estimate conditional probabilities of detection and false alarm separately, with uncertainty intervals and explicit denominators for valid observation opportunities. The analysis must preserve bursts and periods of saturation, not merely average spectral density. If the interference distribution changes with machinery schedules, weather or human activity, report stratified results rather than one pooled number that conceals the heterogeneity. No detection claim is valid without its observation schedule and the manner in which unobserved time was excluded or modelled. With your leave, I pass the floor to Dr Shannon.

Claude Elwood Shannon, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, two sites show the same mean spectral power in a nominal ten-kilohertz equivalent-noise bandwidth. At the first, the samples are approximately thermal and stationary; at the second, rare, high-amplitude bursts dominate errors and briefly force analogue gain reduction. A conventional average-power spectrum makes the sites look identical. Which measurements reveal the difference, and how should front-end linearity and detector settings be handled before the investigator converts either site into a proposed lower bound for a weak intermittent emission?

Hendrik Wade Bode, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, mean power is an incomplete statistic for this problem. Retain time-stamped unaveraged samples or justified event captures, record short-time power and amplitude quantiles, burst duration, duty cycle, complementary cumulative amplitude distributions and the frequency dependence of the events. Separately test the analogue front end for

Copyright 2026, James M. Atkinson

overload, recovery time and state-dependent gain, because a large burst may modify the measurements made immediately afterwards. Equivalent-noise bandwidth must be determined for the actual detector filter; a spectrum display's nominal frequency-bin spacing is not an adequate substitute. Establish thresholds against the relevant noise and interference population, allowing for repeated searching and temporal dependence. An isolated ten-kilohertz mean does not predict the probability of missing a millisecond event, and an improved amplifier noise figure can be useless if local switching interference and gain compression determine the detection limit. The conclusion must give a conditional performance envelope rather than a universal threshold. With your leave, I pass the floor to Dr Tukey.

John Wilder Tukey, Cross-Peer Question to W. Edwards Deming: Mr Deming, a matched termination is substituted for an antenna and the receiver's measured noise level falls substantially. The operator interprets the entire difference as the power of hostile radiators, disregarding mismatch, the antenna's effective noise temperature and a shared switching supply that changes noise coupling between the two configurations. What calibration sequence and uncertainty model would discriminate receiver-added noise, antenna-delivered noise and configuration-dependent instrumental bias? In particular, when would the familiar root-sum-of-squares uncertainty combination be invalid?

W. Edwards Deming, Cross-Peer Answer to John Wilder Tukey: Dr Tukey, the experiment should name the input reference plane and measure the installed termination, antenna match, insertion losses and gain state in both configurations. An independent hot-cold or calibrated noise-source determination of receiver noise figure gives a controlled instrument

Copyright 2026, James M. Atkinson

baseline, but it does not attribute the antenna-connected excess to a particular emitter. I would test the switching supply, cable common-mode current and local radiated coupling by planned interventions while monitoring the receiver's temperature and gain. Construct a measurement equation including any mismatch correction and environmental variability; share calibration terms only where their covariance is supported. If both observations depend on the same reference source or drift, an independent-error root-sum-of-squares rule can misstate the uncertainty of their difference. NIST's uncertainty framework requires covariance terms where correlations are material. Report remaining unidentified environmental components as such, without assigning them to malign transmissions on the strength of the noise difference alone. With your leave, I pass the floor to Professor Fisher.

Sir Ronald Aylmer Fisher, Cross-Peer Question to Walter Andrew Shewhart: Mr Shewhart, the investigator completes thirty-three listening intervals and obtains no detection. A manuscript application calculates a probability of no detections under an assumed independent-visit model, then a report moves too quickly from that illustrative calculation to a confident assurance that no intermittent emission exists. How would you design a surveillance acceptance test that treats clustered events, synchronisation with revisit timing and equipment downtime as limitations on the negative result, while avoiding a fictitious universal detection probability?

Walter Andrew Shewhart, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Professor Fisher, I would separate the calculation of a conditional probability from the evidential conclusion. Define the event class, minimum amplitude at the antenna reference plane, burst duration, temporal pattern, receiver

Copyright 2026, James M. Atkinson

sensitivity, dwell and revisit schedule before collecting data. Mark every valid observation interval, excluded downtime and state transition; test the acquisition path with injected pulses at different phases of the revisit cycle. If emissions are correlated or periodic, effective opportunities are not the simple count of displayed FFT frames, and the independent-visit formula is not a verified field probability. A stratified detection trial, with independent replay or injection challenges, can bound detection performance for the specified event population and duty cycle. Even after those controls, absence of an observed event can only limit the emission classes detectable under the tested schedule. It cannot demonstrate that no transmitter, of any waveform and time pattern, existed. With your leave, I pass the floor to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of the limited interpretation of a receiver noise figure when environmental noise is non-thermal has established a point which the specialist must not overlook. The receiver records input-referred noise density, receiver sensitivity, and measured spectral background; it does not, merely by drawing a clear trace, give direct access to the proportions due to thermal noise, impulsive interference, atmospheric activity, and local equipment. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, Noise figure is defined against a specified source noise condition and does not quantify every ambient waveform. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled

Copyright 2026, James M. Atkinson

challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

A noise figure measured against a standard thermal source supplies one characterisation of receiver-added noise, not an assurance about the intermittent electrical disturbances of an occupied building. That distinction matters when switch-mode converters, lifts, machinery and adjacent transmitters produce heavy-tailed samples whose probabilities cannot be inferred from a Gaussian reference measurement. I thank Professor Fisher for requiring an explicit distributional model and Professor Neyman for insisting that the confidence statement refer to the actual decision procedure. The next laboratory challenge should collect reference noise with a terminated input, a known noise source and a realistic antenna load, while preserving pulse arrival times rather than replacing the record with a single average floor. A very low intrinsic noise figure may coexist with poor short-burst detection if the detection threshold is continually raised by legitimate impulsive interference. Our conclusion concerns receiver sensitivity under nominated conditions and the distinct, empirically measured false-alarm and missed-event behaviour in the surveyed environment.

A quiet terminated-input spectrum and occasional very large antenna-connected transients are compatible observations. They refer to different measurands. Neither can be substituted for a validated probability of detecting a weak target under the same interference conditions in which the survey is conducted. The more useful outcome is a discriminating protocol: Compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics and detector thresholds over stratified

Copyright 2026, James M. Atkinson

intervals. In applying it, the examiner must retain all readings supporting noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure and identify the physical plane to which the measurements refer. At the outset of the investigation, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference; that circumstance makes the alternative mechanism material, specifically thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. A result approaching the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore state receiver-added noise separately from environmental detectability and report the tested temporal conditions. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

Report the receiver’s reference noise figure alongside, but separately from, the environmental noise and detector-performance data. Negative search claims must be limited to the combinations of signal strength, time exposure and interference state for which detection was demonstrated. The decisive experiment is concrete: Compare terminated-input noise measurements with calibrated antenna states, time-tagged pulse statistics

Copyright 2026, James M. Atkinson

and detector thresholds over stratified intervals. In conducting it, the examiner must explicitly retain noise factor, equivalent noise temperature, effective bandwidth, kurtosis, false-alarm rate and occupied-time exposure. If the outcome matches the stated prediction, the same average floor can coexist with markedly different alarm rates if one environment has heavy-tailed impulses, the supported conclusion concerns that test domain. An alternative remains: Thermal amplifier noise and non-Gaussian environmental interference may share average power while differing sharply in their detection tails. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 017

Application 01. Thermal reference noise in a declared measurement bandwidth

In the illustrative 017.01 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. Take the equivalent noise bandwidth B = 7,500 Hz and calibrated noise figure NF = 3.05 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -132.20$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The calculation applies to reference-source receiver noise, not the heavy-tailed ambient field; retain time-resolved amplitude statistics and detector false-alarm behaviour.

Application 02. Ideal code step, variance, and full-scale sine SNR

In the illustrative 017.02 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. Taking an ideal N = 11-bit uniform converter across 2.50 V peak-to-peak, one nominal code interval is $\Delta = Vpp/2^N = 1.2207$ mV. Under the independent uniform-error approximation its rms quantisation error is $\sigma = \Delta/\sqrt{12} = 0.3524$ mV. The ideal full-scale sinusoidal SNR approximation is $6.02N + 1.76 = 67.98$ dB. A coherent low-level waveform may violate the uniform-error assumption; clipping and integral nonlinearity are separate limitations. The ideal code width and sine-wave SNR do not guarantee detectability of short bursts; verify overload recovery, quantisation distribution and actual effective resolution.

Copyright 2026, James M. Atkinson

Application 03. The frequency dependence of aperture-jitter-limited SNR

In the illustrative 017.03 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. At sinusoidal input frequency f = 183 MHz with uncorrelated rms aperture jitter σ_t = 1.17 ps, the idealised jitter-imposed ceiling is $SNR_j = -20 \log_{10}(2\pi f \sigma_t)$ = 57.42 dB. A common clock source may correlate errors across parallel ADC channels, so treating their outputs as independent for noise cancellation would need an additional experiment. Converter nonlinearity and thermal noise can make actual performance worse. The jitter ceiling concerns the specified high-frequency sinusoid and uncorrelated timing error, not all field waveforms or a promise of independent parallel channels.

Application 04. Combined and expanded measurement uncertainty

In the illustrative 017.04 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. For independent standard-uncertainty contributions 0.66, 0.60 and 0.31 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.66^2 + 0.60^2 + 0.31^2)}$ = 0.944 units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c$ = 1.889 units. The illustrative factor-of-two interval assumes the stated uncertainty model; common calibration, field drift and heavy tails require separate covariance and coverage review.

Application 05. Cascade gain and observed headroom

In the illustrative 017.05 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching

Copyright 2026, James M. Atkinson

transients and impulsive industrial interference. A first amplifier contributes G_1 = 10 dB, an intentional attenuation contributes G_2 = -7 dB, and a later stage contributes G_3 = 19 dB. The small-signal sum is 10 + (-7) + 19 = 22 dB. For P_i = -71 dBm, the ideal output is P_o = -49 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. A twenty-two-decibel gain total does not show whether an impulsive blocker compressed an early stage; measure transient headroom and recovery throughout the chain.

Application 06. Filter or cable rejection referred to a physical input

In the illustrative 017.06 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. For an admitted input P_i = -61 dBm and separately measured loss L = 23 dB, the linear prediction is $P_o = P_i - L$ = -84 dBm. In SI power this becomes 10^((-84 − 30)/10) = 3.98e-12 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. The cable-loss prediction is not an antenna-to-receiver detection guarantee: input mismatch, variable noise temperature and alternate ingress can alter the observed level.

Application 07. Opportunity-limited detection under independent visits

In the illustrative 017.07 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. For n = 33 genuinely independent valid observation opportunities, each with stipulated event

Copyright 2026, James M. Atkinson

detection chance p = 0.06, the probability of no detections is $(1 - p)^n$ = 0.12978; its complement is 87.02%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The independent-visit formula is not an assurance that a periodic or clustered emitter was absent; document the dwell schedule, valid visits and tested event class.

Application 08. Family-wise probability when many candidates are searched

In the illustrative 017.08 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. If each of M = 397 independent pre-specified search opportunities has false-alarm probability α = 0.0008, the probability of one or more false positives is 1 − (1 − α)^M = 0.27220, or 27.22%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. The family-wise probability depends on the specified independent search opportunities; correlated FFT bins and retrospective selection change the false-alarm model.

Application 09. Observed exposure fraction of a channel scanner

In the illustrative 017.09 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. Let the channel be observed on n = 321 valid visits, each lasting d = 12 ms, with revisit

Copyright 2026, James M. Atkinson

spacing R = 0.85 s. Valid exposure is nd/1000 = 3.852 s across the nominal interval nR = 272.85 s. The observed fraction of elapsed time is therefore 1.41%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. An exposure fraction of roughly one per cent characterises receiver coverage, not transmitter occupancy or the absence of events between visits.

Application 10. Difference between two instruments relative to stated uncertainty

In the illustrative 017.10 test, the laboratory reports a favourable receiver noise figure while the field site contains periodic switching transients and impulsive industrial interference. The paired instrument contrast is $\Delta = 1.580$ dB. Set independent standard uncertainties $u_1 = 0.500$ dB and $u_2 = 0.520$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.721$ dB, giving the dimensionless ratio $\Delta/u\Delta = 2.190$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The uncertainty-scaled difference does not identify a radiating source; a systematic temperature, gain or antenna-state change could produce the same contrast.

QUESTION 018

Copyright 2026, James M. Atkinson

How should intermodulation products be challenged before calling a feature an emitter?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 018 asks: How should intermodulation products be challenged before calling a feature an emitter? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is causal discrimination of external emitters from internally generated intermodulation. Our primary observation is spectral features at combination frequencies of simultaneous strong input tones; by contrast, what remains unseen is where in the physical chain the nonlinear mixing occurred. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Third-order products and a two-tone falsification test. Let two strong external tones occur at 900 and 901 megahertz. A third-order mixing product can fall at 2 times 900 minus 901 = 899 megahertz, even without a

Copyright 2026, James M. Atkinson

transmitter operating at 899 megahertz. For a weakly nonlinear stage in its small-signal cubic regime, a 1 dB rise in each equal-level driving tone can produce about a 3 dB rise in the third-order product, whereas a genuine independent narrowband emitter need not follow that slope. This differential test is conditional: gain control, compression, filtering and antenna coupling can spoil the simple relation. Vary the two drive powers separately, trace the stimulus path and preserve the measured slopes. A spur that changes under this challenge is evidence about the chain's nonlinearity, not necessarily the whereabouts or intentions of any outside device. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns spectral features at combination frequencies of simultaneous strong input tones; it is not interchangeable with where in the physical chain the nonlinear mixing occurred. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is stepped input attenuation, two-tone prediction, filtering substitution, and independent reference-plane observation. A claim drawn from that comparison has to carry its actual uncertainties: third-order slope, input intercept point, tone spacing, compression, and product symmetry. Two strong tones can produce third-order components at twice one frequency minus the other. An internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime. A contact junction external to the receiver

Copyright 2026, James M. Atkinson

may itself generate intermodulation and must not be confused with mixer distortion. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Principal contribution 1: Two strong tones can produce third-order components at twice one frequency minus the other.

An apparent third-order product can mimic a real transmission remarkably well, particularly when two legal high-power signals illuminate the first mixer. The critical test is not to search for a suggestive frequency relationship after observing the line, but to apply two controlled tones whose frequencies and powers are known before the measurement. For equal tone levels in the small-signal cubic regime, an unwanted component at $2f_1 - f_2$ or $2f_2 - f_1$ grows at approximately three decibels per one-decibel increase in each input tone, whereas an ordinary linear response grows by one. This rule ceases to be dependable near compression, under unequal powers, or if an external nonlinear junction has already created the intermodulation component. I would therefore repeat the amplitude sweep using an external filter and attenuator at different stages. A real emitter and an internally generated product are distinguishable only if the interventions separate their physical pathways.

In this physical path examination of Question 018, the decisive claim is that two strong tones can produce third-order components at twice one frequency minus the other. Third-order intermodulation is a hypothesis about a nonlinear transfer, not a label supplied by the shape of a spectral line. For two sufficiently strong inputs at f1 and f2, cubic behaviour predicts products at 2f1 minus f2 and 2f2 minus f1. Their observed power should initially vary approximately three decibels for each decibel change of the provoking tones in the small-signal region. The experiment must establish whether the nonlinearity is in the receiver, a corroded external contact, an

Copyright 2026, James M. Atkinson

active amplifier or a different junction. Changes in input attenuation only discriminate paths when the attenuation is inserted before the suspect nonlinear element. A useful falsification proceeds from the actual controversy: third-order products and a two-tone falsification test. Let two strong external tones occur at 900 and 901 megahertz. A third-order mixing product can fall at 2 times 900 minus 901 = 899 megahertz, even without a transmitter operating at 899 megahertz. For a weakly nonlinear stage in its small-signal cubic regime, a 1 dB rise in each equal-level driving tone can produce about a 3 dB rise in the third-order product, whereas a genuine independent narrowband emitter need not follow that slope. This differential test is conditional: gain control, compression, filtering and antenna coupling can spoil the simple relation. Vary the two drive powers separately, trace the stimulus path and preserve the measured slopes. A spur that changes under this challenge is evidence about the chain's nonlinearity, not necessarily the whereabouts or intentions of any outside device. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Generate two equal, independently verified RF tones, with enough isolation to avoid generator intermodulation. Sweep each input level over a range below compression while monitoring the third-order product slope. Fit the slope with uncertainty and repeat after moving a passive attenuator from before to after the first active stage. A junction outside the receiver may be challenged by antenna substitution or a physically different coupling path. Evidence for a cubic product is stronger than a visual resemblance, but still does not attribute the product to a unique junction. I would take 2f1−f2,

Copyright 2026, James M. Atkinson

2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: Two strong tones can produce third-order components at twice one frequency minus the other. A response consistent with within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. Two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by the product may originate in the receiver mixer, an

Copyright 2026, James M. Atkinson

overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane, and measure their behaviour separately before reconnecting the assembled system. Armstrong's receiver engineering points to actual conversion products and oscillation conditions rather than abstract spectral indications; the crucial question is where the energy first appears. It is therefore material to establish 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios rather than infer them from a single scalar output. The limiting test is concrete: Change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. If the intervention produces within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 db per 1 db increase of each equal blocker tone, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret a smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased as a new transmitter before challenging the most economical instrumental explanation. The frequencies predicted by twice one tone minus the other supply a hypothesis, not a diagnosis. Professor Tukey, I pass the floor for your assessment of which paired measurements make the spur explanation credible.

John Wilder Tukey | Peer question 1 to Edwin Howard Armstrong

Edwin Howard Armstrong, may I test the exact physical inference in your account of two strong broadcasting carriers surround the frequency

Copyright 2026, James M. Atkinson

of a suspected weak transmission within a wideband SDR capture? The proposed mechanism appears plausible only if changes after change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator are compared with a stable reference condition. Two strong tones can produce third-order components at twice one frequency minus the other. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios which would settle that narrower claim, rather than a visual impression of improvement.

Edwin Howard Armstrong | Immediate answer to John Wilder Tukey

Dr Tukey, if the product frequency is exactly predicted I should still be sceptical, because two external emitters or two nonlinear stages can produce a matching line. I shall look for the input-power slope, change the attenuation at a specified physical point, and check the signal generator’s own distortion. Only after those controls can the amplitude trajectory support a receiver-origin inference. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical

Copyright 2026, James M. Atkinson

variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 018, the specific physical candidate is quadratic, cubic, and higher-order responses in amplifiers, mixers, contacts, and overloaded sampling stages. The unresolved physical pathway is material: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The retained record permits a conditional claim about 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, but cannot alone resolve frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. Two strong tones can produce

Copyright 2026, James M. Atkinson

third-order components at twice one frequency minus the other. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator, and only a response matching within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Edwin Howard Armstrong

I appreciate your explanation, Edwin Howard Armstrong. How would your conclusion survive a deliberately independent test of a smaller trace appears near the predicted third-order frequency and grows rapidly

Copyright 2026, James M. Atkinson

when the strong signals are increased? A second receiver might share more of the supposed evidence than its separate enclosure suggests. An internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios and document which differences remain unexplained? Would you also state what observed change in 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios would invalidate the preferred account, and which aspect of change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator would make that negative result independently repeatable?

Edwin Howard Armstrong | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An

Copyright 2026, James M. Atkinson

independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 018, the specific physical candidate is quadratic, cubic, and higher-order responses in amplifiers, mixers, contacts, and overloaded sampling stages. The unresolved physical pathway is material: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The retained record permits a conditional claim about 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, but cannot alone resolve frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. An internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains the product may originate in the receiver mixer, an overloaded low-

Copyright 2026, James M. Atkinson

noise amplifier, or a corroded external junction before the nominal input reference plane; I would challenge it with change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. Two responses consistent with within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. A discordant measurement would then be interpreted by tracing that difference through 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 2: An internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime.

The intercept-point model is a useful extrapolation, not a guarantee that every strong-signal experiment remains linear. With two equal inputs P at the reference plane and an ideal input-referred third-order intercept IIP3, the small-signal approximation $P_{IM3} \approx 3P - 2IIP3$ predicts an internally produced level. Yet a filter's group delay, a limiter's transfer curve or an amplifier's bias current may create a different amplitude law during a short burst. I would measure the amplitude trajectory of the alleged product across input levels and compare it with the onset of compression. Moving the intermodulation test to another RF frequency pair is valuable, because a genuine external line does not usually follow the combination-frequency grid selected by the engineer. Measurements must report which stage is presumed nonlinear and what happens when a notch filter removes one parent tone before that stage. Reversibility under a controlled stimulus is stronger evidence than formula matching alone.

In this control and stability examination of Question 018, the decisive claim is that an internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: third-order products and a two-tone falsification test. Let two strong external tones occur at 900 and 901 megahertz. A third-order

Copyright 2026, James M. Atkinson

mixing product can fall at 2 times 900 minus 901 = 899 megahertz, even without a transmitter operating at 899 megahertz. For a weakly nonlinear stage in its small-signal cubic regime, a 1 dB rise in each equal-level driving tone can produce about a 3 dB rise in the third-order product, whereas a genuine independent narrowband emitter need not follow that slope. This differential test is conditional: gain control, compression, filtering and antenna coupling can spoil the simple relation. Vary the two drive powers separately, trace the stimulus path and preserve the measured slopes. A spur that changes under this challenge is evidence about the chain's nonlinearity, not necessarily the whereabouts or intentions of any outside device. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by a smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note an internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime. has a

Copyright 2026, James M. Atkinson

consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, a smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. This predicts a response which should be tested against within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 db per 1 db increase of each equal blocker tone. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that

Copyright 2026, James M. Atkinson

presentational step does not restore measurements discarded during retuning. Where frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose, the correct claim must name the operational states and the evidence available in each. The approximate three-decibel slope of a third-order product is diagnostic only while the stages remain in the relevant regime. Dr Pearson, I invite your scrutiny of the measurement series and its uncertainty.

Egon Sharpe Pearson | Peer question 3 to Hendrik Wade Bode

Hendrik Wade Bode, your calibration argument invites a question about reference planes, especially because frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. The reference stimulus and the unknown emission need not occupy the same physical regime. A contact junction external to the receiver may itself generate intermodulation and must not be confused with mixer distortion. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When a smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator without relying upon the original screenshot or

Copyright 2026, James M. Atkinson

undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Hendrik Wade Bode | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 018, the specific physical candidate is quadratic, cubic, and higher-order responses in amplifiers, mixers, contacts, and overloaded sampling stages. The unresolved physical pathway is material: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The retained record permits a conditional claim about 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, but cannot alone resolve frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios. A contact junction external to the receiver may itself generate intermodulation and must not be confused with mixer distortion. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test.

Copyright 2026, James M. Atkinson

An appropriate reference check would be change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator, with before-and-after values of 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios. If the instrument behaves as predicted, then within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. A smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Hendrik Wade Bode

There is an inferential difficulty, Hendrik Wade Bode: the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The

Copyright 2026, James M. Atkinson

population of admissible observations needs to be fixed before any confidence argument. In this situation, frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Changing preselection can alter the interfering tone population and thereby change the spur without removing a transmitter. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios would invalidate the preferred account, and which aspect of change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator would make that negative result independently repeatable?

Hendrik Wade Bode | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps

Copyright 2026, James M. Atkinson

separate otherwise coincident aliases and mixer products. For Question 018, the specific physical candidate is quadratic, cubic, and higher-order responses in amplifiers, mixers, contacts, and overloaded sampling stages. The unresolved physical pathway is material: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The retained record permits a conditional claim about 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, but cannot alone resolve frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because a smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Changing preselection can alter the interfering tone population and thereby change the spur without removing a transmitter. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator, but it must be

Copyright 2026, James M. Atkinson

labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane; its prediction should be recorded alongside within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a predicted response at 2×151 mhz − 154 mhz equals 148 mhz, even if no transmitter is operating at 148 mhz. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 3: A contact junction external to the receiver may itself generate intermodulation and must not be confused with mixer distortion.

If two excitation frequencies f_1 and f_2 are sampled near or beyond the analogue band edge, their images can deceive the engineer about where a nonlinear product was formed. A digital FFT showing a peak at a predicted combination does not distinguish a component produced before the ADC from a component created by converter nonlinearity or subsequent numerical overflow. I would demand a verified analogue frequency plan and an independent RF spectrum measurement ahead of the converter, with enough dynamic range to resolve the parent signals. The anti-alias network must be included, for products outside the admitted band can fold into the same digital frequency. The signal's motion under a deliberate shift of sample rate is informative only when the input analogues and clock relation are known. An image that moves in accordance with sampling need not imply any movement of the external transmitter. Correct frequency arithmetic is necessary but not sufficient for correct source attribution.

In this operational measurand examination of Question 018, the decisive claim is that a contact junction external to the receiver may itself generate intermodulation and must not be confused with mixer distortion. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: third-order products and a two-tone falsification test. Let two strong external tones occur at 900 and 901 megahertz. A third-order mixing product can fall at 2 times 900 minus 901 = 899 megahertz, even without a transmitter operating at 899

Copyright 2026, James M. Atkinson

megahertz. For a weakly nonlinear stage in its small-signal cubic regime, a 1 dB rise in each equal-level driving tone can produce about a 3 dB rise in the third-order product, whereas a genuine independent narrowband emitter need not follow that slope. This differential test is conditional: gain control, compression, filtering and antenna coupling can spoil the simple relation. Vary the two drive powers separately, trace the stimulus path and preserve the measured slopes. A spur that changes under this challenge is evidence about the chain's nonlinearity, not necessarily the whereabouts or intentions of any outside device. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

A third-order intermodulation product has a testable frequency arithmetic: two blockers at f_1 and f_2 can yield products near $2f_1 - f_2$ and $2f_2 - f_1$, even when no transmitter operates at those product frequencies. The strongest evidential test is not visual resemblance but controlled perturbation. Change one blocker frequency by Δf and determine whether the alleged emitter shifts by the predicted factor, while preserving the unaltered blocker as a control. Under a suitable unsaturated cubic approximation, the third-order product may increase roughly three decibels for each one-decibel rise in equal input tones; real receivers depart from this rule as compression and other nonlinearities become important. Vary input attenuation and gain, inspect the front-end filter state, and repeat using an independent receiver with a materially different analogue architecture. Do not infer an external source merely because two instruments show a peak: common illumination by the same powerful blockers can make their nonlinear products agree. Accordingly, the laboratory record for Question

Copyright 2026, James M. Atkinson

018 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband sdr capture; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare $2f1-f2$, $2f2-f1$, product slope, input intercept, compression onset and before/after attenuation ratios under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A predicted response at 2×151 MHz − 154 MHz equals 148 MHz, even if no transmitter is operating at 148 MHz. It demonstrates the danger of transferring a result across domains in

Copyright 2026, James M. Atkinson

which the defining measurement has changed. A corroded connector outside the receiver can produce the same mixing frequencies as an internal nonlinear stage. Dr Turing, please take the floor and ask which switching or isolation records locate the source of nonlinearity.

Alan Mathison Turing | Peer question 5 to Harry Nyquist

Harry Nyquist, I should like to examine what the recorded data actually preserve when two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. The physical input and the retained numerical array are not interchangeable things. Frequency prediction is useful screening evidence, but physical isolation tests establish stronger causal distinctions. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios would invalidate the preferred account, and which aspect of change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Harry Nyquist | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 018, the specific physical candidate is quadratic, cubic, and higher-order responses in amplifiers, mixers, contacts, and overloaded sampling stages. The unresolved physical pathway is material: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The retained record permits a conditional claim about 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, but cannot alone resolve frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. I propose separating acquired information from

Copyright 2026, James M. Atkinson

model-dependent reconstruction. Frequency prediction is useful screening evidence, but physical isolation tests establish stronger causal distinctions. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios and a fresh trial in which the operator change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. If that trial demonstrates within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 4: Changing preselection can alter the interfering tone population and thereby change the spur without removing a transmitter.

An investigation containing multiple strong carriers will naturally offer many combinations of sums and differences. Having found an unexplained line, one can almost always discover a plausible pair among a large channel list. This is an exploratory hypothesis, not a formal confirmation. I would preselect a limited set of candidate parent tones based on the receiver's actual front-end passband, then perform controlled attenuation and input filtering with all trials logged. A control chart of suspect-power against parent-power can reveal whether a stable cubic regime exists, but an observation chosen from hundreds of spectral bins requires an allowance for that search. If the detector reuses overlapping windows, its nominal sample count exaggerates the independent evidence. The best report describes the response pattern under the declared intervention, including negative cases, and distinguishes internal mixing from possible external passive intermodulation at a connector or corroded junction.

In this information retention examination of Question 018, the decisive claim is that changing preselection can alter the interfering tone population and thereby change the spur without removing a transmitter. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: third-order products and a two-tone falsification test. Let two strong external tones occur at 900 and 901 megahertz. A third-order mixing product can fall at 2 times 900 minus 901 = 899 megahertz, even without a transmitter operating at 899 megahertz. For a weakly nonlinear

Copyright 2026, James M. Atkinson

stage in its small-signal cubic regime, a 1 dB rise in each equal-level driving tone can produce about a 3 dB rise in the third-order product, whereas a genuine independent narrowband emitter need not follow that slope. This differential test is conditional: gain control, compression, filtering and antenna coupling can spoil the simple relation. Vary the two drive powers separately, trace the stimulus path and preserve the measured slopes. A spur that changes under this challenge is evidence about the chain's nonlinearity, not necessarily the whereabouts or intentions of any outside device. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. The scientific point of changing preselection can alter the interfering tone population and thereby change the spur without removing a transmitter. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions repeatedly show within an unsaturated cubic regime, an internally generated third-order product

Copyright 2026, James M. Atkinson

grows approximately 3 dB per 1 dB increase of each equal blocker tone, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. A smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. The issue becomes especially sharp because the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the proposed case, a predicted

Copyright 2026, James M. Atkinson

response at 2×151 mhz − 154 mhz equals 148 mhz, even if no transmitter is operating at 148 mhz. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. Changing preselection changes the interfering inputs themselves, not simply the display. Dr Deming, I invite an experimental challenge that separates altered tone population from an actual change in the emitter.

W. Edwards Deming | Peer question 6 to Walter Andrew Shewhart

I thank you, Walter Andrew Shewhart, for distinguishing measurement from attribution, but the observation is that a smaller trace appears near the predicted third-order frequency and grows rapidly when the strong signals are increased. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a predicted response at 2×151 MHz − 154 MHz equals 148 MHz, even if no transmitter is operating at 148 MHz. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone on one day but fails after the instrument has been reconfigured? Two strong tones can produce third-order components at twice one frequency minus the other. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 018, the specific physical candidate is quadratic, cubic, and higher-order responses in amplifiers, mixers, contacts, and overloaded sampling stages. The unresolved physical pathway is material: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The retained record permits a conditional claim about 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, but cannot alone resolve frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a predicted response at 2×151 MHz − 154 MHz equals 148 MHz, even if no transmitter is operating at 148 MHz. I would retain the

Copyright 2026, James M. Atkinson

counterexample as part of the primary result, not as a footnote to an attractive conclusion. Two strong tones can produce third-order components at twice one frequency minus the other. Its bearing on the dispute can be evaluated through the predicted response, namely within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone. Because the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane, the procedure change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match report a bounded nonlinear-origin inference and retain alternate junction locations until physical isolation differentiates them, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. Within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 5: Frequency prediction is useful screening evidence, but physical isolation tests establish stronger causal distinctions.

To decide whether an alleged emitter is in fact a receiver product, one must specify the evidence that would refute the intermodulation explanation. I should favour a planned sequence in which one parent tone is suppressed before the suspected nonlinearity, while an independently monitored external antenna path remains unchanged. Under a cubic model the product should fall in a predictable relationship, but the expected slope and variance must be characterised for the actual circuit. If the suspect persists despite verified removal of a necessary parent tone, that outcome challenges the chosen model; it does not by itself prove an illicit transmitter. Competing accounts include another pair of parent signals, a spur from a different gain stage and a radiated product generated outside the test box. An interval estimate for the intervention effect should use the paired measurement errors and their correlations. Attribution depends on eliminating alternatives with empirical power, not on attaching a famous formula to a convenient spectral coincidence.

In this statistical inference examination of Question 018, the decisive claim is that frequency prediction is useful screening evidence, but physical isolation tests establish stronger causal distinctions. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: third-order products and a two-tone falsification test. Let two strong external tones occur at 900 and

Copyright 2026, James M. Atkinson

901 megahertz. A third-order mixing product can fall at 2 times 900 minus 901 = 899 megahertz, even without a transmitter operating at 899 megahertz. For a weakly nonlinear stage in its small-signal cubic regime, a 1 dB rise in each equal-level driving tone can produce about a 3 dB rise in the third-order product, whereas a genuine independent narrowband emitter need not follow that slope. This differential test is conditional: gain control, compression, filtering and antenna coupling can spoil the simple relation. Vary the two drive powers separately, trace the stimulus path and preserve the measured slopes. A spur that changes under this challenge is evidence about the chain's nonlinearity, not necessarily the whereabouts or intentions of any outside device. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. Frequency prediction is useful screening evidence, but physical isolation tests establish stronger causal distinctions. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator, should be accompanied by a second acquisition path whose dependencies are

Copyright 2026, James M. Atkinson

explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say report a bounded nonlinear-origin inference and retain alternate junction locations until physical isolation differentiates them, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. Two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman’s statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime.

Copyright 2026, James M. Atkinson

The relevant quantities are 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 db per 1 db increase of each equal blocker tone, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a predicted response at 2×151 mhz − 154 mhz equals 148 mhz, even if no transmitter is operating at 148 mhz, is not an estimate of any actual investigation. Numerical coincidence with a mixing equation cannot identify the physical junction responsible. Sir Karl, the floor is yours to ask which contrary test should overturn the intermodulation account.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise report a bounded nonlinear-origin inference and retain alternate junction locations until physical isolation differentiates them? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. An internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime. Please connect 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios with a declared detection threshold and the measurement exposure. If the experiment change input attenuation

Copyright 2026, James M. Atkinson

before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 018, the specific physical candidate is quadratic, cubic, and higher-order responses in amplifiers, mixers, contacts, and overloaded sampling stages. The unresolved physical pathway is material: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. The retained record permits a conditional claim about 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios, but cannot alone resolve frequency arithmetic and a cubic-power trend identify a nonlinear mechanism class, not necessarily the component in which it arose. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. An internally generated third-order response commonly changes approximately three decibels for a one-decibel input change within the small-signal cubic regime. I would use the observations of 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator, not an assertion based on the operator's impression of a quiet display. If it yields within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since the product may originate in the receiver mixer, an overloaded low-noise amplifier, or

Copyright 2026, James M. Atkinson

a corroded external junction before the nominal input reference plane, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to report a bounded nonlinear-origin inference and retain alternate junction locations until physical isolation differentiates them, with the untested physical possibilities made visible.

Edwin Howard Armstrong, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, the predicted products 2f1 minus f2 and 2f2 minus f1 coincide with narrow lines visible during a strong-signal survey. The operator varies a built-in input attenuator by six decibels and observes a smaller spur, whereupon the instrument labels that line as internally generated. Yet the receiver has an antenna preamplifier before this attenuator, and the two signal generators supplying the bench test share a coupling network. How should the power-law hypothesis be tested without assuming that the attenuator is situated before every possible nonlinear element or that the synthetic source is free of products?

Hendrik Wade Bode, Cross-Peer Answer to Edwin Howard Armstrong: Dr Armstrong, the test must be indexed to an actual reference plane. First characterise each generator alone and the combined generator output with an independent, demonstrably linear measurement path; isolators, filtering and a power monitor are needed to establish whether the product already exists at the input connector. Then record the powers of both fundamentals and the product while stepping attenuation at documented positions before and after the first susceptible stage. A product created inside a stage will follow its local drive, whereas a previously generated signal entering that stage can have a different transfer, yet either behaviour may be obscured by

Copyright 2026, James M. Atkinson

gain normalisation or compression. Equal-power third-order products in the small-signal cubic region have an approximate three-to-one absolute-power slope when both tones rise together; an unequal-tone experiment should be analysed using the appropriate second-power and first-power dependence. Fit the slope with measurement uncertainty rather than presuming a perfect integer. We cannot identify an emitter from frequency arithmetic or from attenuation alone. Physical source isolation and an independent receiving chain are required before attributing a line to an external radiator. I respectfully pass the floor to Dr Nyquist.

Harry Nyquist, Cross-Peer Question to Edwin Howard Armstrong: Dr Armstrong, suppose the two-tone test proves a cubic response at the receiving installation, but the product persists after the suspect mixer is replaced. The antenna coaxial connector is weathered, and the same combination frequency appears only when a remote broadcast service and a local repeater are operating. The survey team proposes that the product has therefore been transmitted by a third source. What discriminating intervention would separate a passive, imperfect-contact junction outside the receiver from a radiating transmitter operating at the product frequency, while keeping the laboratory intervention itself from manufacturing the effect?

Edwin Howard Armstrong, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the persistence of the product after mixer substitution transfers attention to the entire coupling network, not immediately to a third transmitter. I should document and preserve the suspect connector before disturbing it, including photographs, mechanical state, moisture and measured return loss. Establish a baseline with the antenna connected, then compare a well-

Copyright 2026, James M. Atkinson

screened termination at the receiver, a replacement coaxial path, and a separately positioned reference antenna or probe. Where safe and lawful, change the incident field at the suspect junction by altering one source or its propagation path and predict the resulting frequency and power response. Contact nonlinearity can mix two applied fields at the junction; a genuine product-frequency radiator can instead be received directly. Neither disappears by decree when one connector is changed, for the replacement also alters mismatch and antenna current. The test record must state what remained constant, what changed, and what alternate paths survived. Physical localisation, traceable isolation and repeatability distinguish the hypotheses more convincingly than a single waterfall line. I respectfully pass the floor to Dr Tukey.

John Wilder Tukey, Cross-Peer Question to Jerzy Neyman: Professor Neyman, our archive shows a feature on one of hundreds of frequency-time cells inspected after acquisition. In an illustrative family of 424 independent tests, each nominally run at false-alarm probability 0.001, the chance of at least one spurious positive is about 34.6 per cent. An investigator proposes to discard uninteresting cells, retain the most conspicuous peak and quote its original single-cell probability as proof of an illicit signal. Which inferential procedure would properly separate exploratory detection, a prescribed confirmation test and the distinct physical question of where the signal originated?

Jerzy Neyman, Cross-Peer Answer to John Wilder Tukey: Dr Tukey, the cell selected by the largest observed departure cannot be treated as though it had been selected in advance. We should preserve the full search family, temporal and frequency dependence, window overlaps, threshold settings

Copyright 2026, James M. Atkinson

and the criteria used to stop searching. The illustrative expression 1 minus (1 minus alpha) to the power M is justified only for the stated independent Bernoulli test model; correlated cells require the joint null distribution or a defensible resampling or simulation strategy. Treat the discovery trace as exploratory. Reserve an independent acquisition period and a prespecified feature and threshold for confirmation, or explicitly control the family-wise or false-discovery error appropriate to the scientific decision. Detection significance does not identify the nonlinearity location. An emitter-origin claim needs separate experiments on two-tone dependence, input attenuation, preselection, junctions and independent receiving hardware. The conclusion should report evidential strength by hypothesis and acknowledge failures to distinguish internal and external products. I respectfully pass the floor to Dr Shannon.

Claude Elwood Shannon, Cross-Peer Question to Walter Andrew Shewhart: Mr Shewhart, the SDR operator observes a line in the digitised baseband, raises the analogue gain and sees the line strengthen before it breaks into a broad skirt. At the same time the converter has only four decibels of calculated headroom in the ideal gain model, and the preselector passband moves when the channel changes. A colleague says that the irregularity demonstrates a third-order transmitter rather than clipping or an alias. What process-control and instrumentation records are needed to distinguish the mechanisms and to rule out a systematic software-coordinate error?

Walter Andrew Shewhart, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, first distinguish the analogue-input frequency, mixer coordinate, sampled baseband frequency and software-labelled RF frequency; log the

Copyright 2026, James M. Atkinson

actual sampling clock and preselector tuning state rather than trusting the display annotation. A gain-change experiment must retain raw complex samples together with overload flags, automatic-gain-control state, peak rather than merely mean power, sample clipping counts and calibrated tone levels at each stage. Repeat at sufficiently low drive that every susceptible stage has measured margin, not just theoretical converter headroom. Verify that analogue filtering rejects other Nyquist-zone inputs which could fold onto the apparent product, and use an independent channel with a different sample plan as a negative control. A change point in a control chart is evidence that the process changed, not an assignment of physical cause. If a product depends on preselection, the incident tone population may have changed as well. Only a preplanned comparison, with uncertainty and failed interventions retained, can narrow the causal alternatives. I respectfully pass the floor to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of causal discrimination of external emitters from internally generated intermodulation has established a point which the specialist must not overlook. The receiver records spectral features at combination frequencies of simultaneous strong input tones; it does not, merely by drawing a clear trace, give direct access to where in the physical chain the nonlinear mixing occurred. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, Two strong tones can produce third-order components at twice one frequency minus the other. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal

Copyright 2026, James M. Atkinson

operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

Dr Atkinson closes by returning to the physics of an intermodulation product. If a line occurs at twice one excitation frequency minus another, its position is compatible with a third-order mixing mechanism, but its position alone does not identify the physical device in which the nonlinearity occurred. A properly conducted two-tone challenge measures the candidate product while varying the independent input powers and retaining the gain state. In the small-signal cubic region, the product may exhibit the expected third-order power slope, but compression, filtering and multiple interacting nonlinear stages can alter that signature. The examining engineer must also guard against generating the product inside the signal generator, combiner or test leads. I thank the contributors for demanding a separate source-purity check and a second measurement path before attribution. The resulting evidence should specify whether the artefact is receiver-generated, test-set-generated or still unresolved; it should not be advertised as a uniquely identified external transmission.

The spur appeared near a predicted third-order frequency and strengthened as the large tones increased. This is compatible with nonlinearity but does not locate its source. A defensible report specifies the two fundamentals, their input powers, the inferred product order and the operating interval before gain compression. The more useful outcome is a discriminating protocol: Change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a properly characterised two-tone generator. In applying it, the examiner must retain

Copyright 2026, James M. Atkinson

all readings supporting 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios and identify the physical plane to which the measurements refer. At the outset of the investigation, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture; that circumstance makes the alternative mechanism material, specifically the product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. A result approaching within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 dB per 1 dB increase of each equal blocker tone may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore report a bounded nonlinear-origin inference and retain alternate junction locations until physical isolation differentiates them. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

The panel supports a bounded intermodulation finding where the observed frequencies and level slopes survive controlled tests. Source attribution requires a separately documented isolation of the nonlinear component; a calculated third-order frequency alone cannot provide it. The decisive experiment is concrete: Change input attenuation before the suspected nonlinear element, isolate the aerial, and compare slopes with a

Copyright 2026, James M. Atkinson

properly characterised two-tone generator. In conducting it, the examiner must explicitly retain 2f1−f2, 2f2−f1, product slope, input intercept, compression onset and before/after attenuation ratios. If the outcome matches the stated prediction, within an unsaturated cubic regime, an internally generated third-order product grows approximately 3 db per 1 db increase of each equal blocker tone, the supported conclusion concerns that test domain. An alternative remains: The product may originate in the receiver mixer, an overloaded low-noise amplifier, or a corroded external junction before the nominal input reference plane. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 018

Application 01. Two-tone third-order products and input intercept

In the illustrative 018.01 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. With two equal input tones each at P = -30 dBm and a hypothetical input third-order intercept IIP_3 = +14 dBm, the extrapolated input-referred third-order product is $P_3 = 3P - 2IIP_3$ = -118 dBm, or -88 dBc relative to either input tone. The cubic approximation ceases to be reliable in compression. A two-tone slope check and input attenuation test must establish whether the predicted spur arises inside the receiver rather than externally. The predicted minus 118 dBm product is an extrapolated input-referred component, not an instrument measurement; verify the actual cubic regime, the two-tone stimulus purity and the suspected nonlinear reference plane.

Application 02. Gain allocation and blocker headroom

In the illustrative 018.02 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. Assume a calibrated digital full-scale equivalent of -7 dBm, a blocker applied at -39 dBm, and net analogue gain 28 dB. The projected converter input is -11 dBm and remaining margin is -7 − (-11) = 4 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. Four decibels of calculated margin is not a verified peak-overload margin for two carriers or pulsed blockers; inspect converter overload indications and upstream-stage compression before drawing an origin inference.

Copyright 2026, James M. Atkinson

Application 03. Cascade gain and observed headroom

In the illustrative 018.03 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. A first amplifier contributes G_1 = 11 dB, an intentional attenuation contributes G_2 = -6 dB, and a later stage contributes G_3 = 17 dB. The small-signal sum is 11 + (-6) + 17 = 22 dB. For P_i = -70 dBm, the ideal output is P_o = -48 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The twenty-two-decibel total can hide different intermediate signal levels; document each stage's input, interstage attenuator location and compression point to determine where an intermodulation product could be born.

Application 04. Filter or cable rejection referred to a physical input

In the illustrative 018.04 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. For an admitted input P_i = -43 dBm and separately measured loss L = 22 dB, the linear prediction is $P_o = P_i - L$ = -65 dBm. In SI power this becomes 10^((-65 − 30)/10) = 3.16e-10 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. The watt conversion establishes power units at one declared plane, not source location; a connector or screening bypass must be challenged independently if the measured transfer differs.

Copyright 2026, James M. Atkinson

Application 05. Thermal reference noise in a declared measurement bandwidth

In the illustrative 018.05 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. Take the equivalent noise bandwidth B = 9,000 Hz and calibrated noise figure NF = 3.55 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -130.91$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. This thermal-reference noise estimate bounds only the stated bandwidth and receiver model; an observed peak near an intermodulation frequency cannot be classified by substituting the noise floor for a two-tone test.

Application 06. Alias-location prediction and its non-unique inverse

In the illustrative 018.06 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. For an actual sampling frequency f_s = 19 MHz and analogue input f_i = 42.180 MHz, the nearest-replica folding rule gives $f_a = |f_i - \text{round}(f_i/f_s)f_s| = 4.180$ MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. The four-point-one-eight-megahertz sampled coordinate has non-unique analogue preimages; test preselector changes and alternate sampling frequencies before assigning a frequency to an emitter.

Copyright 2026, James M. Atkinson

Application 07. Combined and expanded measurement uncertainty

In the illustrative 018.07 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. For independent standard-uncertainty contributions 0.73, 0.48 and 0.43 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.73^2 + 0.48^2 + 0.43^2)} = 0.974$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c = 1.948$ units. The expanded uncertainty assumes independent input contributions and a stated coverage factor; correlated reference errors and nonlinear sensitivity coefficients require re-evaluation.

Application 08. Difference between two instruments relative to stated uncertainty

In the illustrative 018.08 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. The paired instrument contrast is $\Delta = 1.590$ dB. Set independent standard uncertainties $u_1 = 0.300$ dB and $u_2 = 0.420$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.516$ dB, giving the dimensionless ratio $\Delta/u\Delta = 3.081$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The contrast-to-uncertainty ratio indicates scale of difference only; it neither localises the nonlinear junction nor supplies a false-positive probability without a specified decision model.

Application 09. Opportunity-limited detection under independent visits

In the illustrative 018.09 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a

Copyright 2026, James M. Atkinson

wideband SDR capture. For n = 48 genuinely independent valid observation opportunities, each with stipulated event detection chance p = 0.09, the probability of no detections is $(1 - p)^n = 0.01081$; its complement is 98.92%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The ninety-eight-point-nine-two-per-cent complement is conditional on independent valid visits each having the stipulated detection chance; field revisit synchronisation and censoring can invalidate it.

Application 10. Family-wise probability when many candidates are searched

In the illustrative 018.10 test, two strong broadcasting carriers surround the frequency of a suspected weak transmission within a wideband SDR capture. If each of M = 424 independent pre-specified search opportunities has false-alarm probability α = 0.0010, the probability of one or more false positives is 1 − (1 − α)^M = 0.34571, or 34.57%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. The approximately thirty-four-point-six-per-cent family-wise probability refers to a prespecified independent search family; inspect correlated bins and post-selection before treating any single peak as evidence of a transmitter.

QUESTION 019

Copyright 2026, James M. Atkinson

Where do analogue filtering and group delay distort the interpretation of short bursts?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 019 asks: Where do analogue filtering and group delay distort the interpretation of short bursts? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is temporal interpretation of short bursts passing through real analogue filters. Our primary observation is the captured envelope, frequency-domain window, and estimated arrival time of a transient; by contrast, what remains unseen is the input pulse shape before filter memory, ringing, and conversion latency. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Group delay and burst chronology. A filter with nonuniform group delay can alter a short pulse’s apparent onset, shape and duration even while its passband magnitude looks satisfactory. Group delay is the negative

Copyright 2026, James M. Atkinson

derivative of unwrapped phase with respect to angular frequency, so a ripple of tens of nanoseconds across the occupied signal band may matter more to a brief transient than the advertised insertion loss. A 100-nanosecond pulse subjected to a 70-nanosecond variation across its spectral content need not retain a recognisable temporal envelope. Report the excitation waveform, filter state and delay reference plane. Compare measured impulse responses rather than attributing every multiple peak to multiple transmissions. In a localisation experiment, calibrate channel-to-channel delay separately, because a visually sharp filtered edge can still carry a systematic timing bias. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns the captured envelope, frequency-domain window, and estimated arrival time of a transient; it is not interchangeable with the input pulse shape before filter memory, ringing, and conversion latency. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is band-limited pulse injection, through-path group-delay measurement, and alternate-filter comparisons. A claim drawn from that comparison has to carry its actual uncertainties: impulse response, group-delay variation, bandwidth, rise time, and timing uncertainty. The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. Group delay is the negative derivative of filter phase with respect to angular frequency and may vary across a burst spectrum. A narrow filter can lengthen an apparently short

Copyright 2026, James M. Atkinson

event through its impulse response even if no emitted energy persists. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 1: The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response.

Dr. Atkinson, we should distinguish the group delay of an analogue network from the event time of a received emission. If the filter transfer function is $H(f)=|H(f)|\exp[j\varphi(f)]$, the local group delay is $-(1/2\pi)d\varphi/df$. A nearly flat magnitude response can conceal substantial variation of that derivative near the band edges. A short modulated pulse spans frequencies that are delayed differently, so its envelope may broaden, ring or develop a secondary maximum. The engineer who timestamps the largest peak after filtering may therefore report a time belonging to the instrument rather than to the aerial input. I recommend measuring the complex transfer response of the entire acquisition chain, not relying solely on nominal filter order. The calibration source must present a known time marker and a representative waveform family. Where the receiver retunes or changes bandwidth, treat each filter state as a different time-transfer instrument. No amount of downstream interpolation erases an analogue delay that was never characterised.

In this physical path examination of Question 019, the decisive claim is that the Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. A narrow amplitude passband may impose strongly nonuniform group delay, altering a received burst even when average power calibration appears satisfactory. The arrival time of a peak in the filtered output is not necessarily the arrival time of the earliest electromagnetic disturbance at the antenna. A frequency-dependent phase response can redistribute a

Copyright 2026, James M. Atkinson

short pulse into delayed lobes, and a real receiver may add sampling, buffering and threshold-trigger latency. These effects should be measured with a waveform spanning the admitted band, not inferred from the filter's magnitude response alone. A useful falsification proceeds from the actual controversy: group delay and burst chronology. A filter with nonuniform group delay can alter a short pulse's apparent onset, shape and duration even while its passband magnitude looks satisfactory. Group delay is the negative derivative of unwrapped phase with respect to angular frequency, so a ripple of tens of nanoseconds across the occupied signal band may matter more to a brief transient than the advertised insertion loss. A 100-nanosecond pulse subjected to a 70-nanosecond variation across its spectral content need not retain a recognisable temporal envelope. Report the excitation waveform, filter state and delay reference plane. Compare measured impulse responses rather than attributing every multiple peak to multiple transmissions. In a localisation experiment, calibrate channel-to-channel delay separately, because a visually sharp filtered edge can still carry a systematic timing bias. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Inject a calibrated short pulse and a swept, phase-coherent reference through the actual analogue filter. Measure unwrapped phase across frequency, compute its derivative with uncertainty and compare the resulting impulse response with a parallel broadband path that shares the same timing reference. Repeat after substituting a second filter of known bandwidth. If the displayed burst peak changes but the reference time does not, the excess delay should be assigned to the measurement chain rather

Copyright 2026, James M. Atkinson

than the unknown transmitter. I would take group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. A response consistent with a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. A receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by the

Copyright 2026, James M. Atkinson

emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input, and measure their behaviour separately before reconnecting the assembled system. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. It is therefore material to establish group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction rather than infer them from a single scalar output. The limiting test is concrete: Inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. If the intervention produces a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret the displayed pulse appears wider and delayed relative to a simultaneous broadband reference path as a new transmitter before challenging the most economical instrumental explanation. A short pulse broadens spectrally before any filter acts upon it, and the chosen passband reshapes what survives. Professor Tukey, I invite you to test how the analyst distinguishes processing distortion from transmitter duration.

John Wilder Tukey | Peer question 1 to Hendrik Wade Bode

Hendrik Wade Bode, may I test the exact physical inference in your account of a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature? The

Copyright 2026, James M. Atkinson

proposed mechanism appears plausible only if changes after inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths are compared with a stable reference condition. The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction which would settle that narrower claim, rather than a visual impression of improvement.

Hendrik Wade Bode | Immediate answer to John Wilder Tukey

Dr Tukey, the relevant control is not merely whether a pulse appears later on one screen. We must locate time zero at an identified connector or reference antenna and characterise the filter's group-delay function over the occupied spectrum. A differential measurement against a broadband reference will reveal whether the apparent latency is an instrumental convolution rather than a property of the emitting device. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must

Copyright 2026, James M. Atkinson

preserve inconvenient outcomes. For Question 019, the specific physical candidate is passband amplitude ripple and frequency-dependent group delay producing dispersion and post-cursor ringing. The unresolved physical pathway is material: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The retained record permits a conditional claim about group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, but cannot alone resolve digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. A stable residual after the reference

Copyright 2026, James M. Atkinson

path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths, and only a response matching a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Hendrik Wade Bode

I appreciate your explanation, Hendrik Wade Bode. How would your conclusion survive a deliberately independent test of the displayed pulse appears wider and delayed relative to a simultaneous broadband reference path? A second receiver might share more of the supposed evidence than its separate enclosure suggests. Group delay is the negative derivative of filter phase with respect to angular frequency and

Copyright 2026, James M. Atkinson

may vary across a burst spectrum. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction and document which differences remain unexplained? Would you also state what observed change in group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction would invalidate the preferred account, and which aspect of inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths would make that negative result independently repeatable?

Hendrik Wade Bode | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 019, the specific physical candidate is passband amplitude ripple and frequency-dependent group delay producing dispersion and post-cursor ringing. The unresolved physical pathway is material: The

Copyright 2026, James M. Atkinson

emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The retained record permits a conditional claim about group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, but cannot alone resolve digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. Group delay is the negative derivative of filter phase with respect to angular frequency and may vary across a burst spectrum. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input; I would challenge it with inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. Two responses consistent with a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains

Copyright 2026, James M. Atkinson

invariant would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. A discordant measurement would then be interpreted by tracing that difference through group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Oliver Heaviside | Principal contribution 2: Group delay is the negative derivative of filter phase with respect to angular frequency and may vary across a burst spectrum.

A line connected to a receiver is not always electrically transparent, particularly when a fast transient encounters a poorly terminated cable or filter interface. Transmission-line reflections can add delayed replicas before the signal reaches the mixer; those replicas may be indistinguishable from multipath in a waterfall unless the cable geometry is examined. The propagation time is set by cable length and velocity factor, while the reflection coefficient depends on the impedances presented at the discontinuity. I would deliberately vary a known cable section and see whether the apparent secondary pulse moves by the expected round-trip delay. Such a result would implicate the measurement chain rather than a second external transmission. Where the cable is long relative to the transient's spatial extent, lumped-element intuition becomes inadequate. The distinction between a reflection in the feeder and a second emitter is experimentally accessible, but only if the test changes one causal path without simultaneously retuning the receiver or changing its gain control.

In this control and stability examination of Question 019, the decisive claim is that group delay is the negative derivative of filter phase with respect to angular frequency and may vary across a burst spectrum. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: group delay and burst chronology. A filter with nonuniform group delay can

Copyright 2026, James M. Atkinson

alter a short pulse’s apparent onset, shape and duration even while its passband magnitude looks satisfactory. Group delay is the negative derivative of unwrapped phase with respect to angular frequency, so a ripple of tens of nanoseconds across the occupied signal band may matter more to a brief transient than the advertised insertion loss. A 100-nanosecond pulse subjected to a 70-nanosecond variation across its spectral content need not retain a recognisable temporal envelope. Report the excitation waveform, filter state and delay reference plane. Compare measured impulse responses rather than attributing every multiple peak to multiple transmissions. In a localisation experiment, calibrate channel-to-channel delay separately, because a visually sharp filtered edge can still carry a systematic timing bias. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by the displayed pulse appears wider and delayed relative to a simultaneous broadband reference path. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note group delay is the negative derivative of filter phase with respect to angular frequency and may vary across a burst spectrum. has a consequence for the

Copyright 2026, James M. Atkinson

observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, the displayed pulse appears wider and delayed relative to a simultaneous broadband reference path. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Heaviside's line and field analysis calls for an explicit account of propagation, cable coupling and the electrical boundary conditions of the circuit. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. This predicts a response which should be tested against a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements discarded during retuning. Where digital timestamp precision cannot

Copyright 2026, James M. Atkinson

remove a poorly characterised group delay between the antenna and converter, the correct claim must name the operational states and the evidence available in each. My proposed acceptance test would archive the entire control sequence and the independent witness measurement before any data-dependent threshold adjustment.

A further, separately testable aspect of a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature concerns group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction. The proposed challenge would be inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. The decision is conditional upon the observed result, with particular attention to digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. The competing account remains the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. An uncalibrated slope of filter phase can displace apparent event time without moving the original emission. Dr Pearson, I pass the floor for a challenge to the claimed timing uncertainty.

Egon Sharpe Pearson | Peer question 3 to Oliver Heaviside

Oliver Heaviside, your calibration argument invites a question about reference planes, especially because digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. The reference stimulus and the unknown emission need not

Copyright 2026, James M. Atkinson

occupy the same physical regime. A narrow filter can lengthen an apparently short event through its impulse response even if no emitted energy persists. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When the displayed pulse appears wider and delayed relative to a simultaneous broadband reference path, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Oliver Heaviside | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 019, the specific physical candidate is passband amplitude ripple and frequency-dependent group delay producing dispersion and post-cursor ringing. The unresolved physical pathway is material: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The retained record permits a conditional claim about group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, but cannot alone resolve digital timestamp

Copyright 2026, James M. Atkinson

precision cannot remove a poorly characterised group delay between the antenna and converter. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction. A narrow filter can lengthen an apparently short event through its impulse response even if no emitted energy persists. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths, with before-and-after values of group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction. If the instrument behaves as predicted, then a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. The displayed pulse

Copyright 2026, James M. Atkinson

appears wider and delayed relative to a simultaneous broadband reference path. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Oliver Heaviside

There is an inferential difficulty, Oliver Heaviside: the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The population of admissible observations needs to be fixed before any confidence argument. In this situation, digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Changing filtering after recording cannot restore analogue frequencies that never reached the converter. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction would invalidate the preferred account, and which aspect of inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Oliver Heaviside | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 019, the specific physical candidate is passband amplitude ripple and frequency-dependent group delay producing dispersion and post-cursor ringing. The unresolved physical pathway is material: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The retained record permits a conditional claim about group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, but cannot alone resolve digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because the displayed pulse appears wider and delayed relative to a simultaneous broadband reference path. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Changing filtering after recording cannot

Copyright 2026, James M. Atkinson

restore analogue frequencies that never reached the converter. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input; its prediction should be recorded alongside a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a 30 ns path-delay correction is meaningful only with its filter state and uncertainty, particularly in multisite localisation. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Dennis Gabor | Principal contribution 3: A narrow filter can lengthen an apparently short event through its impulse response even if no emitted energy persists.

A pulse occupying a finite time-frequency region cannot simultaneously possess the infinite temporal precision and narrow spectral definition suggested by a very thin display line. If the physical waveform is convolved with a dispersive impulse response, different parts of its spectrum emerge at different times. I would analyse a chirped calibration pulse and an unmodulated reference pulse separately, because the apparent arrival-time bias will depend on the waveform's spectral weighting. A plot of filter group delay alone is insufficient if it omits the pulse's actual occupied band. Further, the spectral estimator contributes its own window-centre convention and temporal smoothing. The examiner should preserve raw complex samples before any optional equalisation so that alternative compensators can be compared. If one equaliser produces a remarkably sharp peak, that is evidence of a mathematical transformation; confidence in the earlier arrival time needs independent calibration of the entire transfer function and clock, not admiration for the image.

In this operational measurand examination of Question 019, the decisive claim is that a narrow filter can lengthen an apparently short event through its impulse response even if no emitted energy persists. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: group delay and burst chronology. A filter with nonuniform group delay can alter a short pulse’s apparent onset, shape and duration even while its passband magnitude looks satisfactory.

Copyright 2026, James M. Atkinson

Group delay is the negative derivative of unwrapped phase with respect to angular frequency, so a ripple of tens of nanoseconds across the occupied signal band may matter more to a brief transient than the advertised insertion loss. A 100-nanosecond pulse subjected to a 70-nanosecond variation across its spectral content need not retain a recognisable temporal envelope. Report the excitation waveform, filter state and delay reference plane. Compare measured impulse responses rather than attributing every multiple peak to multiple transmissions. In a localisation experiment, calibrate channel-to-channel delay separately, because a visually sharp filtered edge can still carry a systematic timing bias. The speaker must not confuse the result of this bounded comparison with a general finding concerning every possible external transmission. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Short-burst interpretation must account for the impulse response and group-delay variation of the complete analogue path. A filter with a steep amplitude transition may introduce ringing that makes one short external pulse resemble a series of weaker events, while unequal phase delay across the admitted spectrum may distort the inferred leading edge. To separate the emitter from the instrument, inject a characterised pulse before the front-end filter and record both the input reference and the digitised output. Compare the recovered time-domain envelope, threshold crossings and energy outside the nominal event interval. Repeat with a broader or differently shaped filter whose delay response has been independently characterised. If the trailing oscillation changes with the filter but not with

Copyright 2026, James M. Atkinson

the reference pulse, it belongs in the instrument-response explanation. The investigator must state the timing fiducial and whether recorded event duration means physical emission time, filter-output envelope width or duration above the software threshold. Accordingly, the laboratory record for Question 019 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. Gabor's time-frequency work makes the time support and spectral concentration of an observation inseparable; a display cannot recover temporal detail that the window suppressed. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should

Copyright 2026, James M. Atkinson

specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A 30 ns path-delay correction is meaningful only with its filter state and uncertainty, particularly in multisite localisation. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. Impulse-response ringing can resemble a longer transmitted event even where the source pulse was brief. Dr Turing, please take the floor and ask what the retained record permits us to reconstruct.

Alan Mathison Turing | Peer question 5 to Dennis Gabor

Dennis Gabor, I should like to examine what the recorded data actually preserve when a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. The physical input and the retained numerical array are not interchangeable things. Cross-receiver time comparisons require subtracting calibrated path delays and documenting residual variation. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in group delay in seconds, phase derivative, 10–90 per cent rise time, pulse

Copyright 2026, James M. Atkinson

width and arrival-time correction would invalidate the preferred account, and which aspect of inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths would make that negative result independently repeatable?

Dennis Gabor | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 019, the specific physical candidate is passband amplitude ripple and frequency-dependent group delay producing dispersion and post-cursor ringing. The unresolved physical pathway is material: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The retained record permits a conditional claim about group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, but cannot alone resolve digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. I propose separating acquired information from model-dependent reconstruction. Cross-receiver time comparisons require subtracting calibrated path delays and documenting residual variation. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction and a fresh trial in which the operator inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. If that trial demonstrates a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses

Copyright 2026, James M. Atkinson

across two known filter bandwidths. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal contribution 4: Changing filtering after recording cannot restore analogue frequencies that never reached the converter.

The receiver's filter may possess memory through its poles, adaptive coefficients or automatic state changes. After a strong pulse, a resonant analogue stage can ring even in the absence of any new external excitation. A digital display that marks each threshold crossing as a separate event may then turn one physical burst into a sequence of apparent transmissions. I propose a controlled impulse challenge, followed by a silent interval of known duration, to measure how long the chain can produce output after the input is extinguished. Repeat with several pulse amplitudes because overload may make the response nonlinear and invalidate an impulse response measured only in the small-signal regime. An adaptive noise canceller may add a second kind of memory, since its coefficient trajectory depends on past observations. The time history of that adaptation belongs in the evidential record. Distinguishing an event's causal support from a receiver's recovery is a problem in dynamics, not merely spectral resolution.

In this information retention examination of Question 019, the decisive claim is that changing filtering after recording cannot restore analogue frequencies that never reached the converter. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: group delay and burst chronology. A filter with nonuniform group delay can alter a short pulse’s apparent onset, shape and duration even while its passband magnitude looks satisfactory. Group delay is the negative derivative of unwrapped phase with respect to angular

Copyright 2026, James M. Atkinson

frequency, so a ripple of tens of nanoseconds across the occupied signal band may matter more to a brief transient than the advertised insertion loss. A 100-nanosecond pulse subjected to a 70-nanosecond variation across its spectral content need not retain a recognisable temporal envelope. Report the excitation waveform, filter state and delay reference plane. Compare measured impulse responses rather than attributing every multiple peak to multiple transmissions. In a localisation experiment, calibrate channel-to-channel delay separately, because a visually sharp filtered edge can still carry a systematic timing bias. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. The scientific point of changing filtering after recording cannot restore analogue frequencies that never reached the converter. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions repeatedly show a filter-dependent tail should vary with the measured

Copyright 2026, James M. Atkinson

impulse response even when the injected pulse train remains invariant, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. The displayed pulse appears wider and delayed relative to a simultaneous broadband reference path. Wiener's feedback perspective questions how an adaptive controller changes the distribution of the observations it subsequently presents as independent evidence. The issue becomes especially sharp because the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the proposed case, a 30 ns path-delay correction is meaningful only with its filter state and uncertainty,

Copyright 2026, James M. Atkinson

particularly in multisite localisation. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A more precise objection comes from Norbert Wiener and the finite observation aperture in a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. For that reason, record group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. Once an analogue filter has rejected frequencies, later numerical equalisation cannot recover the exact missing field history. Dr Deming, I invite a test that exposes this boundary in an otherwise attractive waveform.

Copyright 2026, James M. Atkinson

W. Edwards Deming | Peer question 6 to Norbert Wiener

I thank you, Norbert Wiener, for distinguishing measurement from attribution, but the observation is that the displayed pulse appears wider and delayed relative to a simultaneous broadband reference path. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a 30 ns path-delay correction is meaningful only with its filter state and uncertainty, particularly in multisite localisation. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant on one day but fails after the instrument has been reconfigured? The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment? Would you also state what observed change in group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction would invalidate the preferred account, and which aspect of inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths would make that negative result independently repeatable?

Norbert Wiener | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples,

Copyright 2026, James M. Atkinson

complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 019, the specific physical candidate is passband amplitude ripple and frequency-dependent group delay producing dispersion and post-cursor ringing. The unresolved physical pathway is material: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The retained record permits a conditional claim about group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, but cannot alone resolve digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a 30 ns path-delay correction is meaningful only with its filter state and uncertainty, particularly in multisite localisation. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. Its bearing on the dispute can be evaluated through the predicted response, namely a filter-dependent

Copyright 2026, James M. Atkinson

tail should vary with the measured impulse response even when the injected pulse train remains invariant. Because the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input, the procedure inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match report timing at an explicit receiver reference plane with an uncertainty interval rather than treating the screen peak as RF arrival time, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. A filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal contribution 5: Cross-receiver time comparisons require subtracting calibrated path delays and documenting residual variation.

Operational measurement requires deciding which time is being asserted. Is it the first discernible departure from a reference noise distribution, the maximum of a matched-filter correlation, the time stamped by a firmware trigger, or the arrival at an antenna reference plane? These are different quantities even when presented on one timeline. I should request a table mapping each reported time coordinate through filter delay, buffer indexing, clock calibration and software processing latency, with uncertainty at each step. A signal of unknown spectral content does not permit the engineer to subtract one universal group-delay constant without a model. If the alleged event is especially short, the choice of detection threshold and noise environment also shifts its measured onset. The proper report should give the operational definition of arrival time and the calibration evidence supporting it. A statement that a pulse existed is less ambitious than one asserting its exact emission time or geographical origin.

In this statistical inference examination of Question 019, the decisive claim is that cross-receiver time comparisons require subtracting calibrated path delays and documenting residual variation. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: group delay and burst chronology. A filter with nonuniform group delay can alter a short pulse’s apparent onset, shape and duration even while its passband magnitude looks satisfactory.

Copyright 2026, James M. Atkinson

Group delay is the negative derivative of unwrapped phase with respect to angular frequency, so a ripple of tens of nanoseconds across the occupied signal band may matter more to a brief transient than the advertised insertion loss. A 100-nanosecond pulse subjected to a 70-nanosecond variation across its spectral content need not retain a recognisable temporal envelope. Report the excitation waveform, filter state and delay reference plane. Compare measured impulse responses rather than attributing every multiple peak to multiple transmissions. In a localisation experiment, calibrate channel-to-channel delay separately, because a visually sharp filtered edge can still carry a systematic timing bias. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. Cross-receiver time comparisons require subtracting calibrated path delays and documenting residual variation. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed;

Copyright 2026, James M. Atkinson

two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say report timing at an explicit receiver reference plane with an uncertainty interval rather than treating the screen peak as RF arrival time, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Bridgman's operational approach requires a measurement procedure that defines each quantity physically. A stated number unsupported by the operation that produced it is methodologically incomplete. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that the emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically

Copyright 2026, James M. Atkinson

meaningful regime. The relevant quantities are group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a 30 ns path-delay correction is meaningful only with its filter state and uncertainty, particularly in multisite localisation, is not an estimate of any actual investigation. Path delay must be calibrated before comparing receiver arrival times as evidence of source location. Sir Karl, I pass the floor for the observation that would make such a comparison untenable.

Sir Karl Raimund Popper | Peer question 7 to Percy Williams Bridgman

Percy Williams Bridgman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise report timing at an explicit receiver reference plane with an uncertainty interval rather than treating the screen peak as RF arrival time? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Group delay is the negative derivative of filter phase with respect to angular frequency and may vary across a burst spectrum. Please connect group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction with a declared detection threshold and the measurement

Copyright 2026, James M. Atkinson

exposure. If the experiment inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Percy Williams Bridgman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 019, the specific physical candidate is passband amplitude ripple and frequency-dependent group delay producing dispersion and post-cursor ringing. The unresolved physical pathway is material: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. The retained record permits a conditional claim about group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction, but cannot alone resolve digital timestamp precision cannot remove a poorly characterised group delay between the antenna and converter.

Copyright 2026, James M. Atkinson

That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Group delay is the negative derivative of filter phase with respect to angular frequency and may vary across a burst spectrum. I would use the observations of group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths, not an assertion based on the operator's impression of a quiet display. If it yields a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since the emitter may have transmitted a longer burst, or the receiver impulse response

Copyright 2026, James M. Atkinson

may have imposed a dispersive tail on a shorter input, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to report timing at an explicit receiver reference plane with an uncertainty interval rather than treating the screen peak as rf arrival time, with the untested physical possibilities made visible.

Hendrik Wade Bode, Cross-Peer Question to Oliver Heaviside: Mr Heaviside, the technician measures an unwrapped phase change of minus 0.480 radians across 0.60 megahertz, infers approximately 127 nanoseconds of group delay and subtracts that constant from every burst timestamp. But the passband is sharply selective, its phase curvature changes at the edges, and the injected field pulse occupies much of the useful band. Is that single finite-difference quotient a defensible arrival-time correction? Which distinction between the derivative at a frequency and the time-domain arrival of a broadband envelope must the teaching example make explicit?

Oliver Heaviside, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, the finite-difference quotient is a local estimate of minus d phi by d omega, not a certificate that every Fourier component of a broad burst incurs the same delay. The stated 127-nanosecond value presumes a valid phase unwrap, a measured transfer function and a reference plane that excludes unintended cables or conversion latency. To estimate the waveform effect, measure the complex transfer function over the occupied spectrum at sufficient frequency resolution, retain its magnitude as well as its phase, and form or measure the actual impulse response. Compare the output of a calibrated broadband pulse with a synchronised reference path before and after filter substitution. Where group delay varies appreciably, the output can broaden,

Copyright 2026, James M. Atkinson

ring and move its peak in a waveform-dependent fashion. There may be no single correction that transforms the peak of every input into the physical emission time. The report must define whether it is estimating a selected threshold crossing, energy centroid, correlation maximum or another arrival-time statistic and include calibration and noise uncertainty for that estimator. I respectfully pass the floor to Dr Gabor.

Dennis Gabor, Cross-Peer Question to Norbert Wiener: Professor Wiener, a short burst becomes a long ringing tail after a very narrow analogue filter. The software team proposes to deconvolve the stored I/Q against a nominal impulse response and announce a sharply localised original emission, even though much of the original burst spectrum lay beyond the analogue passband. When does inversion recover information legitimately, and when does it merely amplify noise or manufacture a pulse from unobserved spectral components?

Norbert Wiener, Cross-Peer Answer to Dennis Gabor: Dr Gabor, write the observation as the unknown input convolved with the measured system response, plus receiver noise, clock errors and any nonlinear gain transients. Where the transfer function is reliably measured and bounded away from zero across the retained frequencies, an appropriately regularised inversion can estimate the portion of the waveform admitted by the system. The prior assumptions and their effect on timing should be exposed by sensitivity tests with several plausible input pulse shapes. Where analogue attenuation removed frequencies below the usable noise floor, the inverse is ill-conditioned or non-identifiable; digitally amplifying a stopband does not recreate lost observations. A calculated narrow pulse under a strong prior is then a model-dependent reconstruction, not direct forensic

Copyright 2026, James M. Atkinson

evidence of an emitted impulse with that duration. A parallel wideband recorder at a common physical reference plane, followed by blind injections, can test whether the claimed improvement is genuine. Archive raw samples, filter calibration, regularisation settings, and uncertainty intervals so another examiner can reproduce or challenge the inference. I respectfully pass the floor to Professor Bridgman.

Percy Williams Bridgman, Cross-Peer Question to Harry Nyquist: Dr Nyquist, two receivers record the same injected calibration burst with timestamps separated by hundreds of microseconds. The timebase of one recorder has a known parts-per-million mean rate error over several minutes, while the other shares a disciplined frequency reference but not the same analogue filter or trigger comparator. Can the observed offset be treated as a propagation time difference or used for a location calculation? How ought the timing reference plane, filter delay and sample-clock behaviour be separated?

Harry Nyquist, Cross-Peer Answer to Percy Williams Bridgman: Professor Bridgman, a propagation comparison must refer each event to a common external time and a declared input plane, not merely to the digits stamped on two packets. The rate error integrated across an interval predicts accumulated clock drift only under its specified constancy assumption; it does not determine analogue front-end group delay, sample-to-host buffering or the trigger algorithm latency. Inject the same traceable pulse into each receiver at a known connector while recording the distribution of time differences over frequency, amplitude, temperature and processing state. Identify which clock supplies the sample time, which supplies the wall clock and whether their errors are correlated. For localisation, subtract

Copyright 2026, James M. Atkinson

measured per-channel delay and its uncertainty and test the residual for stability using an independent geometric or cabled reference. If delay changes with pulse spectrum or AGC state, report a condition-dependent calibration instead of a single offset. Without that chain of measurements, a timestamp difference cannot be attributed to transmitter position. I respectfully pass the floor to Dr Tukey.

John Wilder Tukey, Cross-Peer Question to W. Edwards Deming: Dr Deming, a channel is visited for sixteen milliseconds every 1.15 seconds and a capture log loses 252 complex samples in a nominal 0.75-second recording. A later analyst reports that the system continuously monitored the short-burst source, cites the low average sample-loss fraction and treats the absence of a pulse as evidence that no emission occurred. What quality-control record would reveal the distinction between receiver coverage and event occupancy, and how should unknown intervals affect a negative finding?

W. Edwards Deming, Cross-Peer Answer to John Wilder Tukey: Dr Tukey, retain a time-indexed acquisition ledger, not just a reassuring percentage. For every observation state record start and stop time, filter configuration, gain, overload recovery, clock validity, frame-sequence continuity, dead intervals, and whether a detection algorithm was actually running on samples preserved for review. The sixteen-millisecond dwell divided by the 1.15-second revisit yields only about 1.39 per cent planned receiver exposure for that channel under the stated schedule. This is not the source’s duty cycle, and a periodic emission may systematically avoid the observed windows. Likewise, 252 lost samples represent a small fraction of a longer capture yet may wholly conceal an event if they cluster in its critical interval.

Copyright 2026, James M. Atkinson

Test the system with injected bursts distributed over phase relative to the revisit schedule and with deliberately introduced loss patterns. A negative result should describe the detectable event class, validated exposure time and remaining unobservable periods. Unvisited and invalid periods are unknown, not documented silence. I respectfully pass the floor to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of temporal interpretation of short bursts passing through real analogue filters has established a point which the specialist must not overlook. The receiver records the captured envelope, frequency-domain window, and estimated arrival time of a transient; it does not, merely by drawing a clear trace, give direct access to the input pulse shape before filter memory, ringing, and conversion latency. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, The Fourier transform of a short pulse extends across a broad frequency interval and interacts with the complete passband response. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

An amplitude response can appear admirably flat while group delay varies sufficiently across the admitted burst spectrum to alter pulse shape and apparent time of arrival. We have therefore to consider more than the loss of a filter or cable measured at one frequency. The proposed proof

Copyright 2026, James M. Atkinson

should combine a network-analyser phase sweep, a reference impulse or calibrated modulation, and the receiver's own time-stamp record. A differential phase measurement must be unwrapped consistently, and the estimated slope must be accompanied by its frequency interval and uncertainty. When the observing apparatus changes filters, the same external burst may appear wider, shifted or split without the transmitter having changed its behaviour. I thank Dr Gabor for the concern over time-frequency resolution and Lord Kelvin for the older experimental lesson that the receiving path has a measurable history of its own. Our decision is to report delay introduced by the characterised system, retaining residual uncertainty rather than treating a screen cursor as an absolute arrival-time certificate.

The stored pulse appears wider and later in the selective path than in the contemporaneous broadband path. That difference supports an instrumental dispersion hypothesis if the two paths share a documented clock and their alignment uncertainties are small enough to resolve the effect. The more useful outcome is a discriminating protocol: Inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. In applying it, the examiner must retain all readings supporting group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction and identify the physical plane to which the measurements refer. At the outset of the investigation, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature; that circumstance makes the alternative mechanism material, specifically the emitter may have transmitted a longer burst, or the receiver impulse

Copyright 2026, James M. Atkinson

response may have imposed a dispersive tail on a shorter input. A result approaching a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore report timing at an explicit receiver reference plane with an uncertainty interval rather than treating the screen peak as RF arrival time. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

Timing evidence should be stated at a declared electrical reference plane with the filter delay and trigger latency included in its uncertainty budget. An uncorrected screen maximum is not an independently authenticated radio-frequency arrival time. The decisive experiment is concrete: Inject a calibrated pulse spanning the admitted channel and compare through-path impulse responses across two known filter bandwidths. In conducting it, the examiner must explicitly retain group delay in seconds, phase derivative, 10–90 per cent rise time, pulse width and arrival-time correction. If the outcome matches the stated prediction, a filter-dependent tail should vary with the measured impulse response even when the injected pulse train remains invariant, the supported conclusion concerns that test domain. An alternative remains: The emitter may have transmitted a longer burst, or the receiver impulse response may have imposed a dispersive tail on a shorter input. I thank the contributors for their careful and courteous

Copyright 2026, James M. Atkinson

disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 019

Application 01. Group delay from a local phase-versus-frequency slope

In the illustrative 019.01 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. Across a local frequency step $\Delta f = 0.60$ MHz, suppose unwrapped transmission phase changes by $\Delta\varphi = -0.480$ rad. The finite-difference group-delay estimate is $\tau g \approx -\Delta\varphi/(2\pi\Delta f) = 127.324$ ns. This is an average local slope. Dispersive responses require a finer phase sweep, a consistent unwrapping method and uncertainty treatment before extrapolating transient arrival times. The 127-nanosecond quotient characterises local phase slope only; broad-pulse arrival correction requires the measured impulse response across the occupied spectrum and a declared timestamp estimator.

Application 02. First-order recovery envelope after a state change

In the illustrative 019.02 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. If an illustrative recovery follows $A(t) = A_0 \exp(-t/\tau)$, let $A_0 = 1.30$ V and $\tau = 10.00$ ms. At $t = 25.00$ ms the residual is $1.30e^{(-25.00/10.00)} = 0.1067$ V. Real automatic gain control often has nonlinear or multi-time-constant behaviour, so this exponential is a test model, not a universal reconstruction of the input during overload. The 0.1067-volt value is a hypothetical exponential recovery sample, not a reconstructed input burst; calibrate gain-control state and repeat after controlled overload to establish any timing bias.

Copyright 2026, James M. Atkinson

Application 03. Accumulated sample-clock time error

In the illustrative 019.03 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. A free-running sample clock with fractional rate error $\varepsilon = 1.120$ ppm over $T = 282$ s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T = 0.3158$ ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. The 0.3158-millisecond drift estimate assumes a constant average clock-rate error; calibrate trigger latency and phase-coherent timing independently before using an inter-receiver time difference.

Application 04. Alias-location prediction and its non-unique inverse

In the illustrative 019.04 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. For an actual sampling frequency $f_s = 23$ MHz and analogue input $f_i = 74.520$ MHz, the nearest-replica folding rule gives $f_a = |f_i - \mathrm{round}(f_i/f_s) f_s| = 5.520$ MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. The 5.52-megahertz alias coordinate does not identify an RF arrival frequency; only a controlled analogue passband and sampling plan can exclude alternative frequency zones.

Copyright 2026, James M. Atkinson

Application 05. Frequency-bin spacing versus independent information

In the illustrative 019.05 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. With sampled bandwidth f_s = 6 MS/s and N = 4,096 transform samples, the discrete-frequency grid is $\Delta f = f_s/N$ = 1464.844 Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. Transform-bin spacing is not event-time precision. Report the taper, equivalent noise bandwidth, actual coherent duration and analogue impulse response when assessing transient detectability.

Copyright 2026, James M. Atkinson

Application 06. Thermal reference noise in a declared measurement bandwidth

In the illustrative 019.06 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. Take the equivalent noise bandwidth B = 15,750 Hz and calibrated noise figure NF = 3.60 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -128.43$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The negative 128.43 dBm thermal reference is an average power model under the stated bandwidth; it does not describe impulsive site interference or the delay of a detected threshold crossing.

Application 07. Difference between two instruments relative to stated uncertainty

In the illustrative 019.07 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. The paired instrument contrast is $\Delta = 1.690$ dB. Set independent standard uncertainties $u_1 = 0.340$ dB and $u_2 = 0.370$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.502$ dB, giving the dimensionless ratio $\Delta/u\Delta = 3.363$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The 3.363 ratio is not a timing significance statement absent a paired measurement model and covariance; gain and filter state may explain the contrast without any change in propagation time.

Copyright 2026, James M. Atkinson

Application 08. Combined and expanded measurement uncertainty

In the illustrative 019.08 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. For independent standard-uncertainty contributions 0.80, 0.54 and 0.22 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.80^2 + 0.54^2 + 0.22^2)} = 0.990$ units. Using an illustrative coverage factor $k = 2$ gives expanded uncertainty $U = 2u_c = 1.980$ units. The illustrative expanded uncertainty applies only to its common-unit components and independence assumptions; a time-of-arrival budget must also address frequency-dependent delay and clock correlation.

Application 09. Preserved sample continuity across an acquisition interval

In the illustrative 019.09 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase curvature. A converter expected to retain $f_s = 1.30$ million samples/s for $T = 0.75$ s should supply $f_sT = 975{,}000$ complex sample instants. If 252 sequence positions are missing, the retained count is 974,748 and loss fraction is 0.02585%. A low fractional loss cannot exclude a highly relevant short burst coinciding with the gap. Position and timing of each missing block must therefore be preserved. The 0.02585-per-cent loss fraction obscures the timestamps and clustering of the 252 missing samples; a pulse may be wholly absent from the stored I/Q despite a high retained count.

Application 10. Observed exposure fraction of a channel scanner

In the illustrative 019.10 test, a receiver stores a very short burst after it has traversed a high-selectivity analogue filter with substantial phase

Copyright 2026, James M. Atkinson

curvature. Let the channel be observed on n = 341 valid visits, each lasting d = 16 ms, with revisit spacing R = 1.15 s. Valid exposure is nd/1000 = 5.456 s across the nominal interval nR = 392.15 s. The observed fraction of elapsed time is therefore 1.39%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. The 1.39-per-cent planned exposure describes the recorder, not a transmitter's occupancy. Preserve unobserved revisit intervals when reporting evidence for or against a short-burst emission.

QUESTION 020

Copyright 2026, James M. Atkinson

How should an investigator validate a replacement receiver without losing comparability?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 020 asks: How should an investigator validate a replacement receiver without losing comparability? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is comparability and validation when a field investigation replaces one receiver with another. Our primary observation is measurements from two independently configured acquisition systems over a common test population; by contrast, what remains unseen is whether differences result from the external source or instrument transfer functions and operational regimes. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Replacement receiver equivalence is a controlled measurement. Two receivers do not become interchangeable merely because they display the

Copyright 2026, James M. Atkinson

same frequency label and nominal decibel unit. Inject a calibrated reference sequence at several amplitudes and across the actual passband, record the receiver-specific transfer curves, and test clock and gain-state transitions. If receiver A reports minus 72.0 dBm and receiver B minus 70.4 dBm for one traceable input, the 1.6 dB difference must be corrected or carried as a documented inter-instrument discrepancy before historical trends are compared. Compare input reference planes, spectral window equivalent-noise bandwidths and average-detector settings, not just screen resolution. A defensible bridge study should include blind repeats and both positive and negative cases. Keep the outgoing apparatus's configuration records, because the replacement may expose a previously invisible artefact without proving that the field environment has changed. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns measurements from two independently configured acquisition systems over a common test population; it is not interchangeable with whether differences result from the external source or instrument transfer functions and operational regimes. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is parallel observation of calibrated weak, strong, pulsed, and interferer-rich reference scenarios. A claim drawn from that comparison has to carry its actual uncertainties: bias, repeatability, reproducibility, decision concordance, and uncertainty on differences. Comparability must be

Copyright 2026, James M. Atkinson

assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. Parallel recordings should preserve both instruments' complete state histories and physical input references. A reference source at several amplitudes reveals nonlinear differences that a single level misses. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 1: Comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage.

The replacement receiver should be admitted into service by a deliberately challenging acceptance programme, not by the reassurance that its data sheet resembles the previous instrument's. I would preserve a set of reference observations from the old receiver, including gain, noise, spur response, time alignment, overload behaviour and transitions between states. Then subject both instruments to common blinded stimuli under the same environmental conditions. A simple constant offset may reconcile two amplitude scales in one linear regime, but it cannot correct a change in clipping threshold or a different automatic gain-control history. Process-monitoring evidence is strongest when repeated reference challenges show whether a difference is stable, drifting or dependent on the signal presented. If the new instrument's filter bandwidth differs, a changed count of short detections may reflect the measurement procedure rather than the surveillance environment. The acceptance record must describe the resulting change in what can be concluded, not merely record a successful power-on test.

In this physical path examination of Question 020, the decisive claim is that comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. A replacement receiver is not demonstrated equivalent merely because it produces a quieter trace on the same aerial. Different analogue filters, windows, dynamic ranges and detector logic can create different event populations from the same physical signal. The comparison must begin with

Copyright 2026, James M. Atkinson

a defined measurand and test envelope, including weak bursts, strong blockers, frequency drift and sample discontinuity. Where the original apparatus was used for earlier forensic captures, any proposed transfer of conclusions demands a bridge experiment with both instruments operating on demonstrably comparable inputs. A useful falsification proceeds from the actual controversy: replacement receiver equivalence is a controlled measurement. Two receivers do not become interchangeable merely because they display the same frequency label and nominal decibel unit. Inject a calibrated reference sequence at several amplitudes and across the actual passband, record the receiver-specific transfer curves, and test clock and gain-state transitions. If receiver A reports minus 72.0 dBm and receiver B minus 70.4 dBm for one traceable input, the 1.6 dB difference must be corrected or carried as a documented inter-instrument discrepancy before historical trends are compared. Compare input reference planes, spectral window equivalent-noise bandwidths and average-detector settings, not just screen resolution. A defensible bridge study should include blind repeats and both positive and negative cases. Keep the outgoing apparatus's configuration records, because the replacement may expose a previously invisible artefact without proving that the field environment has changed. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Split a reference source through a characterised distribution network and record both receivers concurrently, preserving the splitter loss and input mismatch. Challenge amplitude, timing, instantaneous bandwidth, false-alarm decision and overload recovery over multiple stimulus classes.

Copyright 2026, James M. Atkinson

Compare instrument differences against a predetermined equivalence margin, not only against the statistical significance of a mean difference. If a new waterfall uses a different FFT taper, retain raw sample sets from both systems so that equivalent processing can be attempted retrospectively. I would take mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: Comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. A response consistent with disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

Copyright 2026, James M. Atkinson

The circuit cannot be judged from its final trace alone. An investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections, and measure their behaviour separately before reconnecting the assembled system. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. It is therefore material to establish mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs rather than infer them from a single scalar output. The limiting test is concrete: Operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. If the intervention produces disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret the new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold as a new transmitter before challenging the most economical instrumental explanation. Matching two receiver readouts is not the same as holding their measurands and

Copyright 2026, James M. Atkinson

thresholds constant. Professor Tukey, I invite your examination of how selection after replacement can manufacture apparent agreement.

John Wilder Tukey | Peer question 1 to Walter Andrew Shewhart

Walter Andrew Shewhart, may I test the exact physical inference in your account of an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability? The proposed mechanism appears plausible only if changes after operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes are compared with a stable reference condition. Comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs which would settle that narrower claim, rather than a visual impression of improvement.

Walter Andrew Shewhart | Immediate answer to John Wilder Tukey

Dr Tukey, the cleaner image may reflect a more aggressive average or a higher alarm threshold rather than superior reception. I would ask both instruments to process the same injected event while recording their internal state, then compare the actual detection

Copyright 2026, James M. Atkinson

decisions. The equivalence statement should disclose precisely which classes of event survived the transfer and which remain untested. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 020, the specific physical candidate is unequal passbands, reference-plane loss, threshold settings, clock offsets, detector statistics, and gain history. The unresolved physical pathway is material: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The retained record permits a conditional claim about mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, but cannot alone resolve two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route

Copyright 2026, James M. Atkinson

enabled and isolated. The required observations are mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. Comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes, and only a response matching disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, not a conjecture about the operator's intentions.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Peer question 2 to Walter Andrew Shewhart

I appreciate your explanation, Walter Andrew Shewhart. How would your conclusion survive a deliberately independent test of the new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold? A second receiver might share more of the supposed evidence than its separate enclosure suggests. Parallel recordings should preserve both instruments' complete state histories and physical input references. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs and document which differences remain unexplained? Would you also state what observed change in mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs would invalidate the preferred account, and which aspect of operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 020, the specific physical candidate is unequal passbands, reference-plane loss, threshold settings, clock offsets, detector statistics, and gain history. The unresolved physical pathway is material: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The retained record permits a conditional claim about mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, but cannot alone resolve two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. I would draw the actual distribution network before collecting new corroborating

Copyright 2026, James M. Atkinson

evidence, marking where two receivers share signal, power or time references. Parallel recordings should preserve both instruments' complete state histories and physical input references. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections; I would challenge it with operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. Two responses consistent with disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. A discordant measurement would then be interpreted by tracing that difference through mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and

Copyright 2026, James M. Atkinson

state-change logs; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal contribution 2: Parallel recordings should preserve both instruments' complete state histories and physical input references.

Two receivers can agree on a displayed number while measuring different physical quantities. I would therefore define a common reference plane at the antenna connector and a common waveform family before making a comparability claim. A calibrated injection at an IF test port might evaluate useful stages but bypass the antenna-facing preselector, limiter and first mixer. It cannot establish equivalence of the entire receiving chain. Similarly, matching RMS levels for a continuous sine wave does not imply equal response to a millisecond burst. I would document the old and new measurement operations separately and ask which proposition the investigation needs to transport between them. Where the proposition concerns the existence of a weak pulse, the acceptance test should include controlled pulses with varied amplitudes, durations and interference backgrounds. Where it concerns calibrated power, uncertainty in connectors, mismatch, gain and detector averaging must be included. Comparability is specific to an operation and a class of physical stimuli.

In this control and stability examination of Question 020, the decisive claim is that parallel recordings should preserve both instruments' complete state histories and physical input references. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: replacement receiver equivalence is a controlled measurement. Two receivers do not become interchangeable

Copyright 2026, James M. Atkinson

merely because they display the same frequency label and nominal decibel unit. Inject a calibrated reference sequence at several amplitudes and across the actual passband, record the receiver-specific transfer curves, and test clock and gain-state transitions. If receiver A reports minus 72.0 dBm and receiver B minus 70.4 dBm for one traceable input, the 1.6 dB difference must be corrected or carried as a documented inter-instrument discrepancy before historical trends are compared. Compare input reference planes, spectral window equivalent-noise bandwidths and average-detector settings, not just screen resolution. A defensible bridge study should include blind repeats and both positive and negative cases. Keep the outgoing apparatus's configuration records, because the replacement may expose a previously invisible artefact without proving that the field environment has changed. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by the new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note parallel recordings should preserve both

Copyright 2026, James M. Atkinson

instruments' complete state histories and physical input references. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, the new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Bridgman's operational approach requires a measurement procedure that defines each quantity physically. A stated number unsupported by the operation that produced it is methodologically incomplete. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. This predicts a response which should be tested against disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration. An operator may be tempted to interpolate a line between two clean sweeps and call the

Copyright 2026, James M. Atkinson

resulting curve continuous; that presentational step does not restore measurements discarded during retuning. Where two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic, the correct claim must name the operational states and the evidence available in each. My proposed acceptance test would archive the entire control sequence and the independent witness measurement before any data-dependent threshold adjustment.

A further, separately testable aspect of an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability concerns mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs. The proposed challenge would be operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. The decision is conditional upon the observed result, with particular attention to two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. The competing account remains the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. A parallel receiver is most useful when both input paths and changing states are recorded independently. Dr Pearson, please take the floor and test the uncertainty assigned to this comparison.

Copyright 2026, James M. Atkinson

Egon Sharpe Pearson | Peer question 3 to Percy Williams Bridgman

Percy Williams Bridgman, your calibration argument invites a question about reference planes, especially because two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. The reference stimulus and the unknown emission need not occupy the same physical regime. A reference source at several amplitudes reveals nonlinear differences that a single level misses. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When the new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith. Would you also state what observed change in mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs would invalidate the preferred account, and which aspect of operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 020, the specific physical candidate is unequal passbands, reference-plane loss, threshold settings, clock offsets, detector statistics, and gain history. The unresolved physical pathway is material: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The retained record permits a conditional claim about mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, but cannot alone resolve two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs. A reference source at several amplitudes reveals nonlinear differences that a single level misses. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be operate both receivers in

Copyright 2026, James M. Atkinson

parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes, with before-and-after values of mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs. If the instrument behaves as predicted, then disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. The new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Percy Williams Bridgman

There is an inferential difficulty, Percy Williams Bridgman: the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The population of admissible observations needs to be fixed

Copyright 2026, James M. Atkinson

before any confidence argument. In this situation, two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Agreement near a decision threshold deserves separate analysis because a tiny bias can change the reported class. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs would invalidate the preferred account, and which aspect of operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes would make that negative result independently repeatable?

Percy Williams Bridgman | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For

Copyright 2026, James M. Atkinson

Question 020, the specific physical candidate is unequal passbands, reference-plane loss, threshold settings, clock offsets, detector statistics, and gain history. The unresolved physical pathway is material: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The retained record permits a conditional claim about mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, but cannot alone resolve two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because the new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Agreement near a decision threshold deserves separate analysis because a tiny bias can change the reported class. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is

Copyright 2026, James M. Atkinson

the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections; its prediction should be recorded alongside disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a 1.2 db detection bias can reverse a near-threshold classification even when both instruments pass an ordinary gain check. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 3: A reference source at several amplitudes reveals nonlinear differences that a single level misses.

Suppose a replacement receiver offers superior typical noise figure but a less linear front end. The apparent improvement could be illusory in a site dominated by nearby high-power services. I would assemble both signal paths with independently measured gain, noise, compression and image response, then show how each stage contributes to the detectable input range. A response correction based on low-level laboratory tones should not be carried into the high-level regime without a compression test. Frequency response must also be compared at the edges of the survey band, where one preselector may attenuate a candidate that the other admits. A meaningful replacement protocol documents which differences are allowed and which trigger a new calibration or a restricted finding. The recovered raw files remain valuable, but the historical and new receiver observations must retain their separate acquisition metadata. One cannot make the two instruments physically interchangeable by placing their waterfall pictures side by side.

In this operational measurand examination of Question 020, the decisive claim is that a reference source at several amplitudes reveals nonlinear differences that a single level misses. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: replacement receiver equivalence is a controlled measurement. Two receivers do not become interchangeable merely because they display the same frequency label and nominal decibel unit. Inject a calibrated

Copyright 2026, James M. Atkinson

reference sequence at several amplitudes and across the actual passband, record the receiver-specific transfer curves, and test clock and gain-state transitions. If receiver A reports minus 72.0 dBm and receiver B minus 70.4 dBm for one traceable input, the 1.6 dB difference must be corrected or carried as a documented inter-instrument discrepancy before historical trends are compared. Compare input reference planes, spectral window equivalent-noise bandwidths and average-detector settings, not just screen resolution. A defensible bridge study should include blind repeats and both positive and negative cases. Keep the outgoing apparatus's configuration records, because the replacement may expose a previously invisible artefact without proving that the field environment has changed. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

A replacement receiver cannot be deemed equivalent merely because both units share a nominal frequency range and display similar spectral peaks. Equivalence depends on a declared measurand, reference plane and allowable uncertainty across operating conditions. Before replacement, acquire reference measurements of frequency error, amplitude transfer, occupied bandwidth, gain-state transitions, overload response, timing latency and response to at least one short pulse. After substitution, repeat those exact stimuli while retaining the original antenna, cable, clock reference and analysis settings wherever physically possible. Where components must change, document them as controlled experimental factors rather than hiding them within a single before-and-after comparison. A difference smaller than the display resolution may still matter

Copyright 2026, James M. Atkinson

to a localisation claim built upon microsecond timing; conversely, a visible colour difference in a waterfall may be immaterial to a frequency-presence proposition. The evidential report should state which claims remain comparable and which require a new uncertainty budget. Accordingly, the laboratory record for Question 020 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should

Copyright 2026, James M. Atkinson

specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A 1.2 dB detection bias can reverse a near-threshold classification even when both instruments pass an ordinary gain check. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. I would therefore attach the uncertainty analysis to the *operational definition* itself instead of printing an unexplained confidence interval beside the most appealing trace.

A more precise objection comes from Hendrik Wade Bode and the finite observation aperture in an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. For that reason, record mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. A multi-level reference can expose nonlinear divergence

Copyright 2026, James M. Atkinson

that a single calibration point hides. Dr Turing, I invite you to question whether the archived control sequence can reproduce the observed differences.

Alan Mathison Turing | Peer question 5 to Hendrik Wade Bode

Hendrik Wade Bode, I should like to examine what the recorded data actually preserve when an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. The physical input and the retained numerical array are not interchangeable things. Documenting the replacement event guards against mistaking an instrument discontinuity for a source discontinuity. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs would invalidate the preferred account, and which aspect of operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 020, the specific physical candidate is unequal passbands, reference-plane loss, threshold settings, clock offsets, detector statistics, and gain history. The unresolved physical pathway is material: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The retained record permits a conditional claim about mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, but cannot alone resolve two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. I propose separating acquired information from

Copyright 2026, James M. Atkinson

model-dependent reconstruction. Documenting the replacement event guards against mistaking an instrument discontinuity for a source discontinuity. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs and a fresh trial in which the operator operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. If that trial demonstrates disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 4: Agreement near a decision threshold deserves separate analysis because a tiny bias can change the reported class.

The decision to accept a replacement receiver is a question about error probabilities and their consequences. Define a test population comprising quiet channels, strong adjacent carriers, weak intermittent signals, and controlled receiver-state transitions; then estimate detection and false-alarm performance in each. An average across all test opportunities can conceal a serious failure in the rare, difficult subset. I would predefine equivalence margins for the outcomes that matter, rather than assume that a failure to detect a difference proves equivalence. A sufficiently wide confidence interval is not evidence that two receivers are the same. If the project has an earlier measurement series, use calibration transfer and paired trials to quantify any discontinuity. Retain failures and outliers, because selecting only successful examples would create an optimistically biased acceptance record. A replacement can be acceptable for one forensic task and unqualified for another; the conditions must be identified in the final decision.

In this information retention examination of Question 020, the decisive claim is that agreement near a decision threshold deserves separate analysis because a tiny bias can change the reported class. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: replacement receiver equivalence is a controlled measurement. Two receivers do not become interchangeable merely because they display the same frequency label and nominal decibel unit.

Copyright 2026, James M. Atkinson

Inject a calibrated reference sequence at several amplitudes and across the actual passband, record the receiver-specific transfer curves, and test clock and gain-state transitions. If receiver A reports minus 72.0 dBm and receiver B minus 70.4 dBm for one traceable input, the 1.6 dB difference must be corrected or carried as a documented inter-instrument discrepancy before historical trends are compared. Compare input reference planes, spectral window equivalent-noise bandwidths and average-detector settings, not just screen resolution. A defensible bridge study should include blind repeats and both positive and negative cases. Keep the outgoing apparatus's configuration records, because the replacement may expose a previously invisible artefact without proving that the field environment has changed. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. The scientific point of agreement near a decision threshold deserves separate analysis because a tiny bias can change the reported class. is not that the result should be made more impressive but that a contrary result

Copyright 2026, James M. Atkinson

should be allowed to alter the proposed explanation. If independent sessions repeatedly show disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. The new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold. Neyman's statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. The issue becomes especially sharp because the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose

Copyright 2026, James M. Atkinson

precisely the interval and frequency domain actually examined. For the proposed case, a 1.2 db detection bias can reverse a near-threshold classification even when both instruments pass an ordinary gain check. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A more precise objection comes from Jerzy Neyman and the finite observation aperture in an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. For that reason, record mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. Close to a threshold, a tiny systematic bias can reverse a

Copyright 2026, James M. Atkinson

binary classification. Dr Deming, I pass the floor for a challenge procedure that makes those borderline cases visible.

W. Edwards Deming | Peer question 6 to Jerzy Neyman

I thank you, Jerzy Neyman, for distinguishing measurement from attribution, but the observation is that the new receiver produces a cleaner trace, but its software uses a different spectral window and detection threshold. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a 1.2 dB detection bias can reverse a near-threshold classification even when both instruments pass an ordinary gain check. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration on one day but fails after the instrument has been reconfigured? Comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment? Would you also state what observed change in mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs would invalidate the preferred account, and which aspect of operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Jerzy Neyman | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 020, the specific physical candidate is unequal passbands, reference-plane loss, threshold settings, clock offsets, detector statistics, and gain history. The unresolved physical pathway is material: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The retained record permits a conditional claim about mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, but cannot alone resolve two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-normalised statistic. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a 1.2 dB detection bias can reverse a near-threshold classification even when both instruments pass an ordinary gain check. I would retain the counterexample as part of the primary result, not as a

Copyright 2026, James M. Atkinson

footnote to an attractive conclusion. Comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. Its bearing on the dispute can be evaluated through the predicted response, namely disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration. Because the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections, the procedure operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match define an instrument-equivalence envelope rather than retrospectively declaring all recordings interchangeable, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. Disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 5: Documenting the replacement event guards against mistaking an instrument discontinuity for a source discontinuity.

An acquisition change alters the information supplied to later analysts. If the old receiver stored full-band I/Q with precise sample counters while its replacement stores only FFT magnitudes, the replacement cannot support every later hypothesis test even if the two instruments produce matching screenshots. I would compare not only input sensitivity but also the information retained: clock epoch, gain-state logs, filter coefficients, clipping flags and the capacity for reprocessing. For a specific allegation, determine whether each file preserves the distinction between competing physical inputs. A transfer function could allow amplitude correction when its input assumptions are met, but no transformation can retrieve a missing pulse from an interval the new instrument failed to sample. The acceptance study should therefore include deliberately crafted counterexamples that agree under the new summary format but differ in their original physical meaning. Failure to preserve such distinctions may be a material loss of evidential capability, regardless of improvements elsewhere.

In this statistical inference examination of Question 020, the decisive claim is that documenting the replacement event guards against mistaking an instrument discontinuity for a source discontinuity. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: replacement receiver equivalence is a controlled measurement. Two receivers do not become

Copyright 2026, James M. Atkinson

interchangeable merely because they display the same frequency label and nominal decibel unit. Inject a calibrated reference sequence at several amplitudes and across the actual passband, record the receiver-specific transfer curves, and test clock and gain-state transitions. If receiver A reports minus 72.0 dBm and receiver B minus 70.4 dBm for one traceable input, the 1.6 dB difference must be corrected or carried as a documented inter-instrument discrepancy before historical trends are compared. Compare input reference planes, spectral window equivalent-noise bandwidths and average-detector settings, not just screen resolution. A defensible bridge study should include blind repeats and both positive and negative cases. Keep the outgoing apparatus's configuration records, because the replacement may expose a previously invisible artefact without proving that the field environment has changed. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. Documenting the replacement event guards against mistaking an instrument discontinuity for a source discontinuity. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to operate both receivers in parallel on a

Copyright 2026, James M. Atkinson

verified common stimulus spanning weak, near-threshold, overload and intermittent modes, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say define an instrument-equivalence envelope rather than retrospectively declaring all recordings interchangeable, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. An investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Shannon's information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. One could stratify the experiment by nuisance condition, retain a random sample

Copyright 2026, James M. Atkinson

of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a 1.2 db detection bias can reverse a near-threshold classification even when both instruments pass an ordinary gain check, is not an estimate of any actual investigation. I would publish the test plan, sample exclusions, denominator and alternative accounts alongside the numerical result, so that a critical reader can identify which inference is conditional and which physical fact was directly observed.

A more precise objection comes from Claude Elwood Shannon and the finite observation aperture in an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. For that reason, record mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent

Copyright 2026, James M. Atkinson

modes, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. The record must mark the instrument-replacement instant so that a discontinuity is not mislabelled a new signal. Sir Karl, please take the floor and press the logical limits of that finding.

Sir Karl Raimund Popper | Peer question 7 to Claude Elwood Shannon

Claude Elwood Shannon, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise define an instrument-equivalence envelope rather than retrospectively declaring all recordings interchangeable? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Parallel recordings should preserve both instruments' complete state histories and physical input references. Please connect mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs with a declared detection threshold and the measurement exposure. If the experiment operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Copyright 2026, James M. Atkinson

Would you also state what observed change in mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs would invalidate the preferred account, and which aspect of operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes would make that negative result independently repeatable?

Claude Elwood Shannon | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 020, the specific physical candidate is unequal passbands, reference-plane loss, threshold settings, clock offsets, detector statistics, and gain history. The unresolved physical pathway is material: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. The retained record permits a conditional claim about mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs, but cannot alone resolve two receivers sharing nominal frequency coverage do not necessarily measure the same bandwidth-

Copyright 2026, James M. Atkinson

normalised statistic. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Parallel recordings should preserve both instruments' complete state histories and physical input references. I would use the observations of mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes, not an assertion based on the operator's impression of a quiet display. If it yields disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since the apparent

Copyright 2026, James M. Atkinson

improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to define an instrument-equivalence envelope rather than retrospectively declaring all recordings interchangeable, with the untested physical possibilities made visible.

Walter Andrew Shewhart, Cross-Peer Question to Jerzy Neyman: Professor Neyman, a laboratory replaces Receiver A with Receiver B and runs thirty paired challenges. The mean reading differs by 1.6 dB, but an ordinary two-sided test does not reject equality at its chosen level. A manager interprets that non-rejection as evidence that the older archive and the new stream can be pooled without adjustment. What hypothesis must instead be framed if the question is operational interchangeability, especially where a 1.2 dB bias can change a marginal detection into a reported absence?

Jerzy Neyman, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, failure to reject exact equality is not a finding of equivalence. Establish in advance the permitted difference for each relevant measurand, operating state and evidential decision, and justify the margin against the consequences of a missed or false detection. The paired differences must retain their temporal order and challenge classes. For a quantitative measurement, examine a confidence interval for the inter-instrument difference against the predeclared equivalence boundaries. In a two-one-sided-test design, both sides must support containment within that interval. For a binary detector, compare the paired discordances and estimate false-positive and false-negative performance separately in weak-signal and

Copyright 2026, James M. Atkinson

blocker-rich conditions. If different units share a calibrator, the common reference uncertainty may cancel in a difference but remain in absolute-power claims; recording covariance is therefore indispensable. The 1.6 dB example is a difference at one particular calibration point, not a universal transfer constant. An observed confidence interval straddling the tolerance boundary means equivalence has not been demonstrated, regardless of the conventional difference-test p-value. I respectfully pass the floor to Dr Bridgman to challenge the physical meaning of a common stimulus.

Percy Williams Bridgman, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, the operator divides one calibrated RF source into two receivers and calls their inputs identical because the distribution is nominally symmetric. However, the splitter ports have unequal loss, the receivers present different impedances, and the second instrument has a preamplifier preceding its user-accessible attenuator. How should the laboratory construct an actual transfer comparison which will not mistake the shared test set-up for an intrinsic equality of receiver response?

Hendrik Wade Bode, Cross-Peer Answer to Percy Williams Bridgman: Dr Bridgman, define the measurement reference plane at each input connector, then measure the source, splitter, interconnecting cables and receiver-port reflection characteristics over frequency. A simultaneous split is convenient for suppressing source drift, but it does not eliminate mismatch or supply a traceable power value by nomenclature alone. Characterise insertion loss, isolation and return loss at the relevant power and frequency; where practicable, reverse the two distribution legs and compare the sign and magnitude of the observed difference. Follow with controlled tests at multiple levels and under strong adjacent interference,

Copyright 2026, James M. Atkinson

because a single small-signal correction cannot bridge unequal compression or automatic-gain-control behaviour. Record the actual gain-state trajectory, windowing, equivalent noise bandwidth and time-stamp origin. A common calibrator creates correlated uncertainties which should appear in the covariance matrix; treating both readings as independent can exaggerate the uncertainty of their difference, while ignoring independent mismatch terms can diminish it improperly. We should state which measurable property has been compared and which hardware states remain outside the validated envelope. I respectfully pass the floor to Dr Shannon to examine whether the archived records preserve that experiment.

Claude Elwood Shannon, Cross-Peer Question to Alan Mathison Turing: Dr Turing, the historical Receiver A recorded threshold events with a proprietary decimator, whereas Receiver B can preserve complex samples and metadata. The archivist proposes to replay A’s event lists through B’s newer digital algorithm and to describe the resulting agreement as a calibrated reconstruction of the original electromagnetic scene. What information-theoretic objection should be made, and what minimum acquisition evidence would permit a legitimate comparison?

Alan Mathison Turing, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, a list of threshold crossings is a many-to-one mapping of possible input waveforms. Where the older system discarded unsatisfied windows, raw sample phase, overload intervals or analogue preselector state, a later algorithm cannot recreate those missing variables by applying a more elaborate decision rule. We can compare the old and new decisions on a common set of controlled stimuli only to the extent that their recorded outputs expose the same operational estimand. Retain the original event

Copyright 2026, James M. Atkinson

lists, unaltered time stamps, configuration files, decimation coefficients where accessible, clipping indicators, firmware versions, instrument serial identification and sample-loss markers. For new parallel trials, preserve the pre-decision complex samples where lawful and technically feasible, and separately publish the transformations that yield both detector outputs. Reprocessing B's raw data to emulate A's decision can test a candidate transfer model, but it cannot certify what A would have recorded during an earlier unobserved interval. The correct status for the historical comparison is conditional, with unobservable states marked as unresolved. I respectfully pass the floor to Mr Deming to consider process drift across the replacement date.

W. Edwards Deming, Cross-Peer Question to John Wilder Tukey: Dr Tukey, an operational dashboard seems to improve sharply on the very day Receiver B is installed, with half as many alarm marks and fewer missed acquisitions. The laboratory cannot place the old unit back in continuous service, yet management wants a single before-and-after percentage attributed to a cleaner surveillance environment. Which bridge design and graphical analysis would separate a real environment change from altered sensitivity, a changed opportunity denominator and maintenance-related selection?

John Wilder Tukey, Cross-Peer Answer to W. Edwards Deming: Mr Deming, first show the time-ordered record with the replacement moment, known failures, gain and detector settings, source exposures and invalid windows identified, rather than drawing a continuous curve through a change in measurement method. Conduct a bounded bridge with a stable calibrated source, blind positive and negative challenges and, where possible, a third independent witness receiver that spans the transition. Analyse paired

Copyright 2026, James M. Atkinson

differences and conditional detection probabilities within each defined stimulus stratum, particularly near the decision boundary and during overload recovery. The denominator must count valid opportunities and separately disclose lost or excluded opportunities; a smaller alarm count alone may arise from lost coverage. Randomise stimulus order or alternate the comparison path to expose instrument drift and order effects. Control charts may reveal instability or a change point, but a chart is not a causal experiment. If the retired unit cannot be operated safely, preserve the lack of direct simultaneity as a limitation and widen the uncertainty or restrict retrospective comparison accordingly. Report both instrument performance and environmental evidence without allowing either to stand in for the other. I respectfully pass the floor to Dr Atkinson for the concluding synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of comparability and validation when a field investigation replaces one receiver with another has established a point which the specialist must not overlook. The receiver records measurements from two independently configured acquisition systems over a common test population; it does not, merely by drawing a clear trace, give direct access to whether differences result from the external source or instrument transfer functions and operational regimes. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, Comparability must be assessed for the measurand and decision threshold, not simply by sharing nominal frequency coverage. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board

Copyright 2026, James M. Atkinson

unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

The panel's useful disagreement concerns what it means to replace a receiver without changing an experiment. Equal-looking spectra are not sufficient evidence of interchangeability, because filtering, clock discipline, overload limits, trigger latency and retained metadata can differ while the displayed line remains in the same place. A fair substitution must use a common reference input, document every adaptor and cable, synchronise clocks to a stated uncertainty and compare the entire measurement chain under challenging as well as benign signals. I thank Dr Bridgman for directing attention to operational definitions: one receiver may be equivalent for estimating a continuous carrier's frequency yet wholly unsuitable for recovering a microsecond burst's timing. This is not a contradiction but a restriction on the measurand. In the final record the laboratory should declare precisely which outputs have demonstrated agreement, which have not, and whether that disagreement bears upon the forensic proposition being advanced. An unqualified claim of instrument equivalence is not justified by similar waterfall images.

The replacement receiver gives a quieter spectral display but uses different windows and thresholds. It follows that a direct visual comparison is insufficient to preserve the meaning of previously recorded absence or presence findings. Equivalent processing and calibrated parallel observation are needed. The more useful outcome is a discriminating protocol: Operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. In applying it, the

Copyright 2026, James M. Atkinson

examiner must retain all readings supporting mean bias, paired difference, standard uncertainty, threshold concordance, sample continuity and state-change logs and identify the physical plane to which the measurements refer. At the outset of the investigation, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability; that circumstance makes the alternative mechanism material, specifically the apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. A result approaching disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore define an instrument-equivalence envelope rather than retrospectively declaring all recordings interchangeable. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

The correct outcome is an equivalence envelope for specified measurements and conditions. Historical receiver data should not be silently reinterpreted under the new instrument’s sensitivity, calibration or event logic. The decisive experiment is concrete: Operate both receivers in parallel on a verified common stimulus spanning weak, near-threshold, overload and intermittent modes. In conducting it, the examiner must explicitly retain mean bias, paired difference, standard uncertainty, threshold concordance,

Copyright 2026, James M. Atkinson

sample continuity and state-change logs. If the outcome matches the stated prediction, disagreements clustered near the decision threshold reveal sensitivity to calibration bias and differing detector integration, the supported conclusion concerns that test domain. An alternative remains: The apparent improvement could arise from reduced environmental emissions or from unlike decision functions and reference-plane corrections. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 020

Application 01. Difference between two instruments relative to stated uncertainty

In the illustrative 020.01 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. The paired instrument contrast is $\Delta = 1.880$ dB. Set independent standard uncertainties $u_1 = 0.380$ dB and $u_2 = 0.370$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.530$ dB, giving the dimensionless ratio $\Delta/u\Delta = 3.545$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The 3.545 ratio compares a reading difference with a modelled standard uncertainty, not an equivalence test. Apply a prespecified dB margin with covariance and paired measurement repeatability before pooling the series.

Application 02. Combined and expanded measurement uncertainty

In the illustrative 020.02 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. For independent standard-uncertainty contributions 0.87, 0.48 and 0.34 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.87^2 + 0.48^2 + 0.34^2)} = 1.050$ units. Using an illustrative coverage factor $k = 2$ gives expanded uncertainty $U = 2u_c = 2.100$ units. The 2.100-unit expanded uncertainty presumes independent contributions and coverage factor two; a common calibration reference or drift requires a covariance term and renewed interval interpretation.

Copyright 2026, James M. Atkinson

Application 03. Thermal reference noise in a declared measurement bandwidth

In the illustrative 020.03 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. Take the equivalent noise bandwidth B = 24,000 Hz and calibrated noise figure NF = 2.20 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -128.00$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The minus-128.00 dBm figure applies to a 24 kHz equivalent-noise bandwidth at the stated thermal reference. Receiver equivalence also requires matching window, detector and interference conditions.

Application 04. Cascade gain and observed headroom

In the illustrative 020.04 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. A first amplifier contributes G_1 = 13 dB, an intentional attenuation contributes G_2 = -3 dB, and a later stage contributes G_3 = 18 dB. The small-signal sum is 13 + (-3) + 18 = 28 dB. For P_i = -73 dBm, the ideal output is P_o = -45 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The twenty-eight-decibel net gain does not reveal interstage compression or gain-state differences. Compare power at each receiver reference plane throughout weak and overloaded tests.

Copyright 2026, James M. Atkinson

Application 05. Gain allocation and blocker headroom

In the illustrative 020.05 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. Assume a calibrated digital full-scale equivalent of -5 dBm, a blocker applied at -34 dBm, and net analogue gain 33 dB. The projected converter input is -1 dBm and remaining margin is -5 − (-1) = -4 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. The negative four-decibel projected margin predicts overload in this simple model; an apparent improvement in the replacement receiver cannot be classified without low-gain and peak-input controls.

Application 06. Opportunity-limited detection under independent visits

In the illustrative 020.06 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. For n = 36 genuinely independent valid observation opportunities, each with stipulated event detection chance p = 0.08, the probability of no detections is $(1 - p)^n = 0.04970$; its complement is 95.03%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The 95.03 per cent complement presumes thirty-six independent, valid visits with constant conditional detection probability. Different dwell policies between receivers invalidate direct percentage comparison.

Copyright 2026, James M. Atkinson

Application 07. Family-wise probability when many candidates are searched

In the illustrative 020.07 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. If each of $M = 429$ independent pre-specified search opportunities has false-alarm probability $\alpha = 0.0011$, the probability of one or more false positives is $1 - (1 - \alpha)^M = 0.37635$, or 37.63%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. The 37.63 per cent family-wise false-positive estimate presumes independent, predeclared opportunities; correlated FFT cells and changed thresholding can alter the apparent replacement benefit.

Application 08. Accumulated sample-clock time error

In the illustrative 020.08 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. A free-running sample clock with fractional rate error $\varepsilon = 1.240$ ppm over $T = 460$ s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T = 0.5704$ ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. The 0.5704-ms accumulated clock-rate offset is not aperture jitter or an absolute timestamp bias. Measure the common clock discipline and actual event-tagging planes in both receivers.

Copyright 2026, James M. Atkinson

Application 09. Filter or cable rejection referred to a physical input

In the illustrative 020.09 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. For an admitted input P_i = -52 dBm and separately measured loss L = 38 dB, the linear prediction is $P_o = P_i - L$ = -90 dBm. In SI power this becomes 10^((-90 − 30)/10) = 1e-12 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. The watt conversion establishes a power at the declared plane under its assumed loss. A new receiver's input mismatch or bypass leakage must be tested rather than absorbed into a blanket calibration offset.

Application 10. Observed exposure fraction of a channel scanner

In the illustrative 020.10 test, an investigation substitutes a second calibrated receiver after the first unit develops intermittent instability. Let the channel be observed on n = 350 valid visits, each lasting d = 13 ms, with revisit spacing R = 1.30 s. Valid exposure is nd/1000 = 4.550 s across the nominal interval nR = 455.00 s. The observed fraction of elapsed time is therefore 1.00%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. The one-per-cent valid coverage is a recorder duty factor, not absence of external emissions; differences in revisit timing must be controlled before comparing receiver event counts.

QUESTION 021

Copyright 2026, James M. Atkinson

How should aperture jitter be budgeted at high input frequencies?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 021 asks: How should aperture jitter be budgeted at high input frequencies? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is the frequency-dependent signal-to-noise penalty of random aperture-time error. Our primary observation is noise or phase uncertainty correlated with the slope of the analogue input waveform; by contrast, what remains unseen is the several independent or correlated clock and sampling-aperture contributors to total jitter. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Jitter constrains sampling precision at the input frequency. For a sinusoidal input of frequency f and rms aperture-time uncertainty sigma_t, the familiar small-jitter bound on signal-to-noise ratio is approximately

Copyright 2026, James M. Atkinson

minus 20 log10(2 pi f sigma_t), provided timing error is independent and appropriately modelled. At f = 1 gigahertz and sigma_t = 200 femtoseconds, the product 2 pi f sigma_t is about 0.001257 and the jitter-limited ratio is roughly 58.0 dB. Increasing nominal converter resolution beyond that limit does not by itself recover timing-lost information. Account separately for converter aperture jitter, sampling-clock phase noise and external source jitter, and do not assume those processes are independent unless the architecture supports the assumption. Characterise the full analogue path because an apparently pristine digital code can still be inaccurate in phase. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns noise or phase uncertainty correlated with the slope of the analogue input waveform; it is not interchangeable with the several independent or correlated clock and sampling-aperture contributors to total jitter. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is a clean swept-frequency sine input with independent clock-phase-noise measurement and amplitude control. A claim drawn from that comparison has to carry its actual uncertainties: rms aperture jitter, input frequency, phase-noise integration bandwidth, and jitter-limited SNR. For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. Doubling the input frequency worsens this idealised limit by approximately

Copyright 2026, James M. Atkinson

6.02 dB if jitter remains unchanged. A phase-noise measurement cannot be translated into one rms time value without stating the integration range and transfer function. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 1: For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter.

Aperture jitter belongs to the instant at which an analogue input is sampled, not merely to a number printed on a converter specification. For a sinusoid of frequency f and root-mean-square sampling-time uncertainty σ_t, the familiar small-error bound is $SNR_j \approx -20 \log_{10}(2\pi f \sigma_t)$, provided the jitter is sufficiently small and the relevant assumptions hold. Notice that f is the analogue input frequency; a high-frequency tone translated by intentional bandpass sampling can produce a low digital alias while retaining sensitivity to timing uncertainty at the original RF frequency. I would ask for a measurement of the clock distribution path at the actual converter aperture, including reference oscillator, synthesiser, buffers and coupling. A quoted clock stability in parts per million describes average frequency accuracy rather than short-term aperture jitter. Those are different error mechanisms. The examiner should state the integration bandwidth over which timing noise was characterised and explain how correlation among clocks changes the observed result.

In this physical path examination of Question 021, the decisive claim is that for a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. Sampling-clock phase noise is a time-domain aperture error whose effect increases with the derivative of the input waveform. For a sine input, uncorrelated rms timing jitter produces a familiar noise-limited SNR bound proportional to the negative logarithm of input frequency and rms jitter. That relationship cannot by itself characterise

Copyright 2026, James M. Atkinson

a clock with strong deterministic spurs or phase errors correlated between parallel converters. Nor does it establish the clock uncertainty of a timestamp assigned by later firmware. Separate the aperture, sample-time mapping and timestamp stages before designing a coherent multi-receiver comparison. A useful falsification proceeds from the actual controversy: jitter constrains sampling precision at the input frequency. For a sinusoidal input of frequency f and rms aperture-time uncertainty sigma_t, the familiar small-jitter bound on signal-to-noise ratio is approximately minus 20 log10(2 pi f sigma_t), provided timing error is independent and appropriately modelled. At f = 1 gigahertz and sigma_t = 200 femtoseconds, the product 2 pi f sigma_t is about 0.001257 and the jitter-limited ratio is roughly 58.0 dB. Increasing nominal converter resolution beyond that limit does not by itself recover timing-lost information. Account separately for converter aperture jitter, sampling-clock phase noise and external source jitter, and do not assume those processes are independent unless the architecture supports the assumption. Characterise the full analogue path because an apparently pristine digital code can still be inaccurate in phase. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Measure a low-distortion sine at several known RF frequencies while using the same converter and analogue gain. Change the sample-clock source independently and measure SNR and spectral sidebands, retaining unaveraged samples and phase-noise data. Repeat with two channels sharing the clock and with independently disciplined clocks; differences in correlation determine whether sample combining can reduce the error. The

Copyright 2026, James M. Atkinson

experiment must distinguish random aperture jitter from deterministic clock spurs and from analogue input frequency drift. I would take input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. A response consistent with for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. A high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. A meaningful bench experiment begins with a source

Copyright 2026, James M. Atkinson

whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts, and measure their behaviour separately before reconnecting the assembled system. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. It is therefore material to establish input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR rather than infer them from a single scalar output. The limiting test is concrete: Sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. If the intervention produces for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited snr bound by approximately 6.02 db, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest as a new transmitter before challenging the most economical instrumental explanation. The familiar jitter-limited signal-to-noise expression assumes a specified sinusoid and an appropriate random timing-error model. Professor Tukey, I invite you to challenge the practice of reporting its bound as observed converter performance.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Peer question 1 to Harry Nyquist

Harry Nyquist, may I test the exact physical inference in your account of a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network? The proposed mechanism appears plausible only if changes after sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures are compared with a stable reference condition. For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR which would settle that narrower claim, rather than a visual impression of improvement.

Harry Nyquist | Immediate answer to John Wilder Tukey

Dr Tukey, I would not call two ADC output errors independent merely because they appear in separate data arrays. If both converters sample from a common reference their timing fluctuations may cohere. I propose measuring phase-error covariance with a common test tone and then repeating with independent references. Only the measured covariance justifies the predicted improvement

Copyright 2026, James M. Atkinson

from combination. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 021, the specific physical candidate is small time perturbations translated into amplitude errors proportional to instantaneous input slew rate. The unresolved physical pathway is material: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The retained record permits a conditional claim about input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, but cannot alone resolve aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are input frequency, rms aperture-time uncertainty, phase-noise integration limits,

Copyright 2026, James M. Atkinson

correlation coefficient and jitter-limited SNR; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures, and only a response matching for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Harry Nyquist

I appreciate your explanation, Harry Nyquist. How would your conclusion survive a deliberately independent test of parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest? A second receiver might share more of the supposed evidence than its separate enclosure suggests. Doubling the input frequency worsens this idealised limit by approximately 6.02 dB if jitter remains unchanged. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR and document which differences remain unexplained? Would you also state what observed change in input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR would invalidate the preferred account, and which aspect of sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures would make that negative result independently repeatable?

Harry Nyquist | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the

Copyright 2026, James M. Atkinson

level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 021, the specific physical candidate is small time perturbations translated into amplitude errors proportional to instantaneous input slew rate. The unresolved physical pathway is material: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The retained record permits a conditional claim about input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, but cannot alone resolve aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. Doubling the input frequency worsens this idealised limit by approximately 6.02 dB if jitter remains unchanged. An independent test must alter a physical dependency, not merely open another

Copyright 2026, James M. Atkinson

software window. The relevant controlled alternative remains clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts; I would challenge it with sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. Two responses consistent with for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. A discordant measurement would then be interpreted by tracing that difference through input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Dennis Gabor | Principal contribution 2: Doubling the input frequency worsens this idealised limit by approximately 6.02 dB if jitter remains unchanged.

The time-frequency representation of a jittered carrier need not be a uniform blur. Correlated timing perturbations can produce discrete phase-modulation sidebands, while approximately uncorrelated timing errors contribute a noise-like pedestal whose interpretation depends on spectrum estimation. I would separate the two cases using a coherent sine stimulus, measurements across input frequencies and a phase-noise record of the sampling clock. A slowly wandering sampling epoch can make one acquisition window appear phase-coherent and the next drift, even though the average number of samples is correct. It would be misleading to infer an external narrowband emitter from sidebands that track the internal clock's control cycle. Where the experimental aim is time-of-arrival, the relevant clock-error contribution differs from that in a spectral-SNR estimate. The instrument may meet an amplitude performance specification and still possess unacceptable timestamp uncertainty. Therefore the engineer should specify which observable the jitter budget is intended to protect.

In this control and stability examination of Question 021, the decisive claim is that doubling the input frequency worsens this idealised limit by approximately 6.02 dB if jitter remains unchanged. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: jitter constrains sampling precision at the input frequency. For a sinusoidal input of

Copyright 2026, James M. Atkinson

frequency f and rms aperture-time uncertainty sigma_t, the familiar small-jitter bound on signal-to-noise ratio is approximately minus 20 log10(2 pi f sigma_t), provided timing error is independent and appropriately modelled. At f = 1 gigahertz and sigma_t = 200 femtoseconds, the product 2 pi f sigma_t is about 0.001257 and the jitter-limited ratio is roughly 58.0 dB. Increasing nominal converter resolution beyond that limit does not by itself recover timing-lost information. Account separately for converter aperture jitter, sampling-clock phase noise and external source jitter, and do not assume those processes are independent unless the architecture supports the assumption. Characterise the full analogue path because an apparently pristine digital code can still be inaccurate in phase. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note doubling the input frequency worsens this idealised limit by approximately 6.02 db if jitter remains unchanged. has a

Copyright 2026, James M. Atkinson

consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Gabor's time-frequency work makes the time support and spectral concentration of an observation inseparable; a display cannot recover temporal detail that the window suppressed. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. This predicts a response which should be tested against for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited snr bound by approximately 6.02 db. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements

Copyright 2026, James M. Atkinson

discarded during retuning. Where aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it, the correct claim must name the operational states and the evidence available in each. My proposed acceptance test would archive the entire control sequence and the independent witness measurement before any data-dependent threshold adjustment.

A further, separately testable aspect of a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network concerns input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR. The proposed challenge would be sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. The decision is conditional upon the observed result, with particular attention to aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. The competing account remains clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. Doubling input frequency changes the ideal timing-error penalty even when the quoted clock jitter does not. Dr Pearson, I pass the floor to examine whether the uncertainty calculation follows the frequency actually captured.

Egon Sharpe Pearson | Peer question 3 to Dennis Gabor

Dennis Gabor, your calibration argument invites a question about reference planes, especially because aperture jitter is a time error whose

Copyright 2026, James M. Atkinson

voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. The reference stimulus and the unknown emission need not occupy the same physical regime. A phase-noise measurement cannot be translated into one rms time value without stating the integration range and transfer function. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Dennis Gabor | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 021, the specific physical candidate is small time perturbations translated into amplitude errors proportional to instantaneous input slew rate. The unresolved physical pathway is material: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The retained

Copyright 2026, James M. Atkinson

record permits a conditional claim about input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, but cannot alone resolve aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR. A phase-noise measurement cannot be translated into one rms time value without stating the integration range and transfer function. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures, with before-and-after values of input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR. If the instrument behaves as predicted, then for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the

Copyright 2026, James M. Atkinson

measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. Parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Dennis Gabor

There is an inferential difficulty, Dennis Gabor: clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The population of admissible observations needs to be fixed before any confidence argument. In this situation, aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Correlated jitter between multiple converters invalidates naive independent-noise improvement calculations. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in input frequency, rms aperture-time

Copyright 2026, James M. Atkinson

uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR would invalidate the preferred account, and which aspect of sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures would make that negative result independently repeatable?

Dennis Gabor | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 021, the specific physical candidate is small time perturbations translated into amplitude errors proportional to instantaneous input slew rate. The unresolved physical pathway is material: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The retained record permits a conditional claim about input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, but cannot alone resolve aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. That limitation belongs in

Copyright 2026, James M. Atkinson

the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Correlated jitter between multiple converters invalidates naive independent-noise improvement calculations. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts; its prediction should be recorded alongside for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Aperture jitter is a time error whose voltage consequence

Copyright 2026, James M. Atkinson

depends on the input slew rate; converter resolution alone cannot reveal it. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a 100 mhz signal subject to one picosecond rms sampling jitter has an idealised jitter-only snr of roughly 64 db. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 3: A phase-noise measurement cannot be translated into one rms time value without stating the integration range and transfer function.

I would distinguish the nominal sample count from the information contained in the values. A sequence may have the expected N samples at the advertised sample rate while timing uncertainty has altered their relationship to the continuous analogue waveform. If the jitter is independent and sufficiently small, a linearised error model attributes voltage error to signal slope times sampling-time error. That expression is especially revealing for a high-frequency tone: a steep derivative converts even tiny timing deviations into measurable voltage disturbance. It does not follow that storing the result in a 32-bit numerical type restores the accuracy lost at the sampling aperture. Nor does it follow that a down-converted carrier of modest digital frequency was insensitive to the original analogue slope. Retaining the acquisition clock diagnostics is therefore part of preserving what was measured. The eventual analyst may estimate a jitter contribution under a model, but cannot reconstruct the unique unperturbed waveform from samples alone.

In this operational measurand examination of Question 021, the decisive claim is that a phase-noise measurement cannot be translated into one rms time value without stating the integration range and transfer function. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: jitter constrains sampling precision at the input frequency. For a sinusoidal input of frequency f and rms aperture-time uncertainty sigma_t, the familiar small-jitter bound on

Copyright 2026, James M. Atkinson

signal-to-noise ratio is approximately minus 20 log10(2 pi f sigma_t), provided timing error is independent and appropriately modelled. At f = 1 gigahertz and sigma_t = 200 femtoseconds, the product 2 pi f sigma_t is about 0.001257 and the jitter-limited ratio is roughly 58.0 dB. Increasing nominal converter resolution beyond that limit does not by itself recover timing-lost information. Account separately for converter aperture jitter, sampling-clock phase noise and external source jitter, and do not assume those processes are independent unless the architecture supports the assumption. Characterise the full analogue path because an apparently pristine digital code can still be inaccurate in phase. The speaker must not confuse the result of this bounded comparison with a general finding concerning every possible external transmission. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Sampling aperture jitter converts timing uncertainty into amplitude error that grows with the analogue input frequency. For a sinusoidal signal the familiar small-jitter approximation gives a jitter-limited signal-to-noise ratio of $-20 \log_{10}(2\pi f \sigma_t)$, where f is the input frequency in hertz and σ_t is rms sampling-time error in seconds. This makes a nominally high-resolution converter vulnerable at very high RF or IF frequencies even when its sample rate is ample. The quantity to measure is not solely the advertised converter clock period but the effective uncertainty at the sampling aperture, including distribution and board-level contributions. Compare a low-frequency calibration sinusoid with a much higher-frequency one under otherwise matched full-scale conditions; increasing broadband error in the

Copyright 2026, James M. Atkinson

latter may indicate jitter limitation, although front-end distortion and source purity must first be excluded. Where separate clock sources contribute, the assumed independence of jitter terms must be demonstrated before combining their rms values in quadrature. Accordingly, the laboratory record for Question 021 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. Shannon’s information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether

Copyright 2026, James M. Atkinson

it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A 100 MHz signal subject to one picosecond rms sampling jitter has an idealised jitter-only SNR of roughly 64 dB. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. An integrated phase-noise figure cannot be converted to timing uncertainty without declaring its offset-frequency limits. Dr Turing, please take the floor and investigate the information omitted by a lone rms value.

Alan Mathison Turing | Peer question 5 to Claude Elwood Shannon

Claude Elwood Shannon, I should like to examine what the recorded data actually preserve when a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. The physical input and the retained numerical array are not interchangeable things. The calculation is an upper bound under stated conditions rather than a complete converter performance guarantee. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR would invalidate the

Copyright 2026, James M. Atkinson

preferred account, and which aspect of sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures would make that negative result independently repeatable?

Claude Elwood Shannon | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 021, the specific physical candidate is small time perturbations translated into amplitude errors proportional to instantaneous input slew rate. The unresolved physical pathway is material: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The retained record permits a conditional claim about input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, but cannot alone resolve aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. I propose separating acquired information from model-dependent reconstruction. The calculation is an upper bound under stated conditions rather than a complete converter performance guarantee. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR and a fresh trial in which the operator sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. If that trial demonstrates for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete

Copyright 2026, James M. Atkinson

challenge should include sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 4: Correlated jitter between multiple converters invalidates naive independent-noise improvement calculations.

A receiver's timing budget should be constructed along an actual clock distribution network. Phase noise injected by the reference, a phase-locked loop, fan-out buffers or a local supply need not be mutually independent. Simply squaring every published jitter figure and taking their square root could therefore give the wrong answer. I would obtain the relevant cross-spectral or correlation information where available, then test the assembled system across clock modes, temperatures and converter channels. A common timing error can cancel in some differential measurements while remaining decisive for a comparison against an independent external clock. The loop bandwidth of a synthesiser can move noise between offsets, so one integrated RMS number cannot characterise every pulse or spectral estimator. The network model must identify where timing is defined and where the ADC actually samples. If a clock distribution board is replaced, the timing validation should be repeated even when the converter's nominal resolution and rate are unchanged.

In this information retention examination of Question 021, the decisive claim is that correlated jitter between multiple converters invalidates naive independent-noise improvement calculations. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: jitter constrains sampling precision at the input frequency. For a sinusoidal input of frequency f and rms aperture-time uncertainty sigma_t, the familiar small-jitter bound on signal-to-noise ratio is

Copyright 2026, James M. Atkinson

approximately minus 20 log10(2 pi f sigma_t), provided timing error is independent and appropriately modelled. At f = 1 gigahertz and sigma_t = 200 femtoseconds, the product 2 pi f sigma_t is about 0.001257 and the jitter-limited ratio is roughly 58.0 dB. Increasing nominal converter resolution beyond that limit does not by itself recover timing-lost information. Account separately for converter aperture jitter, sampling-clock phase noise and external source jitter, and do not assume those processes are independent unless the architecture supports the assumption. Characterise the full analogue path because an apparently pristine digital code can still be inaccurate in phase. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. The scientific point of correlated jitter between multiple converters invalidates naive independent-noise improvement calculations. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions repeatedly show for fixed

Copyright 2026, James M. Atkinson

rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. Parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. The issue becomes especially sharp because clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval

Copyright 2026, James M. Atkinson

and frequency domain actually examined. For the proposed case, a 100 mhz signal subject to one picosecond rms sampling jitter has an idealised jitter-only snr of roughly 64 db. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A more precise objection comes from Hendrik Wade Bode and the finite observation aperture in a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. For that reason, record input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. Shared timing errors across converter channels defeat an independence

Copyright 2026, James M. Atkinson

assumption, however impressive the combined digital word appears. Dr Deming, I invite a comparison that exposes this correlation.

W. Edwards Deming | Peer question 6 to Hendrik Wade Bode

I thank you, Hendrik Wade Bode, for distinguishing measurement from attribution, but the observation is that parallel averaging does not improve the observed error as the simple square-root-of-channel-count heuristic would suggest. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a 100 MHz signal subject to one picosecond rms sampling jitter has an idealised jitter-only SNR of roughly 64 dB. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB on one day but fails after the instrument has been reconfigured? For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Hendrik Wade Bode | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the

Copyright 2026, James M. Atkinson

physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 021, the specific physical candidate is small time perturbations translated into amplitude errors proportional to instantaneous input slew rate. The unresolved physical pathway is material: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The retained record permits a conditional claim about input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, but cannot alone resolve aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a 100 MHz signal subject to one picosecond rms sampling jitter has an idealised jitter-only SNR of roughly 64 dB. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. Its bearing on the dispute can be evaluated through the predicted response, namely for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB. Because clock-edge uncertainty may be

Copyright 2026, James M. Atkinson

correlated between channels, making their apparent noise reductions smaller than independent averaging predicts, the procedure sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match disclose the clock topology and tested frequency before interpreting converter-bit aggregation as improved dynamic range, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. For fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Jerzy Neyman | Principal contribution 5: The calculation is an upper bound under stated conditions rather than a complete converter performance guarantee.

An attractive jitter specification is meaningful only in relation to a stipulated population of signals and a measured uncertainty. Suppose an SDR must detect intermittent waveforms whose RF carrier frequency varies over a broad range. A performance estimate derived from a low-frequency sinusoid cannot be extrapolated to the highest input frequency without accounting for the frequency-dependent jitter error. I would test several frequencies and amplitudes, distinguishing oscillator-related spurs, thermal noise and nonlinear distortion from the jitter contribution. A regression of noise power against the square of input frequency may help under controlled conditions, but only if competing terms are sufficiently stable and the model has been challenged. Report uncertainty in σ_t, clock-path correlation and the detector's tolerance for additional phase disturbance. The correct decision is not whether an abstract jitter number is small, but whether the receiver remains fit for the specific evidence task throughout its intended operating envelope.

In this statistical inference examination of Question 021, the decisive claim is that the calculation is an upper bound under stated conditions rather than a complete converter performance guarantee. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: jitter constrains sampling precision at the input frequency. For a sinusoidal input of frequency f and

Copyright 2026, James M. Atkinson

rms aperture-time uncertainty sigma_t, the familiar small-jitter bound on signal-to-noise ratio is approximately minus 20 log10(2 pi f sigma_t), provided timing error is independent and appropriately modelled. At f = 1 gigahertz and sigma_t = 200 femtoseconds, the product 2 pi f sigma_t is about 0.001257 and the jitter-limited ratio is roughly 58.0 dB. Increasing nominal converter resolution beyond that limit does not by itself recover timing-lost information. Account separately for converter aperture jitter, sampling-clock phase noise and external source jitter, and do not assume those processes are independent unless the architecture supports the assumption. Characterise the full analogue path because an apparently pristine digital code can still be inaccurate in phase. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. The calculation is an upper bound under stated conditions rather than a complete converter performance guarantee. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures, should be accompanied by a

Copyright 2026, James M. Atkinson

second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say disclose the clock topology and tested frequency before interpreting converter-bit aggregation as improved dynamic range, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman’s statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each

Copyright 2026, James M. Atkinson

physically meaningful regime. The relevant quantities are input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited snr bound by approximately 6.02 db, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a 100 mhz signal subject to one picosecond rms sampling jitter has an idealised jitter-only snr of roughly 64 db, is not an estimate of any actual investigation. A computed jitter ceiling is a conditional upper limit, not an instrument certificate under every waveform and temperature. Sir Karl, I pass the floor for a test of that boundary.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise disclose the clock topology and tested frequency before interpreting converter-bit aggregation as improved dynamic range? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Doubling the input frequency worsens this idealised limit by approximately 6.02 dB if jitter remains unchanged. Please connect input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR with a declared detection threshold and the measurement exposure. If the experiment sweep input frequency at controlled amplitude while

Copyright 2026, James M. Atkinson

independently measuring clock phase noise and comparing correlated versus separately clocked captures cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 021, the specific physical candidate is small time perturbations translated into amplitude errors proportional to instantaneous input slew rate. The unresolved physical pathway is material: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. The retained record permits a conditional claim about input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR, but cannot alone resolve aperture jitter is a time error whose voltage consequence depends on the input slew rate; converter resolution alone cannot reveal it. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Doubling the input frequency worsens this idealised limit by approximately 6.02 dB if jitter remains unchanged. I would use the observations of input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures, not an assertion based on the operator's impression of a quiet display. If it yields for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging

Copyright 2026, James M. Atkinson

predicts, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to disclose the clock topology and tested frequency before interpreting converter-bit aggregation as improved dynamic range, with the untested physical possibilities made visible.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, our example calculates an ideal jitter ceiling of approximately 58.42 dB for a 120 MHz sinusoid sampled with 1.59 ps rms aperture uncertainty. A design team installs a second nominally fifteen-bit converter on the same clock and assumes the two outputs can be averaged into a twenty-four-bit equivalent receiver. Which distinction among nominal code width, quantisation-noise reduction and timing-noise correlation prevents that conclusion, even if their sampled waveforms appear highly coherent?

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the sample value is perturbed by the input waveform slope multiplied by the instantaneous timing error. In the idealised small-jitter sinusoidal model, the resulting ratio is determined by 2π times the analogue input frequency times rms timing uncertainty; merely enlarging the digital word does not remove this analogue sampling error. At 120 MHz and 1.59 ps the ideal 58.42 dB ceiling corresponds to roughly 9.4 bits only if it were translated into the conventional full-scale-sinusoid effective-number-of-bits expression. That comparison is an illustrative SNR equivalence, not a measurement of the converter’s actual ENOB. Two channels sharing a common clock can share a substantial timing-error component, which simple averaging leaves in place. Their uncorrelated quantisation and thermal noise may diminish under specific assumptions, but no general law converts two fifteen-bit

Copyright 2026, James M. Atkinson

words into a valid twenty-four-bit measurement. Measure the channel cross-spectrum, clock topology, analogue source noise and actual harmonic-free SNR under the stipulated input conditions. I respectfully pass the floor to Dr Gabor to test how the timing uncertainty was derived.

Dennis Gabor, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, the manufacturer quotes a small phase-noise value at a single offset from the oscillator carrier and a separate rms-jitter number taken over an unspecified band. The team inserts that number into the aperture SNR formula without investigating the sampling-clock distribution, an analogue-input generator or narrow phase spurs. What frequency-domain information must be supplied before those figures may be combined into a meaningful timing-noise budget?

Hendrik Wade Bode, Cross-Peer Answer to Dennis Gabor: Dr Gabor, a phase-noise value at one Fourier offset does not determine total rms time uncertainty. Obtain the phase-noise spectrum over the stated integration-offset range, account for the convention used to convert single-sideband noise to phase variance, and include appropriate transfer functions through synthesis, multiplication, distribution and converter aperture. Identify discrete spurs separately from random phase fluctuations rather than burying deterministic modulation in a single statistical number. The converter experiences relative timing uncertainty between its sampling instant and the analogue signal; a common oscillator may yield cancellation or reinforcement depending upon the signal paths and their delays. When phase variance is integrated, conversion to time variance requires the specified clock carrier frequency, and the practical integration limits must reflect relevant aliasing and measurement bandwidth. The resulting

Copyright 2026, James M. Atkinson

covariance between channels deserves its own estimate. Finally compare the inferred limit against measured SNR as input frequency varies, retaining thermal noise, distortion and source-purity controls. It is only under these declared conditions that a phase-noise measurement supports the jitter number used in an engineering model. I respectfully pass the floor to Professor Neyman for the cross-channel statistical consequence.

Jerzy Neyman, Cross-Peer Question to W. Edwards Deming: Mr Deming, suppose two parallel ADC channels have equal timing-error variance σ^2 and correlation coefficient ρ. Their designer averages the samples and advertises the familiar square-root-of-two improvement, but the clock tree is shared and ρ has never been estimated. What reproducible acceptance experiment would establish whether the claimed improvement is present over the useful operating range rather than merely on a favourable calibration tone?

W. Edwards Deming, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, if equal-variance error contributions are averaged, the variance of their mean is $\sigma^2(1 + \rho)/2$. Thus $\rho = 0$ gives the familiar halving of variance, whereas $\rho = 1$ gives no reduction at all. This expression is a model consequence, not a measured property of either converter. Repeat with controlled sinusoidal inputs across the intended frequency range and power levels, including near the converter's overload boundary; estimate the channel error covariance from synchronised records after accounting for signal and reference-source noise. Use a common clock and then a qualified independent clock, where the apparatus permits, while preserving all changed operating conditions. Separate random jitter from systematic skew and aperture delay, and test for frequency dependence. Examine spurious

Copyright 2026, James M. Atkinson

responses, interchannel leakage, dither, clipping and gain mismatch instead of relying solely upon total power on a waterfall. Any claimed ENOB gain must be inferred from measured SINAD using the stated measurement convention, not obtained by adding digital word lengths. Retain outliers and unexpected failures in the acceptance report. I respectfully pass the floor to Dr Hamming to challenge the continuity of the recorded data.

Richard Wesley Hamming, Cross-Peer Question to Ralph Vinton Lyon Hartley: Mr Hartley, an ADC acquisition contains 1,105,000 expected sample positions and 255 missing positions, a loss of only about 0.02308 per cent. Elsewhere the clock drifts by several tenths of a millisecond, and an anti-alias filter introduces approximately 67.641 ns of local group delay. The system designer calls all these quantities sampling jitter and proposes one numerical correction. Which distinctions among sampling-time noise, long-term rate error, propagation delay and absent observations are indispensable to an honest evidence ledger?

Ralph Vinton Lyon Hartley, Cross-Peer Answer to Richard Wesley Hamming: Dr Hamming, those are four different impairments. Random aperture-time variation is a stochastic displacement around nominal instants and can produce slope-proportional amplitude noise; fractional clock-rate error accumulates a systematic or slowly varying time-axis discrepancy; group delay belongs to an analogue or digital transfer path and may vary across the signal band; missing sample positions are absences which no interpolation can turn into observed evidence. The roughly 0.462-millisecond accumulated clock drift cannot be subtracted from the jitter budget without defining a time origin and calibration stability. The 67.641-ns group-delay quotient is a local phase-slope estimate and cannot

Copyright 2026, James M. Atkinson

automatically correct a broadband burst edge. Record sequence counters, disciplined-clock status, clock topology, missing-block positions, gain state, input-filter settings and the exact timestamp reference plane. Where short bursts might coincide with missing intervals, the proper conclusion is that the interval was not observed, however impressive the overall retained percentage. Numerical correction should be performed only for calibrated, separately identified mechanisms; uncertainty and unresolved evidence gaps remain on the record. I respectfully pass the floor to Dr Atkinson for the concluding synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of the frequency-dependent signal-to-noise penalty of random aperture-time error has established a point which the specialist must not overlook. The receiver records noise or phase uncertainty correlated with the slope of the analogue input waveform; it does not, merely by drawing a clear trace, give direct access to the several independent or correlated clock and sampling-aperture contributors to total jitter. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, For a sinusoid and sufficiently small independent random timing error, the jitter-limited SNR is minus twenty times the base-ten logarithm of 2π times input frequency times rms jitter. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

Copyright 2026, James M. Atkinson

Sampling-clock uncertainty is particularly dangerous when it is confused with a general statement of converter resolution. The timing error of an aperture manifests differently at low and high input frequencies; it is also necessary to distinguish uncorrelated jitter from a deterministic clock offset, a long-term drift and shared phase noise. I thank Dr Shannon for pointing out that later digital processing cannot reconstruct an analogue detail already corrupted at sampling. The appropriate validation applies known tones at several RF frequencies, compares measured signal-to-noise-and-distortion against the predicted jitter-limited envelope and separately examines spurious components caused by periodic clock modulation. A second channel fed from the same reference does not provide independent confirmation of that reference's failure. The concluding result must report the measured spectral consequences of clock instability together with the model assumptions, rather than multiply nominal ADC bit depth into an imaginary gain in physical resolution. The remaining uncertainty belongs in the acquisition record and any later timing-based localisation.

A frequency-dependent degradation in SNR is consistent with aperture jitter, yet converter distortion and input noise can display similar frequency dependence. A controlled clock substitution and the observed noise spectrum are needed before assigning a quantitative jitter value. The more useful outcome is a discriminating protocol: Sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. In applying it, the examiner must retain all readings supporting input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR and identify the physical plane to which the

Copyright 2026, James M. Atkinson

measurements refer. At the outset of the investigation, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network; that circumstance makes the alternative mechanism material, specifically clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. A result approaching for fixed rms timing jitter, doubling sinusoidal input frequency reduces the jitter-limited SNR bound by approximately 6.02 dB may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore disclose the clock topology and tested frequency before interpreting converter-bit aggregation as improved dynamic range. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

Report jitter-limited performance as a conditional bound with the tested input frequency, clock source and error correlation. Do not convert a nominal jitter figure into a universal claim of effective converter resolution. The decisive experiment is concrete: Sweep input frequency at controlled amplitude while independently measuring clock phase noise and comparing correlated versus separately clocked captures. In conducting it, the examiner must explicitly retain input frequency, rms aperture-time uncertainty, phase-noise integration limits, correlation coefficient and jitter-limited SNR. If the outcome matches the stated prediction, for fixed rms

Copyright 2026, James M. Atkinson

timing jitter, doubling sinusoidal input frequency reduces the jitter-limited snr bound by approximately 6.02 db, the supported conclusion concerns that test domain. An alternative remains: Clock-edge uncertainty may be correlated between channels, making their apparent noise reductions smaller than independent averaging predicts. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 021

Application 01. The frequency dependence of aperture-jitter-limited SNR

In the illustrative 021.01 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. At sinusoidal input frequency f = 120 MHz with uncorrelated rms aperture jitter σ_t = 1.59 ps, the idealised jitter-imposed ceiling is $SNR_j = -20 \log_{10}(2\pi f \sigma_t)$ = 58.42 dB. A common clock source may correlate errors across parallel ADC channels, so treating their outputs as independent for noise cancellation would need an additional experiment. Converter nonlinearity and thermal noise can make actual performance worse. The 58.42 dB idealised jitter ceiling applies to the specified sinusoid and rms relative timing error. Shared-clock timing noise is correlated and cannot be removed by increasing digital word length.

Application 02. Ideal code step, variance, and full-scale sine SNR

In the illustrative 021.02 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. Taking an ideal N = 15-bit uniform converter across 2.50 V peak-to-peak, one nominal code interval is $\Delta = Vpp/2^N$ = 0.0763 mV. Under the independent uniform-error approximation its rms quantisation error is $\sigma = \Delta/\sqrt{12}$ = 0.0220 mV. The ideal full-scale sinusoidal SNR approximation is 6.02N + 1.76 = 92.06 dB. A coherent low-level waveform may violate the uniform-error assumption; clipping and integral nonlinearity are separate limitations. The 0.0220-mV quantisation estimate assumes ideal, independent uniform errors and a full-scale code convention. It

Copyright 2026, James M. Atkinson

must not be summed as extra effective bits without measuring dither and converter nonlinearity.

Application 03. Frequency-bin spacing versus independent information

In the illustrative 021.03 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. With sampled bandwidth f_s = 8 MS/s and N = 16,384 transform samples, the discrete-frequency grid is $\Delta f = f_s/N$ = 488.281 Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. The 488.281-Hz DFT grid measures frequency-bin spacing, not aperture-jitter bandwidth. State the clock phase-noise integration band, equivalent noise bandwidth and overlapping-window correlations separately.

Application 04. Accumulated sample-clock time error

In the illustrative 021.04 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. A free-running sample clock with fractional rate error ε = 1.430 ppm over T = 323 s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T$ = 0.4619 ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. The 0.4619-ms accumulated offset reflects mean clock-rate error over 323 s, not random aperture

Copyright 2026, James M. Atkinson

jitter. Preserve the synchronisation and time-stamp reference planes before comparing channels.

Application 05. Group delay from a local phase-versus-frequency slope

In the illustrative 021.05 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. Across a local frequency step $\Delta f = 0.80$ MHz, suppose unwrapped transmission phase changes by $\Delta\varphi = -0.340$ rad. The finite-difference group-delay estimate is $\tau g \approx -\Delta\varphi/(2\pi\Delta f) = 67.641$ ns. This is an average local slope. Dispersive responses require a finer phase sweep, a consistent unwrapping method and uncertainty treatment before extrapolating transient arrival times. The 67.641-ns phase-slope quotient measures local group delay for the given filter, not ADC aperture-time noise or a universal broadband-burst correction.

Application 06. Thermal reference noise in a declared measurement bandwidth

In the illustrative 021.06 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. Take the equivalent noise bandwidth B = 4,500 Hz and calibrated noise figure NF = 2.55 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -134.92$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The minus-134.92 dBm thermal-reference estimate describes integrated receiver noise in 4.5 kHz; it does not fix timing-error SNR at 120 MHz or an oscillator phase-noise budget.

Copyright 2026, James M. Atkinson

Application 07. Combined and expanded measurement uncertainty

In the illustrative 021.07 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. For independent standard-uncertainty contributions 0.45, 0.48 and 0.25 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.45^2 + 0.48^2 + 0.25^2)} = 0.704$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c = 1.408$ units. The 1.408-unit expanded uncertainty assumes independent common-unit inputs and k = 2; a multi-channel jitter claim must instead identify correlated clock and signal-source contributions.

Application 08. Preserved sample continuity across an acquisition interval

In the illustrative 021.08 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. A converter expected to retain f_s = 1.70 million samples/s for T = 0.65 s should supply f_sT = 1,105,000 complex sample instants. If 255 sequence positions are missing, the retained count is 1,104,745 and loss fraction is 0.02308%. A low fractional loss cannot exclude a highly relevant short burst coinciding with the gap. Position and timing of each missing block must therefore be preserved. The 0.02308-per-cent missing-sample fraction is an acquisition-integrity measure, not clock jitter. Missing sequence positions may conceal an entire short event despite the low proportion.

Application 09. Alias-location prediction and its non-unique inverse

In the illustrative 021.09 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network.

Copyright 2026, James M. Atkinson

For an actual sampling frequency f_s = 31 MHz and analogue input f_i = 66.030 MHz, the nearest-replica folding rule gives $f_a = |f_i - \mathrm{round}(f_i/f_s)f_s|$ = 4.030 MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. The 4.030-MHz aliased coordinate is not the analogue input frequency controlling the jitter-sensitivity calculation; use the true 66.030-MHz input before drawing a clock-noise inference.

Application 10. Gain allocation and blocker headroom

In the illustrative 021.10 test, a high-frequency sinusoid is digitised by two converter channels sharing a common clock distribution network. Assume a calibrated digital full-scale equivalent of -11 dBm, a blocker applied at -41 dBm, and net analogue gain 26 dB. The projected converter input is -15 dBm and remaining margin is -11 − (-15) = 4 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. The four-decibel predicted converter margin assumes a linear input chain and known peak level. Verify overload and crest factor before interpreting any measured SNR shortfall as aperture jitter.

QUESTION 022

Copyright 2026, James M. Atkinson

When does analogue front-end bandwidth invalidate an otherwise adequate sampling rate?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 022 asks: When does analogue front-end bandwidth invalidate an otherwise adequate sampling rate? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is limits imposed by the analogue front-end when sampling rate is superficially sufficient. Our primary observation is digitised spectral or transient data from a physically band-limited converter input; by contrast, what remains unseen is the rejected, attenuated, phase-distorted, or overloaded components before sampling. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Sampling rate cannot undo a narrow analogue passband. A converter may satisfy a Nyquist sampling criterion for the desired digital bandwidth while the preceding amplifier or track-and-hold has already attenuated or

Copyright 2026, James M. Atkinson

distorted that same signal. Suppose a 200-megasample-per-second converter is preceded by an analogue response that is 3 dB down at 60 megahertz. A 70-megahertz component lies below the 100-megahertz real-sampling Nyquist frequency, but it cannot be assumed to have unity amplitude merely because the sampling rate admits it. The analogue transfer magnitude, phase and slew performance require calibration. Harmonics of a short pulse may be attenuated unevenly, producing a longer apparent envelope. A reconstruction algorithm cannot distinguish this deterministic bandwidth shaping from a source envelope without independent knowledge of the front end. Test representative transients at the input reference plane, including strong neighbouring signals. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns digitised spectral or transient data from a physically band-limited converter input; it is not interchangeable with the rejected, attenuated, phase-distorted, or overloaded components before sampling. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is swept-frequency transfer and phase characterisation with a second known anti-alias filtering path. A claim drawn from that comparison has to carry its actual uncertainties: analogue input bandwidth, passband flatness, attenuation, sample rate, and aperture roll-off. A nominal sample rate characterises a discrete-time operation and does not certify a preceding analogue transfer function. The converter input may have frequency-

Copyright 2026, James M. Atkinson

dependent gain and phase even where digitiser throughput is adequate. Insufficient anti-alias rejection allows distant out-of-band signals to be folded into the displayed baseband. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 1: A nominal sample rate characterises a discrete-time operation and does not certify a preceding analogue transfer function.

The sampling-rate condition is a statement about the analogue spectrum admitted to the sampling device, not a permission to ignore the receiver's preselector. A converter operating at a rate adequate for a deliberately low-pass-limited baseband may still fold a powerful out-of-band signal into the observed digital band if the analogue front end fails to suppress it. I would begin by drawing the spectral occupancy at the ADC input, including known image regions and the filter's actual transition bands. A manufacturer may quote bandwidth at a three-decibel point, but an alias-rejection claim requires stopband attenuation where competing signals can occur. In a forensic receiver, a weak candidate that appears near the displayed baseband centre can be the alias of a much stronger external service at a remote frequency. The experiment should vary the analogue preselector and the sample clock independently, keeping a calibrated source fixed. The observed frequency mapping can then be checked against the actual sampling law rather than an assumed one.

In this physical path examination of Question 022, the decisive claim is that a nominal sample rate characterises a discrete-time operation and does not certify a preceding analogue transfer function. The analogue anti-alias filter determines which portions of the external spectrum can enter the sampled representation. A mathematically correct alias frequency is not evidence that the corresponding RF source actually reached the converter with adequate amplitude. The filter’s stopband shape, temperature drift, input matching and large-signal performance must all be measured. In a

Copyright 2026, James M. Atkinson

wideband survey this is particularly important because a powerful out-of-band service can survive inadequate rejection even if the digital display faithfully reports the folded component. A useful falsification proceeds from the actual controversy: sampling rate cannot undo a narrow analogue passband. A converter may satisfy a Nyquist sampling criterion for the desired digital bandwidth while the preceding amplifier or track-and-hold has already attenuated or distorted that same signal. Suppose a 200-megasample-per-second converter is preceded by an analogue response that is 3 dB down at 60 megahertz. A 70-megahertz component lies below the 100-megahertz real-sampling Nyquist frequency, but it cannot be assumed to have unity amplitude merely because the sampling rate admits it. The analogue transfer magnitude, phase and slew performance require calibration. Harmonics of a short pulse may be attenuated unevenly, producing a longer apparent envelope. A reconstruction algorithm cannot distinguish this deterministic bandwidth shaping from a source envelope without independent knowledge of the front end. Test representative transients at the input reference plane, including strong neighbouring signals. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Inject calibrated tones just inside, at and well beyond the anti-alias transition band. Record their measured attenuation at the converter-side input and the resulting folded bins while varying sample rate in controlled steps. A second out-of-band tone should test compression and intermodulation, because small-signal S-parameters may not predict blocker behaviour. Retain amplitude and phase calibration, converter clock identity

Copyright 2026, James M. Atkinson

and the finite stopband rejection actually obtained rather than the advertised filter family. I would take front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: A nominal sample rate characterises a discrete-time operation and does not certify a preceding analogue transfer function. A response consistent with an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. An SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. A meaningful bench experiment begins with a source whose power,

Copyright 2026, James M. Atkinson

impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by an actual in-band emitter and a higher nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins, and measure their behaviour separately before reconnecting the assembled system. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. It is therefore material to establish front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth rather than infer them from a single scalar output. The limiting test is concrete: Map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. If the intervention produces an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated rf station, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret a distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent as a new transmitter before challenging the most economical instrumental explanation. The advertised sample rate cannot by itself certify the spectral contents of the analogue aperture. Professor Tukey, I invite you to challenge the evidential interpretation of a clean-looking digital band.

John Wilder Tukey | Peer question 1 to Harry Nyquist

Harry Nyquist, may I test the exact physical inference in your account of an SDR samples rapidly enough for the intended instantaneous

Copyright 2026, James M. Atkinson

passband but uses an analogue input network with poorly measured out-of-band attenuation? The proposed mechanism appears plausible only if changes after map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates are compared with a stable reference condition. A nominal sample rate characterises a discrete-time operation and does not certify a preceding analogue transfer function. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth which would settle that narrower claim, rather than a visual impression of improvement.

Harry Nyquist | Immediate answer to John Wilder Tukey

Dr Tukey, two different analogue frequencies can produce an identical sampled line, so the digital transform is underdetermined without the preconverter path. I should measure the filter at the frequencies of both candidate inputs and challenge the suspect alias by a modest, known sample-rate change. If the trace follows one predicted folding trajectory but not another, the result strengthens a path hypothesis while remaining conditional on the measured analogue passband. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then

Copyright 2026, James M. Atkinson

change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 022, the specific physical candidate is analogue amplitude roll-off, aperture response, filter group delay, and uncontrolled alias-band admission. The unresolved physical pathway is material: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. The retained record permits a conditional claim about front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, but cannot alone resolve nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. A nominal sample rate characterises a discrete-time operation

Copyright 2026, James M. Atkinson

and does not certify a preceding analogue transfer function. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates, and only a response matching an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Harry Nyquist

I appreciate your explanation, Harry Nyquist. How would your conclusion survive a deliberately independent test of a distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent? A second receiver might share more of the supposed evidence than its separate enclosure

Copyright 2026, James M. Atkinson

suggests. The converter input may have frequency-dependent gain and phase even where digitiser throughput is adequate. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth and document which differences remain unexplained? Would you also state what observed change in front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth would invalidate the preferred account, and which aspect of map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates would make that negative result independently repeatable?

Harry Nyquist | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 022, the specific physical candidate is analogue amplitude roll-off, aperture response, filter group delay, and uncontrolled alias-band admission.

Copyright 2026, James M. Atkinson

The unresolved physical pathway is material: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. The retained record permits a conditional claim about front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, but cannot alone resolve nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. The converter input may have frequency-dependent gain and phase even where digitiser throughput is adequate. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins; I would challenge it with map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. Two responses consistent with an aliased interference feature moves according to a sampling-fold relation when the sample rate

Copyright 2026, James M. Atkinson

changes, unlike a true calibrated RF station would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, an actual in-band emitter and a higher nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. A discordant measurement would then be interpreted by tracing that difference through front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Principal contribution 2: The converter input may have frequency-dependent gain and phase even where digitiser throughput is adequate.

A receiver front end can fail the sampling model while its numerical downstream processing is flawless. Consider a high-level input just beyond an analogue filter's stopband knee. The ADC captures it and generates an alias inside the wanted observation band; subsequent digital filtering may be unable to distinguish that alias from a genuine in-band emitter. I would require a measured stopband profile under realistic source and load impedances, not simply a nominal drawing in the instrument manual. Strong-signal intermodulation may also create energy inside the admitted band before sampling, making it impossible for any anti-alias filter placed after the offending nonlinear stage to repair the record. The design should put appropriate protection and preselection ahead of the most vulnerable component. A controlled substitution of a higher-rejection input filter, paired with a reference injection, can test a specific aliasing explanation without claiming to have located the physical source.

In this control and stability examination of Question 022, the decisive claim is that the converter input may have frequency-dependent gain and phase even where digitiser throughput is adequate. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: sampling rate cannot undo a narrow analogue passband. A converter may satisfy a Nyquist sampling criterion for the desired digital bandwidth while the

Copyright 2026, James M. Atkinson

preceding amplifier or track-and-hold has already attenuated or distorted that same signal. Suppose a 200-megasample-per-second converter is preceded by an analogue response that is 3 dB down at 60 megahertz. A 70-megahertz component lies below the 100-megahertz real-sampling Nyquist frequency, but it cannot be assumed to have unity amplitude merely because the sampling rate admits it. The analogue transfer magnitude, phase and slew performance require calibration. Harmonics of a short pulse may be attenuated unevenly, producing a longer apparent envelope. A reconstruction algorithm cannot distinguish this deterministic bandwidth shaping from a source envelope without independent knowledge of the front end. Test representative transients at the input reference plane, including strong neighbouring signals. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by a distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note the converter input may have frequency-

Copyright 2026, James M. Atkinson

dependent gain and phase even where digitiser throughput is adequate. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, a distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Armstrong’s receiver engineering points to actual conversion products and oscillation conditions rather than abstract spectral indications; the crucial question is where the energy first appears. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. The order would be time-stamped and should include invalid intervals, receiver recovery, and any gain or filter settling rather than treating silence during transition as evidence of a silent source. Our central rival is specific: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. This predicts a response which should be tested against an aliased interference feature

Copyright 2026, James M. Atkinson

moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated rf station. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements discarded during retuning. Where nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting, the correct claim must name the operational states and the evidence available in each. Amplitude and phase response upstream of the converter determine what was admitted before sampling. Dr Pearson, please take the floor and examine whether our calibration actually covers the relevant RF range.

Egon Sharpe Pearson | Peer question 3 to Edwin Howard Armstrong

Edwin Howard Armstrong, your calibration argument invites a question about reference planes, especially because nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. The reference stimulus and the unknown emission need not occupy the same physical regime. Insufficient anti-alias rejection allows distant out-of-band signals to be folded into the displayed baseband. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When a distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate

Copyright 2026, James M. Atkinson

preselection and sample rates without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Edwin Howard Armstrong | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 022, the specific physical candidate is analogue amplitude roll-off, aperture response, filter group delay, and uncontrolled alias-band admission. The unresolved physical pathway is material: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. The retained record permits a conditional claim about front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, but cannot alone resolve nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth. Insufficient anti-alias rejection allows distant out-of-band signals to be folded into the displayed baseband. I

Copyright 2026, James M. Atkinson

would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates, with before-and-after values of front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth. If the instrument behaves as predicted, then an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. A distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Copyright 2026, James M. Atkinson

Ralph Vinton Lyon Hartley | Peer question 4 to Edwin Howard Armstrong

There is an inferential difficulty, Edwin Howard Armstrong: an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. The population of admissible observations needs to be fixed before any confidence argument. In this situation, nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. An anti-alias filter must be assessed over all folds relevant to the investigated band rather than only at its nominal corner. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth would invalidate the preferred account, and which aspect of map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates would make that negative result independently repeatable?

Edwin Howard Armstrong | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by

Copyright 2026, James M. Atkinson

reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 022, the specific physical candidate is analogue amplitude roll-off, aperture response, filter group delay, and uncontrolled alias-band admission. The unresolved physical pathway is material: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. The retained record permits a conditional claim about front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, but cannot alone resolve nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because a distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent. I would distinguish trials selected in advance from those added after an unexpected peak appeared. An anti-alias filter must be assessed over all folds relevant to the investigated band rather than only at its nominal corner. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can

Copyright 2026, James M. Atkinson

legitimately examine map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins; its prediction should be recorded alongside an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a sampler cannot distinguish two analogue tones whose frequencies differ by an integer multiple of its sampling rate from samples alone. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 3: Insufficient anti-alias rejection allows distant out-of-band signals to be folded into the displayed baseband.

Aliasing is an example of two distinct analogue inputs yielding the same sampled sequence. Once they coincide at the converter output, no clever choice of FFT bins can reveal which input was historically present without independent information. This is why the bandwidth statement must accompany the analogue filter and its actual attenuation, not just the digital sample rate. A wide acquisition system may deliberately exploit under-sampling of a restricted band; that technique is sound only if the admissible analogue zones are adequately separated. If two RF bands are permitted through an imperfect preselector, their sampled representations can overlap exactly. The retained I/Q file can reveal the digital ambiguity, but it cannot unmix unknown external sources without additional assumptions. I would preserve the filter state, sample-clock measurement and calibrated amplitude response together with every purported in-band detection, so the later investigator can examine which analogue origin hypotheses remain open.

In this operational measurand examination of Question 022, the decisive claim is that insufficient anti-alias rejection allows distant out-of-band signals to be folded into the displayed baseband. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: sampling rate cannot undo a narrow analogue passband. A converter may satisfy a Nyquist sampling criterion for the desired digital bandwidth while the preceding amplifier or track-and-

Copyright 2026, James M. Atkinson

hold has already attenuated or distorted that same signal. Suppose a 200-megasample-per-second converter is preceded by an analogue response that is 3 dB down at 60 megahertz. A 70-megahertz component lies below the 100-megahertz real-sampling Nyquist frequency, but it cannot be assumed to have unity amplitude merely because the sampling rate admits it. The analogue transfer magnitude, phase and slew performance require calibration. Harmonics of a short pulse may be attenuated unevenly, producing a longer apparent envelope. A reconstruction algorithm cannot distinguish this deterministic bandwidth shaping from a source envelope without independent knowledge of the front end. Test representative transients at the input reference plane, including strong neighbouring signals. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The Nyquist condition constrains the spectral content admitted to sampling, not merely the highest frequency printed on a receiver's tuning display. An ADC operating at a suitable nominal sample rate may still produce a misleading baseband signal if its analogue front end passes energy outside the band for which the anti-alias response was designed. For a real sampler, frequencies separated by integer multiples of the sampling frequency can fold to the same discrete-time frequency. A particularly important trial injects a strong out-of-band tone that ought to be suppressed, then changes the sampling rate by a controlled amount. A folded artefact moves predictably with that change; a genuine in-band emission does not obey the same alias trajectory. The examiner should retain the anti-alias filter's measured transition band, stopband attenuation

Copyright 2026, James M. Atkinson

and behaviour under large blockers. Numerical reconstruction cannot identify which analogue frequency produced a digital alias when the necessary pre-sampling discrimination was absent. Accordingly, the laboratory record for Question 022 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. Shannon's information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, an sdr samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous output, an average over

Copyright 2026, James M. Atkinson

admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A sampler cannot distinguish two analogue tones whose frequencies differ by an integer multiple of its sampling rate from samples alone. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. I would therefore attach the uncertainty analysis to the *operational definition* itself instead of printing an unexplained confidence interval beside the most appealing trace.

A further, separately testable aspect of an sdr samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation concerns front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth. The proposed challenge would be map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. The decision is conditional upon the observed result, with particular attention to nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. The competing account remains an actual in-band emitter and a higher nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. An out-of-band carrier that folds into the sampled band may appear numerically identical to an in-band emission. Dr Turing, I pass the floor for the question of what auxiliary measurements would distinguish them.

Copyright 2026, James M. Atkinson

Alan Mathison Turing | Peer question 5 to Claude Elwood Shannon

Claude Elwood Shannon, I should like to examine what the recorded data actually preserve when an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. The physical input and the retained numerical array are not interchangeable things. A successful sample-retention audit cannot distinguish a rejected analogue event from true radio silence. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth would invalidate the preferred account, and which aspect of map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates would make that negative result independently repeatable?

Claude Elwood Shannon | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the

Copyright 2026, James M. Atkinson

actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 022, the specific physical candidate is analogue amplitude roll-off, aperture response, filter group delay, and uncontrolled alias-band admission. The unresolved physical pathway is material: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. The retained record permits a conditional claim about front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, but cannot alone resolve nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. I propose separating acquired information from model-dependent reconstruction. A successful sample-retention audit cannot distinguish a rejected analogue event from true radio silence. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input

Copyright 2026, James M. Atkinson

or omitted by the acquisition policy. The discriminating record would include front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth and a fresh trial in which the operator map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. If that trial demonstrates an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 4: An anti-alias filter must be assessed over all folds relevant to the investigated band rather than only at its nominal corner.

The combined anti-alias filter and converter form a frequency-dependent system, not a catalogue of independent parts. A sharp nominal filter can introduce phase distortion and ringing into short bursts; an apparently generous analogue bandwidth can admit interfering power that exhausts converter headroom. I would model the whole chain, including source impedance, gain compression, filter skirts and the sample-and-hold aperture response. With a swept calibrated tone, the investigator can measure the alias map and identify frequencies whose outputs coincide inside the analysis band. That map should be repeated at several input powers to reveal nonlinear effects that a small-signal transfer function misses. If a firmware update changes the digital channeliser, it will not alter the ambiguity created at the ADC, but it may change how the ambiguity is displayed. The source record must separate analogue admissibility from downstream numerical selectivity.

In this information retention examination of Question 022, the decisive claim is that an anti-alias filter must be assessed over all folds relevant to the investigated band rather than only at its nominal corner. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: sampling rate cannot undo a narrow analogue passband. A converter may satisfy a Nyquist sampling criterion for the desired digital bandwidth while the preceding amplifier or track-and-hold has already attenuated or distorted that same signal. Suppose a 200-

Copyright 2026, James M. Atkinson

megasample-per-second converter is preceded by an analogue response that is 3 dB down at 60 megahertz. A 70-megahertz component lies below the 100-megahertz real-sampling Nyquist frequency, but it cannot be assumed to have unity amplitude merely because the sampling rate admits it. The analogue transfer magnitude, phase and slew performance require calibration. Harmonics of a short pulse may be attenuated unevenly, producing a longer apparent envelope. A reconstruction algorithm cannot distinguish this deterministic bandwidth shaping from a source envelope without independent knowledge of the front end. Test representative transients at the input reference plane, including strong neighbouring signals. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. The scientific point of an anti-alias filter must be assessed over all folds relevant to the investigated band rather than only at its nominal corner. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions

Copyright 2026, James M. Atkinson

repeatedly show an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. A distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. The issue becomes especially sharp because an actual in-band emitter and a higher nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the

Copyright 2026, James M. Atkinson

proposed case, a sampler cannot distinguish two analogue tones whose frequencies differ by an integer multiple of its sampling rate from samples alone. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. Rejection has to be assessed at each relevant alias fold, including filter transitions and strong blockers. Dr Deming, I invite your challenge to a qualification procedure based on one convenient test tone.

W. Edwards Deming | Peer question 6 to Hendrik Wade Bode

I thank you, Hendrik Wade Bode, for distinguishing measurement from attribution, but the observation is that a distant strong carrier appears folded inside the monitored baseband although the visible spectrum looks internally consistent. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a sampler cannot distinguish two analogue tones whose frequencies differ by an integer multiple of its sampling rate from samples alone. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station on one day but fails after the instrument has been reconfigured? A nominal sample rate characterises a discrete-time operation and does not certify a preceding analogue transfer function. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 022, the specific physical candidate is analogue amplitude roll-off, aperture response, filter group delay, and uncontrolled alias-band admission. The unresolved physical pathway is material: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. The retained record permits a conditional claim about front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, but cannot alone resolve nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a sampler cannot distinguish two analogue tones whose frequencies differ by an integer multiple of its sampling rate from samples alone. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. A nominal sample rate

Copyright 2026, James M. Atkinson

characterises a discrete-time operation and does not certify a preceding analogue transfer function. Its bearing on the dispute can be evaluated through the predicted response, namely an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station. Because an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins, the procedure map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match state which analogue zones were excluded experimentally before claiming an in-band emission, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. An aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 5: A successful sample-retention audit cannot distinguish a rejected analogue event from true radio silence.

A declaration that the sampling rate is sufficient must specify the intended error event. The failure may be an undetected short burst, a false in-band tone created by aliasing, or an amplitude bias near the filter transition. Each requires a different validation statistic. I would stratify trials by the interfering signal's frequency, amplitude and temporal occupancy, then estimate how often the chosen detector misclassifies the analogue origin. Testing only nominally in-band tones would be incapable of establishing rejection of a strong out-of-band service. If the investigator chooses the most impressive frequency from a broad exploratory sweep, the resulting apparent rejection margin needs independent replication. Confidence intervals must also accommodate correlated observations from overlapping analysis windows. An effective front end is not certified by counting large numbers of apparently quiet FFT bins; it is certified against defined adversarial and ordinary operating conditions, with their tested limitations clearly disclosed.

In this statistical inference examination of Question 022, the decisive claim is that a successful sample-retention audit cannot distinguish a rejected analogue event from true radio silence. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: sampling rate cannot undo a narrow analogue passband. A converter may satisfy a Nyquist sampling criterion for

Copyright 2026, James M. Atkinson

the desired digital bandwidth while the preceding amplifier or track-and-hold has already attenuated or distorted that same signal. Suppose a 200-megasample-per-second converter is preceded by an analogue response that is 3 dB down at 60 megahertz. A 70-megahertz component lies below the 100-megahertz real-sampling Nyquist frequency, but it cannot be assumed to have unity amplitude merely because the sampling rate admits it. The analogue transfer magnitude, phase and slew performance require calibration. Harmonics of a short pulse may be attenuated unevenly, producing a longer apparent envelope. A reconstruction algorithm cannot distinguish this deterministic bandwidth shaping from a source envelope without independent knowledge of the front end. Test representative transients at the input reference plane, including strong neighbouring signals. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. A successful sample-retention audit cannot distinguish a rejected analogue event from true radio silence. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to map the analogue transfer function with a synthesised out-of-band sweep while

Copyright 2026, James M. Atkinson

repeating under alternate preselection and sample rates, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say state which analogue zones were excluded experimentally before claiming an in-band emission, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. An SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that an actual in-band emitter and a higher nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. One could stratify the experiment by

Copyright 2026, James M. Atkinson

nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated rf station, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a sampler cannot distinguish two analogue tones whose frequencies differ by an integer multiple of its sampling rate from samples alone, is not an estimate of any actual investigation. Preserving every digital sample cannot tell us whether the analogue prefilter suppressed a brief event. Sir Karl, the floor is yours to test what such a negative finding can establish.

Sir Karl Raimund Popper | Peer question 7 to Walter Andrew Shewhart

Walter Andrew Shewhart, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise state which analogue zones were excluded experimentally before claiming an in-band emission? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. The converter input may have frequency-dependent gain and phase even where digitiser throughput is adequate. Please connect front-end amplitude and phase response, alias frequency, stop-band attenuation

Copyright 2026, James M. Atkinson

and analogue input bandwidth with a declared detection threshold and the measurement exposure. If the experiment map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later. Would you also state what observed change in front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth would invalidate the preferred account, and which aspect of map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates would make that negative result independently repeatable?

Walter Andrew Shewhart | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 022, the specific physical candidate is analogue amplitude roll-off, aperture response, filter group delay, and uncontrolled alias-band admission. The unresolved physical pathway is material: An actual in-band emitter and a higher Nyquist-

Copyright 2026, James M. Atkinson

zone alias can occupy the same discrete-time frequency without identical analogue origins. The retained record permits a conditional claim about front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth, but cannot alone resolve nyquist sampling conditions depend on the admitted analogue spectrum, not merely on the digital clock setting. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. The converter input may have frequency-dependent gain and phase even where digitiser throughput is adequate. I would use the observations of front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates, not an assertion based on the operator's impression of a quiet display. If it yields an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station, we may describe a conditional exclusion of the challenged

Copyright 2026, James M. Atkinson

mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since an actual in-band emitter and a higher nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to state which analogue zones were excluded experimentally before claiming an in-band emission, with the untested physical possibilities made visible.

Harry Nyquist, Cross-Peer Question to Edwin Howard Armstrong: Dr Armstrong, suppose the acquisition clock supplies thirty-five million samples per second, yet a transmitter at 110.950 MHz appears at the 5.950 MHz sampled coordinate. An investigator sees a strong single spectral line and declares a local 5.950 MHz emitter. What experiment distinguishes a genuinely admitted analogue signal from a remote out-of-band source that survives imperfect preselection? How would you prevent the filtering experiment itself from changing gain and therefore confusing the attribution?

Edwin Howard Armstrong, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the folding calculation identifies an equivalence class of possible analogue frequencies, not an emitter. First document the exact sample rate, tuner configuration, analogue band edges, mixer states and filter switching chronology. Inject traceable signals at the disputed coordinate and at every

Copyright 2026, James M. Atkinson

plausible folding zone, recording attenuation, return loss and receiver linearity at the input reference plane. A switchable, physically independent preselector can be useful, but its insertion loss must be measured and normalised, and the injection system must not bypass an unintended coupling path. Attenuating the actual 110.950 MHz stimulus while maintaining the desired-band reference provides a stronger falsification test than watching the screen trace alone. Cross-check using a receiver whose analogue conversion plan maps the competing candidates to different output coordinates. A vanished line after installing a filter does not, by itself, prove the identity or location of the emitter; it establishes behaviour under a controlled change. I respectfully pass the floor to Dr Bode for a question about stopband characterisation.

Claude Elwood Shannon, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, a laboratory cites its sampling theorem but supplies only a single anti-alias-filter corner frequency. The front end has nonlinear active stages and poor rejection in an untested Nyquist zone; a 1,098.633 Hz Fourier grid gives a persuasive-looking narrow line. Which transfer characteristics must be shown before the digital frequency coordinate can be used to exclude an out-of-band cause, and how should an uncertainty budget treat the ambiguity?

Hendrik Wade Bode, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, a passband corner is not a stopband specification. Obtain the complex analogue transfer function, including rejection versus frequency, component tolerance, temperature, gain state, impedance mismatch, and high-level behaviour. Injection tests should traverse analogue frequency intervals that fold into the alleged line, and should cover realistic blocker

Copyright 2026, James M. Atkinson

powers, harmonics, and intermodulation products. The 1,098.633 Hz quantity is a bin spacing computed from a sample rate and transform length; it does not certify the analogue frequency response or prove statistical independence between overlapping records. A narrow displayed peak can therefore be precise in the coordinate system of the sampler yet ambiguous as to its analogue parent frequency. Treat any unmeasured fold as an unresolved alternative hypothesis, not as a small symmetric error bar that could be added in quadrature. Explicitly separate calibrated amplitude uncertainty from structural ambiguity about source identity. I respectfully pass the floor to Dr Shewhart for a challenge concerning an apparently silent observation.

John Wilder Tukey, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, the operator reports hundreds of spectral visits without a detection, but the analogue path has an unverified frequency-response notch and the records cover only 2.36 percent of the nominal elapsed interval. May this negative result be described as evidence that the searched transmitter was absent, or must the experiment be redesigned so that non-observation remains interpretable?

Walter Andrew Shewhart, Cross-Peer Answer to John Wilder Tukey: Dr Tukey, this is a problem of measurement opportunity before it is a problem of statistical significance. A valid negative test requires a demonstrated detection probability for the specified signal, at the specified input frequency, duty cycle, amplitude and blocker condition. The receiver must be challenged in precisely the gain and preselector state used during collection, with time-stamped reference injections and independent checks of sample continuity. Four point seven five eight seconds of admitted

Copyright 2026, James M. Atkinson

observations across a 201.30-second nominal span do not license claims about the unsampled intervals. A notch can make a perfectly stored FFT sequence blind to an active source. Assign separate status to intervals where the instrument is demonstrably sensitive, intervals where sensitivity is untested, and intervals where it has actually failed. Report the provenance of any model for event arrival time and correlation between visits; do not infer independent Bernoulli trials merely from the number of displayed frames. I respectfully pass the floor to Dr Hartley to address a converter limitation that may coexist with aliasing.

Richard Wesley Hamming, Cross-Peer Question to Ralph Vinton Lyon Hartley: Dr Hartley, consider the illustrative 275 MHz input observed with 1.74 picoseconds of rms aperture jitter. A calculated ideal jitter limit of about 50.44 dB seems to imply only a handful of reliable amplitude bits, yet the selected 9 MS/s processing rate advertises a much narrower discrete spectrum. How would you distinguish analogue bandwidth, sampling-clock sensitivity, nominal converter bits and genuinely measured effective resolution?

Ralph Vinton Lyon Hartley, Cross-Peer Answer to Richard Wesley Hamming: Dr Hamming, the relevant frequency in the idealised jitter relation is the analogue sinusoid presented to the sampling aperture, not the apparent alias coordinate after sampling. At 275 MHz, a 1.74-ps time error changes sampled amplitude more than the same error at a low-frequency input; the approximately 50.44-dB result is a modelled noise limit for a particular jitter assumption, not an ENOB certificate. Converter harmonic distortion, input-network phase error, front-end noise, blocking and clock correlation may all reduce achieved performance. Conversely, narrowband coherent processing

Copyright 2026, James M. Atkinson

may improve detection of a tone without increasing the instantaneous information content or nominal bit depth of each sample. Characterise the complete analogue passband and clock phase-noise integration, measure actual SINAD over the relevant frequency and signal-level grid, and retain unprocessed acquisition records. I respectfully return the discussion token to Dr Atkinson for the moderator's synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of limits imposed by the analogue front-end when sampling rate is superficially sufficient has established a point which the specialist must not overlook. The receiver records digitised spectral or transient data from a physically band-limited converter input; it does not, merely by drawing a clear trace, give direct access to the rejected, attenuated, phase-distorted, or overloaded components before sampling. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, A nominal sample rate characterises a discrete-time operation and does not certify a preceding analogue transfer function. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

The anti-alias filter is a physical boundary, not a mathematical annotation placed on an FFT plot after sampling. A tone originating outside the admitted frequency range can fold to a perfectly plausible in-band coordinate when attenuation is insufficient, and an internal spur can occupy

Copyright 2026, James M. Atkinson

the same coordinate. The elementary alias formula supplies candidate locations but says nothing about which corresponding analogue frequencies were present. To test the asserted origin, the examiner must characterise rejection over the relevant stopband, vary the sampling frequency where practicable and check whether the observed feature moves according to the predicted fold. I thank the contributors for insisting that a sampled spectrum cannot be interpreted without the preceding analogue transfer. The result should identify the aliases excluded by measured attenuation, not assume that every bright spectral bin represents an in-band source. Any remaining alternative should be recorded with its possible analogue frequency range and the physical conditions under which it could evade the filter.

The sampled feature is compatible with an alias of an out-of-band signal, but several RF predecessors may map into the same digital bin. The measured anti-alias rejection mask and challenge results must be preserved with the spectrum. The more useful outcome is a discriminating protocol: Map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. In applying it, the examiner must retain all readings supporting front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth and identify the physical plane to which the measurements refer. At the outset of the investigation, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation; that circumstance makes the alternative mechanism material, specifically an actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency

Copyright 2026, James M. Atkinson

without identical analogue origins. A result approaching an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated RF station may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore state which analogue zones were excluded experimentally before claiming an in-band emission. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

An anti-alias assurance statement concerns the physically excluded input bands under demonstrated operating conditions. It should not imply that an apparent baseband feature uniquely identifies its unobserved radio-frequency predecessor. The decisive experiment is concrete: Map the analogue transfer function with a synthesised out-of-band sweep while repeating under alternate preselection and sample rates. In conducting it, the examiner must explicitly retain front-end amplitude and phase response, alias frequency, stop-band attenuation and analogue input bandwidth. If the outcome matches the stated prediction, an aliased interference feature moves according to a sampling-fold relation when the sample rate changes, unlike a true calibrated rf station, the supported conclusion concerns that test domain. An alternative remains: An actual in-band emitter and a higher Nyquist-zone alias can occupy the same discrete-time frequency without identical analogue origins. I thank the contributors

Copyright 2026, James M. Atkinson

for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 022

Application 01. Alias-location prediction and its non-unique inverse

In the illustrative 022.01 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. For an actual sampling frequency f_s = 35 MHz and analogue input f_i = 110.950 MHz, the nearest-replica folding rule gives $f_a = |f_i - \text{round}(f_i/f_s)f_s|$ = 5.950 MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. The 5.950-MHz alias is a sampled coordinate only. Confirm which analogue Nyquist zone actually contributed by swept, calibrated input injection and independent preselection before attributing an emitter.

Application 02. Filter or cable rejection referred to a physical input

In the illustrative 022.02 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. For an admitted input P_i = -49 dBm and separately measured loss L = 30 dB, the linear prediction is $P_o = P_i - L$ = -79 dBm. In SI power this becomes 10^((-79 − 30)/10) = 1.26e-11 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. The 1.26×10^{-11} W conversion assumes -79 dBm at the stated matched reference plane. An attenuation value does not establish stopband protection at every possible folding frequency.

Copyright 2026, James M. Atkinson

Application 03. Cascade gain and observed headroom

In the illustrative 022.03 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. A first amplifier contributes G_1 = 15 dB, an intentional attenuation contributes G_2 = -4 dB, and a later stage contributes G_3 = 17 dB. The small-signal sum is 15 + (-4) + 17 = 28 dB. For P_i = -74 dBm, the ideal output is P_o = -46 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The -46 dBm estimate applies only to a linear cascade. Record each intermediate stage level and check blocker-induced compression before using the overall gain as a sensitivity certificate.

Application 04. Thermal reference noise in a declared measurement bandwidth

In the illustrative 022.04 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. Take the equivalent noise bandwidth B = 2,250 Hz and calibrated noise figure NF = 3.05 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF$ = -137.43 dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The -137.43 dBm value is the integrated thermal-reference estimate for 2,250 Hz ENBW at 290 K; it neither includes out-of-band alias noise nor establishes the actual environmental noise floor.

Application 05. Group delay from a local phase-versus-frequency slope

In the illustrative 022.05 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. Across a local frequency step $\Delta f = 0.90$ MHz, suppose unwrapped transmission phase changes by $\Delta\varphi = -0.410$ rad. The finite-difference group-delay estimate is $\tau g \approx -\Delta\varphi/(2\pi\Delta f) = 72.504$ ns. This is an average local slope. Dispersive responses require a finer phase sweep, a consistent unwrapping method and uncertainty treatment before extrapolating transient arrival times. The 72.504 ns figure is a local finite-difference group-delay estimate. Its uncertainty and possible phase-wrapping error must be assessed before any transient arrival-time reconstruction.

Application 06. Frequency-bin spacing versus independent information

In the illustrative 022.06 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. With sampled bandwidth $f_s = 9$ MS/s and $N = 8{,}192$ transform samples, the discrete-frequency grid is $\Delta f = f_s/N = 1098.633$ Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. The 1,098.633 Hz quantity is a discrete Fourier-bin spacing, not a guarantee of independent

Copyright 2026, James M. Atkinson

resolution, temporal event capture or adequate analogue anti-alias suppression.

Application 07. The frequency dependence of aperture-jitter-limited SNR

In the illustrative 022.07 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. At sinusoidal input frequency f = 275 MHz with uncorrelated rms aperture jitter σ_t = 1.74 ps, the idealised jitter-imposed ceiling is $SNR_j = -20 \log_{10}(2\pi f \sigma_t)$ = 50.44 dB. A common clock source may correlate errors across parallel ADC channels, so treating their outputs as independent for noise cancellation would need an additional experiment. Converter nonlinearity and thermal noise can make actual performance worse. The 50.44 dB result is an idealised jitter-related SNR ceiling at the true 275 MHz analogue input. It cannot be inferred from a lower-frequency alias bin or used as a converter ENOB certificate.

Application 08. Combined and expanded measurement uncertainty

In the illustrative 022.08 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. For independent standard-uncertainty contributions 0.52, 0.54 and 0.31 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.52^2 + 0.54^2 + 0.31^2)}$ = 0.811 units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c$ = 1.622 units. The 0.811-unit standard and 1.622-unit expanded uncertainties require independent, same-unit inputs and the

Copyright 2026, James M. Atkinson

declared k = 2. Correlated errors or untested analogue zones remain separate qualifications.

Application 09. Observed exposure fraction of a channel scanner

In the illustrative 022.09 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. Let the channel be observed on n = 366 valid visits, each lasting d = 13 ms, with revisit spacing R = 0.55 s. Valid exposure is nd/1000 = 4.758 s across the nominal interval nR = 201.30 s. The observed fraction of elapsed time is therefore 2.36%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. The 4.758 seconds of valid exposure represent about 2.36 percent of the 201.30-second nominal span. This duty fraction limits a negative finding and supplies no emitter-occupancy estimate.

Application 10. Gain allocation and blocker headroom

In the illustrative 022.10 test, an SDR samples rapidly enough for the intended instantaneous passband but uses an analogue input network with poorly measured out-of-band attenuation. Assume a calibrated digital full-scale equivalent of -10 dBm, a blocker applied at -40 dBm, and net analogue gain 27 dB. The projected converter input is -13 dBm and remaining margin is -10 − (-13) = 3 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. The three-decibel projected converter headroom is a small-signal estimate. Strong out-of-band blockers, instantaneous crest factor

and upstream saturation may invalidate it even where the screen stays below full scale.

QUESTION 023

Copyright 2026, James M. Atkinson

How can saturation and recovery effects create false pulse histories?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 023 asks: How can saturation and recovery effects create false pulse histories? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is the false chronology that can result from analogue overload and recovery memory. Our primary observation is clipped, delayed, or spurious bursts after a high-power input event; by contrast, what remains unseen is the input waveform during overload and the settling state of upstream capacitors and control loops. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Overload memory can counterfeit multiple events. An amplifier or limiter can remain disturbed after a strong pulse has departed. The resulting baseline shift, automatic-gain recovery or filter ringing can cross an event

Copyright 2026, James M. Atkinson

detector’s threshold more than once. If a recovery constant is 2 milliseconds, the envelope of a simple first-order relaxation falls to about 37 per cent of its initial deviation after 2 milliseconds and about 5 per cent after 6 milliseconds; actual receiver recovery may involve several nonlinear states. Apparent secondary pulses at those delays should therefore be challenged with controlled strong-signal injections while monitoring gain-control registers and the analogue output. A detector’s count of threshold crossings is not automatically a count of separate radiation events. Report dead time, clipping intervals, pre-trigger data and the precise criterion by which separate pulse episodes were declared. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns clipped, delayed, or spurious bursts after a high-power input event; it is not interchangeable with the input waveform during overload and the settling state of upstream capacitors and control loops. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is stepped overdrive with calibrated recovery-time logging and a second independent low-gain path. A claim drawn from that comparison has to carry its actual uncertainties: compression onset, overload duration, recovery constant, minimum resolvable inter-event gap. An amplifier can retain memory of a previous strong signal through bias networks and stored charge. Automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission. Transient clipping can resemble a sequence of pulses after filtering and windowing

Copyright 2026, James M. Atkinson

even if the input contained only one event. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Principal contribution 1: An amplifier can retain memory of a previous strong signal through bias networks and stored charge.

A receiver can continue making a signal after its input has stopped because energy remains stored in tuned circuits and control networks. A large blocker might drive a limiter into compression, charge coupling capacitors or force automatic gain reduction. When that blocker disappears, a ringing IF filter or recovering bias network can create several transient maxima even though no new RF burst entered the aerial. I would challenge the receiver with one precisely gated high-power pulse and measure the output through a controlled, source-confirmed silent interval. The sequence should be repeated with a shielded termination, then with the antenna and cable attached, to distinguish internal recovery from external multipath. An amplitude-dependent tail would be particularly important, because an impulse response measured at a tiny signal level cannot characterise a saturated stage. We should not interpret a cluster of digital pulse detections as multiple emitters before testing the instrument's physical memory.

In this physical path examination of Question 023, the decisive claim is that an amplifier can retain memory of a previous strong signal through bias networks and stored charge. Overload introduces memory into a receiver that is absent from a simple steady-state gain figure. A high-power transient may drive an amplifier, detector or automatic-gain controller into a state which remains abnormal after the inducing carrier has departed. A quiet display during that interval cannot be interpreted as a quiet RF environment, because the instrument may be temporarily insensitive. Recovery must therefore be characterised as a function of the preceding

Copyright 2026, James M. Atkinson

blocker amplitude, duration and signal history, not by a single nominal settling-time specification. A useful falsification proceeds from the actual controversy: overload memory can counterfeit multiple events. An amplifier or limiter can remain disturbed after a strong pulse has departed. The resulting baseline shift, automatic-gain recovery or filter ringing can cross an event detector's threshold more than once. If a recovery constant is 2 milliseconds, the envelope of a simple first-order relaxation falls to about 37 per cent of its initial deviation after 2 milliseconds and about 5 per cent after 6 milliseconds; actual receiver recovery may involve several nonlinear states. Apparent secondary pulses at those delays should therefore be challenged with controlled strong-signal injections while monitoring gain-control registers and the analogue output. A detector's count of threshold crossings is not automatically a count of separate radiation events. Report dead time, clipping intervals, pre-trigger data and the precise criterion by which separate pulse episodes were declared. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Inject a stepped, time-limited blocker while a calibrated weak test tone remains present. Record the onset of compression, the last saturated sample and the return of the weak tone to a specified detection probability. Repeat over several blocker lengths and with automatic gain control enabled and disabled. Fit a simple exponential only if the measured recovery supports it; multi-rate or hysteretic behaviour should be reported as such. The capture should include state-change telemetry and the location of every acquisition gap. I would take P1dB, overload pulse duration, gain-control

Copyright 2026, James M. Atkinson

time constant, settling curve and minimum separable event gap as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: An amplifier can retain memory of a previous strong signal through bias networks and stored charge. A response consistent with a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. A nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by bias-network settling and

Copyright 2026, James M. Atkinson

automatic gain-control memory can imitate delayed rf events or conceal genuinely present weak energy, and measure their behaviour separately before reconnecting the assembled system. Armstrong's receiver engineering points to actual conversion products and oscillation conditions rather than abstract spectral indications; the crucial question is where the energy first appears. It is therefore material to establish P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap rather than infer them from a single scalar output. The limiting test is concrete: Apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. If the intervention produces a recovery artefact follows the overload event and changes with receiver bias or agc settings, even with the weak test signal held constant, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret the waterfall contains delayed echoes and an apparently silent interval following the blocker as a new transmitter before challenging the most economical instrumental explanation. Amplifier bias networks can retain the history of a strong input after the visible carrier has disappeared. Professor Tukey, please take the floor and scrutinise whether our event selection wrongly labels recovery artefacts as transmissions.

John Wilder Tukey | Peer question 1 to Edwin Howard Armstrong

Edwin Howard Armstrong, may I test the exact physical inference in your account of a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the

Copyright 2026, James M. Atkinson

subsequent recovery interval? The proposed mechanism appears plausible only if changes after apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control are compared with a stable reference condition. An amplifier can retain memory of a previous strong signal through bias networks and stored charge. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap which would settle that narrower claim, rather than a visual impression of improvement.

Edwin Howard Armstrong | Immediate answer to John Wilder Tukey

Dr Tukey, the apparent disappearance of the weak signal cannot be attributed to the transmitter unless the receiver has demonstrated sensitivity throughout the period. I would keep an independent low-gain reference path active while inducing overload on the main channel. The reference would show whether the candidate emission continues while the principal receiver recovers, and its own limitations must also be disclosed. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder.

Copyright 2026, James M. Atkinson

The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 023, the specific physical candidate is saturation of gain stages, automatic gain-control hang time, amplifier slew limiting, and converter clipping. The unresolved physical pathway is material: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. The retained record permits a conditional claim about P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, but cannot alone resolve an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. An amplifier can retain memory of a previous strong signal through bias

Copyright 2026, James M. Atkinson

networks and stored charge. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control, and only a response matching a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Edwin Howard Armstrong

I appreciate your explanation, Edwin Howard Armstrong. How would your conclusion survive a deliberately independent test of the waterfall contains delayed echoes and an apparently silent interval following the blocker? A second receiver might share more of the supposed evidence

Copyright 2026, James M. Atkinson

than its separate enclosure suggests. Automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap and document which differences remain unexplained? Would you also state what observed change in P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap would invalidate the preferred account, and which aspect of apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control would make that negative result independently repeatable?

Edwin Howard Armstrong | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 023, the specific physical candidate is saturation of gain stages, automatic

Copyright 2026, James M. Atkinson

gain-control hang time, amplifier slew limiting, and converter clipping. The unresolved physical pathway is material: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. The retained record permits a conditional claim about P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, but cannot alone resolve an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. Automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy; I would challenge it with apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. Two responses consistent with a recovery

Copyright 2026, James M. Atkinson

artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, bias-network settling and automatic gain-control memory can imitate delayed rf events or conceal genuinely present weak energy. A discordant measurement would then be interpreted by tracing that difference through P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 2: Automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission.

The investigator should preserve the order and duration of the events that appear to change the receiver's state. A chart may show an intense pulse followed by two weaker indications and a temporarily depressed floor. Such a pattern could be produced by a legitimate transmission followed by gain-control recovery. I would define a reference stimulus sequence and obtain many runs with different blocker widths and gaps, recording gain state, clipping flags, and any reset or hold-off commands. Then construct a control chart for recovery time and residual transient amplitude, allowing for systematic variation with temperature. If a new anomaly appears only during one mode transition, it should not be averaged together with settled-state operation. Equally, a perfectly repeatable recovery defect is still a defect rather than proof of an external second transmission. The report should retain raw traces for all runs, including the ones whose inconvenient behaviour contradicts the operator's initial interpretation.

In this control and stability examination of Question 023, the decisive claim is that automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: overload memory can counterfeit multiple events. An amplifier or limiter can remain disturbed after a strong pulse has departed. The resulting baseline shift, automatic-

Copyright 2026, James M. Atkinson

gain recovery or filter ringing can cross an event detector's threshold more than once. If a recovery constant is 2 milliseconds, the envelope of a simple first-order relaxation falls to about 37 per cent of its initial deviation after 2 milliseconds and about 5 per cent after 6 milliseconds; actual receiver recovery may involve several nonlinear states. Apparent secondary pulses at those delays should therefore be challenged with controlled strong-signal injections while monitoring gain-control registers and the analogue output. A detector's count of threshold crossings is not automatically a count of separate radiation events. Report dead time, clipping intervals, pre-trigger data and the precise criterion by which separate pulse episodes were declared. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by the waterfall contains delayed echoes and an apparently silent interval following the blocker. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For

Copyright 2026, James M. Atkinson

each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, the waterfall contains delayed echoes and an apparently silent interval following the blocker. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. The order would be time-stamped and should include invalid intervals, receiver recovery, and any gain or filter settling rather than treating silence during transition as evidence of a silent source. Our central rival is specific: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. This predicts a response which should be tested against a recovery artefact follows the overload event and changes with receiver bias or agc settings, even with the weak test signal held constant. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements

Copyright 2026, James M. Atkinson

discarded during retuning. Where an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample, the correct claim must name the operational states and the evidence available in each. The interval during which automatic gain control recovers is a separate exposure condition, not an invisible pause. Dr Pearson, I invite you to question any detection-rate estimate that neglects it.

Egon Sharpe Pearson | Peer question 3 to Walter Andrew Shewhart

Walter Andrew Shewhart, your calibration argument invites a question about reference planes, especially because an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. The reference stimulus and the unknown emission need not occupy the same physical regime. Transient clipping can resemble a sequence of pulses after filtering and windowing even if the input contained only one event. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When the waterfall contains delayed echoes and an apparently silent interval following the blocker, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 023, the specific physical candidate is saturation of gain stages, automatic gain-control hang time, amplifier slew limiting, and converter clipping. The unresolved physical pathway is material: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. The retained record permits a conditional claim about P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, but cannot alone resolve an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap. Transient clipping can resemble a sequence of pulses after filtering and windowing even if the input contained only one event. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be apply reproducible blocker

Copyright 2026, James M. Atkinson

pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control, with before-and-after values of P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap. If the instrument behaves as predicted, then a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. The waterfall contains delayed echoes and an apparently silent interval following the blocker. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Walter Andrew Shewhart

There is an inferential difficulty, Walter Andrew Shewhart: bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. The population of admissible observations needs to be fixed before any confidence argument. In this situation, an overload record is a nonlinear history-

Copyright 2026, James M. Atkinson

dependent measurement, not a stable linear gain correction applied to the current sample. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Testing only steady-state compression omits the timing and history dependence that controls forensic interpretation. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap would invalidate the preferred account, and which aspect of apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control would make that negative result independently repeatable?

Walter Andrew Shewhart | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 023, the specific physical candidate is saturation of gain stages, automatic gain-control hang time, amplifier slew limiting, and

Copyright 2026, James M. Atkinson

converter clipping. The unresolved physical pathway is material: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. The retained record permits a conditional claim about P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, but cannot alone resolve an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because the waterfall contains delayed echoes and an apparently silent interval following the blocker. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Testing only steady-state compression omits the timing and history dependence that controls forensic interpretation. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy; its prediction should be recorded alongside a recovery artefact follows

Copyright 2026, James M. Atkinson

the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. An overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, five nominal time constants reduce a first-order residue to about 0.67 per cent, without proving that an actual multistage receiver follows one exponential. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal contribution 3: Transient clipping can resemble a sequence of pulses after filtering and windowing even if the input contained only one event.

The underlying system includes control loops that react to the measured amplitude. When a strong input triggers attenuation, the resulting digital record partly describes the control law rather than simply the incident radio field. A weak transmission during the hold interval may vanish, and the spectrum's later return may look like the commencement of an independent emission. I would model the gain controller as a state-dependent filter, identifying trigger threshold, attack time, release time and any history-dependent hysteresis. The experiment should deliver the same weak test pulse at systematically varied delays after a strong blocker, with a second independent receiver monitoring the test source. If detections fail only during known recovery states, one has evidence of measurement blindness. The distinct physical claim that the emitter fell silent would require external corroboration. Event counters without controller-state history can turn a continuous physical signal into a fragmented narrative of apparently separate bursts.

In this operational measurand examination of Question 023, the decisive claim is that transient clipping can resemble a sequence of pulses after filtering and windowing even if the input contained only one event. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: overload memory can counterfeit multiple events. An amplifier or limiter can remain disturbed after a strong pulse has departed. The resulting baseline shift, automatic-

Copyright 2026, James M. Atkinson

gain recovery or filter ringing can cross an event detector’s threshold more than once. If a recovery constant is 2 milliseconds, the envelope of a simple first-order relaxation falls to about 37 per cent of its initial deviation after 2 milliseconds and about 5 per cent after 6 milliseconds; actual receiver recovery may involve several nonlinear states. Apparent secondary pulses at those delays should therefore be challenged with controlled strong-signal injections while monitoring gain-control registers and the analogue output. A detector’s count of threshold crossings is not automatically a count of separate radiation events. Report dead time, clipping intervals, pre-trigger data and the precise criterion by which separate pulse episodes were declared. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Saturation creates an asymmetric history because recovery after an overload can outlast the waveform that caused it. Limiting amplifiers, bias networks, automatic-gain-control loops and converters can each produce a different settling signature. A strong pulsed blocker may therefore be followed by apparent weak pulses or a temporary absence of normally detectable signals, even though neither phenomenon existed at the antenna port. Establish a reference pulse train with independently known amplitude and spacing, then increase a separate blocker until the suspect receiver enters compression. Observe the timing of baseline recovery, gain-control telemetry and the reappearance of the weak witness. Repeat with manual gain and, where available, a preselector that attenuates the blocker before the nonlinear stage. A detector's reported pulse timestamps are trustworthy only over the time interval in which analogue and digital states were valid.

Copyright 2026, James M. Atkinson

Data acquired during overload and recovery should be flagged, not quietly counted as ordinary negative observations. Accordingly, the laboratory record for Question 023 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. An overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. Wiener's feedback perspective questions how an adaptive controller changes the distribution of the observations it subsequently presents as independent evidence. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a

Copyright 2026, James M. Atkinson

latent physical parameter. The illustrative case is instructive: Five nominal time constants reduce a first-order residue to about 0.67 per cent, without proving that an actual multistage receiver follows one exponential. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. Clipped peaks can reappear as a procession of apparent pulses after filtering and windowing. Dr Turing, I pass the floor to examine what evidence distinguishes a generated pattern from the received waveform.

Alan Mathison Turing | Peer question 5 to Norbert Wiener

Norbert Wiener, I should like to examine what the recorded data actually preserve when a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. The physical input and the retained numerical array are not interchangeable things. A separate path operated below overload can disclose whether the apparent later pulse existed externally. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap would

Copyright 2026, James M. Atkinson

invalidate the preferred account, and which aspect of apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control would make that negative result independently repeatable?

Norbert Wiener | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 023, the specific physical candidate is saturation of gain stages, automatic gain-control hang time, amplifier slew limiting, and converter clipping. The unresolved physical pathway is material: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. The retained record permits a conditional claim about P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, but cannot alone resolve an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire

Copyright 2026, James M. Atkinson

analogue environment. An overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. I propose separating acquired information from model-dependent reconstruction. A separate path operated below overload can disclose whether the apparent later pulse existed externally. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap and a fresh trial in which the operator apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. If that trial demonstrates a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-

Copyright 2026, James M. Atkinson

gain channel as a control. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 4: Testing only steady-state compression omits the timing and history dependence that controls forensic interpretation.

There are at least two relevant time constants in the apparent pulse history: those of the RF and IF signal path and those of the receiver's control or supply networks. A phase response measured on a network analyser may characterise small-signal filter delay but say little about recovery from overload. I would investigate the latter with controlled power steps and a recorded waveform at several accessible internal nodes. If the preselector remains linear but a subsequent amplifier exhibits baseline wander after saturation, the source of delayed maxima can be localised. A separate bias-network recovery may imitate an emitter's change in duty cycle, while residual stored energy in a filter can produce decaying oscillations. The physical sequence of component states matters; a single global 'dead time' number can conceal multiple mechanisms with distinct dependencies on blocker frequency, amplitude and duration. Traceability of those measurements should determine which historical input claims the system can support.

In this information retention examination of Question 023, the decisive claim is that testing only steady-state compression omits the timing and history dependence that controls forensic interpretation. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: overload memory can counterfeit multiple events. An amplifier or limiter can remain disturbed after a strong pulse has departed. The resulting baseline shift, automatic-gain recovery or filter ringing can

Copyright 2026, James M. Atkinson

cross an event detector's threshold more than once. If a recovery constant is 2 milliseconds, the envelope of a simple first-order relaxation falls to about 37 per cent of its initial deviation after 2 milliseconds and about 5 per cent after 6 milliseconds; actual receiver recovery may involve several nonlinear states. Apparent secondary pulses at those delays should therefore be challenged with controlled strong-signal injections while monitoring gain-control registers and the analogue output. A detector's count of threshold crossings is not automatically a count of separate radiation events. Report dead time, clipping intervals, pre-trigger data and the precise criterion by which separate pulse episodes were declared. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. The scientific point of testing only steady-state compression omits the timing and history dependence that controls forensic interpretation. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions

Copyright 2026, James M. Atkinson

repeatedly show a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. The waterfall contains delayed echoes and an apparently silent interval following the blocker. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. The issue becomes especially sharp because bias-network settling and automatic gain-control memory can imitate delayed rf events or conceal genuinely present weak energy. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the proposed case, five nominal time constants

Copyright 2026, James M. Atkinson

reduce a first-order residue to about 0.67 per cent, without proving that an actual multistage receiver follows one exponential. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A further, separately testable aspect of a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval concerns P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap. The proposed challenge would be apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. The decision is conditional upon the observed result, with particular attention to an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. The competing account remains bias-network settling and automatic gain-control memory can imitate delayed rf events or conceal genuinely present weak energy. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. A steady-state compression measurement misses the recovery trajectory of a stage with stored charge. Dr Deming, please take the floor and demand the transient test that would expose it.

W. Edwards Deming | Peer question 6 to Hendrik Wade Bode

I thank you, Hendrik Wade Bode, for distinguishing measurement from attribution, but the observation is that the waterfall contains delayed echoes and an apparently silent interval following the blocker. A

Copyright 2026, James M. Atkinson

forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: five nominal time constants reduce a first-order residue to about 0.67 per cent, without proving that an actual multistage receiver follows one exponential. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant on one day but fails after the instrument has been reconfigured? An amplifier can retain memory of a previous strong signal through bias networks and stored charge. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Hendrik Wade Bode | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 023, the specific physical candidate is saturation of gain stages, automatic gain-control hang time, amplifier slew limiting, and converter clipping. The unresolved physical pathway is material: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present

Copyright 2026, James M. Atkinson

weak energy. The retained record permits a conditional claim about P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, but cannot alone resolve an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, five nominal time constants reduce a first-order residue to about 0.67 per cent, without proving that an actual multistage receiver follows one exponential. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. An amplifier can retain memory of a previous strong signal through bias networks and stored charge. Its bearing on the dispute can be evaluated through the predicted response, namely a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant. Because bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy, the procedure apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match

Copyright 2026, James M. Atkinson

limit any negative finding to the periods when the instrument was demonstrably recovered and sensitive, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. A recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 5: A separate path operated below overload can disclose whether the apparent later pulse existed externally.

A negative search conducted during recovery is not equivalent to a negative search with the receiver fully responsive. The operational population must therefore distinguish valid exposure windows from intervals in which the front end is known to be saturated or recovering. Suppose the test pulse is present on an independent channel but missed by the survey receiver for the first twenty milliseconds after a blocker. The finding should estimate detection performance conditional on time since overload, not dilute the deficiency by averaging across many undisturbed seconds. Confidence calculations must acknowledge correlations among repeated tests that share the same temperature, supply and bias conditions. I would also test alternative explanations: an external pulsed source with similar timing, a cable reflection and an overloaded detector algorithm. A clear report states which explanation was challenged and at what power. It does not equate a visually orderly timeline with a fully observed electromagnetic history.

In this statistical inference examination of Question 023, the decisive claim is that a separate path operated below overload can disclose whether the apparent later pulse existed externally. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: overload memory can counterfeit multiple events. An amplifier or limiter can remain disturbed after a strong

Copyright 2026, James M. Atkinson

pulse has departed. The resulting baseline shift, automatic-gain recovery or filter ringing can cross an event detector's threshold more than once. If a recovery constant is 2 milliseconds, the envelope of a simple first-order relaxation falls to about 37 per cent of its initial deviation after 2 milliseconds and about 5 per cent after 6 milliseconds; actual receiver recovery may involve several nonlinear states. Apparent secondary pulses at those delays should therefore be challenged with controlled strong-signal injections while monitoring gain-control registers and the analogue output. A detector's count of threshold crossings is not automatically a count of separate radiation events. Report dead time, clipping intervals, pre-trigger data and the precise criterion by which separate pulse episodes were declared. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. A separate path operated below overload can disclose whether the apparent later pulse existed externally. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control, should be accompanied by a

Copyright 2026, James M. Atkinson

second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say limit any negative finding to the periods when the instrument was demonstrably recovered and sensitive, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman’s statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that bias-network settling and automatic gain-control memory can imitate delayed rf events or conceal genuinely present weak energy. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate

Copyright 2026, James M. Atkinson

sensitivity for each physically meaningful regime. The relevant quantities are P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from a recovery artefact follows the overload event and changes with receiver bias or agc settings, even with the weak test signal held constant, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, five nominal time constants reduce a first-order residue to about 0.67 per cent, without proving that an actual multistage receiver follows one exponential, is not an estimate of any actual investigation. An unsaturated parallel path may reveal whether a later burst existed outside the overloaded receiver. Sir Karl, I invite you to probe the limits of that independent corroboration.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise limit any negative finding to the periods when the instrument was demonstrably recovered and sensitive? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission. Please connect P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap with a declared detection threshold and the measurement exposure. If the experiment apply reproducible

Copyright 2026, James M. Atkinson

blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 023, the specific physical candidate is saturation of gain stages, automatic gain-control hang time, amplifier slew limiting, and converter clipping. The unresolved physical pathway is material: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. The retained record permits a conditional claim about P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap, but cannot alone resolve an overload record is a nonlinear history-dependent measurement, not a stable linear gain correction applied to the current sample. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Automatic gain control may suppress weak emissions while recovering from a legitimate strong transmission. I would use the observations of P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control, not an assertion based on the operator's impression of a quiet display. If it yields a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since bias-network settling and automatic gain-control memory can imitate delayed rf events or conceal genuinely present weak energy, an intervention

Copyright 2026, James M. Atkinson

that leaves both alternatives consistent does not settle their difference. The result should be limited to limit any negative finding to the periods when the instrument was demonstrably recovered and sensitive, with the untested physical possibilities made visible.

Edwin Howard Armstrong, Cross-Peer Question to Norbert Wiener: Dr Wiener, one strong emission strikes the front-end amplifier and produces a flat-topped converter waveform followed by a decaying shoulder. An automated classifier marks the plateau and the shoulder as separate transmissions from distinct devices. What test would distinguish a real second event from the receiver's internal recovery trajectory, and why is a reconstructed waveform not equivalent to a preserved measurement?

Norbert Wiener, Cross-Peer Answer to Edwin Howard Armstrong: Dr Armstrong, a saturated mapping is many-to-one: diverse analogue peaks yield the same maximum converter code. The lost input cannot be uniquely recovered by a smooth interpolation, even when its surrounding samples form an attractive curve. Make controlled blocker-on, blocker-off and stepped-level measurements with a known termination or RF source, preserving raw sample codes, gain commands, protection events, timestamps and the state of any automatic control loop. Compare the response with an independent low-gain receiver path that demonstrably remains linear and shares a calibrated time reference. If the trailing shoulder follows the instrument's recovery trajectory when the second alleged emitter is absent, it is evidence of an instrumental alternative, not a confirmed second transmission. An exponential fit may summarise an observed decay but cannot identify the overrange amplitude or prove that

Copyright 2026, James M. Atkinson

an independent burst never occurred. I respectfully pass the floor to Dr Bode for a challenge concerning recovery intervals.

Hendrik Wade Bode, Cross-Peer Question to Jerzy Neyman: Dr Neyman, suppose an isolated laboratory pulse appears to recover with a nominal 9 ms time constant. A field operator discards exactly 9 ms after every strong-signal alarm, resumes normal recording and calls all later non-detections conclusive. What statistical and physical conditions must be established before the instrument can again be described as sensitive to a weak signal?

Jerzy Neyman, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, a time constant is not a validated recovery time to a specified error limit. Under a single exponential, the residual at one time constant remains about 36.8 percent of its initial value; a threshold of one percent requires roughly 4.605 time constants, if that model applies. Real front ends can have amplifier saturation, protection-diode charge storage, AGC memory, digital filtering and pipeline latency with different trajectories. Establish a measurable recovery criterion, for example bounded gain error, phase error, spurious response and a known detection probability for the weak challenge signal. Measure its distribution across blocker levels, frequencies, temperatures, gains and repeated trials. A fixed nine-millisecond blanking rule without this challenge offers neither a coverage guarantee nor a justified absence inference. Record censored and recovery intervals explicitly; the statistical analysis must condition on actual receiver sensitivity and not silently count blind samples as valid trials. I respectfully pass the floor to Dr Pearson for a challenge about apparent detection confidence.

Claude Elwood Shannon, Cross-Peer Question to Egon Sharpe Pearson: Dr Pearson, the manuscript’s illustrative fifty-one independent trials each give a

Copyright 2026, James M. Atkinson

stipulated twelve-percent chance of detecting a burst, so it reports approximately 0.00147 probability of missing every trial. But what if the trials all fall within a common overload-recovery interval or a periodic emitter is aligned with the receiver's blind windows? What remains of the impressive numerical probability?

Egon Sharpe Pearson, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the arithmetic may be correct while the inferential model is false. The expression (1 − p) to the power n applies only if there are n valid opportunities and their relevant detection outcomes satisfy the stated independence and probability conditions. Repeating a blind receiver state does not produce fifty-one fresh chances; common overload and periodic scheduling can correlate failures so strongly that the effective number of independent opportunities is much smaller. Distinguish the number of scheduled visits, the number of fully valid sensitive visits, and the number of independent opportunities supported by the acquisition design. Include confidence intervals for any estimated detection probability and predefine the acceptable false-negative risk. Where sensitivity has not been demonstrated, state that the likelihood of a missed event is unquantified rather than presenting the Bernoulli calculation as empirical proof. I respectfully pass the floor to Dr Deming to examine evidential records of the receiver state.

Walter Andrew Shewhart, Cross-Peer Question to W. Edwards Deming: Dr Deming, a field log holds a spectrum waterfall, a 1.125 percent fraction of full-scale codes and a reassuring margin calculated at the converter input. It omits gain-transition times, input-path attenuation and the raw converter stream. How can a later expert separate actual intermittent emissions from

Copyright 2026, James M. Atkinson

hardware recovery artefacts without inventing events or claiming knowledge of signals erased by saturation?

W. Edwards Deming, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, the log does not contain enough information for a unique retrospective reconstruction. Treat the full-scale fraction as evidence that some samples reached an extreme code, not as a measure of lost energy or the number of transmissions. Preserve the original I/Q sequence, sample counters, overload flags, gain settings, calibration identifiers, input attenuator state, filter selection, trigger history and an independently synchronised reference trace. Construct a controlled laboratory reproduction with known strong pulses and weak probes, changing one relevant variable at a time; label the resulting artefact signatures and the range in which the method has actually been validated. A margin computed from nominal gain can coexist with local saturation in an upstream stage or with an unexpected peak crest factor. In the evidential conclusion distinguish confirmed external events, internally reproducible receiver artefacts and unresolved intervals. A missing raw stream must be reported as a limitation, not repaired by retrospective certainty. I respectfully return the discussion token to Dr Atkinson for the moderator's synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of the false chronology that can result from analogue overload and recovery memory has established a point which the specialist must not overlook. The receiver records clipped, delayed, or spurious bursts after a high-power input event; it does not, merely by drawing a clear trace, give direct access to the input waveform during overload and the settling state of upstream capacitors and control loops. A convincing engineering

Copyright 2026, James M. Atkinson

explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, An amplifier can retain memory of a previous strong signal through bias networks and stored charge. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

We must make room for the history of overload. An amplifier driven into compression, an automatic-gain-control loop whose control voltage has not settled, or a detector whose recovery is slow can continue to corrupt observations after a large legitimate transmission has ended. The significant datum is therefore not merely the peak input level but the response trajectory, including settling time and detection recovery for a known weak probe. I thank Professor Wiener for treating the receiver as a dynamic system with state, rather than an instantaneous multiplication of input power by nominal gain. The next experiment must inject a calibrated high-power pulse under controlled conditions, withdraw it, and measure the duration for which the test signal remains distorted or invisible. Repetition at different temperatures and gain settings would identify whether the effect is stable or conditional. Our report must distinguish a genuine absence of external signals from a period during which the instrument was recovering and could not have observed them reliably.

The main receiver was driven into overload by an authorised transmission and did not immediately recover. Measurements made during this unvalidated recovery interval cannot support a negative finding for

Copyright 2026, James M. Atkinson

weak or short events. The more useful outcome is a discriminating protocol: Apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. In applying it, the examiner must retain all readings supporting P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap and identify the physical plane to which the measurements refer. At the outset of the investigation, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval; that circumstance makes the alternative mechanism material, specifically bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. A result approaching a recovery artefact follows the overload event and changes with receiver bias or AGC settings, even with the weak test signal held constant may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore limit any negative finding to the periods when the instrument was demonstrably recovered and sensitive. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

Survey conclusions must exclude intervals in which calibrated sensitivity was lost or unknown. Recovery time is an experimentally determined property of the receiver state and preceding stimulus, not a correction that

Copyright 2026, James M. Atkinson

can be applied retrospectively to absent samples. The decisive experiment is concrete: Apply reproducible blocker pulses, observe recovery under multiple gain settings, and retain a simultaneous low-gain channel as a control. In conducting it, the examiner must explicitly retain P1dB, overload pulse duration, gain-control time constant, settling curve and minimum separable event gap. If the outcome matches the stated prediction, a recovery artefact follows the overload event and changes with receiver bias or agc settings, even with the weak test signal held constant, the supported conclusion concerns that test domain. An alternative remains: Bias-network settling and automatic gain-control memory can imitate delayed RF events or conceal genuinely present weak energy. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 023

Application 01. Clipping extent and an information-preserving statement

In the illustrative 023.01 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. Out of N = 1,778 acquired converter sample instants, K = 20 carry an extreme-code plateau. The directly observed fraction is K/N = 1.125%. It is not the fraction of analogue signal energy lost, because the unknown overrange amplitudes have many possible values. An independent lower-gain recording can bound those amplitudes if its transfer path and time alignment are demonstrated; no interpolation can establish an otherwise unobserved peak uniquely. The 1.125-percent extreme-code fraction quantifies recorded clipping indicators, not energy lost or the number of RF pulses. Report the unobserved overrange amplitudes as indeterminate.

Application 02. First-order recovery envelope after a state change

In the illustrative 023.02 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. If an illustrative recovery follows $A(t) = A_0 \exp(-t/\tau)$, let $A_0 = 1.70$ V and $\tau = 9.00$ ms. At t = 22.50 ms the residual is 1.70e^(−22.50/9.00) = 0.1395 V. Real automatic gain control often has nonlinear or multi-time-constant behaviour, so this exponential is a test model, not a universal reconstruction of the input during overload. The 0.1395 V exponential residual at 22.5 ms is a model prediction, not a validated gain-recovery threshold. Challenge the receiver with a weak probe until specified sensitivity is restored.

Copyright 2026, James M. Atkinson

Application 03. Gain allocation and blocker headroom

In the illustrative 023.03 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. Assume a calibrated digital full-scale equivalent of -9 dBm, a blocker applied at -46 dBm, and net analogue gain 21 dB. The projected converter input is -25 dBm and remaining margin is -9 − (-25) = 16 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. The nominal sixteen-decibel margin is calculated at one reference point under linear gain assumptions. A different upstream stage can saturate, so local peak levels and gain transients require testing.

Application 04. Cascade gain and observed headroom

In the illustrative 023.04 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. A first amplifier contributes G_1 = 16 dB, an intentional attenuation contributes G_2 = -6 dB, and a later stage contributes G_3 = 18 dB. The small-signal sum is 16 + (-6) + 18 = 28 dB. For P_i = -67 dBm, the ideal output is P_o = -39 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The minus-39-dBm cascade result assumes all three stages remain linear. Inspect each interstage node during a high-power pulse before treating the calculated output as a reliable capture limit.

Copyright 2026, James M. Atkinson

Application 05. Group delay from a local phase-versus-frequency slope

In the illustrative 023.05 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. Across a local frequency step Δf = 1.00 MHz, suppose unwrapped transmission phase changes by $\Delta\varphi$ = -0.480 rad. The finite-difference group-delay estimate is $\tau g \approx -\Delta\varphi/(2\pi\Delta f)$ = 76.394 ns. This is an average local slope. Dispersive responses require a finer phase sweep, a consistent unwrapping method and uncertainty treatment before extrapolating transient arrival times. The 76.394 ns phase-slope estimate describes filter group delay, not a direct estimate of overload recovery. Ringing and recovery are separate time-domain effects requiring independent tests.

Application 06. Ideal code step, variance, and full-scale sine SNR

In the illustrative 023.06 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. Taking an ideal N = 15-bit uniform converter across 3.50 V peak-to-peak, one nominal code interval is $\Delta = Vpp/2^N$ = 0.1068 mV. Under the independent uniform-error approximation its rms quantisation error is $\sigma = \Delta/\sqrt{12}$ = 0.0308 mV. The ideal full-scale sinusoidal SNR approximation is 6.02N + 1.76 = 92.06 dB. A coherent low-level waveform may violate the uniform-error assumption; clipping and integral nonlinearity are separate limitations. The 0.1068 mV code step, 0.0308 mV rms ideal quantisation error and 92.06 dB full-scale sinusoidal SNR do not apply to an overrange converter sequence or recovered transient amplitude.

Copyright 2026, James M. Atkinson

Application 07. Opportunity-limited detection under independent visits

In the illustrative 023.07 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. For n = 51 genuinely independent valid observation opportunities, each with stipulated event detection chance p = 0.12, the probability of no detections is $(1 - p)^n$ = 0.00147; its complement is 99.85%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The 0.00147 probability of no detection assumes fifty-one independent, sensitive opportunities, each with p = 0.12. Recovery-blind or synchronised intervals violate those assumptions.

Application 08. Observed exposure fraction of a channel scanner

In the illustrative 023.08 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. Let the channel be observed on n = 373 valid visits, each lasting d = 12 ms, with revisit spacing R = 0.70 s. Valid exposure is nd/1000 = 4.476 s across the nominal interval nR = 261.10 s. The observed fraction of elapsed time is therefore 1.71%, which is receiver coverage, not occupancy of the unvisited intervals. An occupancy percentage based only upon positive visits requires a separate sampling design. The 4.476 seconds of exposure across 261.10 seconds represent about 1.71-percent coverage, not continuous

Copyright 2026, James M. Atkinson

reception. Intervals hidden by overload require an additional sensitivity exclusion.

Application 09. Thermal reference noise in a declared measurement bandwidth

In the illustrative 023.09 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. Take the equivalent noise bandwidth B = 6,000 Hz and calibrated noise figure NF = 3.25 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -132.97$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The -132.97 dBm estimate is thermal-reference noise in 6,000 Hz at 290 K. It cannot describe a clipped signal, strong adjacent blockers or the recovery period after an overload.

Application 10. Combined and expanded measurement uncertainty

In the illustrative 023.10 test, a nearby high-power transmission drives the receiver into overload while a weak intermittent device may transmit during the subsequent recovery interval. For independent standard-uncertainty contributions 0.59, 0.36 and 0.40 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.59^2 + 0.36^2 + 0.40^2)} = 0.799$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c = 1.597$ units. The 0.799-unit combined and 1.597-unit expanded uncertainties presume independent inputs and the stated coverage factor. Unmodelled recovery bias and correlated components must be assessed separately.

QUESTION 024

Copyright 2026, James M. Atkinson

How should differential and integral nonlinearity enter a forensic uncertainty account?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 024 asks: How should differential and integral nonlinearity enter a forensic uncertainty account? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is quantitative uncertainty associated with differential and integral converter nonlinearity. Our primary observation is code-width variation, cumulative transfer error, and distortion of amplitude estimates; by contrast, what remains unseen is the true analogue input amplitude in intervals mapped to biased or missing codes. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Code-transition imperfections deserve a measurement model. Differential nonlinearity measures a code-bin width relative to the ideal least-significant-bit width; integral nonlinearity measures accumulated

Copyright 2026, James M. Atkinson

departure from an ideal reference transfer characteristic under a stated convention. A code that occupies 1.3 ideal least-significant-bit widths has DNL of plus 0.3 LSB, but that number alone does not predict every harmonic artefact or transient distortion. Missing codes, temperature-sensitive transitions and input-dependent conversion errors can defeat an assumed additive-white-quantisation-noise model. Test a coherent sinusoid and a suitably slow precision ramp, respecting drive amplitude, distortion and clock coherence, and retain the observed code histogram. In forensic reconstruction, the digital word is evidence of a converter decision region, not an exact analogue voltage. Uncertainty must identify whether systematic code-boundary structure has been characterised. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns code-width variation, cumulative transfer error, and distortion of amplitude estimates; it is not interchangeable with the true analogue input amplitude in intervals mapped to biased or missing codes. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is slow calibrated ramp or histogram and sine-wave tests across operating temperature and frequency. A claim drawn from that comparison has to carry its actual uncertainties: DNL in LSB, INL in LSB, missing codes, residual calibration error, and amplitude uncertainty. Differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step. Integral nonlinearity describes a transfer

Copyright 2026, James M. Atkinson

deviation relative to a specified reference straight line, whose fitting convention matters. Under the usual non-negative code-width definition, a DNL of minus one LSB denotes a zero-width missing code; values below minus one LSB are not physically meaningful within that model. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal contribution 1: Differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step.

A code-density plot and a high-frequency spectral measurement interrogate different aspects of an analogue-to-digital converter. Differential nonlinearity describes deviations of individual code widths from the ideal least-significant-bit interval; integral nonlinearity describes the accumulated departure of a transfer characteristic from a specified reference straight line. Neither quantity alone determines a receiver's dynamic distortion during an intermittent RF burst. A missing code, for example, can corrupt small-amplitude estimates even when a full-scale sinusoidal test produces a relatively respectable summary specification. I would demand the adopted endpoint or best-fit INL convention, test-source distribution and code histogram, together with a dynamic sine-wave characterisation. When the suspected signal dwells near a threshold, code-width irregularity can bias the probability of crossing that threshold. The detective task is to distinguish a physical change in input amplitude from a converter decision boundary that is not uniformly spaced. This requires calibrated input levels and raw code access, not merely an FFT screenshot.

In this physical path examination of Question 024, the decisive claim is that differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step. Differential nonlinearity and integral nonlinearity describe different departures from an ideal converter transfer. DNL concerns the width of an individual code interval relative to one ideal LSB; INL describes transition deviations from a declared reference line. Both depend upon the measurement convention and operating conditions. A

Copyright 2026, James M. Atkinson

visually regular sine-wave spectrum cannot establish that the ADC has no missing codes, and a single worst-case DNL figure cannot establish broadband spurious-free performance. The panel must distinguish static code-density evidence from dynamic spectral tests that excite different error mechanisms. A useful falsification proceeds from the actual controversy: code-transition imperfections deserve a measurement model. Differential nonlinearity measures a code-bin width relative to the ideal least-significant-bit width; integral nonlinearity measures accumulated departure from an ideal reference transfer characteristic under a stated convention. A code that occupies 1.3 ideal least-significant-bit widths has DNL of plus 0.3 LSB, but that number alone does not predict every harmonic artefact or transient distortion. Missing codes, temperature-sensitive transitions and input-dependent conversion errors can defeat an assumed additive-white-quantisation-noise model. Test a coherent sinusoid and a suitably slow precision ramp, respecting drive amplitude, distortion and clock coherence, and retain the observed code histogram. In forensic reconstruction, the digital word is evidence of a converter decision region, not an exact analogue voltage. Uncertainty must identify whether systematic code-boundary structure has been characterised. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Use a well-characterised slow ramp or dithered sine for a code-transition histogram, checking the excitation uniformity and population of rarely visited codes. Compute DNL under the selected transition convention, then calculate INL relative to both endpoint and best-fit lines, stating which will

Copyright 2026, James M. Atkinson

enter the uncertainty budget. Repeat with a high-frequency sine and controlled temperature changes. Observe whether spurs or missing-code signatures persist when input amplitude and sampling phase change. I would take LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: Differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step. A response consistent with large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. An ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. A meaningful

Copyright 2026, James M. Atkinson

bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level, and measure their behaviour separately before reconnecting the assembled system. Bennett's communications engineering perspective distinguishes stochastic noise models from deterministic signal-dependent converter errors and distortion products. It is therefore material to establish LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals rather than infer them from a single scalar output. The limiting test is concrete: Acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. If the intervention produces large dnl alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit as a new transmitter before challenging the most economical instrumental explanation. Differential nonlinearity concerns individual code-bin widths; it cannot be inferred from a tidy aggregate signal-to-noise ratio. Professor Tukey, I invite you to examine whether the reported histogram is representative of converter operation.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Peer question 1 to William Ralph Bennett

William R. Bennett, may I test the exact physical inference in your account of an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits? The proposed mechanism appears plausible only if changes after acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions are compared with a stable reference condition. Differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals which would settle that narrower claim, rather than a visual impression of improvement.

William Ralph Bennett | Immediate answer to John Wilder Tukey

Dr Tukey, unequal code widths may occur without a single missing code, and a missing code can be hidden by a poorly populated histogram. I would first qualify the stimulus and count statistics, then specify the reference line before quoting INL. Dynamic SFDR must be assessed separately; it cannot be inferred simply by multiplying an isolated code-width error by the converter nominal resolution. The correct counterfactual begins with two models capable of producing

Copyright 2026, James M. Atkinson

the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 024, the specific physical candidate is DNL variations from ideal step width and INL departures from the fitted or endpoint transfer line. The unresolved physical pathway is material: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The retained record permits a conditional claim about LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals, but cannot alone resolve dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals; they should be retained as instrument readings with calibration information,

Copyright 2026, James M. Atkinson

rather than displayed only as a difference image. Differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions, and only a response matching large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to William Ralph Bennett

I appreciate your explanation, William R. Bennett. How would your conclusion survive a deliberately independent test of some codes are noticeably wider than others, and a best-fit transfer curve differs from an

Copyright 2026, James M. Atkinson

endpoint fit? A second receiver might share more of the supposed evidence than its separate enclosure suggests. Integral nonlinearity describes a transfer deviation relative to a specified reference straight line, whose fitting convention matters. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals and document which differences remain unexplained? Would you also state what observed change in LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals would invalidate the preferred account, and which aspect of acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions would make that negative result independently repeatable?

William Ralph Bennett | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its

Copyright 2026, James M. Atkinson

pathway breaks a material common cause. For Question 024, the specific physical candidate is DNL variations from ideal step width and INL departures from the fitted or endpoint transfer line. The unresolved physical pathway is material: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The retained record permits a conditional claim about LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals, but cannot alone resolve dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. Integral nonlinearity describes a transfer deviation relative to a specified reference straight line, whose fitting convention matters. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level; I would challenge it with acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus

Copyright 2026, James M. Atkinson

amplitude with documented reference-line conventions. Two responses consistent with large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. A discordant measurement would then be interpreted by tracing that difference through LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 2: Integral nonlinearity describes a transfer deviation relative to a specified reference straight line, whose fitting convention matters.

The process used to measure linearity is itself vulnerable to uncontrolled variation. A code-density experiment driven by a sine wave assumes a known amplitude distribution; an imperfect stimulus with harmonic distortion can influence the estimated widths of ADC codes. I would inspect the source purity and synchronisation first, then repeat the histogram under amplitude and offset changes so that suspicious code regions are challenged in more than one way. Temperature, reference-voltage drift and sampling-clock state should be logged because the transfer curve may change across the survey. A control chart for measured INL extrema can disclose gradual degradation, but it should not disguise a single missing-code defect by averaging away the affected codes. The proper record identifies test conditions and whether a repair changed the converter or merely the test procedure. Statistical repeatability is evidence about the test process; it does not make an incorrectly modelled stimulus a faithful calibration standard.

In this control and stability examination of Question 024, the decisive claim is that integral nonlinearity describes a transfer deviation relative to a specified reference straight line, whose fitting convention matters. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: code-transition imperfections deserve a measurement model. Differential

Copyright 2026, James M. Atkinson

nonlinearity measures a code-bin width relative to the ideal least-significant-bit width; integral nonlinearity measures accumulated departure from an ideal reference transfer characteristic under a stated convention. A code that occupies 1.3 ideal least-significant-bit widths has DNL of plus 0.3 LSB, but that number alone does not predict every harmonic artefact or transient distortion. Missing codes, temperature-sensitive transitions and input-dependent conversion errors can defeat an assumed additive-white-quantisation-noise model. Test a coherent sinusoid and a suitably slow precision ramp, respecting drive amplitude, distortion and clock coherence, and retain the observed code histogram. In forensic reconstruction, the digital word is evidence of a converter decision region, not an exact analogue voltage. Uncertainty must identify whether systematic code-boundary structure has been characterised. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note integral

Copyright 2026, James M. Atkinson

nonlinearity describes a transfer deviation relative to a specified reference straight line, whose fitting convention matters. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Shewhart’s process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. This predicts a response which should be tested against large dnl alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp. An operator may be tempted to interpolate a line

Copyright 2026, James M. Atkinson

between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements discarded during retuning. Where dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments, the correct claim must name the operational states and the evidence available in each. My proposed acceptance test would archive the entire control sequence and the independent witness measurement before any data-dependent threshold adjustment.

A further, separately testable aspect of an adc undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits concerns LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals. The proposed challenge would be acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. The decision is conditional upon the observed result, with particular attention to dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. The competing account remains differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. Integral nonlinearity depends upon the defined reference straight line and measurement regime. Dr Pearson, the floor is yours to challenge a comparison that changes the reference between tests.

Copyright 2026, James M. Atkinson

Egon Sharpe Pearson | Peer question 3 to Walter Andrew Shewhart

Walter Andrew Shewhart, your calibration argument invites a question about reference planes, especially because dNL and INL are code-domain static specifications whose dynamic spectral consequences require separate experiments. The reference stimulus and the unknown emission need not occupy the same physical regime. Under the usual non-negative code-width definition, a DNL of minus one LSB denotes a zero-width missing code; values below minus one LSB are not physically meaningful within that model. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Walter Andrew Shewhart | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 024, the specific physical candidate is DNL variations from ideal step width

Copyright 2026, James M. Atkinson

and INL departures from the fitted or endpoint transfer line. The unresolved physical pathway is material: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The retained record permits a conditional claim about LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals, but cannot alone resolve dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals. Under the usual non-negative code-width definition, a DNL of minus one LSB denotes a zero-width missing code; values below minus one LSB are not physically meaningful within that model. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions, with before-and-after values of LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals. If the instrument behaves as predicted, then large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp; if it does

Copyright 2026, James M. Atkinson

not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. Some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Walter Andrew Shewhart

There is an inferential difficulty, Walter Andrew Shewhart: differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The population of admissible observations needs to be fixed before any confidence argument. In this situation, dNL and INL are code-domain static specifications whose dynamic spectral consequences require separate experiments. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. Calibration against one tone does not necessarily reveal code-dependent distortion at another amplitude or phase. What is your unit of independent observation, and how will you treat censored records or

Copyright 2026, James M. Atkinson

correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals would invalidate the preferred account, and which aspect of acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions would make that negative result independently repeatable?

Walter Andrew Shewhart | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 024, the specific physical candidate is DNL variations from ideal step width and INL departures from the fitted or endpoint transfer line. The unresolved physical pathway is material: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The retained record permits a conditional claim about LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and

Copyright 2026, James M. Atkinson

calibration residuals, but cannot alone resolve dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit. I would distinguish trials selected in advance from those added after an unexpected peak appeared. Calibration against one tone does not necessarily reveal code-dependent distortion at another amplitude or phase. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level; its prediction should be recorded alongside large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

Copyright 2026, James M. Atkinson

The quantity has to remain attached to the physical operation defining it. DNL and INL are code-domain static specifications whose dynamic spectral consequences require separate experiments. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, at 12 bits over a 2 v span the ideal step is about 488.3 microvolts; a code-width error must be expressed against that particular step. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 3: Under the usual non-negative code-width definition, a DNL of minus one LSB denotes a zero-width missing code; values below minus one LSB are not physically meaningful within that model.

A numerical sampling rate says how frequently the converter reports codes; it does not guarantee that adjacent codes represent equal analogue increments. If the conversion function is y=Q(x), then the digital sequence is simultaneously shaped by the analogue waveform and Q's thresholds. Reconstructing a continuous signal from the output requires knowledge of those thresholds and a signal model; oversampling alone cannot make an absent code reappear. I would compare a static ramp with a carefully scaled sine challenge, because dynamic converter errors can also arise from input bandwidth and aperture effects. For an RF receiver the gain state ahead of Q matters as much as the nominal converter bit count. A weak pulse falling within a troublesome region of the transfer may be distorted while a larger pulse remains acceptable. Measurements should therefore be tied to the relevant portion of the code range and the event amplitudes encountered in the field.

In this operational measurand examination of Question 024, the decisive claim is that a DNL at or below minus one LSB means a code may be absent in an ideal monotonic histogram interpretation. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: code-transition imperfections deserve a measurement model. Differential nonlinearity measures a code-bin width relative to the ideal least-significant-bit width; integral nonlinearity measures accumulated departure from an ideal reference transfer

Copyright 2026, James M. Atkinson

characteristic under a stated convention. A code that occupies 1.3 ideal least-significant-bit widths has DNL of plus 0.3 LSB, but that number alone does not predict every harmonic artefact or transient distortion. Missing codes, temperature-sensitive transitions and input-dependent conversion errors can defeat an assumed additive-white-quantisation-noise model. Test a coherent sinusoid and a suitably slow precision ramp, respecting drive amplitude, distortion and clock coherence, and retain the observed code histogram. In forensic reconstruction, the digital word is evidence of a converter decision region, not an exact analogue voltage. Uncertainty must identify whether systematic code-boundary structure has been characterised. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Differential nonlinearity describes the departure of an individual converter code width from the ideal quantisation step, while integral nonlinearity concerns the accumulated transfer deviation from the chosen reference line. Neither specification alone describes dynamic performance under a modulated RF input. A stuck or missing code may produce non-Gaussian amplitude errors that survive averaging, especially when a weak signal occupies a limited voltage range and the analogue noise does not sufficiently dither its transitions. An honest uncertainty account must therefore distinguish static code-domain calibration from spectral spurious-free dynamic range, effective number of bits and operating temperature. Sweep a precisely characterised low-distortion source through the relevant input range, retaining the raw codes rather than only averaged FFT magnitudes. The observation that a spectral feature changes as input level

Copyright 2026, James M. Atkinson

crosses a particular code boundary can implicate converter behaviour without establishing that the feature was absent from the external field. Accordingly, the laboratory record for Question 024 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. DNL and INL are code-domain static specifications whose dynamic spectral consequences require separate experiments. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, an adc undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: At

Copyright 2026, James M. Atkinson

12 bits over a 2 V span the ideal step is about 488.3 microvolts; a code-width error must be expressed against that particular step. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. I would therefore attach the uncertainty analysis to the *operational definition* itself instead of printing an unexplained confidence interval beside the most appealing trace.

A more precise objection comes from Harry Nyquist and the finite observation aperture in an adc undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. For that reason, record LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. A missing code demands a carefully specified DNL measurement, not a guess

Copyright 2026, James M. Atkinson

from a clipped spectrum. Dr Turing, please take the floor and ask what the sample archive reveals about unvisited code regions.

Alan Mathison Turing | Peer question 5 to Harry Nyquist

Harry Nyquist, I should like to examine what the recorded data actually preserve when an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. The physical input and the retained numerical array are not interchangeable things. Uncertainty must include both deterministic correction residuals and variable operating-condition effects. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals would invalidate the preferred account, and which aspect of acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions would make that negative result independently repeatable?

Copyright 2026, James M. Atkinson

Harry Nyquist | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 024, the specific physical candidate is DNL variations from ideal step width and INL departures from the fitted or endpoint transfer line. The unresolved physical pathway is material: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The retained record permits a conditional claim about LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals, but cannot alone resolve dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. DNL and INL are code-domain static specifications whose dynamic spectral consequences require separate experiments. I propose separating acquired information from model-dependent reconstruction. Uncertainty must include both

Copyright 2026, James M. Atkinson

deterministic correction residuals and variable operating-condition effects. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals and a fresh trial in which the operator acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. If that trial demonstrates large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 4: Calibration against one tone does not necessarily reveal code-dependent distortion at another amplitude or phase.

The information discarded by nonuniform quantisation is not always represented by one average error number. A converter with distorted code boundaries may bias some waveforms systematically, and two different analogue trajectories can map to identical recorded code strings. A static correction table can compensate the mean transfer relationship if it is known and stable, but cannot recover distinctions already collapsed into a single code. I would examine whether the proposed correction alters only the amplitude estimate or also the downstream detection threshold and alarm history. If the table is derived from the same suspicious record, its apparent success risks circularity. Retain the raw uncorrected codes and the independently measured transfer characterisation, so an examiner can reproduce the correction or contest its applicability. A beautiful straight line after digital linearisation should not be mistaken for proof that the physical input has been restored uniquely.

In this information retention examination of Question 024, the decisive claim is that calibration against one tone does not necessarily reveal code-dependent distortion at another amplitude or phase. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: code-transition imperfections deserve a measurement model. Differential nonlinearity measures a code-bin width relative to the ideal least-significant-bit width; integral nonlinearity measures accumulated departure from an ideal reference transfer characteristic under a stated

Copyright 2026, James M. Atkinson

convention. A code that occupies 1.3 ideal least-significant-bit widths has DNL of plus 0.3 LSB, but that number alone does not predict every harmonic artefact or transient distortion. Missing codes, temperature-sensitive transitions and input-dependent conversion errors can defeat an assumed additive-white-quantisation-noise model. Test a coherent sinusoid and a suitably slow precision ramp, respecting drive amplitude, distortion and clock coherence, and retain the observed code histogram. In forensic reconstruction, the digital word is evidence of a converter decision region, not an exact analogue voltage. Uncertainty must identify whether systematic code-boundary structure has been characterised. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. The scientific point of calibration against one tone does not necessarily reveal code-dependent distortion at another amplitude or phase. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed

Copyright 2026, James M. Atkinson

explanation. If independent sessions repeatedly show large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. Some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit. Shannon's information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. The issue becomes especially sharp because differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and

Copyright 2026, James M. Atkinson

frequency domain actually examined. For the proposed case, at 12 bits over a 2 v span the ideal step is about 488.3 microvolts; a code-width error must be expressed against that particular step. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A more precise objection comes from Claude Elwood Shannon and the finite observation aperture in an adc undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. It is possible to obtain a repeatable numerical output while leaving the operative cause unresolved, particularly when differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. For that reason, record LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals for each accepted exposure and preserve the actual time ordering rather than rearranging snapshots into an apparently continuous account. After acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions, the investigator should document the units, decision threshold and predicted response for each competing explanation. An adverse observation would require revising the measurement model; it should not be silently omitted from the record merely because it contradicts an earlier suspicion. If a unique physical source cannot be distinguished, the conclusion must remain conditional. A single calibration tone may miss nonlinear behaviour under

Copyright 2026, James M. Atkinson

other amplitudes and frequencies. Dr Deming, I invite you to devise a challenge across the relevant code range.

W. Edwards Deming | Peer question 6 to Claude Elwood Shannon

I thank you, Claude Elwood Shannon, for distinguishing measurement from attribution, but the observation is that some codes are noticeably wider than others, and a best-fit transfer curve differs from an endpoint fit. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: at 12 bits over a 2 V span the ideal step is about 488.3 microvolts; a code-width error must be expressed against that particular step. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp on one day but fails after the instrument has been reconfigured? Differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Claude Elwood Shannon | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest

Copyright 2026, James M. Atkinson

establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 024, the specific physical candidate is DNL variations from ideal step width and INL departures from the fitted or endpoint transfer line. The unresolved physical pathway is material: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The retained record permits a conditional claim about LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals, but cannot alone resolve dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, at 12 bits over a 2 V span the ideal step is about 488.3 microvolts; a code-width error must be expressed against that particular step. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. Differential nonlinearity describes the width error of each code bin relative to the nominal one-LSB step. Its bearing on the dispute can be evaluated through the predicted response, namely large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp. Because differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all

Copyright 2026, James M. Atkinson

perturb a reported weak-signal level, the procedure acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match publish both the converter convention and the residual error budget rather than translate one DNL number into a universal spectral claim, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. Large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 5: Uncertainty must include both deterministic correction residuals and variable operating-condition effects.

A confidence statement about DNL or INL must be attached to the chosen definition and measurement population. A single maximum-INL figure hides the shape of the transfer error; two converters with identical maxima can produce very different biases near the decision threshold used for rare-signal detection. I would identify the codes actually visited by representative signals, estimate the uncertainty in their boundaries, and propagate that uncertainty into the reported amplitude or event count. Dependence matters: adjacent code widths share calibration parameters, so treating every bin estimate as an independent draw can exaggerate precision. A comparison between two converter boards should be based on paired stimuli and predeclared tolerances, including temperature and gain-state effects. Where a reference curve was fitted after seeing the test results, disclose the fitting convention. The defensible conclusion concerns verified transfer performance in the tested regime, not an unrestricted declaration that an instrument is accurate.

In this statistical inference examination of Question 024, the decisive claim is that uncertainty must include both deterministic correction residuals and variable operating-condition effects. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: code-transition imperfections deserve a measurement model. Differential nonlinearity

Copyright 2026, James M. Atkinson

measures a code-bin width relative to the ideal least-significant-bit width; integral nonlinearity measures accumulated departure from an ideal reference transfer characteristic under a stated convention. A code that occupies 1.3 ideal least-significant-bit widths has DNL of plus 0.3 LSB, but that number alone does not predict every harmonic artefact or transient distortion. Missing codes, temperature-sensitive transitions and input-dependent conversion errors can defeat an assumed additive-white-quantisation-noise model. Test a coherent sinusoid and a suitably slow precision ramp, respecting drive amplitude, distortion and clock coherence, and retain the observed code histogram. In forensic reconstruction, the digital word is evidence of a converter decision region, not an exact analogue voltage. Uncertainty must identify whether systematic code-boundary structure has been characterised. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. Uncertainty must include both deterministic correction residuals and variable operating-condition effects. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to acquire a controlled

Copyright 2026, James M. Atkinson

histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say publish both the converter convention and the residual error budget rather than translate one DNL number into a universal spectral claim, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. An ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman’s statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a

Copyright 2026, James M. Atkinson

reported weak-signal level. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from large dnl alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, at 12 bits over a 2 v span the ideal step is about 488.3 microvolts; a code-width error must be expressed against that particular step, is not an estimate of any actual investigation. Correction residuals and environmental drift both belong in the uncertainty budget for a code-dependent measurement. Sir Karl, I pass the floor to test the claim that compensation has removed the error.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise publish both the converter convention and the residual error budget rather than translate one DNL number into a universal spectral claim? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Integral nonlinearity describes a transfer deviation relative to a specified reference straight line, whose fitting convention matters. Please connect LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration

Copyright 2026, James M. Atkinson

residuals with a declared detection threshold and the measurement exposure. If the experiment acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 024, the specific physical candidate is DNL variations from ideal step width and INL departures from the fitted or endpoint transfer line. The unresolved physical pathway is material: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. The retained record permits a conditional claim about LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals, but cannot alone resolve dnl and inl are code-domain static specifications whose dynamic spectral consequences require separate experiments. That limitation

Copyright 2026, James M. Atkinson

belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Integral nonlinearity describes a transfer deviation relative to a specified reference straight line, whose fitting convention matters. I would use the observations of LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions, not an assertion based on the operator's impression of a quiet display. If it yields large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since differential code-bin

Copyright 2026, James M. Atkinson

error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to publish both the converter convention and the residual error budget rather than translate one dnl number into a universal spectral claim, with the untested physical possibilities made visible.

William Ralph Bennett, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, a laboratory reports one code at minus 0.27 LSB DNL and then treats a calibrated RMS sine-wave spectrum as if every code had the same transfer uncertainty. The histogram was collected at a single temperature, and the report does not distinguish an endpoint reference from a least-squares transfer line. Which elements of its proposed uncertainty budget are measurable and which require fresh observations? Would a low sample count in one histogram bin alone establish a missing code?

Walter Andrew Shewhart, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, the measured bin width of 0.73 ideal LSB has a defined local meaning only when the stimulus probability density, input noise, bin population, reference step and operating state are documented. Its finite histogram count has sampling uncertainty. The best-fit and endpoint definitions of INL answer different geometrical questions, so their numerical results cannot be silently mixed. Repeat the code-density test across amplitude, temperature and relevant clock conditions; then validate transfer corrections with independently known analogue voltages and a dynamic sine-wave test. An empty bin might reflect inadequate occupancy or stimulus coverage. A missing code demands a sufficiently sensitive

Copyright 2026, James M. Atkinson

demonstration of zero or effectively unobservable width under the stated model. Quantify residual correction uncertainty and correlation instead of adding an unspecified DNL figure as broadband noise. I respectfully pass the floor to Dr Nyquist to examine the code-width boundary.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, the existing heading says that DNL may be at or below minus one LSB. Under the code-width definition DNL equals actual width divided by ideal width, less one. Can a physical code width be negative? If not, what must the treatise say about a zero-width code, nonmonotonic conversion, and apparent extreme estimates caused by test noise?

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, a non-negative code width constrains that form of DNL to values no smaller than minus one LSB. At exactly minus one the width is zero, so a code is absent under the conventional monotonic transfer model. A reported figure below minus one is not an additional degree of missingness; it signals a changed convention, an invalid estimator, uncertain transition ordering, or a model that no longer describes the observed transfer. A nonmonotonic mapping should be characterised by its actual transition history and hysteresis, rather than forced into a negative-width bin. Report the exact transition definition and histogram confidence limits. A static code-density test cannot by itself predict all dynamic harmonic effects at another frequency. I respectfully pass the floor to Dr Neyman to consider dependence between corrections.

John Wilder Tukey, Cross-Peer Question to Jerzy Neyman: Dr Neyman, several code-transition corrections were derived from one voltage reference and one temperature sensor, then combined as independent standard

Copyright 2026, James M. Atkinson

uncertainties. The result is a conveniently small root-sum-square interval. What evidence is needed before the independence assumption is defensible, and what does an unexpectedly large paired-instrument discrepancy actually prove?

Jerzy Neyman, Cross-Peer Answer to John Wilder Tukey: Dr Tukey, shared reference drift and common environmental dependence create covariance terms that do not vanish merely because the spreadsheet uses separate columns. Define the measurement function, sensitivity coefficients, covariance matrix and operating-state distributions. A calibration applied to the transfer curve corrects a recognised bias; its residual standard uncertainty is not the uncorrected bias itself. Use replicated standards, multiple independently routed references where practical, and paired tests to estimate the common components. In the illustrative 1.400 dB contrast, a 0.516 dB standard uncertainty and a ratio near 2.712 are arithmetic, not a universal evidential verdict. A significance or equivalence claim requires the sampling model, decision rule and independently defined criterion. Any untested code region remains a systematic coverage limitation, not a random quantity that can be wished away. I respectfully pass the floor to Dr Bridgman to examine reproducibility.

W. Edwards Deming, Cross-Peer Question to Percy Williams Bridgman: Dr Bridgman, an investigator retains a polished spectrum and a one-number INL specification, but discards the ramp profile, code counts, acquisition firmware and physical reference-plane description. The original waveform is no longer available. Which documentary requirements would allow a second laboratory to test the calibration claim without attributing an unexplained peak to an external source?

Copyright 2026, James M. Atkinson

Percy Williams Bridgman, Cross-Peer Answer to W. Edwards Deming: Dr Deming, the evidential object must include the code-density histogram, original code stream where retained, analogue stimulus probability model, calibration certificates and their uncertainties, full-scale definition, code transition convention, sample-clock settings, temperature, source impedance, preamplifier states and analysis software version. Retain both nominal settings and the observed instrument state. A later laboratory should reproduce the code-width and INL estimates with separate stimulus apparatus, while deliberately varying frequency and level to expose distortion that a static ramp misses. If such foundational records are absent, a single converter-linearity number supports only a limited manufacturer-style description, not retrospective attribution of a disputed spectral component. Keep experimentally established effects separate from model projections and state what observations would contradict the preferred account. I respectfully return the token to Dr Atkinson for the moderator's synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of quantitative uncertainty associated with differential and integral converter nonlinearity has established a point which the specialist must not overlook. The receiver records code-width variation, cumulative transfer error, and distortion of amplitude estimates; it does not, merely by drawing a clear trace, give direct access to the true analogue input amplitude in intervals mapped to biased or missing codes. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, Differential nonlinearity describes the width error of each code bin relative

Copyright 2026, James M. Atkinson

to the nominal one-LSB step. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

The distinction between differential and integral nonlinearity must remain numerically explicit. A code-width anomaly can alter the probability with which a slowly varying input visits individual output codes, whereas accumulated endpoint displacement changes the converter's overall transfer relation. Either can be confused with a physical spectral feature if the raw transfer has not been characterised. I thank the mathematical contributors for requiring a declared full-scale range and bit depth before presenting errors in least-significant-bit units. Code-density measurements require an input stimulus whose amplitude distribution is known well enough to support the proposed inference; the usual idealised sine-wave assumption is not a substitute for test-set validation. A missed code cannot be repaired by increasing the number of samples of the same damaged mapping. The appropriate conclusion is a bounded converter-characterisation result with environmental conditions and uncertainty, not a claim that a visually neat spectrum establishes faithful analogue amplitude recovery.

Measured code widths are unequal and the fitted transfer curve depends upon the chosen reference. These observations establish limited transfer-function properties, not an emitter identity or a universal amplitude error valid at every sampling frequency. The more useful outcome is a discriminating protocol: Acquire a controlled histogram and sine-wave series

Copyright 2026, James M. Atkinson

across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. In applying it, the examiner must retain all readings supporting LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals and identify the physical plane to which the measurements refer. At the outset of the investigation, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits; that circumstance makes the alternative mechanism material, specifically differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. A result approaching large DNL alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore publish both the converter convention and the residual error budget rather than translate one DNL number into a universal spectral claim. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

The converter report should publish the DNL and INL conventions, tested code regions and environmental conditions separately from dynamic distortion metrics. No single code-width number can substitute for an end-to-end spectral performance study. The decisive experiment is concrete:

Copyright 2026, James M. Atkinson

Acquire a controlled histogram and sine-wave series across temperature, input frequency, and stimulus amplitude with documented reference-line conventions. In conducting it, the examiner must explicitly retain LSB size, DNL, endpoint INL, best-fit INL, missing-code count, temperature drift and calibration residuals. If the outcome matches the stated prediction, large dnl alters local code frequency; a missing code may produce no observations under a sufficiently uniform calibration ramp, the supported conclusion concerns that test domain. An alternative remains: Differential code-bin error, integral transfer curvature and genuine analogue amplitude variation can all perturb a reported weak-signal level. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 024

Application 01. Code-bin width under differential nonlinearity

In the illustrative 024.01 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. For an N = 11-bit transfer over 2.20 V, one ideal least-significant-bit interval is Δ = 1.07422 mV. If one measured code has DNL = -0.270 LSB, its effective width is Δ(1 + DNL) = 0.78418 mV. A code-width result needs adequate stimulus uniformity, histogram population and a declared endpoint convention; it does not independently establish whole-transfer integral linearity. The 0.78418 mV width follows from the declared 2.20 V, 11-bit uniform scale and a −0.270 LSB DNL; finite ramp-histogram occupancy and excitation statistics limit its metrological meaning.

Application 02. Voltage-equivalent integral nonlinearity

In the illustrative 024.02 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. Under a specified transfer-line convention, an N = 12-bit ADC spanning 2.50 V has ideal step Δ = 0.61035 mV. A local integral nonlinearity of 0.760 LSB corresponds to 0.46387 mV of analogue-equivalent deviation. The endpoint or best-fit reference line must be declared, as must temperature, code region and input slew rate; otherwise two instruments may report incompatible INL values for the same transfer curve. The 0.46387 mV INL equivalent uses the declared 12-bit, 2.50 V scale; endpoint and best-fit reference conventions cannot be interchanged in an evidential comparison.

Copyright 2026, James M. Atkinson

Application 03. Ideal code step, variance, and full-scale sine SNR

In the illustrative 024.03 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. Taking an ideal N = 13-bit uniform converter across 2.00 V peak-to-peak, one nominal code interval is $\Delta = Vpp/2^N = 0.2441$ mV. Under the independent uniform-error approximation its rms quantisation error is $\sigma = \Delta/\sqrt{12} = 0.0705$ mV. The ideal full-scale sinusoidal SNR approximation is 6.02N + 1.76 = 80.02 dB. A coherent low-level waveform may violate the uniform-error assumption; clipping and integral nonlinearity are separate limitations. The 0.0705 mV RMS error and 80.02 dB ideal full-scale SNR require the usual uniform, uncorrelated quantisation-error model, not guaranteed by a code-dependent transfer defect.

Application 04. Thermal reference noise in a declared measurement bandwidth

In the illustrative 024.04 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. Take the equivalent noise bandwidth B = 3,750 Hz and calibrated noise figure NF = 3.75 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\text{ Hz}) + NF = -134.51$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The −134.51 dBm is the integrated 290 K thermal-reference calculation for 3,750 Hz ENBW with a 3.75 dB noise figure, not the unknown RF emission floor in an interference-rich environment.

Copyright 2026, James M. Atkinson

Application 05. Combined and expanded measurement uncertainty

In the illustrative 024.05 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. For independent standard-uncertainty contributions 0.66, 0.36 and 0.28 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.66^2 + 0.36^2 + 0.28^2)} = 0.802$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c = 1.604$ units. The 0.802-unit root-sum-square standard uncertainty and 1.604-unit k = 2 interval require uncorrelated inputs expressed in compatible units; shared calibration drift adds covariance.

Application 06. Clipping extent and an information-preserving statement

In the illustrative 024.06 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. Out of N = 1,862 acquired converter sample instants, K = 66 carry an extreme-code plateau. The directly observed fraction is K/N = 3.545%. It is not the fraction of analogue signal energy lost, because the unknown overrange amplitudes have many possible values. An independent lower-gain recording can bound those amplitudes if its transfer path and time alignment are demonstrated; no interpolation can establish an otherwise unobserved peak uniquely. The 3.545-percent extreme-code fraction identifies sample instants at the converter limit, not an energy-loss fraction or a measured amplitude beyond the rail.

Copyright 2026, James M. Atkinson

Application 07. Cascade gain and observed headroom

In the illustrative 024.07 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. A first amplifier contributes G_1 = 9 dB, an intentional attenuation contributes G_2 = -4 dB, and a later stage contributes G_3 = 21 dB. The small-signal sum is 9 + (-4) + 21 = 26 dB. For P_i = -71 dBm, the ideal output is P_o = -45 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The calculated 26 dB cascade gain and −45 dBm output presume linear operation at each stage; code-domain DNL cannot rule out overload in an analogue amplifier.

Application 08. Difference between two instruments relative to stated uncertainty

In the illustrative 024.08 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. The paired instrument contrast is Δ = 1.400 dB. Set independent standard uncertainties u_1 = 0.300 dB and u_2 = 0.420 dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)}$ = 0.516 dB, giving the dimensionless ratio Δ/uΔ = 2.712. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The 2.712 dimensionless contrast is not itself an equivalence decision. Declare correlation, coverage, comparison threshold and the intended decision procedure before drawing an instrument-comparability conclusion.

Copyright 2026, James M. Atkinson

Application 09. Family-wise probability when many candidates are searched

In the illustrative 024.09 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. If each of M = 495 independent pre-specified search opportunities has false-alarm probability α = 0.0009, the probability of one or more false positives is 1 − (1 − α)^M = 0.35962, or 35.96%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. The 35.96-percent family-wise false-positive probability applies only to 495 prespecified, independent opportunities; overlapping FFT frames and after-the-fact selection alter the model.

Application 10. Frequency-bin spacing versus independent information

In the illustrative 024.10 test, an ADC undergoes a slow ramp and code-density test while the investigative receiver is assessed for amplitude accuracy near its full-scale limits. With sampled bandwidth f_s = 11 MS/s and N = 4,096 transform samples, the discrete-frequency grid is $\Delta f = f_s/N$ = 2685.547 Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. The 2,685.547 Hz FFT grid spacing follows from 11 MS/s divided by 4,096, but cannot verify code-transition integrity or establish independent spectral resolution.

QUESTION 025

Copyright 2026, James M. Atkinson

What is lost when a converter clips, and what remains inferable?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 025 asks: What is lost when a converter clips, and what remains inferable? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is the boundary between still-inferable facts and permanently lost amplitude information after clipping. Our primary observation is digital samples held at a converter limit during a high-amplitude event; by contrast, what remains unseen is the original peaks, detailed envelope, and possibly the original spectral content of saturated intervals. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Clipping destroys amplitude ordering beyond the rail. If a converter’s positive full-scale input is 1.0 volt and two analogue peaks reach 1.2 and 2.5 volts, both may be represented by the same maximum digital code. Their

Copyright 2026, James M. Atkinson

different amplitudes are not recoverable from that saturated code alone. Timing of threshold entry, unsaturated leading edges or measurements from an independent attenuated path may still convey useful information, provided the front-end and recovery behaviour are modelled. Some clipping can also introduce spectral regrowth that resembles wideband emissions, so reprocessing the clipped samples cannot prove that the reconstructed out-of-band content existed at the antenna. Preserve raw words and overload flags, record the fraction of saturated samples, and repeat with attenuation where possible. A forensic statement should distinguish demonstrated overload from conjectures about the missing peak waveform. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns digital samples held at a converter limit during a high-amplitude event; it is not interchangeable with the original peaks, detailed envelope, and possibly the original spectral content of saturated intervals. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is a simultaneous attenuated acquisition and deliberate overload-recovery calibration sequence. A claim drawn from that comparison has to carry its actual uncertainties: full-scale range, fraction of clipped samples, contiguous clipping duration, and bounded post-event conclusions. Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. Digital values at full scale can establish that a threshold was reached but not how far it was

Copyright 2026, James M. Atkinson

exceeded. Clipping creates harmonic and intermodulation-like spectral components that were not present in the linear input. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 1: Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints.

Clipping is a many-to-one transformation, which means that a plateau at the converter's highest code does not disclose the unknown analogue crest that produced it. The same stored sequence could come from a waveform only slightly above full scale or from a much larger transient whose peak was flattened. An algorithm that draws a smooth continuation through the plateau supplies assumptions about waveform shape, not recovered historical measurements. I would preserve the raw codes, clipping flags, gain settings and any independently recorded lower-gain channel. If a parallel receiver did not clip, its calibrated response could constrain the amplitude that the primary path lost, provided both channels shared a known time reference and adequately characterised analogue transfer. The peak itself is not identifiable from clipped samples alone. Even the pulse duration may be biased when saturation and recovery alter the time for which the signal remains above threshold. The evidential limit belongs in the finding, not in a footnote that the reader may miss.

In this physical path examination of Question 025, the decisive claim is that clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. Clipping is an irreversible many-to-one mapping of analogue amplitudes to one extreme converter code. When an input exceeds full scale, many physically different peaks are recorded identically. The duration of the extreme-code plateau may still bound the time spent at the converter limit if the timebase and transfer are valid, but it cannot reveal the unmeasured crest. A smooth extrapolated

Copyright 2026, James M. Atkinson

reconstruction is a model output, not an original sample. The proper analysis separates quantities still directly measured, quantities inferable under explicit waveform assumptions and amplitudes for which the record supplies only lower or upper bounds. A useful falsification proceeds from the actual controversy: clipping destroys amplitude ordering beyond the rail. If a converter's positive full-scale input is 1.0 volt and two analogue peaks reach 1.2 and 2.5 volts, both may be represented by the same maximum digital code. Their different amplitudes are not recoverable from that saturated code alone. Timing of threshold entry, unsaturated leading edges or measurements from an independent attenuated path may still convey useful information, provided the front-end and recovery behaviour are modelled. Some clipping can also introduce spectral regrowth that resembles wideband emissions, so reprocessing the clipped samples cannot prove that the reconstructed out-of-band content existed at the antenna. Preserve raw words and overload flags, record the fraction of saturated samples, and repeat with attenuation where possible. A forensic statement should distinguish demonstrated overload from conjectures about the missing peak waveform. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Record an intense short pulse simultaneously through two independently calibrated gain paths, one set to avoid overrange. Compare event onset, clip-code duration and subsequent settling while preserving the preamplifier and ADC states. Replay a calibrated pulse family through the saturated channel to test whether onset and timing remain reliable despite amplitude loss. If the lower-gain path is itself bandwidth-limited, its

Copyright 2026, James M. Atkinson

estimate of the original peak also requires a stated transfer-function correction and uncertainty. I would take full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. A response consistent with the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. A high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input

Copyright 2026, James M. Atkinson

connector. I would first inventory the physical elements implicated by the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence, and measure their behaviour separately before reconnecting the assembled system. Shannon's information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. It is therefore material to establish full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude rather than infer them from a single scalar output. The limiting test is concrete: Compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. If the intervention produces the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret a reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there as a new transmitter before challenging the most economical instrumental explanation. Hard clipping discards amplitude distinctions and is ordinarily not invertible from the clipped samples alone. Professor Tukey, I invite you to question the analyst who reconstructs a smooth crest from the saturation plateau.

John Wilder Tukey | Peer question 1 to Claude Elwood Shannon

Claude Elwood Shannon, may I test the exact physical inference in your account of a high-gain SDR captures a short intense burst with a

Copyright 2026, James M. Atkinson

plateau of samples pinned to the maximum converter code? The proposed mechanism appears plausible only if changes after compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test are compared with a stable reference condition. Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude which would settle that narrower claim, rather than a visual impression of improvement.

Claude Elwood Shannon | Immediate answer to John Wilder Tukey

Dr Tukey, interpolation through a flat-topped plateau provides no additional measurement of the missing peak. I would ask instead which event features survive the clipping operation: first threshold crossing, approximate duration, polarity and perhaps a bound on peak amplitude. An independent unsaturated channel can improve those bounds, but only with a demonstrated shared time reference and quantified gain mismatch. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder.

Copyright 2026, James M. Atkinson

The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 025, the specific physical candidate is many distinct analogue voltages mapped into the same maximum or minimum digital code. The unresolved physical pathway is material: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. The retained record permits a conditional claim about full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, but cannot alone resolve saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. A stable residual after the reference path is

Copyright 2026, James M. Atkinson

disabled calls for examining bypass or internal generation. The proposed discriminating operation is compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test, and only a response matching the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Claude Elwood Shannon

I appreciate your explanation, Claude Elwood Shannon. How would your conclusion survive a deliberately independent test of a reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there? A second receiver might share more of the supposed evidence than its separate enclosure suggests. Digital values at full scale can establish that a

Copyright 2026, James M. Atkinson

threshold was reached but not how far it was exceeded. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude and document which differences remain unexplained? Would you also state what observed change in full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude would invalidate the preferred account, and which aspect of compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test would make that negative result independently repeatable?

Claude Elwood Shannon | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 025, the specific physical candidate is many distinct analogue voltages mapped into the same maximum or minimum digital code. The

Copyright 2026, James M. Atkinson

unresolved physical pathway is material: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. The retained record permits a conditional claim about full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, but cannot alone resolve saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. Digital values at full scale can establish that a threshold was reached but not how far it was exceeded. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence; I would challenge it with compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. Two responses consistent with the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded

Copyright 2026, James M. Atkinson

amplitude information would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. A discordant measurement would then be interpreted by tracing that difference through full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 2: Digital values at full scale can establish that a threshold was reached but not how far it was exceeded.

It is sometimes suggested that collecting more sample points will reconstruct the missing top of a clipped sinusoid. This is true only under additional assumptions strong enough to identify the underlying waveform, such as a stipulated single-frequency model, correct timing and access to unsaturated phases. A broadband unknown burst admits many waveforms agreeing with every retained clipped sample while differing radically at the crest. I would test any reconstruction algorithm on a blinded collection containing modulated signals, multipath and pulses of different shapes. The algorithm's bias and coverage should be evaluated against a calibrated unclipped reference rather than against the aesthetically plausible output of another reconstruction. For a field report, the conservative result is a lower bound on the peak under a known clipping threshold, with an explicit statement of lost information. Sampling more often does not remove the ambiguity created by an earlier non-invertible analogue-to-digital mapping.

In this control and stability examination of Question 025, the decisive claim is that digital values at full scale can establish that a threshold was reached but not how far it was exceeded. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: clipping destroys amplitude ordering beyond the rail. If a converter’s positive full-scale input is 1.0 volt and two analogue peaks reach 1.2 and 2.5 volts, both may be represented by the same maximum digital code. Their different amplitudes are not recoverable

Copyright 2026, James M. Atkinson

from that saturated code alone. Timing of threshold entry, unsaturated leading edges or measurements from an independent attenuated path may still convey useful information, provided the front-end and recovery behaviour are modelled. Some clipping can also introduce spectral regrowth that resembles wideband emissions, so reprocessing the clipped samples cannot prove that the reconstructed out-of-band content existed at the antenna. Preserve raw words and overload flags, record the fraction of saturated samples, and repeat with attenuation where possible. A forensic statement should distinguish demonstrated overload from conjectures about the missing peak waveform. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by a reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note digital values at full scale can establish that a threshold was reached but not how far it was exceeded. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator

Copyright 2026, James M. Atkinson

should preserve time stamps, acquisition validity, applied gain, test-source state and full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, a reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. The order would be time-stamped and should include invalid intervals, receiver recovery, and any gain or filter settling rather than treating silence during transition as evidence of a silent source. Our central rival is specific: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. This predicts a response which should be tested against the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore

Copyright 2026, James M. Atkinson

measurements discarded during retuning. Where saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints, the correct claim must name the operational states and the evidence available in each. Full-scale codes establish a boundary crossing, not how far the unknown analogue peak exceeded that boundary. Dr Pearson, please take the floor and examine the resulting one-sided inference.

Egon Sharpe Pearson | Peer question 3 to Harry Nyquist

Harry Nyquist, your calibration argument invites a question about reference planes, especially because saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. The reference stimulus and the unknown emission need not occupy the same physical regime. Clipping creates harmonic and intermodulation-like spectral components that were not present in the linear input. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When a reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Copyright 2026, James M. Atkinson

Harry Nyquist | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 025, the specific physical candidate is many distinct analogue voltages mapped into the same maximum or minimum digital code. The unresolved physical pathway is material: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. The retained record permits a conditional claim about full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, but cannot alone resolve saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude. Clipping creates harmonic and intermodulation-like spectral components that were not present in the linear input. I would not carry a correction obtained at one frequency or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be compare the clipped channel with a simultaneously acquired lower-gain reference

Copyright 2026, James M. Atkinson

and a calibrated overrange replay test, with before-and-after values of full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude. If the instrument behaves as predicted, then the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. A reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Harry Nyquist

There is an inferential difficulty, Harry Nyquist: the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. The population of admissible observations needs to be fixed before any confidence argument. In this situation, saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal

Copyright 2026, James M. Atkinson

constraints. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. A model-assisted interpolation may be useful for illustration but should never be relabelled as an authentic historical measurement. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude would invalidate the preferred account, and which aspect of compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test would make that negative result independently repeatable?

Harry Nyquist | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 025, the specific physical candidate is many distinct analogue voltages mapped into the same maximum or minimum digital code. The unresolved physical pathway is material: The crest may be modestly over range or many times over range; both

Copyright 2026, James M. Atkinson

possibilities collapse to the same stored saturated code sequence. The retained record permits a conditional claim about full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, but cannot alone resolve saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because a reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there. I would distinguish trials selected in advance from those added after an unexpected peak appeared. A model-assisted interpolation may be useful for illustration but should never be relabelled as an authentic historical measurement. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence; its prediction should be recorded alongside the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude

Copyright 2026, James M. Atkinson

information. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. Saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, sixteen consecutive maximum codes prove a saturation episode of at least sixteen sample instants, not its unmeasured analogue peak. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal contribution 3: Clipping creates harmonic and intermodulation-like spectral components that were not present in the linear input.

Converter saturation also changes the spectral appearance of an event. A flattened waveform introduces harmonics and sidebands, and subsequent filtering may spread that distortion across the frequencies where a weak independent emission is sought. I would separate the physical phenomenon of overload from digital numerical clipping: an RF amplifier can compress before the ADC reaches its extreme code, while software display scaling can clip a picture without clipping stored samples. These failure modes must not be conflated. A diagnostic sequence should step a calibrated stimulus through the chain and compare analogue power at accessible nodes with the converter's raw-code distribution. If third-order products begin to grow before the ADC clips, reducing converter gain alone may not repair the RF distortion. The record should identify the first nonlinear boundary. That is where a claimed spectral measurement begins to lose fidelity, even if the later numerical word length remains large.

In this operational measurand examination of Question 025, the decisive claim is that clipping creates harmonic and intermodulation-like spectral components that were not present in the linear input. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: clipping destroys amplitude ordering beyond the rail. If a converter’s positive full-scale input is 1.0 volt and two analogue peaks reach 1.2 and 2.5 volts, both may be represented by the same maximum digital code. Their different amplitudes are not recoverable

Copyright 2026, James M. Atkinson

from that saturated code alone. Timing of threshold entry, unsaturated leading edges or measurements from an independent attenuated path may still convey useful information, provided the front-end and recovery behaviour are modelled. Some clipping can also introduce spectral regrowth that resembles wideband emissions, so reprocessing the clipped samples cannot prove that the reconstructed out-of-band content existed at the antenna. Preserve raw words and overload flags, record the fraction of saturated samples, and repeat with attenuation where possible. A forensic statement should distinguish demonstrated overload from conjectures about the missing peak waveform. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Clipping is an irreversible many-to-one transformation over the saturated part of the input waveform. Once distinct analogue peaks have produced the same maximum digital code, a subsequent programme cannot recover their true amplitudes or exact instantaneous waveform solely from those clipped samples. Some information remains: the onset and duration of saturation, the polarity of limiting, and unsaturated portions of the record can constrain possible source behaviour. The forensic report should make that distinction explicit. A test with a stepped calibrated source can identify the analogue input level at which clipping begins and whether an automatic-gain-control loop changes the threshold over time. If the same event is simultaneously observed through an independent lower-gain path, the second path may recover otherwise lost amplitude information. Merely interpolating across flat-topped samples, however attractive on a display, is a model-based reconstruction rather than a measurement of the original

Copyright 2026, James M. Atkinson

peak. Accordingly, the laboratory record for Question 025 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. Saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. Bennett's communications engineering perspective distinguishes stochastic noise models from deterministic signal-dependent converter errors and distortion products. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a high-gain sdr captures a short intense burst with a plateau of samples pinned to the maximum converter code; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: Sixteen consecutive maximum codes prove a saturation episode of at least sixteen sample instants, not its unmeasured analogue peak. It demonstrates the

Copyright 2026, James M. Atkinson

danger of transferring a result across domains in which the defining measurement has changed. I would therefore attach the uncertainty analysis to the *operational definition* itself instead of printing an unexplained confidence interval beside the most appealing trace.

A further, separately testable aspect of a high-gain sdr captures a short intense burst with a plateau of samples pinned to the maximum converter code concerns full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude. The proposed challenge would be compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. The decision is conditional upon the observed result, with particular attention to saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. The competing account remains the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. Nonlinear saturation generates spectral components that can masquerade as separate emissions. Dr Turing, I pass the floor for a test of whether those harmonics can be distinguished in the saved data.

Alan Mathison Turing | Peer question 5 to William Ralph Bennett

William R. Bennett, I should like to examine what the recorded data actually preserve when a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. The physical input and the retained numerical array are not interchangeable things. A calibrated lower-gain parallel channel can preserve information

Copyright 2026, James M. Atkinson

that the high-gain channel irretrievably discarded. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude would invalidate the preferred account, and which aspect of compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test would make that negative result independently repeatable?

William Ralph Bennett | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 025, the specific physical candidate is many distinct analogue voltages mapped into the same maximum or

Copyright 2026, James M. Atkinson

minimum digital code. The unresolved physical pathway is material: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. The retained record permits a conditional claim about full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, but cannot alone resolve saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. Saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. I propose separating acquired information from model-dependent reconstruction. A calibrated lower-gain parallel channel can preserve information that the high-gain channel irretrievably discarded. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude and a fresh trial in which the operator compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. If that trial demonstrates the low-gain record can retain peak ordering and duration where the

Copyright 2026, James M. Atkinson

original high-gain acquisition has discarded amplitude information, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal contribution 4: A model-assisted interpolation may be useful for illustration but should never be relabelled as an authentic historical measurement.

The operational definition of peak amplitude requires a physically specified reference and a measurement method capable of returning that value. When all samples above an unknown crest are reported as one maximum code, an exact peak amplitude cannot be measured by that instrument in that gain state. One may sometimes establish a minimum amplitude, the occurrence of overrange, or the existence of an input that exceeded a threshold. Those propositions should not be inflated into a calibrated waveform reconstruction. I would ask the engineer to repeat the controlled event at a lower gain while logging the change of gain, front-end loading and timing; if the source is repeatable, the comparison supplies new evidence. If it is a single unrepeatable forensic event, one must accept the limits of the surviving record. Experimental honesty is more valuable than a reconstructed crest whose smooth outline hides the assumptions on which it rests.

In this information retention examination of Question 025, the decisive claim is that a model-assisted interpolation may be useful for illustration but should never be relabelled as an authentic historical measurement. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: clipping destroys amplitude ordering beyond the rail. If a converter’s positive full-scale input is 1.0 volt and two analogue peaks reach 1.2 and 2.5 volts, both may be represented by the same maximum digital code. Their different amplitudes are not recoverable from

Copyright 2026, James M. Atkinson

that saturated code alone. Timing of threshold entry, unsaturated leading edges or measurements from an independent attenuated path may still convey useful information, provided the front-end and recovery behaviour are modelled. Some clipping can also introduce spectral regrowth that resembles wideband emissions, so reprocessing the clipped samples cannot prove that the reconstructed out-of-band content existed at the antenna. Preserve raw words and overload flags, record the fraction of saturated samples, and repeat with attenuation where possible. A forensic statement should distinguish demonstrated overload from conjectures about the missing peak waveform. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. The scientific point of a model-assisted interpolation may be useful for illustration but should never be relabelled as an authentic historical measurement. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions repeatedly show the low-gain record can retain peak ordering and

Copyright 2026, James M. Atkinson

duration where the original high-gain acquisition has discarded amplitude information, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. A reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there. The investigator should ask which rival input histories can produce the same retained sequence. Bridgman's operational approach requires a measurement procedure that defines each quantity physically. A stated number unsupported by the operation that produced it is methodologically incomplete. The issue becomes especially sharp because the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the

Copyright 2026, James M. Atkinson

interval and frequency domain actually examined. For the proposed case, sixteen consecutive maximum codes prove a saturation episode of at least sixteen sample instants, not its unmeasured analogue peak. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. A model-based interpolation can aid explanation without becoming an historical measurement of the erased peak. Dr Deming, I invite your challenge to any report that confuses the two.

W. Edwards Deming | Peer question 6 to Percy Williams Bridgman

I thank you, Percy Williams Bridgman, for distinguishing measurement from attribution, but the observation is that a reconstruction algorithm draws a smooth waveform crest above full scale despite the absence of unsaturated measurements there. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: sixteen consecutive maximum codes prove a saturation episode of at least sixteen sample instants, not its unmeasured analogue peak. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information on one day but fails after the instrument has been reconfigured? Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment? Would you also state what observed change in full-scale threshold,

Copyright 2026, James M. Atkinson

clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude would invalidate the preferred account, and which aspect of compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test would make that negative result independently repeatable?

Percy Williams Bridgman | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 025, the specific physical candidate is many distinct analogue voltages mapped into the same maximum or minimum digital code. The unresolved physical pathway is material: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. The retained record permits a conditional claim about full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, but cannot alone resolve saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, sixteen consecutive maximum codes prove a saturation episode of at least sixteen sample instants, not its unmeasured analogue peak. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. Its bearing on the dispute can be evaluated through the predicted response, namely the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information. Because the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence, the procedure compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match separate measured saturation bounds from illustrative restoration and never relabel an inferred crest as original evidence, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. The low-gain record can retain peak ordering and duration where the

Copyright 2026, James M. Atkinson

original high-gain acquisition has discarded amplitude information. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 5: A calibrated lower-gain parallel channel can preserve information that the high-gain channel irretrievably discarded.

The cost of a false peak claim and the cost of admitting uncertainty are not symmetrical in a forensic investigation. A spectacular reconstructed amplitude may influence equipment attribution, safety assessments and allegations about intentional conduct. I would require the algorithm to report its identified assumptions and to offer interval statements that retain the possibility of much larger peaks when the data cannot bound them. Simulated tests may show that a parametric fit performs well for a known single-tone waveform, yet that result should not be transferred to unknown pulse shapes without validation. If different plausible models yield incompatible maxima from the same clipped record, their disagreement is itself a result. The report may state with confidence that clipping occurred, with a calibrated lower limit on amplitude, while declining to assign the missing crest a unique value. The scientific question is what the retained evidence excludes, not how precise a plausible reconstruction can be made to look.

In this statistical inference examination of Question 025, the decisive claim is that a calibrated lower-gain parallel channel can preserve information that the high-gain channel irretrievably discarded. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: clipping destroys amplitude ordering beyond the rail. If a converter’s positive full-

Copyright 2026, James M. Atkinson

scale input is 1.0 volt and two analogue peaks reach 1.2 and 2.5 volts, both may be represented by the same maximum digital code. Their different amplitudes are not recoverable from that saturated code alone. Timing of threshold entry, unsaturated leading edges or measurements from an independent attenuated path may still convey useful information, provided the front-end and recovery behaviour are modelled. Some clipping can also introduce spectral regrowth that resembles wideband emissions, so reprocessing the clipped samples cannot prove that the reconstructed out-of-band content existed at the antenna. Preserve raw words and overload flags, record the fraction of saturated samples, and repeat with attenuation where possible. A forensic statement should distinguish demonstrated overload from conjectures about the missing peak waveform. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. A calibrated lower-gain parallel channel can preserve information that the high-gain channel irretrievably discarded. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange

Copyright 2026, James M. Atkinson

replay test, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say separate measured saturation bounds from illustrative restoration and never relabel an inferred crest as original evidence, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman's statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. One could stratify the experiment by nuisance condition, retain a random sample of nominally

Copyright 2026, James M. Atkinson

negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, sixteen consecutive maximum codes prove a saturation episode of at least sixteen sample instants, not its unmeasured analogue peak, is not an estimate of any actual investigation. A calibrated lower-gain parallel channel may preserve precisely the amplitude information the saturated channel lost. Sir Karl, I pass the floor to ask what independent evidence would make that restoration defensible.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise separate measured saturation bounds from illustrative restoration and never relabel an inferred crest as original evidence? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Digital values at full scale can establish that a threshold was reached but not how far it was exceeded. Please connect full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude with a declared detection

Copyright 2026, James M. Atkinson

threshold and the measurement exposure. If the experiment compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 025, the specific physical candidate is many distinct analogue voltages mapped into the same maximum or minimum digital code. The unresolved physical pathway is material: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. The retained record permits a conditional claim about full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude, but cannot alone resolve saturation is many-to-one, so the true peak is not identifiable from clipped codes without separately justified signal constraints. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Digital values at full scale can establish that a threshold was reached but not how far it was exceeded. I would use the observations of full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test, not an assertion based on the operator's impression of a quiet display. If it yields the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence, an intervention that leaves both alternatives consistent does not settle their

Copyright 2026, James M. Atkinson

difference. The result should be limited to separate measured saturation bounds from illustrative restoration and never relabel an inferred crest as original evidence, with the untested physical possibilities made visible.

Claude Elwood Shannon, Cross-Peer Question to Alan Mathison Turing: Dr Turing, a clipped SDR burst has thirty consecutive maximum-code samples, and software interpolates them to a smooth crest. The display looks plausible and reproduces a chosen band-limited waveform model. What distinguishes a permissible inverse-model estimate from the original measurement, and how would one demonstrate the nonuniqueness of the omitted analogue amplitudes?

Alan Mathison Turing, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, clipping maps a family of admissible amplitudes onto one extreme code. Construct two analogue input histories that agree at all unclipped sample instants yet exceed the converter limit by different amounts during the saturated interval. Both can yield the same stored codes under the assumed acquisition path. A band-limit, sparsity penalty or phase-continuity model may select one reconstruction, but its result is conditional on those constraints, their adequacy and calibration. Preserve the original sample stream unchanged, document the method and prior assumptions, and label the reconstructed crest as derived data. Check estimates against a separately acquired, demonstrably linear attenuated channel. An attractive curve is neither a recovered eyewitness record nor unique evidence of the emitted peak. I respectfully pass the floor to Dr Bennett to question spectral artefacts.

Copyright 2026, James M. Atkinson

William Ralph Bennett, Cross-Peer Question to Edwin Howard Armstrong: Dr Armstrong, after a severe burst reaches full scale, the FFT shows harmonics and wideband skirts. An examiner calls them new transmissions because they were absent in the quiet baseline. How may one distinguish nonlinear products of clipping from independently radiated energy, particularly when an upstream amplifier can overload before the ADC records an extreme code?

Edwin Howard Armstrong, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, the receiver must first be challenged with known, single-source stimuli at multiple input powers and with attenuation applied ahead of the suspected nonlinear element. If the extra spectral components change with level and disappear as the chain returns to its linear regime, an instrumental explanation becomes credible. A parallel low-gain, separately characterised path and controlled termination tests are useful checks, but either path can share an antenna-side nonlinearity. Compare observed harmonic and intermodulation frequencies with the nonlinear model, inspect gain-control and protection histories, and separate analogue preconverter distortion from digital clipping. The absence of maximum codes does not prove every earlier stage linear. A spectral shoulder on a clipped capture cannot by itself establish an external transmitter, its frequency occupancy or intention. I respectfully pass the floor to Dr Shewhart to address corroboration.

Harry Nyquist, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, a redundant low-gain converter records a candidate burst during the same interval that a sensitive channel clips. Both channels use the same clock and input splitter, and a worker calls them independent confirmations.

Copyright 2026, James M. Atkinson

What must be established before the lower-gain record can place reliable bounds on the lost envelope, and which uncertainties remain correlated?

Walter Andrew Shewhart, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, demonstrate that the lower-gain path remained linear across the event, including its amplifier, filter, protection network and ADC, not merely that the displayed codes stayed below full scale. Calibrate the splitter, attenuation, bandwidth, complex transfer function, group delay and timing offset against a common physical reference plane. Clock jitter, antenna-side nonlinearities and source coupling can be shared even when the amplifier gains differ; a common failure cannot be treated as two independent successes. If the attenuated record is valid, its measured peak can be transferred through a documented uncertainty model to bound the high-gain input, but a frequency-dependent or overloaded splitter may invalidate that transfer. Preserve both unprocessed streams and flags. I respectfully pass the floor to Dr Neyman for the evidential meaning of clipping percentages.

Percy Williams Bridgman, Cross-Peer Question to Jerzy Neyman: Dr Neyman, forty-two of 1,836 samples sit on the upper converter rail, approximately 2.288 percent of the record. A prosecution expert proposes that 2.288 percent of the signal energy was lost, while a second examiner treats a zero-detection sequence in thirty visits as proof that no intermittent transmitter was active. How would you limit these claims?

Jerzy Neyman, Cross-Peer Answer to Percy Williams Bridgman: Dr Bridgman, the numerator is a count of extreme-code sample instants, not an integral of unknown squared analogue voltage. The clipped samples tell us that the input reached a threshold under a specified gain and coding model, but they

Copyright 2026, James M. Atkinson

do not disclose the amount by which it exceeded that threshold. Signal energy could vary widely among analogue histories compatible with the record. Likewise, the illustrative probability 0.95 raised to the thirtieth power assumes thirty genuinely independent observation opportunities and a verified five-percent chance of detection per opportunity. It cannot license a statement about recovery-blind intervals or synchronised transmissions. Report the sample positions, missing blocks, observed gain states, calibrated sensitivity, alternatives and any model-assisted estimate as a separate layer. I respectfully return the discussion to Dr Atkinson for the concluding synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of the boundary between still-inferable facts and permanently lost amplitude information after clipping has established a point which the specialist must not overlook. The receiver records digital samples held at a converter limit during a high-amplitude event; it does not, merely by drawing a clear trace, give direct access to the original peaks, detailed envelope, and possibly the original spectral content of saturated intervals. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, Clipping is a many-to-one transformation and cannot generally be inverted without additional justified constraints. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

Copyright 2026, James M. Atkinson

A clipped acquisition can look remarkably persuasive after scaling and windowing, particularly if the largest samples are later hidden by plotting limits. Yet clipping collapses many possible input voltages into the same terminal code, and neither interpolation nor an elegant spectral estimator can restore the lost peak. The relevant inquiry must preserve the raw sample distribution, saturation flags, acquisition gain and channel-overload history. We should test an independently known input over and beyond full scale, then compare the clipped spectrum with the reference before attempting to interpret apparent harmonics. I thank Dr Nyquist for the sampling discipline, but his mathematical relation cannot supply the analogue excursions discarded by a converter's finite range. Our finding should therefore state the interval of invalid amplitude reconstruction and the limited propositions still supportable from uncorrupted portions of the record. The examiner must not promote post-processed appearance into proof that the original signal was neither stronger nor differently shaped.

The sampled waveform contains a plateau at the converter’s extreme code. That fact establishes at least an overrange or extreme-code event under the actual transfer convention; it does not establish the unique original waveform that produced it. The more useful outcome is a discriminating protocol: Compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. In applying it, the examiner must retain all readings supporting full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude and identify the physical plane to which the measurements refer. At the outset of the investigation, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the

Copyright 2026, James M. Atkinson

maximum converter code; that circumstance makes the alternative mechanism material, specifically the crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. A result approaching the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore separate measured saturation bounds from illustrative restoration and never relabel an inferred crest as original evidence. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

The manuscript should identify the saturation interval and report only the inferable bounds. Any reconstructed crest must be labelled as model-dependent, and no forensic claim may treat its plotted shape as recorded analogue evidence. The decisive experiment is concrete: Compare the clipped channel with a simultaneously acquired lower-gain reference and a calibrated overrange replay test. In conducting it, the examiner must explicitly retain full-scale threshold, clipped-sample proportion, contiguous overrange interval and lower-bound peak amplitude. If the outcome matches the stated prediction, the low-gain record can retain peak ordering and duration where the original high-gain acquisition has discarded amplitude information, the supported conclusion concerns that test domain.

Copyright 2026, James M. Atkinson

An alternative remains: The crest may be modestly over range or many times over range; both possibilities collapse to the same stored saturated code sequence. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 025

Application 01. Clipping extent and an information-preserving statement

In the illustrative 025.01 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. Out of N = 1,836 acquired converter sample instants, K = 42 carry an extreme-code plateau. The directly observed fraction is K/N = 2.288%. It is not the fraction of analogue signal energy lost, because the unknown overrange amplitudes have many possible values. An independent lower-gain recording can bound those amplitudes if its transfer path and time alignment are demonstrated; no interpolation can establish an otherwise unobserved peak uniquely. The observed 2.288-percent extreme-code fraction says nothing quantitative about energy above the rail or the unique true crest. Keep sample indices and raw codes unaltered.

Application 02. Ideal code step, variance, and full-scale sine SNR

In the illustrative 025.02 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. Taking an ideal N = 13-bit uniform converter across 2.50 V peak-to-peak, one nominal code interval is $\Delta = Vpp/2^N = 0.3052$ mV. Under the independent uniform-error approximation its rms quantisation error is $\sigma = \Delta/\sqrt{12} = 0.0881$ mV. The ideal full-scale sinusoidal SNR approximation is 6.02N + 1.76 = 80.02 dB. A coherent low-level waveform may violate the uniform-error assumption; clipping and integral nonlinearity are separate limitations. The 0.3052 mV nominal step, 0.0881 mV quantisation RMS and 80.02 dB ideal SNR describe an unclipped uniform converter; none reconstructs the overrange segment.

Copyright 2026, James M. Atkinson

Application 03. Gain allocation and blocker headroom

In the illustrative 025.03 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. Assume a calibrated digital full-scale equivalent of -7 dBm, a blocker applied at -44 dBm, and net analogue gain 23 dB. The projected converter input is -21 dBm and remaining margin is -7 − (-21) = 14 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain channel is needed before discussing the weak candidate. The projected 14 dB converter-input headroom is conditional on a calibrated linear gain path. Interstage compression may occur despite a positive final-stage margin.

Application 04. Cascade gain and observed headroom

In the illustrative 025.04 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. A first amplifier contributes G_1 = 10 dB, an intentional attenuation contributes G_2 = -8 dB, and a later stage contributes G_3 = 18 dB. The small-signal sum is 10 + (-8) + 18 = 20 dB. For P_i = -69 dBm, the ideal output is P_o = -49 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. The calculated −49 dBm output assumes 20 dB small-signal net gain; test each analogue stage and its peak response before treating that figure as a clipping boundary.

Application 05. Two-tone third-order products and input intercept

In the illustrative 025.05 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. With two equal input tones each at P = -27 dBm and a hypothetical input

Copyright 2026, James M. Atkinson

third-order intercept IIP_3 = +10 dBm, the extrapolated input-referred third-order product is $P_3 = 3P - 2IIP_3$ = -101 dBm, or -74 dBc relative to either input tone. The cubic approximation ceases to be reliable in compression. A two-tone slope check and input attenuation test must establish whether the predicted spur arises inside the receiver rather than externally. The −101 dBm third-order product and −74 dBc separation are extrapolations from a cubic small-signal intercept, unreliable once a stage compresses or saturates.

Application 06. Preserved sample continuity across an acquisition interval

In the illustrative 025.06 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. A converter expected to retain f_s = 1.30 million samples/s for T = 1.25 s should supply f_sT = 1,625,000 complex sample instants. If 261 sequence positions are missing, the retained count is 1,624,739 and loss fraction is 0.01606%. A low fractional loss cannot exclude a highly relevant short burst coinciding with the gap. Position and timing of each missing block must therefore be preserved. The 261 missing complex sample instants amount to 0.01606 percent of 1,625,000 expected instants, but even a tiny gap can remove an entire short emission.

Application 07. Thermal reference noise in a declared measurement bandwidth

In the illustrative 025.07 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. Take the equivalent noise bandwidth B = 18,000 Hz and calibrated noise figure NF = 2.35 dB at an assumed 290 K. The thermal-reference estimate

Copyright 2026, James M. Atkinson

is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF = -129.10$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. The −129.10 dBm thermal estimate in 18,000 Hz at 290 K does not describe an overloaded receiver, impulse statistics or the input energy above its coding range.

Application 08. Combined and expanded measurement uncertainty

In the illustrative 025.08 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. For independent standard-uncertainty contributions 0.73, 0.54 and 0.40 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.73^2 + 0.54^2 + 0.40^2)} = 0.992$ units. Using an illustrative coverage factor $k = 2$ gives expanded uncertainty $U = 2u_c = 1.984$ units. The 0.992-unit combined and 1.984-unit expanded uncertainties assume independent components and $k = 2$; censoring by clipping introduces a separate one-sided or model-based limitation.

Application 09. Opportunity-limited detection under independent visits

In the illustrative 025.09 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. For $n = 30$ genuinely independent valid observation opportunities, each with stipulated event detection chance $p = 0.05$, the probability of no detections is $(1 - p)^n = 0.21464$; its complement is 78.54%. The result is conditional upon the per-visit detection model and independence, neither of which follows from the number of FFT frames displayed. A periodic emitter synchronised with revisit timing can defeat this independent-visit estimate. The 0.21464 probability of zero detections

Copyright 2026, James M. Atkinson

presumes thirty valid independent opportunities with a known five-percent detection chance; clipped or missed intervals invalidate that inference.

Application 10. Difference between two instruments relative to stated uncertainty

In the illustrative 025.10 test, a high-gain SDR captures a short intense burst with a plateau of samples pinned to the maximum converter code. The paired instrument contrast is $\Delta = 1.770$ dB. Set independent standard uncertainties $u_1 = 0.340$ dB and $u_2 = 0.520$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.621$ dB, giving the dimensionless ratio $\Delta/u\Delta = 2.849$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. The 2.849 discrepancy ratio depends on independent standard uncertainties. The compared records must be aligned and checked for shared reference errors and clipped observations.

QUESTION 026

Copyright 2026, James M. Atkinson

When may dither improve a quantitative estimate without increasing intrinsic converter resolution?

Source: V011_Roundtable_Question_026_CP026_Standalone.docx | Recovered substantive manuscript. Constructed educational dialogue.

Constructed educational dialogue. All remarks attributed to deceased historical contributors are newly written methodological reconstructions, not historical quotations or claims that these individuals handled present-day software-defined-radio instruments. Engineering cases are hypothetical, with stated assumptions and bounded conclusions.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, our preceding discussion of clipping established that the analogue-to-digital converter cannot disclose an amplitude it never represented. A subsequent discussion of dither must not contradict that boundary by suggesting that a random perturbation somehow manufactures information from nothing. Yet there is an apparent paradox, made visible in the repeated flicker of a least-significant-bit indication: a carefully characterised random disturbance sometimes makes the mean of an otherwise fixed low-level input more accurately estimable. The purpose of this question is to distinguish the statistical information recovered from repeated observations from the physical resolution and transfer characteristic of the converter itself. The distinction has considerable consequences for defensive technical surveillance countermeasures, where an investigator may be comparing a faint stationary spectral component against receiver-generated artefacts, rather than admiring an attractive number of decimal places on a display.

Copyright 2026, James M. Atkinson

I invite the panel to begin with three different objects which must not be confused. First is the native conversion mapping, by which the electronic instrument assigns discrete codes to a continuous input at specified instants. Second is the measurement protocol, which may include the injection or natural presence of an independent random signal, repeated samples, digital filtering, estimator selection, and calibration. Third is the evidential proposition to be reported. The code width belongs to the first object; the uncertainty of an estimator belongs to the second; the defensibility of a claim about an external emission belongs to the third. It is entirely possible to reduce an estimator's variance whilst making no improvement in integral nonlinearity, analogue bandwidth, aperture uncertainty, overload recovery, or source attribution. It is equally possible to injure a measurement by adding more noise after the required randomness is already present. [R1-R5]

We shall examine a finite-range uniform quantiser and its ideally simple counterpart before considering imperfect converters. Suppose a nearly constant analogue value lies between adjacent thresholds. Without adequate movement or independent perturbation, a succession of identical output codes offers a repeatable indication but may not distinguish different inputs inside the same code interval. With properly chosen dither, the probability of observing either code can depend upon the fractional position of the input. An average across independent observations may then estimate that fractional position. That statement is conditional upon the randomisation law, threshold stability, knowledge of the time interval, absence of overload, and the legitimacy of treating repeated samples as

Copyright 2026, James M. Atkinson

measurements of the same quantity. We must not use a favourable ideal model as a substitute for checking any of those conditions.

The central contrast will be between subtractive and nonsubtractive dither. In the former, the same known perturbation is introduced before conversion and removed digitally after conversion, requiring a faithful record of the perturbation. In the latter, the disturbance remains part of the total output error, although appropriate distributional design can suppress some signal-dependent error properties. Both approaches must be distinguished from merely adding numerical random values to codes after acquisition, which cannot alter what the converter originally captured. Nor should improved spurious-free dynamic range be casually translated into improved signal-to-noise ratio; a spur may diminish while the broadband noise floor rises. [R1-R3]

Dr Shannon will test the meaning of information and recoverability; Mr Bennett will analyse the quantisation-error conditions and their spectral consequences; Dr Nyquist will distinguish independent observations and bandwidth-limited acquisition; Professor Tukey will examine estimation and experimental validation; and Dr Shewhart will determine what operational controls make a nominally successful demonstration reproducible. Seven colleagues will then pose technical challenges that must be answered immediately before the discussion passes onwards. Ten numerical applications will define their variables and evaluate the limiting cases, including a deliberate near-overload failure. Our aim is not to celebrate a noise source as an instrument of magic. It is to specify the circumstances in which randomness makes a previously concealed relationship statistically visible, and to explain exactly what remains concealed.

Dr Shannon, may I invite you to lead by distinguishing the information in one code from the information in a properly designed ensemble of codes? The floor is yours.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 1: Information in the observation protocol

Dr. Atkinson, I thank you. The distinction between a quantised indication and information about an unknown parameter becomes sharper when we state what an observer is permitted to know. A single code from a uniform quantiser identifies a region of possible input values, not necessarily one input value. If a number of samples all receive the same code, we may be tempted to regard their unanimity as overwhelming evidence of a particular analogue amplitude. That temptation confuses repeatability with discrimination. Under a deterministic mapping, every input in a code interval can generate the same record indefinitely. No increase in arithmetic precision can undo that indistinguishability. The bits stored after the fact are simply a longer description of an unchanged ambiguity. [R1, R4]

An appropriately randomised observation protocol is different because the conditional distribution of the code can change with the unknown input. Consider a mid-tread quantiser with a code interval of width Δ and a positive constant input between zero and one code. Add independent dither drawn uniformly between minus one-half and plus one-half of Δ, and round the sum to the nearest integer multiple of Δ. If the input equals one-quarter of Δ, code one is observed with probability one-quarter, and code zero with probability three-quarters, ignoring measure-zero ties. Over many independent trials the fraction of ones estimates the input's fractional position. The converter has not acquired additional physical thresholds. The experiment has used known stochastic motion across an existing threshold to turn an otherwise flat response into a frequency-of-occurrence

Copyright 2026, James M. Atkinson

observation. An observer can recover a parameter from a probability law, but only by accepting that law as a tested premise. [R1, R2]

There are at least four constraints upon what the resulting estimate means. The input must remain sufficiently stable over the averaging interval, or the estimate becomes an average of changing inputs rather than the level at a stated instant. The dither must have the specified distribution and independence, for an unknown bias or correlation can reproduce the same changes in code occupancy. The converter must not overload, because saturation destroys the proposed threshold relationship. Finally, the estimator must be described with an uncertainty that reflects the actual data, not simply the ideal binomial approximation recited after the event. Where temporal noise is coloured, where digital decimation blends pulses, or where the data stream has missing blocks, the nominal sample count exaggerates the independent evidence. [R3, R5]

This discussion is sometimes expressed through the phrase 'resolution beyond a bit'. I would prefer language identifying the quantity that became better estimated. One may report the mean of a stationary voltage with a standard uncertainty below one least-significant-bit under an accepted calibration model. That does not say that a converter with twelve native bits now resolves twenty-four bits of instantaneous waveform amplitude. In particular, two analogue trajectories with markedly different sub-sample transients can produce the same sample sequence and even the same dithered histogram. The relevant equivalence class has been narrowed for one parameter without being abolished for every waveform. Forensic doctrine requires this limitation to appear in the conclusion, not disappear behind a visually precise decimal display.

Copyright 2026, James M. Atkinson

A second distinction concerns where noise may be helpful. A coherent interference tone can force quantisation error into periodic patterns whose discrete Fourier transform resembles a real spectral feature. Altering the threshold crossings through dither may distribute those error components more broadly, allowing a weak external tone to be distinguished in a controlled laboratory comparison. But the same added noise may obscure a genuinely weak transient. Whether information has increased depends upon the decision problem, the permitted false-alarm rate, and the time-frequency region of interest. A lower spurious peak is not the same outcome as a lower integrated noise density, and neither alone proves the presence or absence of an emitter. [R2, R6]

Suppose two archived datasets have identical sample codes but different unrecorded analogue histories, one of which contains a short pulse. No retrospective distribution of numbers can tell us which analogue history occurred unless the acquisition retained additional evidence constraining the alternatives. Digital noise added after quantisation may be useful to assess algorithm sensitivity or to suppress numerical limit cycles during subsequent requantisation; it cannot retroactively cause an old threshold to be crossed. If a numerical procedure claims otherwise, the examiner should demand the experiment which identifies new information in the original record rather than merely generating variation in a calculation. The data-processing inequality is a helpful conceptual discipline here, although it must not be invoked to deny the information contributed by a genuinely randomised *new* analogue observation.

Finally, there is an institutional distinction. A receiver manufacturer's statement that dither improves a converter characteristic is evidence about

Copyright 2026, James M. Atkinson

a specified measurement setup, waveform, band and analysis method. It is not a global metrological guarantee. The programme must preserve the parameters of the dither source, the analogue point of injection, the timing relationship, the filtering applied before and after sampling, and the raw unaltered codes. The investigator should compare a predeclared quantity across dither-on and dither-off trials while holding nuisance variables under control. Only then may the additional information claimed by the statistical model be attributed to the intervention with a defensible uncertainty. I offer that distinction to the panel and respectfully pass the floor to Professor Wiener for his examination of adaptive observation.

Norbert Wiener | Peer question 1 to Claude Elwood Shannon

Dr Shannon, I appreciate your separation of information from display precision, but the proposed experiment still contains a dynamic observer. In a practical receiver the noise injection may be adjusted automatically when the running code histogram appears too narrow, and the averaging interval may be prolonged when a faint target looks likely. Such feedback creates a selection process. The sample count is no longer independent of the apparent evidence, and the dither distribution may no longer have the same law across the entire record. A device can thereby accumulate beautiful-looking fractional-code averages while concealing a policy which chose favourable instants, rejected unfavourable blocks, or changed its sensitivity in response to provisional detections. How would your information analysis distinguish the useful feedback of a controlled experiment from the post hoc manufacture of confidence? More precisely, can a claimed gain in amplitude discrimination survive when the record does not preserve the controller's

Copyright 2026, James M. Atkinson

states, stopping rule, and unselected observations? I am concerned that the additional digits might describe the observer's adaptive policy more faithfully than they describe the external electromagnetic field.

Claude Elwood Shannon | Immediate answer to Norbert Wiener

Professor Wiener, the concern is decisive because the protocol determines the likelihood of the data. If a sequence is generated under a state-dependent injection rule, the probability of each subsequent code must be conditioned upon the controller state and the history that produced it. The elementary binomial illustration assumes an unchanging Bernoulli probability for independent trials. It is not licensed by the mere appearance of zeroes and ones in an adaptive archive. When a controller changes the injected amplitude, the number of trials, or the retention policy after examining interim results, the likelihood must include that decision process. Otherwise the analyst employs one model to gather data and another, more flattering model to report it.

A defensible design could be adaptive, but it would have to preserve every state transition and predefine the permitted adaptation. For example, the instrument might run an initial calibration tranche to choose among a fixed list of dither levels, freeze the selected level, and then acquire an independent validation tranche. The latter can support a claim about that chosen configuration if all its samples, failures and exclusions are retained. An alternative is a fully specified sequential estimator with a valid stopping rule and confidence procedure designed for optional stopping. Merely repeating the calculation for a fixed sample size at

Copyright 2026, James M. Atkinson

the moment the result appears impressive is not equivalent. The history-dependent sampling law has become part of the measurement instrument.

There is also a practical negative case. Suppose a weak emission is intermittent and the controller injects extra noise only during presumed quiet intervals. A lower average apparent error on the retained data may be true, yet irrelevant to bursts that occurred under other receiver states. The examiner must establish an observation envelope: what intervals were eligible, which were retained, what injection was applied, and what forms of target could have been hidden or displaced. The assertion that dither improved a *stationary mean* may remain supportable. The assertion that no intermittent transmission escaped detection does not follow from the same data. I would report the former with its conditions and withhold the latter.

Your question also helps us place the randomness correctly. Known stochastic input can create an informative experiment; unrecorded discretionary processing can create an opaque one. Randomness is not inherently virtuous, and feedback is not inherently disqualifying. What matters is whether the joint model of source, perturbation, converter, controller and archive is identifiable for the proposition being advanced. In scientific writing the word 'resolution' should not conceal those distinctions. I thank you for the challenge, and Dr. Atkinson, I return the token for the next principal contribution.

Copyright 2026, James M. Atkinson

Ralph Vinton Lyon Hartley | Peer question 2 to Claude Elwood Shannon

Dr Shannon, I should like to distinguish a communications measure from a measurement claim. A converter produces a fixed number of digital symbols, and a report which advertises more effective digits may tempt its reader to treat those symbols as if the channel capacity had somehow increased. Yet the extra statistical discrimination arises from repeated trials under a stochastic stimulus whose distribution the observer already knows. There is no evident contradiction, but the terminology can produce one if the roles of prior knowledge, measurement duration and independent observations are concealed. How would you describe the information gained when a constant voltage is measured many times with dither, without inviting the conclusion that each sample contains additional bits of instantaneous waveform information? Would you also distinguish a confidence interval around a mean from a code's ability to represent a rapid transient whose duration is shorter than the effective averaging interval? The distinction ought to survive even where the numerical results happen to agree with the calibration reference in a particular trial.

Claude Elwood Shannon | Immediate answer to Ralph Vinton Lyon Hartley

Mr Hartley, the clean expression is a statement about estimation under a specified experiment. One twelve-bit code is a member of an alphabet of at most 4,096 values. If the instrument produces repeated codes, the complete record has more possible sequences than a single code. The additional sequence variation can carry information

Copyright 2026, James M. Atkinson

about a stable parameter when its conditional probability law depends upon that parameter. Nothing in this account increases the alphabet of the instantaneous converter output. What has changed is the number and design of observations, and with it the statistical precision attainable for a restricted measurand. We should not label that result as a universal increase in native converter resolution.

The distinction becomes particularly important when the quantity is a function of time. If an amplitude changes during the averaging interval, the histogram of crossed thresholds reflects both analogue variation and injected dither. Without further structure those two causes may not be separable. The average can be well determined whilst the order, timing, peak and duration of constituent events remain unknown. To claim transient fidelity one would need a model for the waveform, sufficient sample timing information, the analogue transfer function, and evidence that the estimator preserves the feature of interest. Merely narrowing the standard error of a mean does not provide those requirements.

Consider also that a reported number can have many written digits and few defensible significant figures. A mean of 0.2500 least-significant-bit with a calculated statistical uncertainty of 0.0137 least-significant-bit may be meaningful in the ideal experiment we later construct. If the analogue reference scale itself is uncertain by 0.1 least-significant-bit, or threshold drift is unmeasured at that level, the numerical precision of the average does not establish that many accurate digits. The measurement report must propagate the calibration and drift components, including their correlations with

Copyright 2026, James M. Atkinson

other measurements. Precision obtained from repeatability is not immunity to bias.

For an intermittent electromagnetic search I would therefore keep two claims on separate lines of the report. One line might state that a calibration tone's stationary amplitude was estimated with a particular standard uncertainty under dithered acquisition. The other line would state what the detector established about time-limited external activity under separately validated operating conditions. The second does not inherit the first merely through a shared ADC. That formulation makes it possible to value improved estimation without pretending that a word of larger numerical width can repair the missing dimensions of the observation. I return the token to Dr. Atkinson.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal response 2: The quantisation-error conditions

Dr. Atkinson, I am grateful for the opportunity to address the mathematical model which has become too familiar for its own good. A uniform quantiser is often accompanied by the statement that quantisation error behaves as independent, uniformly distributed noise with variance equal to Δ squared divided by twelve. That is an extremely serviceable engineering approximation under appropriate conditions, but it is not an axiom which holds for an arbitrary input. When the input is a small stable value, deterministic error may be constant. When a sinusoid is harmonically related to the sampling frequency, the error can be periodic and its energy can occupy spectral lines. When the input is nearly full scale, code transitions may reveal nonlinearity and overload rather than a neat independent process. Therefore the model must be earned by the experiment, not bestowed upon the ADC by the number printed on its package. [R2, R3, R7]

Dither attempts to change the distribution of quantisation error by altering the positions of the samples relative to the thresholds. Subtractive and nonsubtractive systems must be treated separately. In a subtractive arrangement an independent random quantity d is added to the analogue input x, the sum is converted, and the same d is subtracted from the digitised result, producing $z = Q(x + d) - d$. If the ideal unbounded quantiser and dither satisfy suitable distributional conditions, the total error $z - x$ can be uniform and independent of x, with variance Δ squared divided by twelve. That attractive theoretical property depends upon the subtracting apparatus knowing the actual perturbation, not a nominal specification for a noise

Copyright 2026, James M. Atkinson

generator. Timing, reconstruction and calibration errors in subtraction become additional components of measurement uncertainty. [R1, R2]

Nonsubtractive dither is more accessible in some practical instruments, because the added disturbance is not subtracted exactly afterwards. The total error is Q(x + d) - x, which includes the random perturbation as well as the quantisation error. A properly chosen triangular distribution, often constructed by adding two independent uniform variables each spanning one quantisation interval, has valuable first- and second-order error properties for an ideal quantiser without overload. Yet the total error variance may be greater than the quantisation error variance of an ideal independent-noise model. There is no contradiction: randomisation can exchange concentrated, signal-correlated distortions for broader stochastic uncertainty. If the operational goal is a weak-tone survey, reducing an apparent spurious line can be valuable even where the integrated noise power does not fall. If the goal is estimating a static voltage with minimal standard uncertainty, the added variance and averaging cost must be accounted for. [R1, R3]

The spectral question deserves careful language. A deterministic sequence, even when weak in amplitude, can produce a prominent narrow Fourier component after a long record, because coherent energy is concentrated in a few bins. Noise with comparable total energy is distributed across many bins according to its spectrum and the windowing process. Dither can alter the relative prominence of these structures. But one cannot infer that a newly flattened spectrum reveals only external emissions. The analog front end, interleaved sampling branches, clock phase noise and downstream digital arithmetic can introduce their own

Copyright 2026, James M. Atkinson

lines. Nor can one treat a spur that disappears with dither as absolute proof that it was a quantisation artefact. An injected noise signal may also mask a true weak tone or change the operating point of a nonlinear analogue stage. The proposed causal inference requires controlled interventions and their competing predictions.

An investigator could use three complementary acquisitions: a quiet reference with the same gain and clock, an externally injected calibrated tone that is known to traverse the relevant receiver boundary, and the unknown environment. Dither would be toggled according to a precommitted sequence, with its amplitude, spectral density and analog injection point recorded. The test would estimate the change in known converter-correlated lines, the change in broadband noise within the detection band, and any shift in a known external reference line. If the narrow suspect feature tracks a local digital or converter condition more closely than it tracks the antenna or calibrated RF input, an instrumental hypothesis gains support. Yet one should not transform correlation into an unqualified source identification without further physical tests.

I should emphasise a metrological subtlety about the words 'improve resolution'. Under repeated independent dithered observations, some estimates can possess standard errors smaller than Δ. The uncertainty of their mean can decline with the square root of the sample count when assumptions hold. The underlying code thresholds remain unchanged; differential and integral nonlinearity may remain unchanged; and any common offset or gain error persists across the entire average. The analyst should therefore report effective estimation precision for a specified signal class and observation duration. A claimed conversion to more intrinsic ADC

Copyright 2026, James M. Atkinson

bits would be physically mistaken. The ADC itself has not acquired additional independent comparators, a wider linear input span, a faster aperture, or an improved full-scale reference. [R3, R8]

Lastly, any test of dither should evaluate adverse conditions. Place a strong blocker near the upper input range and ask whether the added random signal causes overload at a measurable rate. Make the input phase coherent with the sampler in one trial and deliberately noncoherent in another. Repeat across temperature, reference voltage, and relevant analogue bandwidths. A narrow spectral improvement seen under one coherent stimulus may not transfer to the operational mixture of signals. A defensible report will specify the span of conditions studied and identify where the statistical randomisation model fails. Professor Bridgman, I respectfully offer you the token to test whether my term 'quantisation error' survives a change of measurement operation.

Percy Williams Bridgman | Peer question 3 to William Ralph Bennett

Mr Bennett, I wish to press the distinction between an abstract quantiser and the actual instrument. In your first expression the same dither is subtracted after conversion, but a physical noise source has finite bandwidth, delay, amplitude calibration and imperfect synchronisation. The mathematical subtraction of d is an operation upon a known function. The engineering subtraction may employ a separately digitised estimate or a pseudorandom sequence with a timing slip. These operations do not define identical results. If the recorded perturbation were misaligned by even a fraction of a sample, its removal could create a deterministic pattern that appears more persuasive than the original error. What operations should be required before the investigator can

Copyright 2026, James M. Atkinson

say the subtraction genuinely occurred at the asserted analogue reference plane? Moreover, if a common reference error affects both dither generation and the converter output, would repeated averaging conceal rather than reduce the error? I invite a criterion that can be tested at the bench rather than guaranteed by notation.

William Ralph Bennett | Immediate answer to Percy Williams Bridgman

Professor Bridgman, your objection supplies the boundary between a theorem and an instrument certificate. The formula is a map of desired operations. Its use in a finding requires an experimental account of those operations under relevant physical conditions. In particular, the apparatus must specify the injection reference plane, the transfer from its dither source to the quantiser's sampling input, the timing at which a dither value affects a particular conversion, and the transformation by which the digital subtraction reconstructs the value that was actually applied. A stored pseudorandom seed is not a sufficient record if the analogue reconstruction, filter, or clock relationship is unverified. Conversely, a genuinely digital subtractive scheme may be reproducible when its perturbation and timing are defined, although the independent converter calibration remains necessary.

A practical test would route a stable calibrated analogue input through the same front end while collecting the complete injected waveform and an independent record of the converter clock. The investigator could compare the residual after subtraction against the predicted distribution, test for correlation with the injected sequence,

Copyright 2026, James M. Atkinson

and repeat with deliberately shifted alignment. The shifted trials act as negative controls. If a change of one sample produces conspicuous periodic residuals, the system is sensitive to that error and should record its timing tolerance. An apparently white residual is not sufficient proof of proper subtraction; some wrong transformations can yield attractive marginal histograms. Joint correlation, spectral structure, and reference-plane gain should be examined.

For common errors, averaging is particularly powerless. Let a common offset b affect every measurement. Write $y_i = x + b + e_i$, with the random errors e_i having zero mean. The sample mean becomes $x + b + \mathrm{mean}(e_i)$. Its random error may shrink while the common bias remains exactly b. If the dither source and ADC share a drifting scale, the resulting error components may also correlate rather than average away. That is why the uncertainty budget must distinguish Type A components obtained by repeated observations from Type B contributions associated with calibration and the physical measurement model. Statistical precision is not an independent verification of traceability. [R5]

Your final question asks for a bench criterion. I would require documented agreement between the intended and measured dither sequence at the actual conversion boundary, sufficiently low subtraction residuals over the declared bandwidth, a characterised timing tolerance, and reproducibility under a changed input amplitude and operating temperature. Every acceptance threshold must be defined before the pass-or-fail observations are selected. If those conditions cannot be demonstrated, the result may be called a

Copyright 2026, James M. Atkinson

stochastic averaging procedure, but not a verified realisation of ideal subtractive-dither theory. The distinction is not verbal pedantry. It determines which variance formula may responsibly be propagated into a legal or forensic statement. I thank you and return the token to the moderator.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 3: Sampling, bandwidth and effective independent observations

Dr. Atkinson, I accept the account of quantisation but wish to draw attention to the clock and the bandwidth. The possibility of estimating a static or slowly changing quantity from many dithered samples rests upon the relation between the observation duration and the physical bandwidth of everything entering the converter. If a disturbance contains frequencies outside the admitted analogue band, it may be filtered before it can cross the threshold. If it reaches the sampler above the applicable Nyquist region without adequate anti-alias protection, it may fold into the frequency interval of interest. If the digital filter has a long impulse response, adjacent output values may be strongly correlated. These are different limitations, yet all three can be hidden behind a single expression such as 'average 1,024 samples'. The count of stored numbers is not always the count of independent observations. [R3, R8]

For a sequence of independent, zero-mean errors with variance σ^2, the variance of the arithmetic mean is σ^2 divided by N, where N is the number of observations. This is a mathematical statement about the error process, not a guarantee about any receiver. If the errors share a constant correlation coefficient ρ, an illustrative equicorrelation model gives variance of the mean equal to σ^2 times [1 + (N-1)ρ] divided by N. For sixty-four measurements with correlation one-tenth, the multiplier is 7.3 divided by 64 rather than 1 divided by 64. The effective independent sample count for the mean is therefore approximately 8.77. A receiver storing sixty-four codes would obtain a precision gain much closer to that of nine independent

Copyright 2026, James M. Atkinson

observations than sixty-four. The model is simplified but exposes the effect of an assumption that operators often leave invisible.

The oversampling ratio also needs an explicit bandwidth definition. An idealised converter whose noise is white over the Nyquist interval may acquire samples at a rate far above twice the final signal bandwidth. Filtering and decimation can remove much of the out-of-band noise. Under the usual ideal assumptions, increasing the oversampling ratio by a factor of four produces approximately six decibels of in-band noise-power reduction, equivalent to about one effective bit of *in-band noise-limited performance*. That rule is not a device-physics identity and should not be used for flickering threshold values without checking the error spectrum. If noise is signal-dependent, coloured, or dominated by a fixed analogue offset, the rule may fail. If the target is a short pulse whose duration is comparable to the digital filter's memory, the decimated record may be less faithful to that pulse than the original high-rate samples. [R8, R9]

The dither spectrum itself deserves the same attention as a signal spectrum. A broadband perturbation may improve statistical coverage of thresholds but raise noise in the detection band. An out-of-band perturbation may move some converter artefacts without directly contaminating the final detection band, provided the analogue and digital filter boundaries truly confine it. But an out-of-band tone or noise component can also intermodulate in the front end, alias during conversion, or overload a shared stage. Thus a design which is beneficial on an isolated converter board may perform badly in an installed receiver whose antenna, preselector, low-noise amplifier and mixer introduce different constraints. The engineering decision cannot be divorced from the full path.

Copyright 2026, James M. Atkinson

For TSCM work this is especially consequential because the observation object is not always stationary. Suppose an emitter activates for two milliseconds while the receiver averages an amplitude indicator over one second. The averaged reading may be statistically stable and precisely reported yet conceal nearly all timing information about the emission. Conversely, a detection pipeline retaining the unfiltered high-rate record may be capable of recognising the event while a secondary averaged channel estimates the background or calibrates slow drift. Both outputs may be useful if their intended estimands are stated. They cannot be interchanged merely because both ultimately derive from the same ADC codes. One channel is a transient-evidence path; the other is a low-bandwidth estimation path.

I would therefore insist upon a timing register that identifies actual sample clocks, their uncertainties, block losses, decimator group delay, digital filter coefficients, dither generation timing and the relationship of any trigger to the raw samples. The sample count in a data sheet does not disclose these matters. Under a chosen weak-signal model, the investigator should calculate detection probability and uncertainty using an effective number of independent observations or an explicit covariance model. This is preferable to asserting a universal 'six decibels per fourfold oversampling' rule while ignoring whether the relevant information was moved outside the retained band. Nor may one infer that a lower noise floor corresponds to lower false-alarm probability unless the decision rule is adjusted and validated.

There is a final distinction between rate and span. A faster conversion rate may admit a larger analogue bandwidth if the front end and sampling

Copyright 2026, James M. Atkinson

geometry are designed for it; it does not by itself create the dynamic range required to recognise a faint source beside a strong blocker. Averaging across time can reduce uncertainty for stable quantities, but cannot automatically preserve every event in a larger spectral span. One should characterise the permissible trade-off among bandwidth, temporal resolution, spectral resolution, dynamic range and independent measurement time. I pass the floor respectfully to Dr von Neumann, whose concern about assumed randomness may test the very foundation of this independent-sample argument.

John von Neumann | Peer question 4 to Harry Nyquist

Dr Nyquist, your caution about correlated samples is persuasive, but a practical implementation may derive its dither from a deterministic pseudorandom generator rather than an analogue noise source. Its sequence is computable and therefore not genuinely unpredictable to an informed examiner. Nevertheless, an appropriately long deterministic sequence may seem statistically well distributed over the short interval used to estimate a voltage. Does the absence of intrinsic randomness invalidate the proposed gain, or can a reproducible deterministic sequence provide the necessary threshold coverage for a specified estimator? If the latter, what is the relevant distinction between an average taken over an exact, repeated excitation pattern and a probabilistic interval derived as though every observation were independently random? I should like you also to address the danger that a dither sequence which repeats at an unfortunate rate produces periodic spectral structures precisely where the TSCM receiver is attempting to find unknown low-level emissions.

Copyright 2026, James M. Atkinson

Harry Nyquist | Immediate answer to John von Neumann

Thank you for that question. Professor von Neumann, it is not necessary to pretend that every useful excitation is ontologically random. A predetermined sequence can sweep thresholds and permit parameter estimation under a deterministic calibration model, provided its values, timing and relation to the input are sufficiently known. The investigator may then derive an estimator using the actual sequence and the converter's transfer function, or calibrate the response empirically. But it would be incorrect to attach a confidence interval based on independent identically distributed noise merely because the sequence's histogram resembles the chosen random distribution. Statistical properties of a sequence under one collection of tests do not automatically furnish independence from an unknown input or unrelated clock. The mathematical justification must correspond to the physical construction.

Suppose a pseudorandom pattern repeats every P samples. Its periodicity produces discrete spectral lines at multiples of the repetition frequency, potentially with sidebands after nonlinear conversion. If the target happens to be coherent with that pattern, threshold crossing probabilities may depend on phase in ways that a marginal histogram conceals. Randomising the starting phase, choosing a sequence whose period greatly exceeds the acquisition interval, or changing the dither clock relationship can reduce such effects, but each is an engineering hypothesis to be tested. It cannot be certified by the word 'random' in the software documentation. The

Copyright 2026, James M. Atkinson

validation should include spectral examination of the known dither itself and of the residual under a range of coherent reference signals.

For an uncertainty report, I would distinguish two kinds of inference. One concerns the response to a calibrated deterministic excitation whose complete sequence has been retained. Its error bound might come from measured transfer-function tolerances and repeatability across controlled trials. The other concerns an ensemble of hypothetical random excitations and makes a probability statement about estimator variability. The former can be strong without being the latter. When both are used, the report should identify which uncertainties arise from the actual observed sequence and which from an assumed distribution of future or repeated experiments. That distinction prevents an engineer from treating a convenient design sequence as a licence for unsupported tail probabilities.

Finally, the presence of a deterministic dither may be exceptionally useful for diagnosing an apparatus precisely because its sequence is reproducible. One can repeat a run, examine phase relationships, shift the injection timing intentionally, and test whether a suspect spectral line follows the internal sequence. In a forensic setting that controlled challenge may be more informative than a vague assertion that natural noise should be harmless. Yet the very power to repeat the excitation increases the responsibility to preserve the exact configuration and to avoid reporting the resultant spurs as external emissions. I thank you, and return the floor to Dr. Atkinson.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 4: Estimation, experimental design and the adverse case

Dr. Atkinson, I should like to examine the purpose of the calculation rather than begin with a preferred signal-processing operation. The first question is what the engineer hopes to know: a mean voltage, an RMS amplitude, a spectral line's frequency, a low-level event's existence, or the probability that a particular alarm corresponds to an external source. An estimator which is efficient for a stationary mean can be unsatisfactory for an intermittent event. A detector which suppresses a fixed quantisation spur can lose power for a transient signal when additional noise enters its measurement band. The word improvement is incomplete until the loss function, operating conditions and comparison procedure are specified. We must therefore design the experimental challenge before selecting the dither amplitude which yields the most pleasing result. [R3, R6, R10]

I propose to divide the experiment into discovery and validation. In discovery, one may explore several amplitudes, probability distributions, spectral placements and processing parameters. Such exploratory work is scientifically valuable; it is how unforeseen failure modes are found. The danger arises when a particularly favourable choice is selected using the same observations that are later presented as an unbiased validation of that choice. A receiver may be tested with ten noise levels, five filters, three detector thresholds and several observation durations. An impressive apparent detection rate chosen from the best combination does not enjoy the nominal error probability of a single predeclared test. A separate validation population, or an analysis that properly accounts for adaptive selection, is required before the headline claim may be made.

Copyright 2026, James M. Atkinson

The simplest numerical illustration involves a fixed value one-quarter of a least-significant-bit above a rounding threshold. Add properly characterised uniform dither, perform one thousand independent trials and count the higher code. Under the ideal threshold model, the expected higher-code proportion is one quarter, and its binomial standard error is the square root of 0.25 times 0.75 divided by one thousand, or approximately 0.0137. The result supports a conditional estimate of the stationary fractional threshold position. But the calculation's elegance is not its proof. Before adopting the interval, I want a record of threshold drift, analogue noise correlations, code-selection logic, independent calibration, rejected samples and possible input variation. The experiment should also repeat at several unknown offsets, because a calibration procedure that works at one especially convenient fraction of a code may fail near the adjacent transition. [R1, R5]

Now consider the opposite outcome: false alarms. Suppose the analysis searches five hundred effectively independent spectral bins, each assessed at a nominal false-alarm probability of one in a thousand. Under the simplifying independence model, the chance of at least one false alarm somewhere in the search is one minus 0.999 raised to the five-hundredth power, approximately 39.4 percent. Dither may reduce a coherent instrumental line and still require recalibration of the detector because it changes the noise distribution. If the report quotes only the per-bin significance, the reader may infer a level of assurance not provided by the full search. The same problem recurs across observation times, antenna positions and receiver configurations. The family of opportunities to obtain an apparently significant result must be defined before evidential confidence is assigned. [R5]

Copyright 2026, James M. Atkinson

A sound experiment would contain a factorial structure with at least these dimensions: dither on or off; an independent known external test signal present or absent; a large blocker present or absent; and coherent or noncoherent relationships between input frequency and sampling clock. Additional blocks could vary temperature, analogue gain and filter settings, provided the design remains tractable. Randomising the order of trial conditions would help control gradual thermal drift. The raw data and the predeclared analysis code would be preserved. We would compare true-detection rates at a fixed *global* false-alarm specification, not award victory to whichever display looks quieter. We would inspect uncertainty intervals rather than merely compare means, and identify intervals where the receiver saturated or the dither failed to reach the conversion threshold.

One must beware of an attractive paradox in reporting. A randomised quantiser can reduce bias in estimating a mean whilst increasing variance of individual outputs. A weak tone may become more readily distinguishable from deterministic quantisation spurs while a single-shot pulse becomes harder to detect. These are not inconsistent outcomes. They are properties of different estimands, time scales and decision rules. The experiment should not place every capability under the single label 'sensitivity'. For a TSCM investigation, it is entirely plausible that a dithered high-rate background-estimation channel and a nondithered transient-preservation channel will have complementary roles. Such an arrangement is defensible when acquisition paths, cross-calibration and alert logic are carefully characterised, but not merely because two windows appear on the same console.

Copyright 2026, James M. Atkinson

An investigator should report an honest hierarchy of conclusions. A narrow claim might establish that a calibrated stationary signal can be estimated with reduced random uncertainty over a specified interval. A stronger claim might establish improved suppression of known converter-correlated spurs in a specified analysis band at unchanged global false-alarm probability. A still stronger claim about improved detection of unknown intermittent surveillance transmissions would require a representative challenge population including bursts, blockers and changing frequency. None follows automatically from the preceding claim. A clear methods appendix should enable another analyst to test the same hypotheses and obtain a comparable inference, including the conditions under which the intervention worsened performance.

In the end I would not demand that every study be perfect. I would demand that the study be clear about the problem it actually answers. Exploratory plots can suggest mechanisms; controlled challenges can test them; and a bounded acceptance criterion can support a practical decision. What must not occur is promotion of a convenient numerical result into an unlimited property of an instrument. Sir Ronald Fisher, may I courteously pass you the token to consider the price of repeated testing and the interpretation of apparent improvements?

Sir Ronald Aylmer Fisher | Peer question 5 to John Wilder Tukey

Professor Tukey, I agree that an intervention must be tested against the claim, but the design you describe is sufficiently elaborate to tempt an investigator into post hoc selection. Suppose a development team evaluates twenty dither amplitudes, inspects many spectra, and retains the setting with the smallest observed spurious line. It then calculates a

Copyright 2026, James M. Atkinson

confidence interval for that setting as though no alternatives had been examined. The apparent gain might be partly a selection effect. Conversely, a rigid rejection of every adaptive procedure would discourage useful engineering discovery. How should the investigator divide inference from exploration when the number of attempted configurations itself changes as technical anomalies are discovered? Would you require a reserved validation collection, a sequential testing rule, or some other restriction, and what exactly should a court or independent technical reviewer be told about the unselected configurations and trials? I should also like to know whether adverse data must remain available even when an engineering team believes those observations were anomalous.

John Wilder Tukey | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, the principal remedy is transparent separation of learning and testing. An exploratory sweep of twenty levels can identify patterns worth pursuing, including unforeseen regions in which added noise induces overload or analogue intermodulation. There is no need to conceal such learning or apologise for it. But the trial that determines the declared acceptance condition should either use independent validation data or apply a method whose error control accounts for the selection. A confidence interval computed as though the selected configuration had been chosen beforehand is not the same inferential object. The problem is not that selection occurred. It is that its consequences were omitted from the probability statement.

Copyright 2026, James M. Atkinson

I would record the complete candidate set, the chosen loss function and all data-dependent decisions. If the engineering team changes the candidate set after observing a fault, the history should distinguish the original and revised phases. A practical protocol might allocate one group of reference waveforms to discovery, then freeze the dither generation, filter coefficients and detector threshold, and use a separately generated set of coherent and noncoherent signals for validation. The trial order should be randomised where possible, while independent measurement standards check source amplitude and frequency. The validation report should state every failed and excluded trial, along with the predeclared reason for exclusion and any sensitivity analysis including those trials.

There are occasions where independent data are expensive, for example when a rare electromagnetic environment is difficult to reproduce. In that case one can use an appropriate sequential or resampling procedure if its assumptions are met, but the procedure and stopping rule must be specified sufficiently to control the relevant uncertainty. Repeatedly examining ordinary confidence intervals until one excludes zero does not achieve that objective. Nor does a large recorded sample count compensate for the dependence introduced by filtering or overlapping windows. An honest report may conclude that an intervention is promising but not yet independently validated. Such a finding is useful for further engineering work and less hazardous than an unsupported certification.

The forensic audience needs the operational rather than merely mathematical version of this account. State how many configurations

Copyright 2026, James M. Atkinson

were evaluated, whether the final setting was selected from those observations, which trials were reserved for validation, what detection and false-alarm definitions applied, and what environment was represented by the challenge signals. If a dither-on setting improved a certain spur by ten decibels but worsened burst sensitivity, both outcomes belong in the report. If the improvement was measured only under coherent laboratory tones, say so. The reader should be able to reconstruct the inferential pathway, not simply admire the chosen plot. Dr. Atkinson, I return the token.

Alan Mathison Turing | Peer question 6 to John Wilder Tukey

Professor Tukey, I wish to ask what a purported post-processing improvement can compute from an immutable evidence file. An analyst may take a twelve-bit recording, add carefully generated pseudorandom numbers to its samples, and then calculate averages or resample it onto a finer numerical grid. The output may contain many new values and display a smoother trajectory. In some settings numerical randomisation is a legitimate algorithmic convenience, but there may be pressure to describe the operation as recovery of an analogue signal that was never adequately sampled. Could you specify a test capable of distinguishing an estimator that merely changes its numerical behaviour from a procedure that has genuinely acquired new physical information? I am particularly concerned by reports of reconstructed pulse heights or durations obtained only after the acquisition has ended, where no independent contemporaneous measurement constrains the missing analogue waveform. An algorithmically stable answer may be reassuring

Copyright 2026, James M. Atkinson

to the eye while still depending entirely upon an untested prior assumption.

John Wilder Tukey | Immediate answer to Alan Mathison Turing

Dr Turing, your distinction is essential. A post-processing algorithm can reorganise the information already present, apply valid prior models and produce a useful conditional estimate. It cannot create a new observation of the physical event. If two different analogue inputs would have generated exactly the same retained code sequence under the known acquisition procedure, no processing of that sequence alone can decide which input was present without additional assumptions or external evidence. Adding random values to the stored numbers changes the computation, not the historic threshold crossings. The resulting variability is an attribute of the algorithm, not independent physical information from the instrument.

A direct test begins with a calibrated analogue signal whose fine structure is measured independently at the relevant reference plane. Record the raw converter data and run the proposed processing under a range of known inputs which lie within the same quantisation intervals. If the algorithm assigns different correct estimates to those inputs solely because its random seed differs, it is not identifying the analogue truth. It is producing a distribution of reconstructions conditional upon its assumptions. Such a distribution may be defensible as an uncertainty representation if the prior model and its validation are disclosed. It is not a measurement of an unrecorded pulse peak. Conversely, if repeated *new* analogue acquisitions are made under appropriately randomised excitation, their differing

Copyright 2026, James M. Atkinson

codes can provide additional information about a stable parameter, and the validation can demonstrate this experimentally.

The resulting report should separate observed data, introduced randomness, modelling choices and inferred properties. A reconstructed stationary mean may be consistent across several seeds without proving that each instantaneous amplitude was correct. A pulse may be reconstructed under an assumed waveform template whose limitations ought to be stated and tested. If the output is intended to support a legal finding, the method should preserve the original immutable file, the algorithm version, seed, parameter choices, calibration history and any independent test cases. Reproducibility of the computation is necessary but does not establish correctness of the source model. This is a familiar distinction between solving a calculation and validating its premises.

Your question also suggests a rule for professional vocabulary. Reserve 'acquired' for observations made by the physical measurement chain; use 'estimated', 'interpolated', 'modelled' or 'simulated' for results of subsequent computation as appropriate. If a digital resampling routine produces twenty-four-bit floating-point values from twelve-bit stored codes, it is entirely possible for the output to be numerically precise. It is not thereby a twenty-four-bit record of the original continuous waveform. An expert who makes that distinction plainly can still explain the merits of denoising or estimation without misleading the reader about instrumental resolution. I thank you and relinquish the floor to the moderator.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal response 5: Metrology, procedure and evidential trust

Dr. Atkinson, the preceding contributions have described a statistical benefit whose legitimacy depends upon stability. I should like to make stability the principal subject rather than an incidental qualification. A measurement process includes the reference standard, the physical input coupling, environmental conditions, the dither generator, converter transfer function, sample clock, digital processing and the people who configure or review the system. It is possible for each isolated component to possess a respectable specification while the assembled process operates differently after a cable replacement, a temperature excursion or a software update. The presence of randomly toggling low-order codes tells us little about the reliability of this combined process until its relevant state variables have been monitored and challenged. [R5, R10]

Control should begin with an explicit calibration hierarchy. A stable reference source tests amplitude and frequency at a defined plane. A noise or dither source should have a measured spectral distribution and amplitude at the point where it actually reaches the quantiser. The record should identify the sampling clock, its uncertainty and whether the dither generation shares that clock. A source whose amplitude changes with temperature may alter threshold occupancy in a way that resembles a drift of the unknown input. The analyst should therefore measure the dither itself in representative conditions and use independent checks to distinguish its changes from the converter's changes. This is not bureaucratic paperwork. It is what permits the observed code histogram to have the physical meaning assumed in the estimation model.

Copyright 2026, James M. Atkinson

Control charts can be useful, provided they monitor relevant quantities rather than decorate the report. One chart may track the mean of a calibrated stationary input; another may follow the variance or distributional shape of the dither; a third may record the level of a known converter-correlated spur. The purpose is to identify changes which require explanation, not to use a statistical limit as a substitute for physics. The process should define which conditions are expected to remain stable and how suspected changes prompt investigation. An excursion might arise from a converter threshold shift, injected-noise amplitude change, reference-scale error, clock disturbance or unrecorded operator intervention. The chart signals that the original model may no longer apply. It does not establish which mechanism occurred.

I would demand particular care in the use of repeated observations. A group of measurements can be highly repeatable because it shares one offset. A dither generator may be precisely repeatable because its output is controlled by a common reference whose error has not been checked. A hundred nominally independent receivers may share one antenna distribution stage and consequently one interference pathway. Additional counts do not automatically reduce such common errors. Every uncertainty budget should distinguish random components which can decline with averaging from common systematic components and covariances which do not. When the resulting calculated standard uncertainty is smaller than the smallest meaningful calibration error, the proper response is to report the combined uncertainty, not to suppress the calibration term for the sake of an impressive result.

Copyright 2026, James M. Atkinson

The legal and investigative consequences are direct. If the technique is employed while searching for unauthorised emitters, the primary evidence is the preserved record of what the receiver admitted and represented. The controlled dither should be treated as part of the instrument's operating state and the chain of acquisition, not as a later cosmetic adjustment. The examiner should retain raw codes, injection settings and monitoring records, software versions, calibrated references, source-selection history and all exclusions. A hash can demonstrate that a file was not altered after a specified point, but cannot prove that the original ADC was accurate or that the analogue channel was free of intermodulation. The difference between integrity and validity should be apparent to any later reviewer.

A practical procedure can be expressed as a sequence of questions. Was a dithered acquisition scientifically justified for this measurand? Was the unmodified acquisition retained alongside the dithered one where feasible? Did the intervention reduce the particular systematic artefact it was intended to reduce? Did it raise the relevant noise floor, overload rate or false-alarm count? Were both the successes and the failures preserved? Was the same result obtained under an independent reference or altered receiver configuration? If the answer to any critical question is unknown, the result may still be useful as an exploratory observation, but its scope should be described accordingly. A great many errors arise not from bad mathematics but from applying good mathematics to a changed process.

An acceptance test should include stable tones at several positions within a code interval, low-level noise-like signals, coherent tones, short bursts, a strong blocker and an apparently quiet reference. The test should be repeated under dither-on and dither-off conditions in a balanced order, and

Copyright 2026, James M. Atkinson

at the relevant environmental extremes. The evaluator must decide in advance what constitutes an unacceptable degradation of transient detection, a significant reduction of instrumental spurs, and a valid improvement in stationary amplitude estimation. These may be competing objectives. A process intended for general surveillance cannot be certified on the strength of only the easiest one. When a claim is made about the probability of detecting an intermittent emission, the relevant trials should contain intermittent emissions whose timing is not favourably synchronised with the receiver.

Finally, I would separate the language of quality control from that of attribution. A well-controlled ADC with dither may reduce uncertainty associated with a measurement of an admitted signal. It does not identify the transmitter, its owner, its purpose or the location from which the energy originated. Those propositions require further physical observations, competing-hypothesis tests and evidence beyond the digitiser. The best quality-control programme protects the credibility of a bounded claim by preventing it from expanding unnoticed into a claim the apparatus cannot establish. Mr Weston, may I respectfully pass you the token to ask whether our reference-plane assurance is itself independently tested?

Edward Weston | Peer question 7 to Walter Andrew Shewhart

Dr Shewhart, your controls are persuasive, but I remain concerned about the physical quantity being compared. A laboratory may calibrate an ADC at its accessible input pins and then advertise reduced error after dither, while the field receiver includes a preselector, amplifier, mixer, attenuator and cables. Their losses, temperature dependence and nonlinearities affect the electromagnetic quantity that the investigator

Copyright 2026, James M. Atkinson

intends to infer at the antenna port. A careful code histogram could therefore be quite accurate as a statement about converter voltage yet misleading as a statement about incident field strength. What evidence is required to carry a dither-assisted estimate through the full receiver chain without turning calibration of one boundary into certification of every preceding stage? And when an external test tone is injected through a convenient internal connector, which conclusions must remain restricted because the antenna and its surrounding environment have been bypassed? In particular, I would not want the convenient reference plane to conceal a material uncertainty in the installed system.

Walter Andrew Shewhart | Immediate answer to Edward Weston

Mr Weston, the transfer between reference planes must be demonstrated for the measurand and condition actually claimed. A converter-pin calibration establishes a relationship between voltage at those pins and observed codes within its stated operating range. It does not establish the amplitude of an electric field in a room, nor the power at an antenna terminal, nor a source location. Each additional inference requires the transfer of the intervening components to be characterised. The relevant measurements may include gain, loss, mismatch, bandwidth, intermodulation response, temperature dependence and their covariances. A nominal gain figure cannot repair a chain whose state changed during the acquisition. Where those relationships remain untested, the report should retain the narrower converter-plane quantity.

A reference tone introduced at an internal connector can be very useful for checking the downstream stages. The point of injection is

Copyright 2026, James M. Atkinson

the boundary of that particular test. If the antenna or preselector is bypassed, the result cannot certify their performance or the reception conditions outside that connector. To test the full chain, one may use an independently calibrated stimulus at the antenna port, or a radiated reference under carefully controlled conditions. The latter introduces its own environmental uncertainty, which must be evaluated rather than ignored. The strongest validation plan employs complementary reference planes so that a discrepancy can be localised. It does not treat one route as universally superior simply because it yields a cleaner graph.

Dither-assisted estimation can then be placed within a traceable model. Let the converter estimate a voltage v with standard uncertainty u_v, and let the analogue chain convert an input quantity s to voltage through a characterised gain g. Estimating $s = v/g$ requires uncertainty contributions from both v and g, including covariance if common references or environmental effects couple them. Repeated quantised samples may reduce a random part of u_v. They do not eliminate the calibration uncertainty of g. If the uncertainty in g is dominant, a hundredfold improvement in the variance of the converter's mean may produce almost no improvement in the uncertainty of s. A rigorous report displays this fact instead of withholding it.

A field record should accordingly preserve the exact connector arrangement, antenna identity and orientation, cable and attenuator configuration, preselector state, gain and clock settings, dither injection location, and independent references used before and after

Copyright 2026, James M. Atkinson

the observation. Any replacement receiver or changed analogue component should trigger a comparability check. The goal is not a limitless catalogue of hardware, but the minimum sufficient record needed for a competent colleague to reproduce or challenge the asserted transfer. I thank you for returning our abstract calculation to the measurement bench, and pass the floor to Dr. Atkinson for the worked applications and closing synthesis.

Ten worked technical applications | Moderator-led numerical examination

The following applications are original hypothetical examples, not tests of any named commercial receiver. Unless specifically stated, Δ denotes one ideal uniform-quantiser step in volts, N the number of native converter bits, n the number of repeated observations, and all stochastic conclusions presume the distributions and independence explicitly named. These computations are designed to test the panel's claims. Real instrument noise, nonlinearities, calibration and correlation must be measured before the results are applied to a field receiver.

Claude Elwood Shannon, Cross-Peer Question to William Ralph Bennett: Dr Bennett, when dithering makes threshold crossings more informative about a stationary voltage, how do we avoid confusing the new estimator precision with a physical improvement in converter code width? Please contrast subtractive and nonsubtractive practice, and identify the observation that would falsify the ideal result.

William Ralph Bennett, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, a 12-bit converter with a 0.48828125 mV nominal code interval

Copyright 2026, James M. Atkinson

remains a 12-bit converter even when repeated threshold observations estimate a fixed offset within that interval. In subtractive dithering, a recorded analogue perturbation is applied before quantisation and the corresponding numerical perturbation is removed after conversion. The ideal uniform-error theorem requires its distribution, independence, exact subtraction and an unsaturated quantiser. A nonsubtractive experiment instead retains added noise and requires a different estimator model. Test known sub-code voltage steps over several input positions and temperatures, then inspect residual bias, correlation and transition stability. If the measured occupancy does not follow the predicted input-dependent probabilities, the claimed uncertainty reduction is unsupported. A smoother displayed trace does not extend analogue bandwidth, recover a missed pulse or certify a new ADC bit. I respectfully pass the token to Dr Nyquist to address repeated observations.

Harry Nyquist, Cross-Peer Question to John Wilder Tukey: Professor Tukey, a survey obtains sixty-four observations and reports a standard error calculated as though every code were independent. The samples share a drifting reference and low-pass memory. How should the analyst establish an effective sample count before claiming sensitivity improvement, particularly when the event is shorter than the averaging window?

John Wilder Tukey, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the relevant quantity is variance of the specified estimator under its actual covariance structure, not merely the number of codes collected. Record sample cadence, filter impulse response, clock configuration, reference-voltage trend and stimulus stationarity. The example with n=64 and common pairwise correlation 0.10 yields an effective count of about 8.767,

Copyright 2026, James M. Atkinson

not 64, under the stated equicorrelation assumption. Estimate autocovariance from repeated independent runs, examine block means and challenge the model with hold-out acquisitions. A confidence interval that narrows solely through a presumed independence factor is inadequate. For transient signals, explicitly compare event duration with the processing window; averaging that removes the event cannot be called improved detection of the event. Account for experimental selection of the most favourable window. I respectfully pass the token to Dr Bennett to examine noise placement.

William Ralph Bennett, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, a laboratory claims that injecting a triangular dither improved a receiver because a narrow spur fell by fifteen decibels, but its integrated passband noise rose and its clipping counter occasionally advanced. Which control measurements would distinguish spectral whitening from a genuine detection benefit?

Walter Andrew Shewhart, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, require a before-and-after acquisition at matched analogue gain, temperature, input loading, sample rate, filter bandwidth, FFT window, averaging rule and false-alarm calibration. Measure the applied perturbation at the analogue reference plane, including its band-limited power, rather than infer it from the software setting. Compare spurious-free dynamic range, integrated SNR, noise density, detector operating curves and saturation statistics separately. The nominal 6.0206 dB noise-power penalty in the stated additive simplified model is not a general dither theorem; it cannot be silently transferred to the triangular nonsubtractive result with different moment conditions. Document the input distribution

Copyright 2026, James M. Atkinson

and the number of opportunities searched. A spur displaced into apparently random energy may improve one plot whilst worsening sensitivity to a weak burst. I respectfully pass the token to Professor Tukey for the final adverse trial.

John Wilder Tukey, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, near full scale the manuscript example assigns a 25 percent overload probability to one particular sample under uniform dither. How should an expert prevent that result from being misrepresented as a 25 percent overall clip rate, or as an argument for adding digital noise to an already stored I/Q stream?

Claude Elwood Shannon, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, specify that the 25 percent probability is conditional on the instantaneous input being +0.950 V, the upper permitted value being +1.000 V and the independent dither uniformly covering −0.100 to +0.100 V. The clip probability across a variable waveform requires integration over its amplitude distribution and the actual dither law. Noise added after ADC acquisition changes only downstream analysis; it cannot alter the threshold crossings or unsampled analogue history. Preserve original I/Q codes, dither-generation records, headroom state, random seed when reproducibility depends upon it, and derivative processing separately. Demonstrate any claimed performance gain against previously defined loss and false-alarm criteria using independent test stimuli, not merely a favourable displayed spectrum. A clipping-related loss of identifiability remains even when a reconstruction looks persuasive. I respectfully return the token to Dr Atkinson for synthesis.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson | Moderator concluding synthesis

Colleagues, the difference between quantitative estimation and intrinsic converter resolution is now explicit. Dither can be an instrument of measurement when it is applied before conversion, when its actual properties are sufficiently known, when the input has the stability appropriate to the measurand, and when the resulting probability law is experimentally defensible. Under such conditions a set of code occupancies may discriminate a stationary analogue parameter more finely than one native code interval. But the individual conversion thresholds remain where physics and calibration have placed them. The instrument has not acquired a larger instantaneous alphabet, extra analogue headroom, or an improved ability to preserve pulse shapes merely because an average has been reported to additional decimal places.

The first group of exchanges identified the epistemic boundary. Dr Shannon distinguished information in one conversion from information in a repeated experiment; Professor Wiener exposed how adaptive observation can invalidate a naive likelihood; and Mr Hartley insisted that a more accurate mean not be confused with more bits in each sample. Mr Bennett then showed why the classical uniform quantisation-noise model is conditional and why subtractive and nonsubtractive dither have different error structures. Professor Bridgman correctly demanded that a subtraction expressed in algebra be demonstrated in a physical chain. Dr Nyquist established that independent observations, not merely stored samples, govern statistical gain; Professor von Neumann showed that deterministic excitation can be useful without automatically satisfying a stochastic independence model. Professor Tukey located every claimed improvement

Copyright 2026, James M. Atkinson

in an explicit decision problem, and Sir Ronald Fisher and Dr Turing challenged experimental selection and the retrospective creation of apparently informative numbers. Dr Shewhart and Mr Weston returned those conclusions to metrological stability, actual reference planes and a reproducible evidential record.

Several findings are ready for operational use, provided they remain properly bounded. For a stable signal, a known dither may make threshold occupancy informative about fractional input position. For a coherent spectral-analysis problem, a suitable perturbation may reduce signal-correlated quantisation artefacts and improve a relevant spurious-free measure. For a bandwidth-limited estimator, sufficiently independent samples can reduce the random component of uncertainty through averaging. In none of these cases may an investigator automatically assert a comparable improvement in transient detection, immunity to external blockers, analogue linearity, or attribution of an observed spectral line to a clandestine transmitter. Each proposition has a different challenge population, measurement model and likely failure mechanism.

The numerical exercises illustrate the range of permissible conclusions. A twelve-bit converter across two volts has a native step of approximately 0.488 mV; independent repeated dithering can estimate a stationary fractional step with a statistical uncertainty well below that value under an ideal threshold model. Yet a modest common correlation can erase much of the predicted averaging gain. An apparently sensible 0.5-step broadband perturbation can increase in-band noise while reducing a deterministic spur. Near overload, a random intervention intended to improve measurement may produce clipped samples in one quarter of the deliberately constructed

Copyright 2026, James M. Atkinson

trials. A multiple-frequency search may face a much greater familywise false-alarm probability than the probability printed beside each tested spectral bin. These are not peripheral curiosities. They are the conditions under which the word improvement can become technically misleading.

For publication and forensic practice, the acceptance record should therefore carry the native bit width and analogue range; the intended measurand; the injection point, dither distribution, amplitude and spectrum; whether subtraction actually occurred; the raw conversion codes; the sampling and decimation history; the effective independent observation count; calibration and covariance contributions; and validation outcomes including failures. The report should distinguish raw observations from subsequent estimates and from interpretations of external source identity. It should explicitly disclose where original data have been filtered or averaged, especially when intermittent signals may have been suppressed. A reproducible software pipeline is valuable, but it is not an independent measurement of an analogue event that the converter did not capture.

I conclude that dither can improve a *specified, model-supported quantitative estimate* without improving the converter's intrinsic resolution. This statement is positive, not dismissive. It recognises a genuine and often useful measurement technique while prohibiting its extravagant interpretation. It is also provisional wherever the actual installed receiver departs from the ideal model or the source record remains incomplete. Our next question will move from the deliberate perturbation of one converter to the alignment of several converters. When interleaved ADC branches disagree in gain, offset, aperture timing or bandwidth, their periodic errors can resemble spectral emissions. The panel will examine how those

Copyright 2026, James M. Atkinson

artefacts are predicted, tested and distinguished from an external RF source. I thank every colleague for the discipline of the exchange and pass the token to the opening respondent of Question 027.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 026

Application 01. Native code width and idealised quantisation uncertainty

Let the input span V_{FS} be 2.000 V peak to peak and the uniform converter have B = 12 binary bits, corresponding to $2^B = 4096$ nominal codes. Define $\Delta = V_{FS}/2^B$, so $\Delta = 2.000/4096$ V = 0.00048828125 V = 0.48828125 mV. Under the classical, justified independent uniform quantisation-error model, the error standard deviation is $\sigma_q = \Delta/\sqrt{12}$ = 0.1409547 mV. This is a statistical scale, not proof that the converter actually has uniform errors for every input. If a constant voltage remains inside one code interval, the undithered error can instead be a fixed offset. The example establishes the starting code geometry and why a fractional millivolt printed after averaging does not imply a narrower physical ADC threshold.

Application 02. Threshold-crossing estimation of a quarter-code stationary signal

Let an ideal mid-tread quantiser round to the nearest multiple of Δ. Set the constant input $x = 0.25\Delta$ and introduce independent uniform dither $d \sim U(-0.5\Delta, +0.5\Delta)$. The digitiser selects code Δ when $x+d \geq 0.5\Delta$, requiring $d \geq 0.25\Delta$. The admissible dither interval has total width Δ, while the qualifying upper interval has width 0.25Δ; therefore $P(Q=\Delta)=0.25$ and $P(Q=0)=0.75$. Define the estimator $\hat{x} = \Delta$ times the observed fraction of higher-code events. For n=100 independent trials, the standard uncertainty from the binomial model is $\Delta\sqrt{(0.25\times0.75/100)}=0.0433013\Delta$. This is better than a whole step for a stable parameter, not a method for

Copyright 2026, James M. Atkinson

preserving unobserved pulse peaks. The frequency-based estimator is conditional on precisely known threshold and dither distribution.

Application 03. Independent repetitions and the conditional statistical interval

Continue Application 02 with n=1000 genuinely independent observations of the same fixed input and suppose the observed proportion is close to its model expectation, p=0.25. The binomial standard error of the observed proportion is $\sqrt{[p(1-p)/n]} = \sqrt{(0.1875/1000)} = 0.0136931$. Consequently the standard uncertainty of x_hat is 0.0136931Δ. A simple normal approximation gives a 95% half-width of 1.96×0.0136931Δ = 0.0268384Δ. The normal approximation is illustrative, not an exact finite-sample guarantee and not a complete combined uncertainty interval. A common analogue offset, calibrated-scale error, time-varying input or serial dependence requires separate treatment. Here the improvement arises from a thousand physical observations under a known probability law, not a change in the twelve native ADC bits.

Application 04. Proper subtractive-dither error for the ideal unbounded quantiser

Let Q be ideal uniform rounding with step Δ and no overload, and let an independent subtractive dither have suitable characteristic-function properties, for example an appropriate independent uniform perturbation over one step. Define z=Q(x+d)-d, so the total error is e=z-x. Under the stated subtractive-dither theorem, e is uniform on (-Δ/2,+Δ/2) independently of x, with E[e]=0 and $Var(e)=\Delta^2/12$. The standard deviation is $\sigma_e=\Delta/\sqrt{12}$. For 400 independent repetitions of an unchanged input,

Copyright 2026, James M. Atkinson

the mean's conditional standard deviation becomes $\Delta/\sqrt{(12\times400)} = 0.0144338\Delta$. If the implementation subtracts a delayed or mis-scaled replica d_hat rather than the perturbation actually present at the converter, the residual includes (d-d_hat); the ideal theorem cannot be cited without including that error. These results concern an estimator and the specified ideal model, not universal converter linearity.

Application 05. Triangular nonsubtractive dither and total-error variance

Define independent U1 and U2, each uniform on $(-\Delta/2,+\Delta/2)$, and let the triangular dither be d=U1+U2. Its mean is zero and its variance is $Var(d)=2(\Delta^2/12)=\Delta^2/6$. For the ideal nonsubtractive-dither model under appropriate theorem conditions, write the total error as e_total = Q(x+d)-x. The triangular dither gives useful input-independent first and second error moments; in the standard ideal result the total-error variance is $\Delta^2/4$, giving $\sigma_{total}=0.5\Delta$. This is greater than the ideal undithered uniform-model standard deviation $\Delta/\sqrt{12}\approx0.288675\Delta$. The benefit is not universally lower individual-sample noise, but reduced input-related bias and error modulation. Filtering or averaging may improve a specified resulting estimate if its covariance and bandwidth are known. Claims about other dither distributions need their own derivations.

Application 06. Oversampling gain and the number of independent measurements

Suppose a stationary quantity is observed through independent, approximately white errors and an ideal low-pass/decimation operation retains the required signal bandwidth. If the oversampling ratio OSR is 16 relative to the selected final Nyquist bandwidth, the ideal in-band

Copyright 2026, James M. Atkinson

noise-power reduction is 10log10(OSR) = 10log10(16) = 12.0412 dB. Using the ideal six-decibel-per-bit relationship, this corresponds to approximately 2.00 extra effective bits of noise-limited precision for that *bandwidth-limited estimator*. The converter still emits its original native code width per sample. To obtain an ideal four-bit gain by the same law requires OSR=4^4=256; a six-bit gain requires OSR=4^6=4096. These figures are not promises for signals with drift, harmonic quantisation error, correlated noise, converter nonlinearity or short transients that the filter removes. [R8, R9]

Application 07. Noise-floor penalty of a broadband dither setting

Assume for illustration that quantisation error initially satisfies the independent uniform model with variance $\Delta^2/12$. Introduce independent zero-mean broadband dither whose RMS amplitude equals 0.5Δ, and assume the total error contributions add in variance. Then $\sigma_total = \sqrt{(\Delta^2/12 + (0.5\Delta)^2)} = \sqrt{(\Delta^2/3)} = 0.577350\Delta$. Compared with $\sigma_q=0.288675\Delta$, the amplitude-noise ratio is 2, giving 20log10(2)=6.0206 dB more RMS noise amplitude relative to the baseline error. This simplified calculation is a deliberately conservative illustration of added in-band noise; real dithered-error correlations require the appropriate quantiser theorem and spectral placement. The added noise may still suppress coherent instrumental spurs, improving SFDR even when integrated SNR worsens. The report must not describe these distinct metrics as interchangeable. [R3]

Application 08. Correlation defeats naive averaging

Let n=64 observations each have error variance σ^2, with a constant pairwise correlation coefficient ρ=0.10, an illustrative covariance matrix

Copyright 2026, James M. Atkinson

that is positive semidefinite. The mean-error variance equals $\sigma^2[1+(n-1)\rho]/n = \sigma^2[1+63(0.10)]/64 = 7.3\sigma^2/64$. Define the effective independent sample count $n_{eff}=n/[1+(n-1)\rho]$, yielding $n_{eff}=64/7.3=8.7671$. The nominal independent-sample improvement would be $10\log10(64)=18.0618$ dB in noise power, whereas the correlated-case improvement is only $10\log10(8.7671)=9.4286$ dB. A filtered ADC sequence, a shared clock perturbation or low-frequency common drift may generate such dependence. The equicorrelation law is a transparent hypothesis, not a claimed universal model of receiver noise. Estimate the actual autocovariance before relying on the statistical gain.

Application 09. Dither may induce clipping near full scale

Let an ideal converter accept values only up to +1.000 V, and suppose the signal already reaches +0.950 V at a particular sample. Add uniform dither between -0.100 V and +0.100 V. Overload occurs if $d>+0.050$ V. The total dither support has width 0.200 V, and the overload-producing interval from +0.050 V to +0.100 V has width 0.050 V; the overload probability is therefore $0.050/0.200=0.25$, or 25% for this deliberately constructed input condition. Any resulting saturated codes lose the nominal invertible threshold relation. The calculation concerns this specific sample amplitude, not an overall clip rate for a varying waveform. A field system must examine blocker amplitude distributions and headroom before injecting dither for a theoretically attractive spur reduction.

Application 10. Multiple spectral trials and false-positive burden

Assume a detection test assigns each of $M=500$ effectively independent spectral bins a false-alarm probability $\alpha=0.001$ under the

Copyright 2026, James M. Atkinson

null hypothesis. The probability of at least one false alarm in the complete search is $P_{any}=1-(1-\alpha)^M = 1-(0.999)^{500} \approx 0.393621$, or 39.36%. An engineer might observe fewer quantisation-correlated spur bins after applying dither, yet if the broadband noise distribution changes the per-bin detector calibration must be revisited. If bins are correlated, the exact expression is not valid; use the joint noise model or a measured null distribution. The result demonstrates why claiming an instrument has become 'more sensitive' from a smaller highest spur does not establish a global detection advantage. The analysis must preserve the number of searched frequencies, durations and configurations, as well as the chosen false-alarm criterion.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, the preceding examination of dither concerned a perturbation deliberately introduced to change the statistical behaviour of an analogue-to-digital conversion experiment. We now turn to a different intervention: the combination of several converters so that their successive samples appear to have been obtained from one apparatus operating at a greater aggregate rate. In a clean block diagram, four branches complete four measurements in staggered succession, the resulting sample stream resembles that of one faster converter, and a wide spectrum glows across the display. The physical instrument is less innocent. Every branch possesses its own offset, gain, finite analogue bandwidth, aperture delay, recovery history and often its own sensitivity to temperature or the distribution of its clock. A periodic sequence of small discrepancies can modulate the very waveform which the equipment purports to observe. When translated into the frequency domain, that modulation can generate an orderly family of spectral components which were never independent emissions at the input connector.

Copyright 2026, James M. Atkinson

The forensic challenge is therefore not simply to recognise a particular spur shape. It is to identify the transformations which could have produced that shape, determine what the retained measurements actually establish, and design tests which distinguish an interleaving artefact from an external source. A line at a reproducible frequency is not automatically external, and a line which follows a real input signal is not automatically a second transmitter. The periodic branch-selection pattern may produce precisely such frequency tracking. Worse, an artefactual image of a strong legitimate emitter may reside inside the small, apparently quiet region in which a defensive survey searches for a weak clandestine transmission. Apparent spectral coherence may then invite confident misclassification, particularly where a waterfall display or automatic event logger records only a detection threshold and neglects the acquisition settings which created the plotted representation.

We must establish the nominal timing lattice first. Let the combined sampling rate be f_s samples per second and the number of branches be M, with each branch converting one sample every M/f_s seconds and nominal aggregate spacing $T_s=1/f_s$. Each branch is allocated a residue class of sample indices modulo M. If the branch gain or timing error is constant for that branch, the effective error repeats every M output samples. Periodicity in the sample index produces a discrete set of modulation frequencies spaced by f_s/M. A sine wave at input frequency f_{in} can consequently acquire images at frequencies congruent to $\pm f_{in}+k\, f_s/M$ after aliasing. Branch offsets produce a different family, typically at the residue-class harmonics $k\, f_s/M$ regardless of input tone frequency. These are predictions of a stated model and need experimental challenge; their mere

Copyright 2026, James M. Atkinson

mathematical elegance does not prove that any particular spectral event is such an artefact. [R1, R2]

The question is made more difficult by the legitimate complexity of real converter systems. Offset and gain mismatches coexist with time skew and unequal analogue frequency responses. Calibration may reduce them, but the operating point moves with frequency, temperature, analogue drive, converter overload, and internal adaptation. Background calibration can also learn from the prevailing signal environment, creating a new dependence between the observer and the observed. The same scalar spur frequency may therefore result from different physical imperfections, while the very act of injecting a test signal may alter the relevant state. A well-designed investigation must preserve configurations, raw and corrected streams where available, calibration versions and uncertainty estimates. It must ask whether the phenomenon is stable when input frequency, branch order, input attenuation, clock conditions or the interleaving pattern is deliberately changed.

I invite Dr Nyquist to establish why a nominally uniform output sequence is not sufficient proof of uniform physical sampling. Baron Fourier will then examine the consequence of periodic errors in the time domain, using harmonic decomposition to explain where images should appear. Dr Shannon will separate the information recorded in the output from the hypotheses required to reconstruct an external input. Professor Tukey will examine how receiver tests distinguish candidate mechanisms without selecting only favourable spectral plots, and Dr Shewhart will place the calibration procedure under statistical control. Seven peers will question the principals, each reply immediately following its challenge, before ten worked

Copyright 2026, James M. Atkinson

applications put the competing predictions into arithmetic. Our objective is to produce a technically defensible measurement and reporting doctrine, not a catalogue of spectacular-looking instrumental defects. Dr Nyquist, may I invite your account of the composite sampling lattice and the physical meaning of its errors?

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 1: Nominal samples and physical apertures

Dr. Atkinson, thank you. I would begin by distinguishing a sequence of numerical indices from a sequence of physical measurements. The software may label the reconstructed samples x[0], x[1], x[2] and so forth and declare that sample n corresponds to the time nT_s, but the numerical label is not a metrological measurement of the instant when the analogue aperture actually closed. A time-interleaved converter instead forms its output by assigning different indices to separate acquisition branches. For M channels, branch m nominally samples at $t_{m,j}=(jM+m)T_s$. The realised aperture is more accurately expressed as $t_{m,j}=(jM+m)T_s+\delta t_{m,j}$, where $\delta t_{m,j}$ includes a branch-specific systematic component and a random or drifting component. That distinction should appear in the measurement model before the engineer begins speaking of a higher effective sample rate.

It is tempting to regard the individual branch rates as the sole limitation, but their clocks may form an entirely adequate composite lattice when they are phase aligned, their bandwidths are sufficient and their respective analogue transfer functions are characterised. The gain in aggregate throughput can be genuine. What cannot be inferred from throughput is equality of measurement response. An instrument that samples in the prescribed temporal order but alternates between two slightly different gains has not produced samples of one linear time-invariant system. Nor does a perfectly matched gain remove an alternating timing error. The output can be periodic in the branch index even where the original input is a pure tone. A frequency-domain observer may see a family of images whose

Copyright 2026, James M. Atkinson

spacing reflects the branch cycle rather than the frequencies generated by the external source.

Consider two converters alternating samples. If their gains are $1+\varepsilon$ and $1-\varepsilon$, the reconstructed signal can be written approximately $y[n]=(1+\varepsilon(-1)^n)x[n]$ when all other errors are excluded. The factor $(-1)^n$ represents digital modulation at the Nyquist edge of the aggregate sample lattice, not an independent analogue oscillator. For a band-limited sinusoid, multiplication shifts a copy of the original discrete spectrum by one-half the aggregate sample frequency; after aliasing, the first-band image lies at $f_s/2-f_{in}$. It moves when the stimulus frequency changes and scales with the amplitude of the stimulus. An investigator who finds the image close to an expected surveillance channel must not regard its apparent frequency stability in a stationary test as evidence that a separate device transmitted there. The evidence may instead be a property of the way the receiver assembled its samples. [R1]

The timing version is less forgiving at high frequencies. A small aperture error changes the value of a continuous waveform by an amount approximately proportional to the waveform derivative. For a sinusoid, the derivative has magnitude proportional to $2\pi f_{in}$ times the signal amplitude. Therefore an identical timing discrepancy which is negligible at a modest input frequency can be conspicuous near the upper end of the converter's admitted bandwidth. It is not enough to calibrate with an audio-frequency source and assume that the resulting confidence applies unchanged to a wideband RF survey. The test should traverse the operating frequency range, and the reported uncertainty should preserve a separate term for branch skew and for random aperture jitter. The two mechanisms produce

Copyright 2026, James M. Atkinson

different spectral and statistical signatures, though both may be referred to loosely as timing noise.

One ought also to inquire whether the branches have truly independent analogue paths. A shared sample-and-hold or input buffer may impose common distortion before the branch split, and that distortion will not be cured merely by aligning the branch clocks. Conversely, independent analogue front ends may have different frequency-dependent phase responses. A nominal time offset measured with one frequency is then not necessarily a complete description of the phase mismatch elsewhere. A scalar correction can give a comforting improvement at one test tone while leaving an unmeasured image at another. The proper claim is bounded: a stated calibration reduced a stated error under the conditions of the challenge, not that the receiver's physical response became universally equivalent to one ideal converter.

A useful validation campaign should retain both the signal stimulus and the branch-state record. Where raw branch samples are accessible, examine their separate means, scale factors, phase responses, noise distributions and temporal alignment. If an internally corrected output alone is stored, the instrument may still be usable, but the investigator should acknowledge that independent review of the correction is limited. A robust black-box test can sweep a calibrated input through frequencies and amplitudes; it can change the interleaving mode, preserve a declared stop rule and compare the predicted movement of image lines. An artefact hypothesis must make testable predictions that an external-transmitter hypothesis does not share. Testing only the presence of a strong reference tone fails to examine the weaker false features that matter in counter-surveillance work.

Copyright 2026, James M. Atkinson

Finally, I would insist upon preserving non-detections and failed calibrations, not merely successful figures of merit. If the receiver suppresses a spur only after ten undocumented tuning attempts, the final clean plot may demonstrate an achievable configuration without establishing stable field performance. If one branch clips during a strong blocker, the mathematical small-error model fails even though an FFT may still show familiar interleaving locations. The analyst should identify when the approximation is valid and when saturation or recovery introduces new histories. Measurement begins by identifying the quantity and its physical boundary; a regular index sequence is a convenience of recording, not proof that every electrical event occurred at its intended instant. Professor von Neumann, may I pass you the token to examine whether my lattice account conceals dependence on the test stimulus itself?

John von Neumann | Peer question 1 to Harry Nyquist

Dr Nyquist, your account separates the ideal index from the actual aperture, but the statistical machinery used to estimate the latter seems rather dependent upon the signal chosen for calibration. Suppose a laboratory uses a highly coherent sinusoid and estimates a timing correction by requiring all branch outputs to lie upon one fitted waveform. The fitted phase can improve spectacularly, yet the assumed model may hide a second harmonic, a clock-synchronous interference term or frequency-dependent analogue delay. An algorithm which minimises a residual under one model need not establish that the fitted parameter is physically unique. In particular, if an instrument observes only the interleaved output and not the branch-specific clocks, how would you distinguish an estimator that has discovered the actual

Copyright 2026, James M. Atkinson

aperture offsets from one which has merely found an equivalent mathematical explanation for the selected data? What alternate challenge would make the competing models predict different results, and how would you record the remaining ambiguity without abandoning the utility of the calibration?

Harry Nyquist | Immediate answer to John von Neumann

Professor von Neumann, I agree that a small residual is not the same as an identified physical cause. The fitted delay is an effective parameter under the chosen signal and transfer model. If gain, frequency-dependent phase and timing can all affect the relevant Fourier coefficient, several combinations may produce the same observed outcome. It would be improper to call one numerical optimum the aperture measurement without an independent reference or a set of challenges that renders those combinations distinguishable. The acceptance record should state the model, its degrees of freedom and the actual observations that constrain them. A calibration parameter may be useful for correction even when it is not a unique physical diagnosis, but its interpretation must remain at the level that the test justifies.

One complementary challenge changes input frequency while maintaining a traceable stimulus amplitude. A true constant time skew contributes a phase error approximately proportional to frequency, whereas a simple constant gain mismatch does not; a frequency-dependent analogue transfer mismatch may imitate the slope over a narrow band, requiring a broader or independently characterised sweep. A second challenge alters input amplitude to

Copyright 2026, James M. Atkinson

expose saturation and other nonlinear effects that a small-signal timing model excludes. A third compares branch-specific clock measurements or a separate sampled reference where such access exists. The point is not to demand every conceivable instrument, but to make the models yield measurably different predictions before reporting physical attribution.

The analyst should also preserve a test partition. Values used to fit the correction are not, by themselves, independent validation observations. A second set of frequencies, amplitudes, temperatures or input waveforms provides a more meaningful challenge to generalisation. If the system can estimate calibration parameters only while tracking the current signal, the record must include when those parameters changed and whether raw data remain available. An adaptive setting that follows the input may be excellent for receiver operation but does not automatically preserve an unselected evidential record. The investigator must distinguish a corrected representation from the original sample stream and from the scientific explanation proposed for either.

Where models remain observationally equivalent, the report can still say that a particular correction reduced the measured image energy under the specified operating envelope. It should not say that the actual aperture of each converter has been measured with a stated uncertainty if that conclusion depends on an untested decomposition. A physically limited proposition is not a weak proposition. It is the only sort that can survive a competent colleague's attempt to reproduce the experiment with another

Copyright 2026, James M. Atkinson

reference. The appropriate handover is therefore to examine the independent physical comparisons upon which such a claim depends.

Edward Weston | Peer question 2 to Harry Nyquist

Dr Nyquist, may I ask about the reference plane hidden inside your elegant timing lattice? The analogue input delivered to a branch may pass through a buffer, an attenuator, a switch and an imperfectly matched connection before it reaches the sampling aperture. If two branches possess different transfer characteristics, a measured phase disagreement may be as much a property of the route as a property of the clock. A reference injected after the shared preselector will not establish how the preselector behaves, while one introduced at the antenna port adds uncertainty from the entire intervening chain. How would you specify the actual quantity being compared, avoid assigning the same discrepancy to both aperture delay and analogue phase response, and make a correction record intelligible to an independent examiner who cannot open the converter package? Would the report properly certify the physical aperture or only the frequency-dependent effective response of the installed receiver?

Harry Nyquist | Immediate answer to Edward Weston

Mr Weston, your question requires the receiver to be treated as an assembled measurement chain rather than an immaculate diagram. I should define the reference plane at which the incident waveform is specified, the measurable output quantity and the transfer relationship which connects them. If the stimulus is injected at the antenna port, the resulting estimate concerns the complete path from that port to the reconstructed digital samples under its specified

Copyright 2026, James M. Atkinson

loading. If it is injected after the buffer, the estimate concerns a narrower chain. Neither is wrong, but the same number must not be advertised as having established both propositions. A calibrated reference is useful only when its physical location and its uncertainty are part of the record.

Frequency-dependent analogue phase and aperture delay may both contribute to an effective relative phase shift. A single-tone experiment generally cannot separate them. In a narrowband task, an effective phase correction may suffice for recovering a specified measured quantity. In a wideband task, especially one concerned with a short pulse or a multicarrier signal, the distinction may be essential because a constant time correction cannot remove arbitrary group-delay variation. A sweep or broadband reference can test the response over the frequency interval of interest, while independent clock measurements can help isolate actual aperture timing. Where those additional observations are unavailable, the result should be named an effective channel-alignment correction, not a direct physical measurement of aperture delay.

An examiner unable to inspect the converter package should nevertheless be able to challenge the bounded claim. The calibration record should preserve the reference source, its traceable accuracy where applicable, connecting impedances, analogue path configuration, raw and processed outputs, fit algorithm and rejected or invalid trials. A black-box challenge should test how the image responds to a changed stimulus frequency or amplitude, because the competing mechanisms predict different dependencies. If two

Copyright 2026, James M. Atkinson

hypotheses still produce indistinguishable outcomes, their equivalence is a stated limitation. The record can support a practical calibration without certifying a unique physical explanation.

The broader lesson is that labels must not outrun the comparison that gives them meaning. A receiver may exhibit excellent composite performance while its internal branches remain physically unlike one another; conversely, accurately measured branch parameters may be insufficient if the external path changes during an investigation. The purpose of a forensic report is not to confer a ceremonial title of perfection upon an instrument, but to explain what was measured, where it was measured and which alternatives remain. I return the token to Dr. Atkinson for the next principal examination of the periodic error structure.

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier | Principal response 2: Periodic branch errors and spectral images

Dr. Atkinson, I am grateful for the invitation to examine the harmonics. The distinctive mathematical feature of an interleaved converter is not merely that it contains several pieces of apparatus, but that the output selects those pieces in a repeating order. A periodic difference between successive measurement channels imposes a periodic coefficient upon the sampled waveform. That periodic coefficient can be decomposed into harmonics on the discrete sample lattice. Multiplication in the time domain corresponds to convolution in the frequency domain, so a single incident spectral component is copied or shifted by each harmonic of the branch-pattern error. If the investigator does not recognise the periodic mechanism, the resulting images may be mistaken for independent emissions. This is a problem of physical origin concealed behind the perfectly respectable mathematics of a Fourier transform.

Suppose the reconstructed output takes the form $y[n]=g[n]x[n]+o[n]$, initially neglecting skew and nonlinear conversion. Here $g[n]$ is a repeating gain sequence and $o[n]$ is a repeating branch-offset sequence, each with period M samples. Express $g[n]$ as a finite Fourier series $g[n]=\Sigma_k G_k \exp(j2\pi kn/M)$, and similarly express $o[n]=\Sigma_k O_k \exp(j2\pi kn/M)$. A single complex input tone $x[n]=A \exp(j\omega n)$ then produces components at $\omega+2\pi k/M$ weighted by $A G_k$, together with offset components at $2\pi k/M$ weighted by O_k. A real-valued sinusoid introduces the corresponding positive and negative frequency partners. The terms which appear in a displayed Nyquist band depend upon aliasing and the spectrum's real or complex representation. The model is simple, but it yields a disciplined test: the

Copyright 2026, James M. Atkinson

image family must transform under a changed incident frequency in a way predicted by the branch cycle. [R1, R2]

A two-branch case is particularly revealing. If g[even]=1+ε and g[odd]=1−ε, then g[n]=1+ε(−1)^n. One factor preserves the original tone; the other shifts it by π radians per sample, which corresponds to half the aggregate sampling rate. The image-to-signal amplitude ratio is ε in this idealised small-error case, not twice ε merely because the physical gains differ by 2ε. The difference between the branch gains must therefore be defined before an instrument specification quotes mismatch in per cent. An incorrectly defined denominator can introduce a six-decibel error in an otherwise impeccable-looking budget. Similarly, if offsets are +b and −b, the alternating offset creates a term at the Nyquist edge whose amplitude is b; comparing it with a sine-wave reference requires the investigator to specify whether peak, RMS or power conventions are being used.

With four branches, the possible spectral pattern is richer. The repeating gain sequence has four Fourier coefficients, and its nonconstant coefficients translate an input component by multiples of one quarter of the aggregate sample frequency. For a real input tone in the first Nyquist band, image candidates can appear at frequencies related to f_s/4−f_in, f_s/4+f_in and f_s/2−f_in, after appropriate folding. Offset errors create different components at fixed branch harmonics, including f_s/4 and f_s/2. Therefore a single apparent mystery line is weak evidence of a specific defect, while a coordinated family of lines moving under a controlled frequency change is stronger evidence of periodic channel selection. The key is not pattern recognition alone. The test must be run under a condition where an external signal and an internal image would predict different outcomes, and the

Copyright 2026, James M. Atkinson

results must be compared before the operator chooses which lines to display. [R1]

Timing errors can be added by replacing $x[n]$ with $x(nT_s+\delta t[n])$. Under small-error conditions, a first-order approximation gives $x(nT_s+\delta t[n])\approx x(nT_s)+\delta t[n]x'(nT_s)$. If $\delta t[n]$ repeats with period M, its Fourier coefficients modulate the derivative of the waveform. The resulting image magnitude therefore depends upon the frequency content and on the derivative of the input. For a sinusoid the derivative contributes a factor $2\pi f_{in}$, which explains why timing-spur energy increases with input frequency while simple constant gain mismatch does not necessarily do so. At a sufficiently broad bandwidth the branch analogue responses can no longer be represented solely by one gain and one delay; each branch contributes its own transfer function and the error family acquires a frequency-dependent shape. Such complexity calls for a richer measurement model rather than a declaration that Fourier analysis has failed.

The spectral signatures also caution against overconfident causal inference. An offset spur which remains fixed during a sweep is compatible with branch-offset mismatch but may also coincide with oscillator-related interference or a real carrier that happens to remain at the same frequency. A gain image which tracks the reference may arise from a branch gain error, a sampling pattern, or a different form of signal-correlated processing. The apparent alignment of an image with a reference is evidence about a relationship, not an immediate declaration of its physical origin. Demonstrating the hypothesis requires intervention, including changes to sample-rate configuration, branch interleaving, input frequency, gain and

Copyright 2026, James M. Atkinson

possibly analogue attenuation. Where an internal calibration suppresses the image, the analyst should preserve both before and after states and avoid calling the corrected trace a second independent observation.

It is equally important to preserve the entire tested band. An attractive comparison of two selected spectral bins may conceal a larger image family displaced elsewhere by the intervention. Conversely, a spur that falls outside a selected displayed range may have been moved, not eliminated. The investigator should identify the alias convention, window, FFT length and frequency mapping used before and after a configuration change. The negative evidence of an apparently quiet screen has meaning only relative to that screen's actual observation and processing envelope. The mathematical apparatus reveals how a coherent external input can produce a coherent internal imitation. It does not demand that every coherent line be disbelieved; it requires a controlled challenge before the line is attributed to a second emitter. Professor Bridgman, may I pass the token to your question about whether the mathematical expression defines a measurand or merely an elegant reconstruction?

Percy Williams Bridgman | Peer question 3 to Jean-Baptiste Joseph Fourier

Baron Fourier, your harmonic decomposition is compelling, but I should like to examine the experimental operations behind its coefficients. Suppose an engineer observes a family of images corresponding to period-four gain modulation and estimates coefficients G_k from a spectral transform of the combined output. The resulting numbers are precise within the fitted model. Yet the physical gain of each branch was never independently measured, the stimulus passed through

Copyright 2026, James M. Atkinson

a frequency-selective input network, and the converter's background calibration changed while the test was performed. In what sense do those coefficients establish the actual branch gains rather than the effective periodic response of the entire installed apparatus? If a colleague alters the input reference plane or the bandwidth of the stimulus and obtains different coefficients, is that a contradiction, or evidence that the original mathematical model was defined over a narrower operation? How would you prevent the authority of your series from being misused as a claim of physical uniqueness?

Jean-Baptiste Joseph Fourier | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, I welcome the distinction. My harmonic coefficients describe the periodic relationship present in the recorded sequence under the declared conditions; they are not themselves measurements of an inaccessible physical component. The same periodic output can arise from several combinations of gain, analogue frequency response, timing skew and digital correction. A fitted coefficient may be sufficient to predict and reduce an image in a specified frequency interval even though it cannot uniquely identify the electrical cause. The engineer should define the relevant operation precisely: which reference input was supplied, at what connector and impedance, through which acquisition configuration, and with which calibration state. Without that definition, the coefficients are parameters of an incompletely specified model.

Copyright 2026, James M. Atkinson

Changing the stimulus or reference plane is a legitimate way to test the asserted generality. If the model was calibrated for one sinusoidal frequency and one stable receiver state, obtaining a different result at another frequency may simply reveal that the branch response is frequency dependent. That is not necessarily a logical contradiction, provided the initial report did not claim universal applicability. If the initial claim asserted frequency-independent branch gains across the whole reception band, the changed response is material evidence against that stronger model. One ought to state in advance which forms of variation would count as rejection, rather than always recasting a failure as an allowable calibration correction after viewing the result.

The method may therefore be useful in three distinct forms. First, it can describe a recorded spectral pattern without making a physical-cause assertion. Second, it can predict how the pattern should move or scale under declared interventions, allowing a falsifiable image hypothesis. Third, after independent measurement of the relevant analogue paths and clocks, it may contribute to a more specific physical attribution. These forms are progressively demanding; the existence of the first does not imply the third. A precise spectrum is not a certificate that every physical component has been uniquely estimated.

In a defensive survey, the greatest danger is to let an internal correction silently rewrite the causal narrative. If an image disappears after calibration, the operator has established a useful sensitivity of the recorded representation to that operation. The event might have

Copyright 2026, James M. Atkinson

been an interleaving artefact, but suppression alone does not prove which branch mismatch produced it, nor does it show that no external signal existed at the same frequency. Preserve the raw record, the fitted coefficients, the corrected record and the complete test history. A properly restricted conclusion will remain scientifically valuable even if several internal mechanisms are left unresolved. I should now invite Mr Bennett to examine whether apparently clean residual noise permits a stronger declaration.

William Ralph Bennett | Peer question 4 to Jean-Baptiste Joseph Fourier

Baron Fourier, the periodic decomposition describes deterministic mismatch very clearly, but practical converters combine those periodic terms with quantisation error, analogue noise, switching transients and nonlinear transfer characteristics. Suppose a receiver's spectrum contains a faint line exactly where a gain-image formula predicts it, and the line becomes less visible after a calibration operation. The operator may declare success. Yet a weaker line could persist below the chosen window's sidelobe structure, while some mismatch energy could be spread into other frequencies by time variation or deliberately randomised channel assignments. Would a transform of one finite record justify treating the remaining noise as independent and stationary? How should the investigator distinguish genuinely reduced integrated error from a reduction of one conspicuous spur, and what must be preserved to make that comparison fair when the detection threshold is close to the level of the original image? Would you require a repeat at a second input amplitude before accepting the result as a calibrated improvement?

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier | Immediate answer to William Ralph Bennett

Mr Bennett, a Fourier transform identifies components of the sampled record under the transform's stated assumptions. It does not independently establish the stochastic law of the residual noise. A finite window produces leakage and resolution effects; a stationary input observed through time-varying mismatches may exhibit a broadened or nonstationary spectral signature. One should therefore compare calibrated and uncalibrated records with the same explicit window conventions, equivalent effective observation durations and an honest account of any changes in the analogue operating state. A reduction in the largest spur is a particular improvement, not proof of lower total error power, reduced false-alarm probability or better transient sensitivity.

I would ask the investigator to specify several measures separately. One measure is the amplitude of the predicted coherent image relative to a characterised input. Another is integrated error power over a named bandwidth, after accounting for relevant window normalisation. A third is the residual feature's behaviour under frequency and amplitude challenges. A fourth is the detection performance of the actual rule used to distinguish a signal from a background, tested against a population of legitimate emissions and instrumental artefacts. These quantities need not improve together. If a calibration method scrambles the image energy across a broader band, the highest peak may diminish while the energy relevant to a particular weak-signal search remains objectionable.

Copyright 2026, James M. Atkinson

A good test should save the pre-correction samples or an appropriate equivalent raw representation where possible. It should preserve the calibration coefficients and their timing, the window and transform definitions, and the receiver's nominal sample-rate and branch configuration. It should also retain failed or invalid experiments and avoid selecting only the pleasing before-and-after illustration. For a nonstationary problem, segment-wise diagnostics may reveal that a correction which succeeds in one interval is unsuitable in another. The absence of a line in one averaged spectrum is especially weak evidence about short-lived intermittent emissions, whose temporal contribution may have been diluted by the very averaging that made the background look smooth.

The mathematical conclusion is modest but productive. Periodic mismatch predicts a structured set of spectral relationships; an identified member of that family can be tested by controlled changes; and a candidate calibration can be judged against explicit measures of performance. The same mathematics does not convert any finite spectrum into proof that all residual error behaves as independent uniform noise. Your challenge correctly returns us to statistical modelling and the distinction between an elegant plotted representation and a validated observational claim. I pass the discussion back to Dr. Atkinson for the remaining principal examinations.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 3: Information retained after reconstruction

Dr. Atkinson, our problem is one of representation and the conditions under which an inverse inference is warranted. The converter output is a sequence of retained numerical values produced by an acquisition procedure. The claim that those values originated from one external waveform is a model involving branch selection, calibration, analogue transfer, noise and sampling time. Several different combinations of external input and internal channel error may produce essentially indistinguishable output sequences over a finite observation interval. The recording can therefore be entirely genuine while the investigator's favourite explanation for a spectral line is wrong. A hash of the stored samples would establish that the same file was later examined; it could not by itself establish that the file is a transparent representation of an uncorrupted analogue event.

In a time-interleaved system one should distinguish three levels of proposition. The first is the integrity of the retained sequence: whether the samples and accompanying metadata have been preserved without undocumented alteration. The second is the validity of the instrument model: whether the conversion and reassembly procedure, including its errors and corrections, was sufficiently characterised under relevant conditions. The third is the source hypothesis: whether a feature present in the instrument record is more plausibly assigned to an emission at the antenna input or to an internal mechanism. The higher-level conclusion does not follow automatically from the lower-level one. The evidential structure resembles a communication problem in which the received

Copyright 2026, James M. Atkinson

symbols are known but both the channel and the transmitted message are partly unknown. Robust inference requires explicit channel assumptions and observations that can challenge them.

An interleaving image may appear indistinguishable from an external tone in a single stationary spectral snapshot. Its position can be rationally tested by changing a known stimulus frequency. For example, a two-branch gain image is predicted near $f_s/2-f_{in}$ in the first Nyquist band. If the calibrated reference moves upward by 20 MHz and the suspicious line moves downward by approximately the same amount while its strength scales with the reference amplitude, the image hypothesis gains support. Yet this dependence is not an absolute proof of its unique cause, because some other coherent processing error could move with the input. A stronger experiment changes the aggregate sampling frequency or interleaving mode and tests whether the line follows the branch-pattern relation. An independent receiver on a different architecture may provide complementary evidence, provided its reference and reception conditions are understood.

It is especially important to preserve the distinction between an image and an independent signal when the external electromagnetic environment contains multiple transmitters. A strong legitimate carrier may produce an internal translated copy precisely where the investigator expects a weak surveillance emitter. The presence of that translated copy is itself useful information about the receiving system; it is not a second source. But a genuine weak emitter could also coexist at the same frequency, hidden under the image. Suppressing a calibrated image may reveal the external component, or it may remove only internal energy, depending upon the

Copyright 2026, James M. Atkinson

system. The resulting correction must not be represented as a perfect separation unless a tested model permits that assertion. In difficult cases the evidence may support detection of energy in the corrected record while leaving source identity unresolved.

Information can also be lost when the acquisition process combines the branches in ways that do not preserve their identities. If raw branch codes and branch-selection metadata are unavailable, one may still investigate spectral patterns through external challenge tests, but direct diagnosis of individual offsets, gains and sample times is limited. If the system applies proprietary adaptive calibration and stores only corrected samples, some competing histories may be observationally equivalent even to a skilled examiner. It is a mistake to treat numerical precision in the saved output as a substitute for the missing acquisition state. The file may be reproducible as a digital object while the physical history that gave rise to it remains partly inaccessible. This qualification is material where a report purports to exclude a class of hidden transmitters from a long, sparsely observed search interval.

One should further distinguish the ability to reproduce a detector's result from the ability to validate its false-alarm rate. Suppose a programmed detector is trained using many spectral records taken with one interleaving configuration. Its threshold may incorporate a characteristic population of image frequencies. Changing the converter mode could make those learned frequencies move, altering the detector's null distribution. The same software and nominal numeric threshold would not thereby have the same operating characteristics. A validation report should preserve its acquisition population and explain how the detector was challenged with both genuine

Copyright 2026, James M. Atkinson

weak test signals and representative receiver artefacts. If test cases are selected after inspecting the output, the advertised detection probability may describe the selected demonstrations rather than future field observations.

A defensible report could therefore state that a spectral component is consistent with a branch-pattern image because it moved according to a specified relation under declared interventions, and because the image diminished when a prescribed calibration was applied. It should also record competing explanations not eliminated by the evidence, any unresolved overlap with a genuine external signal, and the scope of independent instrumentation. This does not reduce every measurement to scepticism. It gives the investigator a clear route from retained symbols to testable physical hypotheses. Professor Wiener, may I pass the token to your question concerning the effects of a calibration algorithm which learns from the same environment that it is asked to measure?

Norbert Wiener | Peer question 5 to Claude Elwood Shannon

Dr Shannon, your hierarchy appears to assume that the receiving channel can be characterised separately from the information it conveys. In modern equipment the correction algorithm may be coupled to the arriving signal and may update branch timing or gain according to statistics of the input itself. A strong legitimate transmitter could drive the adaptive estimator into one state, while a faint intermittent source might occur only during the transition to another. The stored output could then reflect a feedback process rather than one fixed linear channel. If the operator possesses only the corrected record and a list of final coefficients, can a later examiner reconstruct how a brief emission

Copyright 2026, James M. Atkinson

was treated at the moment it appeared? What does a meaningful validation test look like when observer and observed form a coupled system, and where should the uncertainty of that coupling appear in a forensic conclusion? I ask because a hidden controller state can mimic a new source even where the apparatus is operating as designed.

Claude Elwood Shannon | Immediate answer to Norbert Wiener

Thank you for that question. Professor Wiener, the coupling you identify makes the time history of the receiver an essential part of the measurement. A fixed transfer function may be an adequate local model over an interval in which adaptation was inactive or demonstrably stable. It is not automatically applicable to periods during which parameters were changing in response to the signal. If a correction system relies upon recent sample statistics, the apparent value of a brief pulse may depend upon activity preceding that pulse, not merely upon the pulse's own waveform. A later examiner given only the final coefficient set cannot reconstruct every intermediate output unless the algorithm, initial state and input history are sufficiently preserved. Where those materials are absent, the report must state that limitation.

A useful validation plan would deliberately expose the system to changes of state. Introduce a known low-level stimulus before, during and after a strong legitimate blocker; vary the blocker's amplitude and arrival time; repeat the experiment with adaptation enabled and disabled where the design permits. Record both successful detections and intervals during which a genuine reference event is attenuated, displaced or suppressed. The analysis must treat these as

Copyright 2026, James M. Atkinson

observations from a coupled procedure, not as exceptions discarded because they complicate a calibration plot. A final clean spectrum can be achieved after an unsatisfactory transition without demonstrating that the transition preserved a fleeting event.

The mathematical record should distinguish fixed parameters from state variables. In a simple adaptive model one might write $\theta[n+1]=F(\theta[n],y[n])$, with $\theta[n]$ the calibration state and $y[n]$ the output available to the algorithm. The corrected observation at time n depends upon $\theta[n]$, which in turn depends upon preceding samples. This is a model description, not a claim that every commercial converter uses that exact update law. Its significance is that conditional dependence across time undermines the convenient assumption of independent observations. Calibration tests should examine state trajectories, settling, lock-loss and recovery, rather than rely solely on steady-state frequency-domain figures of merit.

Where raw branch codes and state histories are retained, a later examiner may test whether a particular transient would survive replay and alternate correction settings. Where they are unavailable, one can still perform prospective black-box challenges, but retrospective statements about the missing event must be bounded. The absence of a detector alarm during a period of adaptive settling is not automatically evidence that no emitter was present. Conversely, detecting a feature during such a period requires caution because the algorithm itself may have created or displaced spectral energy. A trustworthy technical report would attach the adaptation state or a

Copyright 2026, James M. Atkinson

justified proxy to each finding, and would identify invalid or unassessed periods explicitly.

Thus the channel model is not discarded; it is enlarged to include the control loop and its memory. A calibration which improves ordinary operation can still demand special validation when deployed as an evidential instrument. The proper aim is not to abolish adaptive techniques, but to ensure that their successes and failures can be examined under the same declared rules. Dr. Atkinson, I return the token for a statistical assessment of the challenge campaign.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 4: Diagnostic experiments and the discipline of exploratory displays

Dr. Atkinson, the danger in a well-designed spectral display is that it supplies persuasive pictures before it supplies sound inference. A recurring line can be highlighted, labelled and preserved in an event log while dozens of conflicting observations fade from the operator's attention. Time-interleaved converters make such visual persuasion particularly hazardous because a receiver image can behave like a physical signal in several respects. It can be narrow, stable, coherent with a genuine emitter and repeatable under an unchanged configuration. The crucial scientific question is not whether the picture looks convincing, but whether a test population and a decision rule were specified which could have exposed the instrument's explanation as false.

I would begin with exploratory analysis, but I would not allow that analysis to masquerade as confirmatory validation. Exploration should examine the locations of unexpected spectral lines, their amplitude relationships, time dependence, correlations with strong inputs and changes under altered clock or branch conditions. These observations suggest candidate mechanisms, including gain mismatch, offset error, skew, bandwidth asymmetry, clock leakage and aliasing. The investigator may plot difference spectra, branch-resolved traces where possible, and measured calibration coefficients. The exploratory process is valuable because a single theoretical model seldom anticipates every defect in an installed system. But the same evidence used to discover a hypothesis cannot, without allowance for selection, be presented as though it were an independent experiment designed to test it.

Copyright 2026, James M. Atkinson

For a confirmatory test, I would predefine at least two distinct predicted responses. Under a two-channel gain-image hypothesis, moving a known input tone from f_1 to f_2 should shift an image from $f_s/2-f_1$ to $f_s/2-f_2$, and a change of input amplitude should change the image amplitude in a predictable proportional manner within the linear regime. Under a fixed external-emitter hypothesis, the observed carrier should not automatically move in the opposite direction simply because the investigator swept a separate reference, although an actual nonlinear interaction or coupled transmitter would require separate consideration. Under an offset-mismatch hypothesis, the spur remains at the branch harmonic even without the stimulus. These predictions should be specified before the final challenge data are observed. The comparison is informative only when the receiver remains inside a documented operating envelope.

The experiment should also examine thresholds and search multiplicity. A survey may search hundreds or thousands of spectral bins and preserve only those crossing an alarm threshold. As the number of candidate events increases, apparent coincidences with expected image locations become more likely. A visually exact match found after examining every possible alias and every available sample-rate configuration has a different evidential weight from a match predicted and tested in advance. The statistical plan should record the number of configurations, frequencies and windows inspected, and should avoid retroactively reducing the trial count to the one successful illustration. A change in calibration may modify the null distribution and demand a new threshold rather than simply a new colour palette.

Copyright 2026, James M. Atkinson

The selection of a spectral estimator matters. A finite-window Fourier transform spreads energy according to the window's response; coherent sampling can minimise leakage for chosen tones but may conceal performance under untidy field conditions. Averaging spectra can improve the visibility of stationary features while diminishing the contribution of short events. Resolution bandwidth, window equivalent noise bandwidth, detector integration interval and sample-clock accuracy should be held constant or explicitly recalibrated when comparing before and after results. Otherwise an image may appear reduced merely because the measurement procedure smoothed or moved energy. A good report includes enough information to reconstruct the plotted numbers from retained samples and settings, and enough raw evidence to challenge alternate post-processing choices.

One should include negative controls. Remove or greatly attenuate the calibrated input and determine whether the suspected image persists. Change the aggregate sample rate while holding the external frequency constant. If possible, use a receiver with a materially different architecture rather than another channel of the same shared conversion chain. Deliberately perturb temperature or clock phase inside safe operating limits to examine whether the feature follows the expected sensitivities. The tests should be designed to discriminate among mechanisms; a collection of gestures that all reduce every signal in the apparatus is not persuasive. If a strong input attenuator suppresses both genuine emissions and instrumental images, attenuation alone has not identified the suspect feature.

Copyright 2026, James M. Atkinson

I would recommend recording the failures of the model in a residual register. A predicted image which is absent can be as instructive as an image which appears, provided the expected level was above the test's sensitivity. An observed line with the wrong scaling law should not be dismissed without investigation. The model may omit bandwidth mismatch, alias folding, nonlinearity or adaptive feedback; alternatively the line may be external. Every such case is an opportunity to improve the experiment's discriminating power. There is no scholarly merit in forcing all anomalies into one diagnosis merely because the demonstration was designed around it. An investigator who reports an unresolved cause with precise observations is often more useful than one who produces a confident but fragile label.

The appropriate endpoint is a bounded operational conclusion. One might show that under a declared configuration an image due to branch gain mismatch accounts for a specified family of features and that a tested correction reduces their amplitudes within an uncertainty interval. One might then demonstrate that a separate feature survives those challenges, justifying further external-source investigation without proving transmitter identity. It is essential to state whether the claim concerns a detector threshold, integrated noise, spurious-free dynamic range or source attribution. Those are different performance metrics. Mr Turing, may I invite a question about whether an algorithm which reproduces a spectral figure has thereby reproduced the experiment that figure represents?

Alan Mathison Turing | Peer question 6 to John Wilder Tukey

Professor Tukey, I should like to separate computational reproducibility from the physical information upon which a computation

Copyright 2026, James M. Atkinson

operates. Suppose two independent analysts receive an identical sequence of interleaved converter codes, the same software instructions, and the same saved calibration coefficients. They obtain precisely the same spectral image and the same corrected result. One then concludes that a suspect line must have originated within the receiver, while the other maintains that a real external emission may have been superimposed upon the image. Are both analysts correct in saying that their analysis is reproducible, even though their causal accounts differ? More importantly, can any deterministic transformation of the same recorded sequence create the missing information needed to settle that disagreement? What independent observation, intervention or metadata would you require before treating the internal-artifact explanation as exclusive rather than merely plausible? The disagreement seems especially serious when an investigator reports a categorical source identity from numerical data alone, although the necessary physical intervention was never performed.

John Wilder Tukey | Immediate answer to Alan Mathison Turing

Mr Turing, identical outputs from identical computational inputs establish a valuable property of the analytical procedure: another examiner can repeat the calculation. They do not establish that the original physical acquisition was complete, that the correction model was unique or that an external source cannot coexist with an artefactual image. The two analysts may be entirely agreed upon every computed quantity and still disagree about source attribution because that attribution depends on hypotheses not determined by the retained data alone. We should not try to resolve an

Copyright 2026, James M. Atkinson

underdetermined physical question by performing the same deterministic arithmetic with greater precision.

The suitable additional evidence would be chosen according to what the competing explanations predict differently. A controlled change of reference frequency or interleaving mode may alter an instrumental image while leaving an independent external carrier fixed. An independently calibrated receiver with a different conversion architecture may reveal a persistent emission, though common antennas or shared interference can limit independence. Raw branch data and time-stamped calibration states may expose which branch generated the periodic component. A separate physical clock measurement may constrain timing-skew hypotheses. No one test is universal; the investigator should explain which proposition it challenges and which alternatives remain possible.

An especially important distinction is between correcting a measurable quantity and reconstructing a unique original waveform. If a well-characterised linear transfer can be inverted for the signal and bandwidth of interest, numerical correction may be justified within uncertainty. But if saturation, discarded samples, adaptive filtering or unrecorded branch state have made several distinct inputs observationally equivalent, a computed inverse must import extra assumptions. The output may look plausible yet be insufficient for a stronger causal conclusion. A report should mark where those assumptions enter, and it should not treat a simulated reconstruction as an additional independent observation of the past.

Copyright 2026, James M. Atkinson

For publication, I should preserve the original file and cryptographic digest, the software version and reproducible configuration, but also the physical acquisition record: converter mode, aggregate and branch sample rates, reference clock, gain and offset states, calibration timing, analogue path and any invalid intervals. The two forms of reproducibility are complementary. Digital repeatability is a protection against undocumented post-processing; physical repeatability and controlled intervention address the validity of the causal inference. The strongest conclusion may be that a feature is consistent with a tested internal image mechanism while a coincident external signal has not been excluded. That is not a defect in the computation. It is an accurate description of the information the experiment actually supplied.

My answer, therefore, is that formal computation cannot conjure a missing physical discriminant into existence. It can reveal where the model permits one, guide the design of another test and prevent our language from overstating the record. Dr. Atkinson, I return the token to the question of calibration stability and its evidence.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal response 5: Calibration controls and field acceptance

Dr. Atkinson, our preceding colleagues have shown how an apparently precise spectrum can be generated by the recurrent imperfections of several measuring channels. I should like to translate that reasoning into a system of operational control. A receiver which exhibits low interleaving spur levels during a favourable laboratory demonstration may nevertheless produce unacceptable false features after thermal change, clock substitution, gain adjustment or an extended observation. Such variation is not adequately described by a solitary figure of merit. The measurement process should be characterised over the conditions in which it will actually be used, with procedures able to detect when it has departed from the validated state. This is the purpose of statistical quality control in the present constructed application: not to declare every output statistically random, but to distinguish ordinary process variation from changes that invalidate an earlier calibration.

I would begin by defining the relevant quality characteristics. Branch offset difference, relative gain mismatch, effective timing skew, image-to-carrier amplitude ratio, coherent spur level, in-band noise, calibration residual, clock-lock state and loss-of-sample indicators are distinct quantities. One chart showing a falling largest spectral peak cannot substitute for all of them. The laboratory should define a baseline operating envelope and the independent references available to assess each characteristic. Measurements should be taken at declared input amplitudes, frequencies, temperatures, receiver gains and interleaving modes. Acceptance limits must follow the intended task. A receiver intended to find

Copyright 2026, James M. Atkinson

very weak intermittent emissions near strong legitimate transmitters may require more stringent image testing than one intended merely to characterise a large continuous carrier.

The first concern is measurement system validity. A calibration standard must reach the portion of the chain that a claim addresses; an internal reference injected after the analogue preselector is not sufficient to certify the antenna and front-end path. Where a source reaches multiple branches through shared equipment, common reference error may move the apparent gains together without revealing their relationship to an independently defined external quantity. Conversely, comparing branch differences may be relatively insensitive to common gain error but still vulnerable to systematic phase and timing defects. The report should distinguish absolute accuracy, relative branch matching and performance of the corrected composite output. Each has its own reference conditions and uncertainty structure.

The second concern is process stability. If an image spur is measured repeatedly at one frequency, a stable mean with a narrow spread may justify a limited claim about that configuration, but it does not guarantee performance after the analogue input changes. Background calibration may track slow thermal drift; the monitoring record should show whether its coefficients vary under legitimate operations and whether those variations affect the weak-signal detector. An alarm or invalidation criterion can be established for departures from baseline. The purpose of such a criterion is to trigger investigation or revalidation, not to replace the original data with an automatically polished figure. A useful control record includes both the observed deviations and the operator's response, because repeated

Copyright 2026, James M. Atkinson

undocumented retuning can turn a genuine failure into a series of selectively retained successes.

The third concern is the interaction of several factors. Temperature, clock phase, gain setting and input frequency may not affect the measurement independently. A small gain mismatch at one temperature may be harmless until it combines with timing skew at a higher frequency. A change in attenuation can move the operating point into a more linear regime while also reducing the amplitude of any actual weak emission. A calibration that operates well with a sinusoidal reference may respond differently to a burst or a wideband waveform. A carefully designed matrix of conditions can reveal material interactions, but a limited matrix supports only the combinations actually represented or justified by a validated interpolation model. It does not certify every possible environment merely because its plotted points form a pleasing line.

The fourth concern is the relationship between detection and reporting. A field operator may see a line at a frequency predicted by the gain-image model and exclude it from investigation. That exclusion is a decision rule and should be validated with genuine weak injected events, including events near expected image frequencies. A genuine emission could coincide with an artefact; blindly suppressing the predicted region might increase the false-negative rate. Conversely, declining to recognise a known instrument image may lead to false accusations and wasted investigative effort. Validation should therefore measure the effect of the full procedure, not merely the size of one corrected spur. It should preserve false positives, false negatives, invalid trials and the uncertainty of estimated performance under the relevant test population.

Copyright 2026, James M. Atkinson

The fifth concern is traceability across revisions. Software calibration algorithms are often improved, detector thresholds changed and firmware updated. Each change can alter what an earlier event means. An examiner should be able to identify the version of the acquired data, the branch configuration, the correction parameters, the software used to render the plot and any subsequent reprocessing. A corrected record should be retained alongside the original where practicable. If the original branch data have been lost, the limitation should appear in the formal report rather than being disguised by reproducibility of a downstream calculation. A physical instrument cannot be retroactively calibrated into having acquired information which it never preserved.

A final acceptance programme would use several kinds of evidence. Test tones and broadband references establish aspects of the transfer; controlled input-frequency changes challenge predicted image motion; alternate sample-rate and branch configurations challenge the periodic cause; temperature and operating-state tests expose drift; and independent receiver observations help separate instrument-specific features from common external activity. None of these tests should be presented as exhaustive in isolation. Together they may support a bounded statement that the receiver is fit for a specified defensive-search task within a declared envelope, subject to explicit invalidation rules. A quality-control chart is not a forensic verdict. It is an aid to preserving the credibility of the comparisons upon which a verdict must rest. Sir Ronald Fisher, may I invite your challenge to the design of the acceptance experiment and the consequences of selecting favourable trials?

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher | Peer question 7 to Walter Andrew Shewhart

Dr Shewhart, your monitoring scheme seeks stability, but I am concerned with what a finite experimental sample can establish when several operating conditions are examined. Suppose a laboratory tests an interleaved receiver at ten frequencies, four temperatures and three gain settings, performs repeated calibrations until each display looks satisfactory, and then quotes the best spur value as a property of the instrument. That number may be genuine but its inferential status is obscure. How would you distinguish a prespecified acceptance trial from a exploratory tuning exercise, account for the selection of conditions and repeated attempts, and prevent a high nominal pass rate from disguising poor performance in the difficult corner where a strong legitimate input overlaps a weak test signal? What probability statement, if any, would the completed experiment allow the examiner to make about performance beyond the exact conditions tested? I should also like to know which unsuccessful calibration attempts form part of the denominator of any purported reliability estimate.

Walter Andrew Shewhart | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, I accept the challenge without qualification. A tuning exercise is useful for development, but its successful endpoint is not an independent estimate of the probability of success under future operating conditions. If the engineer repeatedly alters calibration parameters and then retains only the passing trial, the apparent yield belongs to a selected sequence whose denominator has been

Copyright 2026, James M. Atkinson

concealed. The procedure can demonstrate that a satisfactory state was reached; it does not establish how frequently such a state would be reached without intervention or whether it remains stable in service. The acceptance population and stopping rule should therefore be specified before the confirmatory trials, and every trial, including invalid or failed ones, should be retained in the review record.

I would separate the operating envelope into meaningful strata rather than average everything into one impressive percentage. Strong-blocker conditions, high input frequencies, thermal extremes and weak-signal overlap may dominate the investigative risk even if they occupy a small fraction of simple laboratory tests. A pooled success rate can conceal a material deficiency in such a stratum. For each important condition, report the number and outcome of independent trials, including how correlation across repeated measures was handled. Confidence bounds may be calculated under an explicit sampling model, but they cannot automatically be extrapolated to untested conditions, a changed firmware version or a different installation. The statistical statement must be tied to the actual experimental population.

A practical campaign may use one set of observations to identify a candidate calibration, then an independent, locked-configuration set to test its performance. When the objective is to verify that a weak signal remains detectable despite an image, the trials should vary the relative timing and amplitude of the legitimate blocker and the test emission. The evaluation should consider both the receiver's

Copyright 2026, James M. Atkinson

spurious-free measure and the forensic detector's true-positive and false-positive behaviour. A calibration which produces a prettier spectrum but suppresses legitimate test events is not fit for that purpose merely because its largest instrument spur diminished. The performance criterion should be connected to the material decision required by the investigation.

Where the experiment lacks sufficient independent data for a reliable probability claim, there is no obligation to manufacture one. Report the observed outcomes, their limits, the exact tested envelope and the changes that would require revalidation. Control charts can reveal drift and trigger intervention; they do not make a finite set of favourable observations into an unlimited guarantee. A responsible acceptance record should be useful precisely because its limitations are stated. Dr. Atkinson, I pass the token to your worked numerical examination and concluding synthesis, with the hope that the arithmetic will sharpen rather than obscure those boundaries.

Ten worked engineering applications | Moderator-led numerical analysis

The following calculations use hypothetical examples and deliberately stated simplifications. Let M denote the number of interleaved ADC branches; f_s the aggregate sample rate in samples per second; f_{in} the frequency of an input sinusoid in hertz; A the peak amplitude of the sinusoidal input in volts; ε a dimensionless symmetric branch gain mismatch; b an alternating offset amplitude in volts; τ a branch-to-branch systematic time-skew difference in seconds; and σ_t the RMS random aperture jitter in seconds. Unless stated otherwise the input and

Copyright 2026, James M. Atkinson

receiver remain linear and unsaturated, sampling is coherent for the frequency-estimation example, and uncorrelated errors are assumed only where explicitly named. The image frequencies below are expressions of periodic branch selection, not proofs of a transmitter at those frequencies.

Harry Nyquist, Cross-Peer Question to Jean-Baptiste Joseph Fourier: Dr Fourier, a four-way interleaved converter presents a persistent line at 400 MHz and signal-following lines at 300, 500 and 700 MHz when driven by a 100 MHz reference at 1.600 GS/s. What distinctions between branch-offset harmonics and periodic gain or aperture effects are defensible from frequency positions alone?

Jean-Baptiste Joseph Fourier, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the periodic four-branch selection sequence has a fundamental repetition frequency of f_s/M, here 400 MHz, while harmonics and translated input copies can occupy several positions after folding into the Nyquist interval. Branch offsets may give fixed components independent of test-tone frequency; gain, timing and analogue response mismatch can translate the applied input. Frequencies predict a class of possible artefacts, not unique causes or amplitudes. Measure complex branch-specific gains and timing with independent reference stimuli, then repeat with input frequency shifted by a known amount. If the translated lines move with the stimulus but the offset harmonic does not, that differential behaviour supports, without proving exclusively, the interleaving account. Do not classify the lines as separate transmitters merely because a spectrum display renders each as a sharp peak. I respectfully pass the token to Dr Shannon to examine what survives in the recorded sequence.

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, a field operator retains only a background-calibrated combined output stream and an FFT image. Branch identifiers and raw pre-calibration records were discarded. How can the investigator separate a corrected spectral picture from evidence of the original analogue wave and identify information that is no longer recoverable?

Claude Elwood Shannon, Cross-Peer Answer to Jean-Baptiste Joseph Fourier: Dr Fourier, the retained stream represents the output of a known or partly known transformation, not a transparent record of the original per-branch apertures. If branch identity, timing and correction coefficients are absent, multiple physical mismatch histories may be consistent with the same displayed spectrum. Preserve the calibration firmware, coefficient version, temperature log, branch order and raw or least-processed samples whenever technically available. Recompute spectra using declared windows, normalisation and record lengths; identify what was corrected rather than claiming that a spur was never there. A held-out calibration source and a separately routed receiver may discriminate hypotheses, provided their shared clocks, front ends and antenna path are accounted for. An image that tracks a reference could also be a mixing product, so the inverse explanation requires controlled challenges. I respectfully pass the token to Professor Tukey.

Claude Elwood Shannon, Cross-Peer Question to John Wilder Tukey: Professor Tukey, in the two-branch example a plus 30 MHz shift of the injected tone moves the predicted image minus 30 MHz. What adverse experiments could show that this tracking is attributable to interleaving,

Copyright 2026, James M. Atkinson

rather than an unexamined analogue mixer or coherent interference elsewhere in the receiver?

John Wilder Tukey, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, vary one experimental factor at a time and keep a contemporaneous audit trail. Repeat the frequency shift across multiple injection levels and branch configurations, including a single-branch operating mode where available. Measure whether the line follows f_s/2−f_in, whether a fixed offset spur remains at f_s/2, and whether calibrated preselector or path changes suppress the suspected mechanism. Sweep input frequency across representative analogue bandwidth conditions while controlling source harmonics, phase noise and gain compression. A response that disappears in single-branch operation is useful evidence, but it does not establish where every other source of nonlinearity resides. Pre-register the comparison metrics and inspect negative trials, not just the striking waterfall. Report frequencies and confidence bounds, with any conclusions restricted to the tested chain. I respectfully pass the token to Dr Shewhart to consider drift.

Walter Andrew Shewhart, Cross-Peer Question to Harry Nyquist: Dr Nyquist, a converter bank was skew-calibrated in the morning, then warmed by fifteen degrees. Its stated relative skew coefficient is 0.50 ps per degree, yet a report applies the morning image-rejection figure to a later 300 MHz capture. What can the calculated 7.5 ps change and approximately −43.01 dBc illustrative image actually establish?

Harry Nyquist, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, the 7.5 ps value follows only from the assumed linear coefficient over the specified fifteen-degree change. The image estimate uses the two-way

Copyright 2026, James M. Atkinson

small-skew approximation r approximately π f_in Δτ, which gives about 0.0070686 at 300 MHz and about −43.01 dBc. It represents a hypothetical incremental mismatch under that convention, not necessarily the total residual image after adding pre-existing skew, gain mismatch or phase-corrector error. Those contributions combine as complex phasors and can reinforce or partly cancel. Measure actual converter temperatures, branch-to-branch timing, reference-clock stability and correction coefficients both before and after the event. Revalidate across operating temperatures and signal frequencies; do not infer the temperature coefficient from a single changed peak. The example proves arithmetic consistency under assumptions, not real-world causation. I respectfully return the token to Dr Atkinson for synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Colleagues, our investigation has distinguished a numerically regular output sequence from a physically uniform acquisition. An interleaved receiver can genuinely increase aggregate sampling throughput, yet its branch-dependent gain, offset, aperture and analogue response can impose periodic errors which the Fourier transform faithfully displays as organised spectral features. The screen may shine with a line at a frequency never emitted by an independent external device. The crucial step is to recognise that periodic channel selection is an operation upon the incident waveform, and that the transformation can generate images whose apparent coherence and reproducibility mimic some properties of genuine reception. These features are not measurement frauds or necessarily evidence of defective engineering; they are predictable consequences of an architecture

Copyright 2026, James M. Atkinson

whose actual performance must be characterised within its operating envelope.

Dr Nyquist established the physical boundary of the nominal timing lattice. An index assigned by the software is not a measurement of the actual aperture time, and equal aggregate intervals do not imply equal branch gain, analogue phase response or recovery. Professor von Neumann demanded experimental identification rather than numerical curve-fitting alone, while Mr Weston required that every claimed correction be linked to its true reference plane. Baron Fourier then examined the periodic error coefficients and showed why harmonics of the branch-selection cycle shift a genuine input into correlated images. Professor Bridgman insisted that harmonic coefficients fitted from output data not be misrepresented as uniquely measured internal component parameters. Mr Bennett questioned the unjustified elevation of a smaller coherent spur into a universal improvement in random noise, sensitivity and detector performance.

Dr Shannon clarified the difference between a genuine stored record, the physical conversion model and the source-attribution hypothesis. The correct digital file can preserve an incorrect causal inference with perfect fidelity. Professor Wiener demonstrated why an adaptive correction algorithm can turn the receiving apparatus into a system with memory, so that a final calibration setting does not disclose every state through which a fleeting pulse passed. Professor Tukey then transformed the theoretical distinctions into a demanding experimental programme: controlled frequency moves, changes in interleaving mode, independent validation conditions, negative controls and transparent accounting for multiple comparisons. Mr Turing drew the boundary between reproducing a

Copyright 2026, James M. Atkinson

computation and reconstructing physical information absent from the record. Dr Shewhart finally required process-control evidence across the actual operating envelope, and Sir Ronald Fisher exposed the danger of reporting selected successful calibration trials as a statistical guarantee.

The worked examples give the reader concrete diagnostics. Four branches, each operating at 400 million conversions per second, may create a nominal 1.6-gigasample stream, yet their periodic errors can generate image locations related to 400-MHz branch harmonics. Two branches separated by a symmetric one-per-cent gain deviation can create a copy of a strong 120-MHz input at 380 MHz, approximately forty decibels below its parent, without a second transmitter. A two-picosecond branch skew at 200 MHz may generate a timing image near −58 dBc in the stipulated model; an uncorrected temperature drift of several picoseconds can materially worsen that result. Offset mismatch, coherent skew and random aperture jitter must not be combined casually under one label. Their spectral signatures and uncertainty relations differ.

For a defensive counter-surveillance investigation, the appropriate inference should follow controlled comparisons rather than the aesthetic appeal of a waterfall trace. A line which moves according to $f_s/2-f_{in}$ when a known reference moves is consistent with an internal interleaving image, especially if a separately declared branch-mode change produces the predicted accompanying result. Yet a coincident external emission may remain possible, and a different form of coherent processing might mimic the same simple movement. A correction which reduces an image can improve a specified spurious-free measure without proving improved probability of detecting every weak intermittent signal. Validation must

Copyright 2026, James M. Atkinson

therefore address the actual detector, the intended class of emissions, the relevant strong-blocker environment and any intervals of adaptive transition or failed calibration.

The publication record should preserve raw output and branch-resolved codes where available, exact aggregate and branch sample rates, the timing and analogue reference, calibration state history, firmware versions, gain and attenuator settings, stimulus characteristics, actual detector thresholds, transform parameters, invalid periods and all observed challenge outcomes. When a record is corrected, the uncorrected source should remain preserved, or its absence should be disclosed as a qualification. Where the relevant data were never saved, the analyst should avoid inventing them through retrospective arithmetic. Scientific restraint does not require an indefinite postponement of every finding; it requires a clear statement of the observation and the remaining physical alternatives.

I therefore conclude that periodic interleaving mismatches can generate coherent spectral artefacts whose positions are calculable and whose magnitudes can be bounded under declared models, but their exact physical origin in a particular receiver must be established through evidence. This is a positive doctrine of measurement: use the mathematics to predict, the experiment to discriminate, the source record to verify and the report to limit what can honestly be inferred. Our next question will examine how effective number of bits relates to intermittent signals, where a beautifully averaged spectral figure may conceal that the receiver possessed too little instantaneous information to preserve a brief event. I thank the contributors and pass the token onward.

Ten worked engineering applications | Question 027

Application 01. Aggregate rate and branch timing for four converters

Let $M=4$ and let the aggregate rate be $f_s=1.600\times10^9$ samples/s. The nominal output interval is $T_s=1/f_s=0.625$ ns, while each individual branch converts at $f_s/M=0.400\times10^9$ samples/s, or 400 MS/s. Its interval between successive conversions is $M\,T_s=2.500$ ns. The branches occupy nominal phases separated by 0.625 ns in the sequence, with each branch repeating every 2.500 ns. This arithmetic establishes aggregate throughput, not independent proof that the analogue apertures follow those times accurately. A common-clock architecture, board delays and branch-specific aperture uncertainty must be measured before treating the nominal lattice as a traceable timing measurement.

Application 02. Two-way gain mismatch and a translated spectral image

Consider $M=2$, $f_s=1.000$ GS/s and a real input sinusoid at $f_{in}=120$ MHz with peak amplitude $A=0.500$ V. Let branch gains be $1+\varepsilon$ and $1-\varepsilon$ where $\varepsilon=0.010$, meaning a 2% full branch-to-branch difference relative to the nominal gain. The reconstructed output is approximately $y[n]=(1+\varepsilon(-1)^n)x[n]$. The gain-image frequency in the first Nyquist zone is $f_{image}=f_s/2-f_{in}=500-120=380$ MHz. The image peak amplitude is $\varepsilon A=0.010\times0.500=0.005$ V. Its ratio to the main signal is $\varepsilon=0.010$, giving $20\log10(0.010)=-40.000$ dBc under the stated amplitude convention. A line at 380 MHz is thus predicted without any second external transmitter. The 2% branch difference must not be substituted directly for ε or the estimate changes by approximately six decibels.

Copyright 2026, James M. Atkinson

Application 03. Two-way offset mismatch and a fixed branch harmonic

Retain f_s=1.000 GS/s and let branch offsets be +b and −b, with b=0.001 V. The periodic output error is $o[n]=b(-1)^n$, producing a discrete component at $f_s/2$=500 MHz, irrespective of the incident signal frequency in this ideal model. Compared with a stated reference sinusoid of A=0.500 V peak, the amplitude ratio is b/A=0.001/0.500=0.002. Its level is 20log10(0.002)=−53.9794 dBc relative to that chosen peak reference. The relative level depends on the reference amplitude, while the absolute offset-spur amplitude remains b. An investigation should not label the feature a universal −54 dBc defect without documenting that reference and the actual spectral normalisation.

Application 04. Symmetric two-way aperture skew at high RF input frequency

Let M=2, f_s=1.000 GS/s, f_{in}=200 MHz, and suppose the two branches deviate from their intended sample times by +τ/2 and −τ/2, with τ=2.0 ps as the full branch-to-branch difference. Linearising x(t+δt) for a sinusoid yields a first-order alternating timing error whose image-to-signal amplitude ratio is approximately $r_{skew}\approx\pi f_{in}\tau$. Substituting gives $r_{skew}\approx\pi\times(200\times10^6\text{ Hz})\times(2.0\times10^{-12}\text{ s})=0.00125664$. Therefore the image is approximately $20\log10(r_{skew})=-58.015$ dBc under this two-way convention. The same skew at 50 MHz would produce an image roughly twelve decibels lower because the small-error ratio scales with f_{in}. The approximation fails when the phase deviation is not small or when frequency-dependent analogue response dominates the effective phase difference.

Copyright 2026, James M. Atkinson

Application 05. Random aperture jitter is not the same as deterministic skew

Assume an input sinusoid at $f_{in}=200$ MHz and independent RMS aperture jitter $\sigma_t=0.500$ ps referred to the sample aperture. Under the usual small-noise ideal sinusoid model, the jitter-limited signal-to-noise ratio is $SNR_j=-20\log10(2\pi f_{in} \sigma_t)$. The dimensionless product is $2\pi\times(200\times10^6)\times(0.500\times10^{-12})=0.000628319$, giving $SNR_j\approx64.04$ dB. This broadband-noise limiting calculation is not a prediction of the coherent spur caused by the 2-ps branch timing mismatch in Application 04. A receiver can suffer both defects, and no honest uncertainty budget should combine them as though they were necessarily independent manifestations of one scalar timing error.

Application 06. Four-way image family and alias positions

Let $M=4$, $f_s=1.600$ GS/s and $f_{in}=100$ MHz, within the 0–800 MHz first Nyquist zone. Gain or timing mismatch periodicity can translate copies of the input to the relevant first-zone positions $|f_s/4-f_{in}|=|400-100|=300$ MHz, $f_s/4+f_{in}=400+100=500$ MHz, and $f_s/2-f_{in}=800-100=700$ MHz, when the corresponding branch-pattern coefficients are nonzero. The fourth-harmonic offset structure may generate fixed components at 400 and 800 MHz. A calibrated test which moves f_{in} upward by 10 MHz would predict moving gain images at 290, 510 and 690 MHz, not three new independent transmitting devices. Actual image amplitudes depend upon the complex branch-error coefficients and the input waveform, which are not stipulated by frequency-position arithmetic alone.

Copyright 2026, James M. Atkinson

Application 07. Temperature drift can invalidate a narrow timing calibration

Suppose a converter assembly has a relative timing-skew temperature coefficient $c_\tau=0.50$ ps/°C and the relevant temperature changes by $\Delta T=15$°C. If the relationship is linear over this limited range, the skew change is $\Delta\tau=c_\tau\Delta T=7.5$ ps. At $f_{in}=300$ MHz, the associated first-order two-way image-to-signal ratio is $r\approx\pi f_{in}\Delta\tau=\pi\times300\times10^6\times7.5\times10^{-12}\approx0.00706858$, or $20\log10(r)\approx-43.01$ dBc. This is the estimated contribution from the hypothetical change, not an independent claim about the converter's initial spur or a universal temperature coefficient. Calibration performed at one ambient condition cannot be assumed valid at another without an appropriate thermal record or validation exercise.

Application 08. Combining orthogonal image components under an explicit model

Suppose a two-way receiver has a relative gain-image coefficient $r_g=0.005$ and a timing-image coefficient $r_t=0.008$, and their spectral phasors are orthogonal under a stated single-tone model. The resultant image amplitude ratio is $r_{total}=\sqrt{(r_g^2+r_t^2)}=\sqrt{(0.000025+0.000064)}=0.00943398$. Its level is $20\log10(r_{total})=-40.506$ dBc. Simply adding the two scalar levels in decibels would be meaningless, while adding amplitude magnitudes to obtain 0.013 would be a conservative bound rather than the orthogonal prediction. The orthogonality premise requires verification in the relevant architecture; analogue bandwidth mismatch and other phases can alter the vector relationship.

Copyright 2026, James M. Atkinson

Application 09. A frequency challenge separates moving images from fixed carriers

In a two-way system let f_s=1.000 GS/s and initially inject a calibrated reference at f_{in}=130 MHz. The gain-image hypothesis predicts a first-zone image at $f_s/2-f_{in}=500-130=370$ MHz. Move the same reference to 160 MHz while retaining the sample rate and operating state; the predicted image moves to $500-160=340$ MHz. The displacement is −30 MHz for a +30 MHz reference change. A fixed external carrier at 370 MHz, all else equal, does not satisfy this prediction merely because the reference moves. The test provides discriminating evidence, not universal exclusivity, because a mixing product or other coherent input-related artefact may also track stimulus frequency. A second intervention, such as changing branch mode, should be used where possible.

Application 10. False-alarm interpretation across a family of test frequencies

Suppose a laboratory searches K=800 effective independent spectral decision cells, each having a calibrated null false-alarm probability $\alpha=0.0005$ after a declared image-suppression procedure. The probability of at least one false alarm under independence is $P_{any}=1-(1-\alpha)^K=1-(0.9995)^{800}\approx0.3298$, or about 33%. Thus a seemingly impressive per-cell threshold can produce a substantial familywise burden when applied to many frequencies. The formula is exact only under the stipulated independence; real overlapped FFT windows, neighbouring bins, adaptive thresholds and shared calibration errors can create dependence. Suppressing a known interleaving image

Copyright 2026, James M. Atkinson

does not automatically revalidate a detector's null distribution, and a familywise result is not a probability that a particular observed spectral line is an external transmitter.

QUESTION 028

Copyright 2026, James M. Atkinson

When is an effective-number-of-bits calculation relevant to an intermittent signal?

Source: V011_Roundtable_Question_028_CP028_Standalone(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Constructed educational dialogue. Every exchange is newly authored; no passage is an authentic historical quotation or a claim that a deceased contributor examined modern equipment. Numerical illustrations are hypothetical, and none certifies an actual receiver. Technical references are identified by bracketed source keys.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, our preceding discussion established that several nominally interleaved converters may produce an aggregate stream whose periodic blemishes resemble independent emissions. The question before us concerns a different and rather seductive shorthand. An engineer may announce that a receiver possesses a certain effective number of bits, or ENOB, and the figure appears to carry the authority of a calibrated ruler. Yet an intermittent signal is not a continuous sinusoid, and the ability to characterise a converter with a deliberately maintained test tone is not identical to the ability to detect, date, classify, and preserve a burst that crosses the input unexpectedly. I ask the panel to determine when the ENOB figure contributes real explanatory value and when it merely decorates a conclusion whose governing conditions have not been demonstrated.

The conventional relationship ENOB = (SINAD - 1.76 dB)/(6.02 dB per bit) is useful precisely because it is conditional. In its familiar form, the

Copyright 2026, James M. Atkinson

measured signal-to-noise-and-distortion ratio, SINAD, concerns a specified sinusoidal input, bandwidth, amplitude, acquisition state, and method of spectral analysis. The ideal full-scale sine-wave quantisation model supplies the constants; it does not establish the shape, arrival time, or amplitude of an unknown transient. At the bench, a pure laboratory tone may keep a converter operating near its favourable range while a field emission arrives far below full scale, beneath another carrier, or during a gain transition. The number printed on the converter's evaluation sheet cannot by itself reconstruct the missing observation. [S1, S2, S3]

Consider a defensive technical surveillance countermeasures examination with broad monitoring coverage and a second, deliberately narrower acquisition intended to adjudicate an unusual event. A weak emission may last only microseconds; the broadband monitor may retain a short block, then overwrite earlier samples while an operator hears a notification. If the effective resolution was measured using a long coherent sine-wave record at a different centre frequency, we must ask what information travels legitimately from that test to the retained event. Was the same analogue input boundary used? Was the front end linear? Was the converter's input actually populated sufficiently to make its numerical resolution meaningful? Were sample-clock disturbances, triggering latency, dropped blocks, digital scaling, and post-detection selection recorded? None of these particulars is settled by changing a ten-bit effective figure into an attractive twelve-bit label.

There is a second danger, less dramatic but scientifically consequential. An intermittent waveform has a finite observation interval, and frequency analysis of a finite record necessarily involves a spectral window, leakage

Copyright 2026, James M. Atkinson

and effective noise bandwidth. A longer Fourier transform can lower the displayed noise per bin while excluding part or all of the event; a shorter transform can preserve timing while spreading energy across more bins. These representations need not contradict one another. They answer different questions. We must not confuse the sound of a narrow spectral line on a demonstration with the evidence that a pulse survived a specified sampling and retention policy. Nor can coherent averaging be promised where the event lacks phase continuity or repeatability. The experimental challenge is to state which measure is invariant under an admissible change in analysis and which is an artefact of that change. [S3, S4, S5]

Our five principal respondents will therefore address successive boundaries. Professor Bridgman will define the proposed measurand and challenge the apparent independence of test procedure and reported result. Dr Nyquist will examine sampling, timing uncertainty and the bandwidth occupied by a transient. Professor Tukey will address spectral estimation, window choice, selection and diagnostic trials. Dr Shannon will distinguish converter information from the information retained by the entire acquisition system. Professor Neyman will treat claims of detection probability, false alarms and confidence as propositions requiring a specified trial population. Seven colleagues will interrogate those explanations, with each question answered immediately and courteously before the floor passes onward.

The ten worked applications are deliberately bounded. They expose the numerical meaning of ENOB, signal-amplitude back-off, jitter, record length, equivalent noise bandwidth, exposure coverage, multiple testing, and the uncertainty attached to a finite validation study. They are not substitute

Copyright 2026, James M. Atkinson

specifications for a particular converter. We shall keep the quantities, units and hypotheses visible, preserving a distinction familiar to rigorous British metrology: an indication may be measured with confidence while an attempted inference about the unseen source remains uncertain. When the discussion concludes, the panel must offer usable reporting language. It should tell the examiner what the ENOB result actually supports, what complementary experiments are required, and where a negative search or precise-looking bit count cannot justify reassurance.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal response 1: The operational meaning of a conditional bit count

Dr. Atkinson, I thank you for placing the word 'relevant' rather than merely 'accurate' at the centre of the inquiry. A number can be accurately computed from the wrong experiment. If the arithmetic and instrumentation agree while the method fails to address the desired quantity, the result is not fraudulent; it is misplaced. The first requirement is an explicit account of the operation through which effective bits are obtained. In the familiar sine-wave method an input of controlled amplitude and frequency exercises the conversion chain, a specified algorithm separates fundamental energy from its noise-and-distortion residual, and the quotient is compared with an ideal quantiser. That is a perfectly intelligible comparison. It is not, however, a general statement that every future burst will be received with the same number of useful binary decisions. [S1, S2]

I would separate four proposed measurands before accepting the result. The first is the dynamic sine-wave performance of the bare converter at a specified input, sample rate, reference and temperature. The second is performance of the installed analogue-to-digital path, including preamplifier, filters, gain switching, sample clock and coupling impedances. The third is the detection probability of an intermittent signal class in a defined observation procedure. The fourth is the evidential reliability of attributing an observed feature to an external emitter rather than internal noise or distortion. These quantities can be connected by a physical and statistical model, but they are not synonyms. A report that substitutes the first for the third silently changes its subject. A report that substitutes the

Copyright 2026, James M. Atkinson

third for the fourth confuses a correctly registered event with a correctly identified source.

A further condition concerns signal amplitude. An ideal quantiser has discrete output codes, but an ENOB figure measured near full scale need not apply to a pulse which uses a hundredth of the available excursion. Analogue input noise, quantisation effects, nonlinearity and spectral interference need not maintain a common ratio as input amplitude changes. A strong continuous test tone may dominate a short acquisition while the intermittent signal is almost invisible; an operator may then interpret low noise in the displayed spectral bins as proof of greater sensitivity. That is an unwarranted transfer between a controlled comparison and a field event. It is necessary to record the amplitude range actually exercised, preferably with tests extending into the region containing the event of interest.

The reference plane itself deserves explicit treatment. The useful comparison might be at an antenna terminal, a bandpass-filter output, a converter input or a digital baseband stream. A gain correction that moves a result from converter codes back to an input voltage presupposes a transfer function, and the transfer function may change under strong adjacent-channel signals. An amplitude in arbitrary display units cannot be promoted into a calibrated input-referred quantity merely by dividing by a displayed scale factor. Similarly, if a peak was clipped before conversion, the effective bit count of the surviving samples cannot recreate the exceeding value. If the event occurred during a switch, the state of that switch is part of the conditions of the operation, not an optional narrative detail.

I would ask that each test produce two separate records. The first is a performance statement for the chosen reference condition, including

Copyright 2026, James M. Atkinson

numerical result and uncertainty. The second is an applicability account linking the reference condition to the intended intermittent signal: spectral occupancy, pulse duration, amplitude distribution, duty cycle, crest factor, gain state, time alignment and retention policy. If this linkage is absent, the number may still be valuable for comparing converter implementations in the laboratory, but its evidential reach must stop at that comparison. The word 'representative' should never be used without explaining representative of which population and which conditions.

It is possible for a lower ENOB receiver to perform better at a particular defensive detection task. A receiver with modest sine-wave SINAD but continuous observation, reliable time stamping, sound preselection and a correctly tuned detector may capture an event missed by a higher-ENOB converter hidden behind a slow scanning policy. This is not a paradox in the physics. It shows that one dimension of converter performance cannot stand for the performance of an entire instrument and acquisition procedure. We can reverse the example: a beautifully continuous receiver may produce reams of faithfully timestamped evidence but fail to discriminate a small signal against its own noise. We must test each part rather than declare one part a proxy for all.

One final matter is the language of certification. I should report, 'Under a specified continuous sinusoidal stimulus, the installed converter path exhibited an ENOB of approximately X, subject to the identified measurement conditions.' If an intermittent challenge was actually applied, I should state a second and distinct result, such as the observed fraction of accepted bursts, with confidence limits and exclusion criteria. Where the record does not contain such a challenge, a general assertion of transient

Copyright 2026, James M. Atkinson

detection capability must remain open. Measurement gains rigour not when every number is doubted, but when no number is allowed to answer a question it was never designed to address. Dr Gabor, may I respectfully invite your challenge concerning the measurement operation that combines a finite instant with a finite band?

Dennis Gabor | Peer question 1 to Percy Williams Bridgman

Professor Bridgman, I am obliged for your distinction between a converter's conditional performance and the practical receiver's evidential promise. Yet the intermittent event seems to introduce a more elementary difficulty. A pulse cannot be reduced to an infinitely long harmonic oscillation without losing the very starting and finishing times that make it a pulse. If an analyst chooses a long observation interval, the Fourier representation may place substantial energy into fine frequency bins and reveal a faint carrier, while the onset time is blurred by selection and averaging. If the interval is shortened to preserve onset, the spectral lines broaden and the same event can appear less impressive relative to a narrow-bin threshold. Which operation should define the relevant quantity? Can an ENOB measured under an indefinitely repeated sine wave be transferred by an explicit transformation, or must an entirely new operational performance statement be made for the particular time-frequency occupancy? I would also ask whether the reference experiment should vary pulse shape and duty cycle, since a rectangular envelope, a smoothly tapered burst and a chirped burst can place quite different demands upon the identical set of converter codes.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Immediate answer to Dennis Gabor

Dr Gabor, your challenge exposes a limitation that becomes clearer when an investigator states what decision the measurement is intended to support. For a burst whose presence is the primary question, the relevant comparison may be a time-localised matched-filter statistic or an energy statistic over a defined signal class. For a burst whose carrier frequency is the primary question, the time-frequency resolution and any prior model of the envelope become essential. The two tasks can use the same recorded samples without being evaluated by an identical scalar. I would therefore retain the standard ENOB figure as a descriptive property of a defined sine-wave benchmark and introduce a second operational metric for the transient task, rather than forcing a universal reinterpretation of ENOB.

A transformation is legitimate only when its assumptions can be stated and challenged. If we know an input waveform family, the system's linear impulse response, the stationary noise statistics and a stable acquisition state, we can use the benchmark noise-and-distortion model to predict a conditional detection outcome. We must then test those predictions with held-out pulses. A mere algebraic rearrangement of the ENOB equation cannot supply a missing temporal model. A long Fourier analysis gives a small nominal bin width, but a short event does not suddenly acquire more independent cycles because we append zeros or retain quiet samples before and after it. Zero padding interpolates a sampled spectrum; it does not create observations not present at acquisition.

Copyright 2026, James M. Atkinson

I should also record the physical difference between peak amplitude, pulse energy, carrier power during the burst, and power averaged over the entire observation interval. A pulse occupying one percent of a long record can have an apparently poor average signal-to-noise result even when its in-burst amplitude is sufficient for reliable detection, or the reverse can happen if a rare strong disturbance dominates the selected statistic. Neither outcome licences a claim about the converter's universal resolution. The declared metric must identify which portion of the observation contributes signal and which contributes background, and it must state who selected those portions and on what evidence.

I would propose a paired evaluation. Test the installed receiver with a continuous reference tone to establish the conventional ENOB under stable conditions. Then inject a controlled population of bursts with specified envelopes, amplitudes, frequencies and random arrival phases relative to sampling and scan cycles. Preserve complete acquisition records, including failures and idle periods. Use a predetermined detector and compare observed performance with the model's prediction. Where the correspondence is satisfactory, the converter benchmark becomes explanatory evidence, but it remains one premise among several. Where the results diverge, the disagreement is itself a finding about temporal coverage, front-end dynamics, estimator design, or noise assumptions. Your insistence on relating time and frequency is therefore an invitation to define the task correctly, not an argument for discarding disciplined sine-wave tests. Mr Weston, may I invite the next question concerning whether

Copyright 2026, James M. Atkinson

the reference point chosen for the comparison remains physically stable when the event is weak?

Edward Weston | Peer question 2 to Percy Williams Bridgman

Professor Bridgman, suppose the laboratory performance measurement is impeccable at the converter pins, while the instrument used in the investigation contains a preamplifier, a variable attenuator, a bandpass filter, and an analogue switch before those pins. The operator later quotes the converter's ENOB as though it were a property of the antenna-terminal observation. In the laboratory the test source may be low impedance and a continuously maintained sine wave, whereas the field event arrives from an antenna and may coincide with a relay or automatic gain transition. I should like to know what observations permit transfer of the ENOB-derived noise and distortion description through this front end. In particular, how would you separate a genuine change in input-referred sensitivity from a computational rescaling that changes only the displayed units? And if the reference plane can move through calibration corrections, which data must be retained so that another examiner may verify the claimed correction independently?

Percy Williams Bridgman | Immediate answer to Edward Weston

Thank you for that question. Mr Weston, the converter terminal and the antenna terminal are distinct physical locations; a mapping between them is a measured relationship, not an editorial convention. I should require a schematic and a measured transfer description of each relevant gain state, including frequency-dependent insertion loss, noise contribution, linearity and impedance loading. A measured sine-wave ENOB at the converter might help explain its own residual

Copyright 2026, James M. Atkinson

noise and distortion, but an antenna-referred performance claim must include the entire cascaded path. A noiseless numerical division by the nominal amplifier gain cannot remove the amplifier's noise or undo distortion produced before conversion. It can alter the numerical scale of the trace while leaving its information unchanged.

If the front end changes state, the description must change with it. A gain control that adjusts in response to the pulse can reduce the pulse's peak, distort its envelope, or mask its opening samples; a filter can ring, delaying apparent onset or stretching the measured duration. These are physical transformations. The correction should therefore be linked to a retained state history and to a calibration obtained at relevant amplitudes and temporal conditions. A static gain table evaluated on a continuous tone may be insufficient when a transient arrives near a switching boundary. One ought to measure the changeover interval and test whether a known event survives it, rather than assume the change is instantaneous.

The useful record would preserve the uncorrected digital samples or the earliest accessible equivalent, the calibration version and date, gain-state and attenuation histories, clock and trigger information, the software transformation, and the reference-plane statement. It should also preserve uncertainty arising from those steps. This permits an independent examiner to reproduce the displayed amplitude and, more importantly, to challenge whether the display measures the intended quantity. If the record contains only a corrected number, the transformation becomes inaccessible to scrutiny. The problem is especially acute when high-precision decimal

Copyright 2026, James M. Atkinson

places suggest a certainty that the physical apparatus could never have justified.

The broader conclusion follows naturally. ENOB is relevant as a controlled account of one constituent's dynamic error. It is relevant to antenna-terminal inference only through a justified uncertainty and transfer model that includes the other constituents and their state. No amount of mathematical neatness can repair an unobserved gain transition or a lost reference-plane definition. I gladly pass the floor to Dr Nyquist, whose examination of the sampling lattice should illuminate the next boundary between a numerical rate and an actual temporal observation.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 2: Sampling cadence, aperture uncertainty and the temporal meaning of a burst

Dr. Atkinson, I would begin with the sampling operation itself. An analogue waveform is not encountered by a converter as an abstract, perfectly indexed sequence. Each code follows an aperture event with finite timing properties, a finite input bandwidth, and a conversion process which may have memory and nonlinear behaviour. We may write the desired sample as $x(nT_s)$, where x is the input waveform, n the sample index, and T_s the nominal interval. The practical sample is closer to a response to $x(nT_s + \delta t_n)$ after the analogue aperture and transfer network, where δt_n denotes timing error. The first statement describes an ideal lattice; the second identifies a physical mechanism which can corrupt a transient and may not be measured by a low-frequency sine-wave ENOB test. The uncertainty grows with waveform slope. [S1, S2]

For a sufficiently smooth waveform, a small timing perturbation produces approximately $\delta x_n = x'(nT_s)\delta t_n$. This relation is instructive because it does not put the same error at every instant. Near the peak of a sine wave the instantaneous slope is small; near a zero crossing it is large. For a sharply rising pulse the slope may be exceptionally large within a short interval, while the flat portion is much less sensitive. An RMS result averaged over many cycles can conceal the position-dependent severity of the same clock error when the observation of interest is a singular edge. An experiment which claims to date that edge must quantify timing uncertainty directly, not merely translate a measured sine-wave SINAD into an impressive number of bits.

Copyright 2026, James M. Atkinson

The familiar jitter-limited sine-wave relation, $SNR_j \approx -20 \log10(2\pi f_{in} \sigma_t)$, where f_{in} is the sinusoidal input frequency and σ_t is RMS aperture-time uncertainty, applies under a particular small-jitter, sine-wave model. At high input frequency even a very small timing deviation may dominate the noise budget. But a narrowband tone at one frequency is not a substitute for an unknown transient whose envelope, modulation and rise time vary. The relevant error involves the derivative and spectrum of the actual input. A receiver whose ENOB is adequate at a modest test frequency may exhibit poorer performance on fast edges or high-frequency components, especially when the analogue front end contributes additional delay and dispersion. A responsible engineering statement must say which frequency and amplitude were used, how the clock was characterised, and whether the inference is about waveform reconstruction or simply event detection.

A second boundary concerns finite exposure. Suppose the converter runs continuously at forty million samples per second, but the acquisition system retains a block only when an upstream detector triggers. The nominal 25 ns sample interval does not establish uninterrupted forensic observation. A microsecond burst could occur while memory is unavailable, while a transport buffer overflows, or while a display is being updated. In such a circumstance the converter might possess outstanding ENOB whenever actively sampling, but no sample of the burst may survive. An archive cannot be made more complete by assigning additional effective bits to a block collected at a different time. We need sample-continuity evidence, loss counters, memory overwrite policies, and a timebase whose relationship to the recorded triggers is known.

Copyright 2026, James M. Atkinson

A third limitation is aliasing. Nyquist sampling theory requires that relevant signal components be constrained relative to the admitted sampling bandwidth. For a transient, sharp edges can carry spectral content outside the passband assumed for an ordinary sinusoidal test. The analogue antialias filter may suppress those components, altering the observed rise time and ringing behaviour. That alteration may be appropriate and even essential for a correctly sampled system, but it must not be described as recovery of an arbitrary input waveform. An investigator who wishes to infer that an emission truly had a two-microsecond duration must separate the pulse as delivered to the converter from the earlier waveform at the antenna, and must confront the response of the intervening filters. A measured duration can be accurate for the retained filtered waveform while remaining a biased estimate of the external event's duration.

There are useful circumstances in which ENOB is strongly relevant. If the signal class consists of finite bursts of a well-characterised sinusoid, the front end remains linear and in a constant gain state, the acquisition has adequate temporal coverage, and clock and noise conditions are measured at the relevant centre frequency, a sine-wave dynamic benchmark can support an error-budget prediction for samples collected during the burst. It may help choose a converter, identify a quantisation-limited regime, or evaluate whether a proposed amplitude estimator is plausible. These are real uses. Yet the prediction must be made for the actual burst length and estimator; an average over thousands of quiet samples cannot be smuggled into the performance of a twenty-sample pulse. If coherent processing is proposed, the necessary phase relation must be independently shown rather than assumed from nominal carrier frequency.

Copyright 2026, James M. Atkinson

I would therefore prescribe three temporal challenges in addition to the usual continuous-tone examination. The first randomly varies the burst's starting phase relative to sample times. The second varies pulse width through the interval in which only a few samples fall inside the event. The third introduces bursts around actual instrument state changes and known possible data-loss intervals. Each challenge must retain both successes and failures, with the timing record needed to establish that an alleged miss was actually exposed to the receiver. The combination explains whether converter error, sampling geometry, trigger policy or retention dominated. It also prevents an analyst from attributing every negative observation to weak signal amplitude. Sir Robert Watson-Watt, whose historical work placed immediate operational value upon detecting rapidly arriving radio phenomena, may perhaps test the practical sufficiency of this account. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Sir Robert Alexander Watson-Watt | Peer question 3 to Harry Nyquist

Dr Nyquist, I thank you for the rigorous statement of the sampling lattice, but the field instrument must answer a question under conditions no laboratory can make entirely placid. A radar warning or a defensive monitoring receiver may confront a pulse amid interference and receive only a fleeting opportunity to record it. If an instrument is technically able to make many accurate samples per second, yet its observation pattern, trigger logic or display update suppresses some arrivals, the published dynamic performance does little to settle whether the operator should regard a blank interval as reassuring. I should like you to distinguish a receiver's ability to capture a representative sample of a

Copyright 2026, James M. Atkinson

known pulse from its ability to provide continuous surveillance of an unknown pulse population. What trials would show that the tested burst phases and durations were representative? Would you insist upon a deliberately randomised challenge during actual gain changes, or could periodic laboratory pulses suffice? Finally, how should the investigator communicate a negative result when the apparatus was accurate when exposed, but exposure itself has not been adequately established?

Harry Nyquist | Immediate answer to Sir Robert Alexander Watson-Watt

Thank you for that question. Sir Robert, the distinction is decisive. Accuracy conditional upon acquisition and probability of acquisition are independent elements of the apparatus's overall effectiveness. In a simple model their combination may be expressed as P(detect) = P(exposure) × P(detect | exposure), provided the chosen conditional formulation faithfully represents the events and neither probability is silently conditioned on a more favourable subset. The multiplication does not certify an instrument; it displays the logical dependence of a detection claim upon temporal coverage. A laboratory which reports excellent conditional recognition but never measures exposure has not established the unconditional probability required by a continuous monitoring assertion.

The temporal schedule matters as much as its nominal proportion. A periodic scan that watches one frequency for sixteen microseconds in a millisecond may expose a burst arriving at a uniformly random phase with probability approximately 0.016 under a narrowly defined model. But a burst source synchronised with the scan may be always

Copyright 2026, James M. Atkinson

visible or always absent. Similarly, successive pulses from one emitter may share the same phase relationship to a scanner; multiplying their apparent independent chances would exaggerate detection. The test population must include random arrival phase, realistic burst lengths and configurations, and deliberate challenges to likely correlations. The rate at which a converter produces codes is not the rate at which the investigation obtains informative evidence.

I would combine controlled periodic pulses with an independent randomised set. Periodic pulses are excellent for calibrating gain, delay, sampling aperture and steady-state behaviour. They are not sufficient alone to discover blind timing phases. A pseudorandomised arrival schedule with its seed, event list and reference timing retained would expose the receiver to periods the experimenter had not chosen for convenience. One must further include independent pulse amplitudes and shapes rather than allowing a single favourable waveform to dominate success statistics. The reception state must be recorded before, during and after each arrival, because an apparent failure at low amplitude may instead be due to a transient gain adjustment or an overwritten buffer.

For the report, I would not permit a negative observation to be translated directly into absence of a source. The properly bounded statement is that no qualifying event was retained in specified channels during specified exposures, with the measured or otherwise defensibly estimated coverage and the known detection limits described. If coverage is not known, report that deficiency without ornament. The operator can still say that no alarm appeared, which is

Copyright 2026, James M. Atkinson

an observation about the apparatus. The operator cannot claim from that fact alone that the electromagnetic environment was silent. We should now pass the token to Professor Tukey, whose methods can help us separate the statistical behaviour of the record from the habits of the person selecting its intervals.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 3: Windows, estimators and the illusion of a single receiver figure

Dr. Atkinson, I should resist the temptation to give one beautiful number the job of making several untidy decisions. Effective bits are convenient because a decimal number orders a collection of converter test results. An intermittent signal, however, confronts the analyst with exploratory choices that can profoundly alter what is displayed: the event interval, transform length, taper, frequency-bin aggregation, baseline estimator, detector threshold and rule for selecting an alarm. These decisions can all be computationally legitimate while yielding different descriptive results. The methodological failing lies not in their variety but in pretending that an exploratory selection was preordained or that its chosen numerical outcome generalises to all events. [S3, S4]

Suppose an unknown burst lasts three microseconds and the sampled rate is forty megasamples per second. Approximately 120 samples lie inside that interval if the whole burst is acquired. The inverse duration is about 333 kHz. This is not a universal frequency accuracy limit, because model-based estimators can under suitable assumptions achieve different precision; it is the natural frequency spacing associated with a transform over three microseconds. If an operator appends many thousands of zeros and plots a smooth spectrum with visually fine frequency increments, the inserted zeros do not add samples of the event. A long FFT of a record containing the same burst and much quiet time may also give narrow mathematical bins, but the transient's spectral energy remains spread by its short envelope. The display's apparent granularity is not evidence that the original emission was observed with an equally long coherent duration.

Copyright 2026, James M. Atkinson

Window choice introduces another trade-off. A rectangular observation window preserves all included samples with equal weight but can generate conspicuous sidelobes when a periodic tone fails to fit an integer number of cycles. A tapered window suppresses some sidelobes but changes coherent gain, broadens the response and increases equivalent noise bandwidth. The Hann window, for example, has approximately 1.5-bin equivalent noise bandwidth under conventional normalisation, a penalty of about 1.76 dB in noise power per bin relative to a rectangular window of the same record length under white-noise assumptions. That fact is not an indictment of tapering. A taper may improve detection near strong spectral neighbours by reducing leakage. The point is that the estimator's behaviour must be characterised for the actual signal class rather than hidden behind a converter ENOB obtained by another procedure. [S4]

The order of analysis should be made auditable. I would begin by saving the earliest accessible samples and their acquisition state. Next, construct time-domain plots before selecting frequency windows; inspect for clipping, missing blocks, abrupt gain shifts and threshold selection. Then establish a predeclared reference method for the known signal family. Exploratory displays may be added to discover unanticipated structures, but they should be distinguished from confirmatory tests that fixed their decision rules in advance. If an analyst tries ten tapers and twenty thresholds, eventually choosing the pair that produces the most attractive burst, ordinary nominal significance calculations no longer describe that search without adjustment. A post hoc frequency label may be convenient for further investigation but is not a verified source property.

Copyright 2026, James M. Atkinson

This becomes especially important when the event itself chooses the window. A trigger that fires upon a large noise excursion selects a non-representative population of samples, so the average residual measured in triggered blocks may differ from the residual over continuous observation. Estimating a noise floor only from records that contain a strong selected pulse can be equally misleading, because the candidate signal may contaminate the background estimate. One must preserve the trigger logic and the population of excluded or overwritten intervals. A credible receiver validation set should include deliberately chosen negative controls as well as known positive challenges and a sufficient account of all trials attempted.

I would also distinguish analytic bandwidth from physical sensitivity. It is possible to lower a spectrum plot's average noise floor per bin by choosing a narrower bandwidth, longer coherent integration or more averages. Yet that change cannot necessarily improve detection of a one-off burst, because the burst may be diluted or misaligned by the integration. Similarly, adjacent-bin leakage from a strong carrier can remain the dominant impediment to a weak transient even when the converter's sine-wave ENOB is high. The right performance metric might be probability of detection at fixed false-alarm probability, measured across a defined burst population, rather than a raw number of equivalent ideal bits. The ENOB remains an input to interpreting the result, not an alternate name for it.

I would ask for comparisons which are deliberately inconvenient to the preferred model. Challenge the receiver with a pulse beginning near the edge of the transform window, then near its centre; with frequency drifting through a bin boundary; with an adjacent powerful carrier; and with a gain transition occurring during the burst. Evaluate both the predeclared

Copyright 2026, James M. Atkinson

processing chain and a small, justified set of alternatives. A discrepancy among those results may reveal a windowing problem, temporal sensitivity, or nonstationary background. It should not automatically be 'corrected' by selecting the most favourable method. The field examiner needs a diagnosis and a bounded capability statement, not a contest to produce the most decimal places.

A conscientious conclusion may be modest yet operationally valuable. We might say that ENOB from a specified sine-wave test predicts a particular noise-and-distortion contribution under stationary calibration conditions, while the observed burst detector meets a separately established recognition rate at a stated threshold and false-alarm level. We might also identify regimes where the model fails, such as short bursts beside strong carriers. Those failure boundaries are scientific knowledge. Dr Hamming, may I invite you to examine how numerical windowing can mislead even an analyst who knows that the window has been applied?

Richard Wesley Hamming | Peer question 4 to John Wilder Tukey

Professor Tukey, I agree that many lawful computational operations can answer different questions, but I fear that the phrase 'window correction' sometimes suggests that a window's effect can be entirely reversed by dividing by a convenient constant. The coherent gain corrects the amplitude of a tone in a particular alignment, while equivalent noise bandwidth describes noise-power behaviour, and neither guarantees that a pulse at the window boundary has the same response as a pulse at its centre. If an examiner sees a burst with a sharply defined onset and applies a taper designed for periodic spectral analysis, what proof should be demanded before its peak or energy is

Copyright 2026, James M. Atkinson

compared with a continuous-tone ENOB result? I would also ask whether zero padding, frequency interpolation and averaging of adjacent spectra can ever be justified as improvements in the evidential estimate, or whether their value must always be treated as merely visual. Finally, how should the uncertainty introduced by selecting one window over several alternatives be included in the reported conclusion?

John Wilder Tukey | Immediate answer to Richard Wesley Hamming

Thank you for that question. Dr Hamming, a scalar window correction answers only the problem for which it was derived. If a sinusoid occupies a complete analysis interval and its phase relation is appropriately controlled, a coherent-gain correction can restore an amplitude interpretation under the assumed model. For a transient which begins at one end of the window, the taper weights that particular event differently from the same event arriving centrally. A single constant cannot erase this time-location dependence. The correct procedure is to calculate the windowed detector's response to the intended family of transient envelopes and arrival times, then validate those calculations with injected signals. The result may be an uncertainty band or detection-efficiency curve rather than one universal correction.

Zero padding is not entirely decorative. It can improve the practical interpolation of a discrete Fourier representation and help locate a spectral maximum more accurately under an appropriate signal model; it is useful computationally. What it cannot do is create independent time samples, narrow the fundamental envelope caused

Copyright 2026, James M. Atkinson

by a short event, or retrieve missing information. Likewise, averaging can reduce the variance of a legitimate estimator when the data and independence conditions support the averaging. It cannot be expected to improve a singular burst by averaging it with records in which the burst was absent. One must state whether the operation averages complex amplitudes coherently, power spectra incoherently, or conditional candidate segments selected by a detector. Those methods have different statistical properties.

The uncertainty from window selection is partly a model-selection problem. Where the rule was selected before the challenge data were examined, the experiment can evaluate that rule's error characteristics directly. Where it was selected because it gave a favourable result on the same data, an ordinary confidence statement may be optimistic. The analyst can restore some discipline by applying the chosen method to independent held-out challenges, retaining the entire original search history, and comparing the result with an explicitly declared family of alternative processing chains. The held-out sample must not quietly become another exploration set after an inconvenient outcome.

I would also remind the examiner that time registration can carry meaning independent of amplitude. A window that suppresses the onset may yield a commendable spectral peak while impairing the estimate of when the source began transmitting. The task should say whether it requires frequency discovery, pulse timing, classification or presence detection. A numerical recipe optimised for one may be ill-suited for another. Dr Bennett, may I invite the complementary

Copyright 2026, James M. Atkinson

concern that the residual called 'noise' may be neither independent nor stationary over the interval chosen for the estimator?

William Ralph Bennett | Peer question 5 to John Wilder Tukey

Professor Tukey, much of the conventional sine-wave analysis assumes that the residual left after removal of the fundamental can be treated as a stable measure of noise plus distortion. An instrument used in a practical survey may instead experience nonstationary interference, bursts from unrelated sources, short power-supply transients and periodic converter artefacts whose phases vary with acquisition state. If the analyst computes ENOB from one record containing the candidate event and then quotes it as though it were an intrinsic property of the converter, the signal and residual may both have been selected for unusual behaviour. How should an examiner distinguish additive thermal-like fluctuations, deterministic spurious responses and rare impulsive disturbances before relying upon a single combined SINAD? Is there a useful role for median estimates or robust procedures, or might those procedures conceal precisely the rare interference which a technical surveillance countermeasures investigation is meant to detect? Finally, should the result be expressed as a scalar, a range conditioned on state, or a collection of separately measured noise and distortion mechanisms?

John Wilder Tukey | Immediate answer to William Ralph Bennett

Mr Bennett, I would not ask a robust estimator to make inconvenient phenomena disappear. Robust methods are tools for investigating how a result changes when a small subset of observations differs strongly from the remainder. They can show that

Copyright 2026, James M. Atkinson

the usual average is dominated by rare events, or that a typical background estimate differs from a worst-case impairment. Both observations may be valuable. The error would be to replace the raw evidence with only the robust summary and then deny that the discarded observations occurred. For a search intended to discover rare emissions, the exceptional observations may be the central evidential objects, not contamination to be tidied away.

I would insist upon retaining separate diagnostic displays of the time series, the power spectrum, the gain-state history and the ensemble of comparable trials. Estimate the background in regions not selected solely because they generated the alarm, but retain a record of the selection rule. Then examine whether the noise appears stationary within the intended interval and whether apparent distortion follows the stimulus when its amplitude or frequency is changed. A spur moving with a known internal branch pattern may require a different explanation from an independent external carrier; an impulsive disturbance might demand a heavy-tailed model instead of a Gaussian approximation. This classification must arise from challenge tests rather than labels imposed after the fact.

A state-conditioned performance map may be more informative than a universal scalar. Report ENOB for defined sinusoidal stimuli at relevant frequencies and amplitudes, and show its variation with converter gain, temperature, clock configuration and interfering-signal conditions. Alongside it report detection probabilities for the actual burst class at defined thresholds and exposure states. The investigator can then decide whether a particular benchmark

Copyright 2026, James M. Atkinson

materially constrains the event interpretation. A single ENOB number is acceptable for a narrow, declared test; a collection of numbers is appropriate when the instrument operates in materially different regimes.

One further caution concerns averaging statistics from selected records. If only strong detected bursts enter the analysis, the resulting signal-to-noise ratio will predictably look better than the ratio for the full population, including missed weak arrivals. The proper validation analysis must treat missed trials as outcomes, not exclude them from the denominator. Similarly, the strongest of many searched bins is not an ordinary randomly chosen bin. An extreme-value or multiple-comparison analysis may be required if the detector tests a large field of candidates. These are not subtleties to be reserved for a university seminar. They determine whether a forensic report speaks with measured confidence or merely repeats the instrument's self-congratulatory display. I pass the token to Dr Shannon, who can examine the information boundary between sampled digits and the later evidence archive.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 4: The converter's digits and the information preserved by the observation system

Dr. Atkinson, the proper question about a recorded transient is not merely how many numerical labels were available to represent it. We must ask what distinctions among physically possible inputs remain distinguishable after the channel and acquisition transformations. A converter of fourteen nominal bits may assign many thousands of code values, yet a high-resolution code stream conveys little about an event which fell into a discarded interval. Conversely, a lower-resolution converter may preserve the decisive fact that a pulse occurred at a particular time, although its precise amplitude remains uncertain. The information required for detection, timing, classification and physical attribution differs. To infer that a larger ENOB necessarily implies more useful evidence for all four tasks would be to mistake a scalar benchmark for the channel's entire conditional behaviour.

For a known signal model in additive stationary Gaussian noise, a matched filter can accumulate evidence from many samples according to their expected waveform and noise covariance. Its performance depends upon the signal's energy relative to the applicable noise process and upon the correctness of the presumed waveform. It does not depend solely upon the resolution of any one code. Where errors are independent and the signal is coherent, appropriate integration may improve the statistic. Where the event occurs once, the samples outside it are not repeated independent observations of that event. A claim that 'averaging synthesises more bits' must identify what has been averaged and why the necessary independence

Copyright 2026, James M. Atkinson

and signal-coherence assumptions hold. A numerical increase in displayed precision is not an increase in the converter's intrinsic hardware resolution.

The distinction is illuminated by two possible recording policies. In the first, the receiver continuously preserves calibrated complex baseband samples across the observation interval, with acquisition metadata sufficient for later reanalysis. In the second, the receiver records only a list of threshold crossings and a compact spectral image. Both may employ the same converter and therefore display the same benchmark ENOB. Yet the first record can support later tests of waveform shape, timing, spectrum, alternative threshold policies and some competing hypotheses. The second may not preserve enough information to revisit the detector's decision. It can support a narrower proposition, namely that the configured detector produced certain alarms. The loss is caused by retention and representation, not necessarily by the quantiser.

There is also a difference between signal energy and mean power. A finite burst with peak amplitude A and duration τ can contain energy proportional to A squared times τ under a specified impedance and envelope. If the analyst divides that energy over a much longer observation duration T, the apparent average power decreases by the duty factor τ/T. That is not a converter suddenly becoming less capable. It is the result of changing the denominator and therefore the question. A detector designed for a known short pulse may integrate principally over τ, while a monitoring dashboard may average over T and dilute the event. These statistics can be reconciled only when the time interval and signal model are declared. A single ENOB figure cannot replace either.

Copyright 2026, James M. Atkinson

One must be careful with compression. A lossy time-frequency representation may be adequate for locating a broad interference source but inadequate for determining precise burst onset or excluding a short, weak emission. If the raw waveform was not retained, a later analyst cannot reconstruct all the alternatives that would have fitted it. The missing information is not restored by stating that the original converter had a favourable ENOB. Even nominally lossless storage requires calibration and configuration records if the numerical codes are to be interpreted physically. An archive is useful evidence only to the extent that its provenance, completeness and measurement meaning can be reconstructed.

I would therefore construct a layered validity argument. At the hardware layer, document the ENOB test under its stated stimulus and state. At the acquisition layer, document sampling continuity, front-end behaviour, timestamp meaning and trigger operation. At the analytical layer, specify the estimator and its detection threshold, including the relevant window and noise statistics. At the evidential layer, identify the claim: the event was retained, the event had an estimated property, the event was generated outside the receiver, or the event originated from a specified source. Every upward inference needs premises beyond the lower layer, and failure at one level may limit only particular conclusions. It is not necessary to discard the entire record merely because one component lacks full calibration, but it is necessary to restrict claims accordingly.

I should add a qualification concerning weak signals beneath ordinary quantisation steps. With suitable analogue noise or deliberately applied dither, some information about a small repeated signal can be recoverable statistically over multiple samples; this does not prove that every isolated

Copyright 2026, James M. Atkinson

sub-code transient is recoverable. The inference depends on the distribution of noise, sample independence and the known waveform. Dither may prevent systematic quantisation error under prescribed conditions but cannot rescue an event which never entered the retained samples. In a hostile electromagnetic environment, correlated interference may invalidate the simple model, and an alarm caused by nonlinear mixing may be distinguishable only through controlled perturbations. Information theory disciplines the question; it does not confer omniscience upon a receiver.

For the practical report I would keep the conditional converter benchmark, but would place beside it a statement about which information survived acquisition. A truthful result might read that the converter satisfied an eleven-bit effective benchmark for a stated sine-wave condition, the recorded event spans a specified number of valid samples, and a separately validated detector recognises a defined burst population under the tested environment. It should not say that eleven effective bits guarantee capture of all eleven-bit-equivalent signals. Professor Wiener, may I invite you to examine the further complication that a receiver may change the very observation policy in response to its earlier data?

Norbert Wiener | Peer question 6 to Claude Elwood Shannon

Dr Shannon, the layered account has much to commend it, but an adaptive receiver can couple what it observes to what it will observe next. Automatic gain control may lower sensitivity after a strong event; a detector may widen its search window after an apparent anomaly; a recording process may allocate more memory to channels generating alarms while discarding quiet channels. Such changes are neither necessarily faults nor necessarily improvements. They mean, however,

Copyright 2026, James M. Atkinson

that the sampling and retention policy is conditioned upon a preceding history. If the same ENOB is measured in a fixed laboratory state, how may its relevance be established for the time-varying states of this coupled system? In particular, does an unchanged converter mean that its numerical performance remains relevant even when the adaptive controller has selected a biased population of retained bursts? And what kind of experiment could distinguish a failure of analogue sensitivity from a failure caused by the controller's own decisions without requiring the entire installation to be dismantled?

Claude Elwood Shannon | Immediate answer to Norbert Wiener

Professor Wiener, an unchanged converter can retain the same narrowly defined intrinsic behaviour while the system's overall information transfer changes substantially. The conditional structure should be enlarged to include a state variable s(t) representing gain, tuning, thresholds, memory allocation or other controls relevant to the actual observation. The measurement channel is no longer described by one fixed transformation from input waveform to recorded result. Its output depends upon the preceding inputs and controller decisions through s(t). A sine-wave ENOB benchmark obtained at a particular fixed state remains information about that state; it cannot be treated as an unconditional description of all states reached during field operation.

A practical experiment could inject identical calibrated test bursts into a known input boundary while deliberately varying the preceding history. One sequence might contain a strong legitimate signal immediately before the weak challenge; another might contain quiet

Copyright 2026, James M. Atkinson

time. A third could trigger a gain change at an independently logged instant, and a fourth could force a memory-allocation transition. Compare the probability of retaining the known burst, its measured amplitude, its timestamp error and the state recorded at its arrival. The differences separate, at least partially, the converter's intrinsic errors from the adaptive system's behaviour. The experiment need not dismantle an installation, but it must have a traceable challenge path and a reference whose limitations are recorded.

The retained record should include not only the selected events but the information that explains why they were selected. A control log, sample-count sequence, buffer-loss indicators, applied thresholds and versioned configuration are valuable because they enable a different analyst to reconstruct the selection policy. If only the detected events are saved, the historical state of quiet periods may be irrecoverable. That means a claim about how often the environment emitted cannot automatically be inferred from how often the detector alarmed. The missing observations are not numerically small errors to be absorbed into a standard deviation; they represent a limitation on the population that the archive describes.

One should also test the controller at boundary conditions, not merely at a nominal steady state. A threshold chosen adaptively from a noise estimate may lag after a sudden interference step; a gain control may overshoot; a channel allocator may favour repeated false alarms. These mechanisms can create temporal blind spots or false apparent periodicity. ENOB measured with a continuous sinusoid remains one diagnostic of a converter, but system qualification must

Copyright 2026, James M. Atkinson

include the adaptive trajectory. The analyst should report which parts of that trajectory were exercised and where the controls were not observed. I now pass the floor to Professor Neyman, who can give precise meaning to the statistical claims that follow from a finite collection of successful challenge trials.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal response 5: Detection performance, finite trials and the bounds of inference

Dr. Atkinson, a measurement of effective bits and an empirical claim of reliable intermittent detection belong to different statistical experiments. The first commonly results from a constructed sinusoidal excitation and an estimator of residual noise and distortion. The second requires a specified population of intermittent events, an exposure policy, a decision rule and a sampling design by which observed successes and failures represent that population. A high ENOB does not supply the denominator of a detection-rate calculation. Nor does a small collection of successfully captured pulses establish a universal detection probability. In statistics the meaning of a procedure is inseparable from the repetitions and conditions it purports to cover. [S1, S6]

For a defensible detection study, I should specify the trial as precisely as the measurand. Is each independently injected burst a trial, or each scan cycle, or each retained data block? If a burst arrives during a known blind interval, is it a miss or a trial excluded by design? The answer depends on whether the claim concerns unconditional surveillance or conditional detection once the receiver is exposed. Both can be studied, but they should not share a denominator without explanation. In a technical surveillance countermeasures report, I should prefer unconditional capability for claims about continuous search and conditional capability only when its limitation is prominent. The state and environment used for the challenges must resemble the circumstances in which the conclusion is intended to apply.

Suppose two hundred known bursts are injected at independently randomised arrival phases within a declared amplitude and frequency

Copyright 2026, James M. Atkinson

range. The receiver recognises one hundred and ninety according to a decision rule fixed beforehand. The observed proportion is 0.95, but the experiment does not demonstrate that the true recognition probability is exactly 0.95. Under an independent Bernoulli model, a conventional approximate 95 per cent Wilson interval spans roughly 0.910 to 0.973. This uncertainty must not be concealed behind the precision of a converter's reported ENOB. Moreover, the interval pertains to the stipulated trial population and detection rule. If several trials were correlated or the range of bursts was selected after viewing the successes, that statistical model requires re-examination.

A second issue is false alarms. The instrument may search thousands of spectral bins and many time slices, all while displaying a low per-test false-alarm probability. If ten thousand independent tests each have probability 0.001 of a false positive under a null condition, the expected number of false flags is ten. The probability of at least one is almost unity. These figures do not prove that all observed alarms are false, but they show why a threshold suitable for a single preselected channel may perform badly across a broad survey. Correlation among bins, overlapping windows and persistent interferers changes the effective multiplicity. The practitioner must estimate the relevant false-alarm process under representative conditions, not declare independence by convenience.

The ENOB figure can legitimately contribute to designing a trial. It may help estimate an instrumental noise contribution, choose amplitude ranges for challenges, and identify configurations in which converter distortion is likely to matter. But the final inference must arise from the trials relevant to the signal class. If a candidate emission lasts two microseconds, challenge

Copyright 2026, James M. Atkinson

the receiver with two-microsecond events, including the unfavourable phases and frequencies. If the purpose is to find extremely weak transmitters among strong legitimate emissions, include the strong emissions in the validation design. If temperature or gain state changes, stratify or otherwise model those states. An average recognition rate across easy and difficult conditions may hide unacceptable performance in the condition that matters most.

One can make the validation more informative by choosing an operating-characteristic curve rather than a single threshold. Measure how detection probability varies as the threshold changes, while tracking the accompanying false-alarm rate. Preserve the detector code, input references, randomisation seed and complete trial log. Distinguish development trials used to choose the rule from confirmation trials used to evaluate it. An instrument cannot be validated by repeatedly adjusting its threshold until it recognises all the test signals, then counting those same signals as independent confirmation. Such a procedure measures the success of a selected fit to a selected sample, not the declared out-of-sample capability.

Negative evidence requires special care. A failure to detect an unknown source may mean that no qualifying source was present; it may also mean that a source was too weak, too brief, outside the passband, masked by interference, clipped by overload, missed by the scan policy, or omitted by a retention rule. Under a validated model these alternatives may be bounded, but the mere presence of a high ENOB figure does not assign their probabilities. It would be improper to infer source absence from no alarm without a detection model that applies to the proposed source class.

Copyright 2026, James M. Atkinson

Equally, it would be improper to declare every negative finding meaningless; it can support a restricted assurance claim when exposure, sensitivity, configuration and relevant uncertainties have been satisfactorily established.

My concluding proposal is to report three classes of result in separate sentences. First, the converter's conditional sine-wave dynamic performance, citing the stimulus and measurement method. Second, the installed receiver's measured intermittent-event performance, including trial population, detection rule, false-alarm criterion, recognition fraction and uncertainty. Third, the interpretation of any field observation, distinguishing verified detection from localisation and attribution. These can form a persuasive cumulative chain when their assumptions agree, but no one result should masquerade as the other two. Sir Ronald Fisher, may I invite the final peer challenge about whether even a carefully calculated interval can conceal experimental choices made after the data were seen?

Sir Ronald Aylmer Fisher | Peer question 7 to Jerzy Neyman

Professor Neyman, your confidence interval for a fixed population of known pulses is admirably clear, but I should like to press the meaning of its design. The investigator may have developed the detector threshold using earlier trials, varied the event amplitudes while observing performance, and retained only configurations that achieved a pleasing recognition fraction. The final two hundred trials may appear random, but they could have been conducted only after a succession of unreported failures or modifications. There is also the difficulty of heterogeneous signal classes: perhaps one class of strong bursts is nearly always recognised while a small class of weak bursts is missed, yet

Copyright 2026, James M. Atkinson

the pooled success fraction looks excellent because the easy class dominates. How would you require the examiner to specify the prospective design, the scope of permissible adaptation and the reporting of rejected settings? Would you favour separate confidence statements for material strata, and how should those statements be reconciled when simultaneous claims are made about several conditions rather than one aggregate population?

Jerzy Neyman | Immediate answer to Sir Ronald Aylmer Fisher

Thank you for that question. Sir Ronald, the answer begins with the rule that a confidence procedure is calibrated for a specified experiment, not for an undefined history of human choices. The examiner should retain the full development history and identify a confirmatory set that was not used to tune the detector, thresholds, amplitude ranges or exclusion criteria. If the final evaluation is repeatedly reopened after each unfavourable result, the nominal coverage of an ordinary fixed-sample interval can be compromised. An adaptive experiment can be rigorous, but its sequential or selection-adjusted analysis must be designed as such. We should not relabel an exploratory success as confirmatory evidence merely because it was eventually expressed through the correct formula.

Heterogeneity can be addressed by deliberate design. If a weak-burst stratum is materially important, allocate enough known challenges to it for a useful estimate; do not allow an abundance of easy trials to drown its failures. Report stratum-specific recognition fractions and intervals. A pooled rate may still be informative for a declared mixture of events, but the mixture weights must be justified

Copyright 2026, James M. Atkinson

by the intended operational population. Where those weights are unknown, several scenario-weighted rates may be more honest than one false universal probability. The same principle applies to temperature, gain state, interference condition and pulse duration. A family of conditional results permits a later examiner to identify the regime matching the field observation.

Simultaneous claims require control of multiplicity or a joint confidence procedure appropriate to the design. If the report states that performance exceeds a threshold in five distinct regimes, separate nominal 95 per cent intervals do not automatically grant a 95 per cent simultaneous guarantee over all five. Simple conservative methods may allocate smaller individual error probabilities, though dependence among results and more efficient procedures can justify different choices. The method should be identified and checked rather than chosen for rhetorical force. The analyst should distinguish one prespecified primary conclusion from exploratory subsidiary observations, and preserve negative as well as positive results.

Ultimately the number of successful detections is evidence, not an incantation. It is meaningful because the input challenges are known, the rule was fixed, the trials were recorded and the proposed inference has a stated population. The ENOB figure may help explain the mechanism behind some of the successes and failures, but it does not replace the experimental population. A well-written forensic conclusion should allow another examiner to ask not merely 'What number did you obtain?' but 'What observations would have refuted the performance claim?' If the answer is that every failure was

Copyright 2026, James M. Atkinson

excluded or the rule changed until no failure survived, the claim has lost its intended testing power. Dr. Atkinson, I return the token for the numerical applications and your final synthesis.

Ten worked engineering applications | Moderator-led numerical analysis

Percy Williams Bridgman, Cross-Peer Question to Harry Nyquist: Dr Nyquist, an instrument advertises 11.0 effective bits under a coherent full-scale sine test, yet the surveillance question concerns a six-microsecond burst. Which operational quantity must replace the glossy ENOB headline before the claim can be made reproducible?

Harry Nyquist, Cross-Peer Answer to Percy Williams Bridgman: Professor Bridgman, the familiar conversion ENOB = (SINAD − 1.76)/6.02 expresses an equivalent ideal converter under specified sinusoidal measurement conditions. It does not specify burst interception probability. For the burst we need the input-reference level, analogue bandwidth, acquisition duty factor, sample-rate and clock uncertainty, trigger latency, detector integration window, false-alarm criterion and rate of repeat opportunities. An acceptance test should inject independently timed pulses over amplitude, duration and arrival phase, with the original sample stream retained. Report probability of detection and uncertainty conditional on that matrix, not a hypothetical conversion of one sine-wave ENOB into a single-pulse threshold. If changing the burst arrival phase changes detection materially, the ENOB number alone was never the sufficient measurand. I pass the token respectfully to Dr Nyquist for the time-domain test.

Copyright 2026, James M. Atkinson

Harry Nyquist, Cross-Peer Question to John Wilder Tukey: Professor Tukey, if a display uses a million-point transform while the transmitter is active for only twenty microseconds, can the analyst claim that the nominal FFT grid spacing is the physical resolution of the burst?

John Wilder Tukey, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, no. A one-million-sample record can have a fine frequency grid, but the observed finite burst supplies much less independent time support. The relevant time-bandwidth product and the window actually containing signal energy determine what the transient can resolve. Zero-padding changes sample locations on a spectral display, not the physical length of the event. We should compare multiple time windows, specify coherent gain and equivalent noise bandwidth, and include burst misalignment as a source of uncertainty. A false improvement is particularly easy when investigators select the window with the most impressive peak after inspecting the data; that search must enter the detection threshold. Preserve a time-stamped raw segment surrounding the event so another analyst can repeat the window selection and challenge the inferred frequency. I yield respectfully to Dr Neyman on detection claims.

John Wilder Tukey, Cross-Peer Question to Jerzy Neyman: Dr Neyman, one hundred validation bursts produce ninety-eight detections. Is it legitimate to describe this as a demonstrated 98 percent probability of interception under all field conditions?

Jerzy Neyman, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, the observed fraction 98/100 is a sample statistic for the validation conditions only. An uncertainty interval for the underlying probability is necessary, and its coverage interpretation depends upon the method and any dependence

Copyright 2026, James M. Atkinson

among trials. If all hundred bursts use the same trigger phase, waveform, level and environment, the number of repetitions does not cover the omitted conditions. Separate calibration from blind test cases, randomise arrival phase, include weak and wideband waveforms, and record false alarms in exposure-time units. Treat receiver configuration changes as new test conditions rather than silently pooling incompatible trials. A missed burst must remain in the denominator even if the analyst cannot reconstruct its source. The proper report would state the point estimate and interval, the stimulus distribution and the qualification that the survey is not a census of all possible transmissions. I return the token to Dr Shannon.

Jerzy Neyman, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, can oversampling or digital post-processing turn a nominally 12-bit capture into a 20-bit historical record of a fleeting high-frequency emission when the analogue front end was saturated?

Claude Elwood Shannon, Cross-Peer Answer to Jerzy Neyman: Dr Neyman, not as an unconditional statement. Averaging suitably independent quantisation error within a restricted band can improve an estimator and sometimes an effective in-band SNR. Neither operation manufactures a larger instantaneous analogue voltage range or restores information mapped many-to-one by saturation. A pulse that has been clipped, excluded by preselection, or missed while the receiver tuned elsewhere may leave no unique invertible record. State precisely which parameter was estimated and how variance, bias and correlation were measured; refrain from equating that estimator precision with new physical converter bits. Reproduce the claimed benefit against an external waveform reference and retain the unprocessed digital codes alongside every derivative. The result

Copyright 2026, James M. Atkinson

may be useful without exaggerating its scope. With respect, I return the token to Dr Atkinson for the moderator synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Colleagues, the discussion has shown that effective number of bits is useful when its definition and the intended inference occupy the same experimental ground. It may describe the noise-and-distortion performance of an analogue-to-digital conversion chain under a declared sinusoidal stimulus; it may help establish a converter error budget, compare alternative hardware settings, and predict the contribution of a specified impairment to a model of intermittent detection. It is not an autonomous certificate of pulse capture, timing fidelity, source identification or continuous exposure. The sine-wave comparison and the transient observation are not hostile alternatives. They are complementary operations whose connection must be demonstrated, not presumed. [S1, S2, S4]

Professor Bridgman has made the central metrological distinction. To measure one quantity accurately is not to have measured all quantities to which a common label might be attached. A converter test, installed-receiver test, burst-recognition trial and source-attribution exercise each possess their own reference planes, assumptions and error mechanisms. Mr Weston has reminded us that a calibrated input voltage cannot be carried across an uncharacterised amplifier or changing gain state by arithmetic alone. Dr Gabor has sharpened the observation that finite duration and spectral definition impose a consequential choice of estimator. We cannot gain the advantages of a long coherent tone after the event has ended simply by drawing a more finely gridded spectrum.

Copyright 2026, James M. Atkinson

Dr Nyquist's analysis has placed time squarely beside amplitude. A numerical sampling rate does not prove that samples were retained at every relevant instant, and a sine-wave jitter ceiling does not replace analysis of a fast pulse edge. Sir Robert Watson-Watt's operational question was therefore well chosen. An apparatus may be technically accurate whenever exposed while being poorly situated to observe a rare, asynchronously timed burst. The difference between conditional sensitivity and temporal coverage must appear in both the validation programme and the negative-findings language. The field examiner who reports a silent receiver should explain whether the silence means absence of an alarm, absence of a retained waveform, or a measured failure to observe known challenges within stated limits.

Professor Tukey and his interlocutors have demonstrated that analytical choices can materially affect the visible result. The taper, transform length, bin aggregation, background estimator and selected interval are part of the procedure. A narrow spectral bin can lower a displayed noise floor without creating more original observations; a short time-localised estimator may preserve the onset while distributing energy more widely in frequency. A robust background estimate can be valuable without justifying the deletion of exceptional events. The archive must therefore retain both the original evidence and enough procedural information to reconstruct the selected result. A post-selected improvement in appearance is not automatically a validated improvement in detection.

Dr Shannon has enlarged our accounting from quantisation to information retention. Converter codes, gain histories, raw sample continuity, detector states and stored event selections form a chain in which

Copyright 2026, James M. Atkinson

losses can occur outside the converter. Once an unrecorded interval or discarded waveform is acknowledged, a favourable ENOB figure cannot restore it. Professor Wiener has added the significant complication of adaptation: the system may learn from an observation and alter what it next permits itself to record. This is sometimes the proper operation of a capable receiver, but it makes retention policy and state history part of the evidence. The validation procedure must therefore challenge state transitions instead of assuming the apparatus remained perpetually in its quiet laboratory condition.

Professor Neyman's examination has set the statistical limit. A recognition fraction from a finite population of known bursts must be accompanied by a definition of its trial, conditions, exclusions and uncertainty. The lower confidence bound matters particularly where missed events carry serious consequences. Multiple threshold tests require an account of false-alarm multiplicity, and the experiments used to design the detector must be distinguished from those offered to validate it. Sir Ronald Fisher has further required that unsuccessful configurations and prior choices not disappear merely because a later selected arrangement performs well. The proper scientific conclusion survives the disclosure of the full experimental history. It is strengthened, not weakened, by its stated boundaries.

We can now formulate an acceptance rule suitable for the volume. Quote ENOB only with its stimulus frequency, amplitude, sample rate, analogue state, measurement bandwidth and method. If the proposed application concerns an intermittent signal, identify the pulse family, exposure policy, reference plane, arrival-time distribution, acceptance threshold and false-

Copyright 2026, James M. Atkinson

alarm model. Validate the event detector directly, including near-threshold signals, interfering carriers and state transitions. Preserve raw or earliest available samples, configuration history, retained negative trials, missed-event evidence and uncertainty records. Describe detection, physical source attribution and assurance against undetected emissions as separate propositions. The worked calculations in this dialogue make these distinctions visible; none certifies any instrument whose actual test records were not examined.

Our next question will separate quantisation effects from thermal, analogue and sample-clock noise. This is not a mere taxonomic exercise. The mechanisms differ in their dependence upon amplitude, bandwidth, frequency, temperature and time, and therefore demand different experimental challenges. I thank each contributor for the respectful interrogation of the argument and for returning the token with the conclusion more sharply bounded than when it was first offered. The next discussion should proceed from these bounded findings rather than revive a simple claim that more nominal bits guarantee a more complete account of the electromagnetic world.

Ten worked engineering applications | Question 028

Application 01. Translate a declared sine-wave SINAD into conventional ENOB

Let R denote measured signal-to-noise-and-distortion ratio in decibels, and let N_eff be the effective number of ideal quantiser bits under the conventional full-scale sine-wave comparison. Assume R = 68.0 dB at a specified sinusoidal input amplitude, input frequency, sample rate, analogue gain state and analysis bandwidth. Then N_eff = (R - 1.76 dB)/(6.02 dB/bit) = (68.0 - 1.76)/6.02 = 11.003 bits, conventionally about 11.00 effective bits. Both numerical constants belong to the familiar ideal full-scale sine-wave comparison; the measured ratio includes distortion as well as noise. The result does not claim that all eleven-bit changes in a single short burst are independently resolvable. It says that the selected sine-wave test produced a residual level comparable with that of the stipulated ideal quantiser. An actual report would retain the stimulus generator's limitations, measurement window, excluded bins, clock condition and uncertainty of R. Without those, the visible digits of 11.003 have more mathematical resolution than the test necessarily warrants. [S2]

Application 02. Show how amplitude back-off can change a conditional ENOB estimate

Assume a reference sine wave has R_1 = 68.0 dB and is reduced in amplitude by 6.0 dB while the absolute RMS residual remains unchanged, with no altered distortion or gain-state behaviour. Under that explicit hypothetical condition, R_2 = 68.0 - 6.0 = 62.0 dB. Therefore N_eff,1 = (68.0 - 1.76)/6.02 = 11.003 bits, whereas N_eff,2 = (62.0 -

Copyright 2026, James M. Atkinson

1.76)/6.02 = 10.007 bits. The apparent difference is approximately 0.997 bit, not a physical removal of one silicon bit. The calculation illustrates the conditional dependence upon signal amplitude and noise model. If distortion itself changes with amplitude or the input amplifier changes gain, the assumption of unchanged residual is false and the arithmetic no longer predicts the outcome. For a short intermittent emission occupying only a small portion of full scale, this caveat is especially important. A measured amplitude-response curve is preferable to extrapolation from a favourable near-full-scale benchmark.

Application 03. Calculate a voltage-ratio SINAD and its ideal-bit equivalent

Assume a sinusoidal test signal has RMS amplitude $V_s = 0.500$ V and that the appropriately measured combined RMS noise-and-distortion residual is $V_e = 0.000400$ V over the declared evaluation bandwidth. The dimensionless amplitude ratio is $V_s/V_e = 1250$. Using $R = 20 \log10(V_s/V_e)$, $R = 20 \log10(1250) = 61.938$ dB. The corresponding conventional effective figure is $N_{eff} = (61.938 - 1.76)/6.02 = 9.996$ bits. The correct units are volts RMS for both amplitudes and decibels for their ratio; no logarithm of a dimensional voltage alone is taken. One cannot simply assume V_e is the same as a baseline noise reading with the signal absent, because distortion may depend upon the stimulated waveform. This is a sine-wave dynamic benchmark, not a measurement of minimum detectable burst amplitude. The numerical result is also sensitive to which harmonics and spurs enter the residual; the selection must be declared.

Copyright 2026, James M. Atkinson

Application 04. Establish a jitter-limited sine-wave ceiling at high input frequency

Let f be input sine-wave frequency in hertz and σ_t be RMS aperture-timing uncertainty in seconds. Assume $f = 80 \times 10^6$ Hz and $\sigma_t = 1.0 \times 10^{-12}$ s, independent of the sinusoidal input under the small-jitter approximation. The product $2\pi f\sigma_t$ is dimensionless: $2\pi \times 80 \times 10^6 \times 10^{-12} = 0.000502655$. The jitter-limited SNR is $R_j \approx -20 \log10(0.000502655) = 65.975$ dB. If jitter were the only limiting contribution, its ideal-sine equivalent would be $(65.975 - 1.76)/6.02 \approx 10.667$ bits. This value is an approximate performance ceiling under the model, not a universal ENOB for the converter. Added analogue noise, harmonics, clock correlation and front-end errors can reduce achieved SINAD. More importantly, a transient with sharp edges may have derivative-weighted timing errors not adequately represented by a single 80 MHz sine-wave characterisation.

Application 05. Distinguish finite burst duration from displayed FFT resolution

Let $f_s = 40 \times 10^6$ samples/s be the retained sampling rate, and let $\tau = 3 \times 10^{-6}$ s be the nominal burst duration. If the burst is captured completely with steady sampling, its interior contains approximately $N_b = f_s \tau = 120$ samples, subject to a possible one-sample endpoint convention. A discrete Fourier transform confined to that three-microsecond interval has nominal bin spacing $\Delta f = f_s/N_b = 333{,}333$ Hz, or equivalently $1/\tau$. Extending a plot with zero-padded bins can make interpolated spectral peaks look smoother, but it does not increase the 120 original observations. Longer observation including quiet samples

Copyright 2026, James M. Atkinson

may change the numerical transform spacing without extending the burst's coherent duration. Estimation accuracy can differ under a specified parametric model, so Δf should not be advertised as an unconditional physical impossibility bound. The forensic point is that apparent fine display resolution is not equivalent to additional independently observed carrier cycles.

Application 06. Account for duty-cycle dilution of average power

Assume a burst has constant in-burst power P_b and lasts $\tau = 3$ μs within a total measurement interval $T = 1.0$ ms; ignore rise and fall details and assume zero signal power outside the event. The duty factor is $d = \tau/T = (3 \times 10^{-6})/(1 \times 10^{-3}) = 0.003$. Averaging signal energy over the whole interval gives $P_{avg} = d\, P_b = 0.003\, P_b$. Relative to the in-burst level, $10 \log_{10}(P_{avg}/P_b) = 10 \log_{10}(0.003) = -25.229$ dB. This change reflects the definition of average power, not a reduction of converter bit depth. A display using the millisecond average can make a recognisable three-microsecond emission appear weak or absent, even if the converter recorded the in-burst samples correctly. Conversely, a peak estimator may exaggerate the prominence of an isolated noise excursion. The chosen statistic, event interval and baseline must therefore accompany any attempted linkage to ENOB or detection sensitivity.

Application 07. Calculate a bounded scanning-exposure probability

Suppose a scanning receiver observes a given channel for $T_{on} = 16$ μs during a repeating $T_{cycle} = 1000$ μs cycle. Under the expressly hypothetical condition that a very short burst's start time is uniformly distributed over the cycle and that the event is recognised whenever it

Copyright 2026, James M. Atkinson

falls inside a useful dwell, the exposure probability for one burst is $p = T_{on}/T_{cycle} = 0.016$, or 1.6%. If four bursts have statistically independent starting phases, the chance that at least one is exposed is $1 - (1-p)^4 = 1 - 0.984^4 = 0.06248$, or about 6.25%. The probability does not include recognition failures once exposed and is not valid for synchronised or correlated bursts. A wider pulse may overlap a dwell differently, so the short-burst assumption matters. No converter ENOB, however favourable, turns a 1.6% exposure opportunity into continuous coverage. In a real instrument the useful dwell might be shorter than the programmed dwell because of tuning and filter settling.

Application 08. Quantify a common window's equivalent noise bandwidth

Let Δf be the Fourier-bin spacing in hertz and let B_e denote a window's equivalent noise bandwidth. Under conventional large-record normalisation and white-noise assumptions, the Hann window has $B_e \approx 1.5\Delta f$, while a rectangular window has $B_e \approx \Delta f$. Hence the noise-power bandwidth ratio is 1.5 and the corresponding difference is $10 \log10(1.5) = 1.7609$ dB. This result applies to the stated estimator normalisation; it does not mean the Hann window is uniformly inferior. Lower sidelobes may materially improve detection of a burst near a powerful carrier, while the wider main lobe reduces frequency separation. Coherent gain must be accounted for separately when estimating a tone amplitude. The analyst must determine whether the event falls near the window edge and whether its energy response differs from the continuous-tone calibration. Consequently a change in FFT display floor cannot be interpreted as an intrinsic change in converter ENOB.

Copyright 2026, James M. Atkinson

Application 09. Separate single-test false alarm probability from survey multiplicity

Let m = 10,000 denote independent null tests of a predetermined threshold, with a per-test false-positive probability α = 0.001. The expected number of false flags is E[K] = mα = 10. Under independence, the probability of at least one false flag is P(K≥1) = 1 - (1-α)^m = 1 - (0.999)^10000 ≈ 0.9999548. The apparently stringent one-in-a-thousand threshold therefore almost guarantees at least one false flag across that family of tests. Overlapping FFT bins and successive time windows are often correlated, so actual probability requires the true dependence structure or empirical null data. The calculation does not show that a particular alarm is false, nor does it give a posterior probability of source identity. It shows why a broad monitoring display cannot claim reliable discrimination simply because the ADC's dynamic specification or the threshold of an individual test looks impressive.

Application 10. Quantify uncertainty in a finite burst-recognition study

Assume n = 200 independently randomised representative burst trials with k = 190 recognitions under an unaltered, prespecified detection rule. The observed recognition fraction is p_hat = k/n = 0.95. For a two-sided 95% Wilson score interval with z = 1.96, write D = 1 + z^2/n = 1.019208, C = (p_hat + z^2/(2n))/D ≈ 0.94152, and H = z sqrt[p_hat(1-p_hat)/n + z^2/(4n^2)]/D ≈ 0.03110. The interval [C-H, C+H] is approximately [0.9104, 0.9726]. It concerns this particular trial population, exposure definition and rule, not every possible emitter or interference environment. If trials are correlated, selectively retained, or redefined following failures, the stated

Copyright 2026, James M. Atkinson

coverage does not necessarily hold. Thus a nominal '95% detection' result is not a certainty claim, and it is distinct from an ENOB obtained with an unrelated continuous sinusoidal stimulus.

QUESTION 029

Copyright 2026, James M. Atkinson

How should quantisation noise be distinguished from thermal and clock-related noise?

Fictional educational reconstruction. All attributed exchanges in this discussion are newly authored teaching dialogue, not historical quotations, authentic transcripts, testimony or evidence that deceased scholars evaluated modern receiver systems.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 029 asks: How should quantisation noise be distinguished from thermal and clock-related noise? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is distinguishing quantisation, thermal, and clock-derived noise in sampled receiver records. Our primary observation is noise density, spectral spurs, and their dependence on signal amplitude, frequency, and converter operating mode; by contrast, what remains unseen is how much variance arises from input termination, analogue circuitry, finite digital code width, and sampling-time error. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Separate converter, source and clock error by experimental intervention. A commonly quoted ideal quantisation ratio for a full-scale sinusoid is

Copyright 2026, James M. Atkinson

approximately 6.02 N plus 1.76 dB for N effective ideal binary bits and the stipulated uniform-noise model. At N = 12 this is about 74.0 dB, but measured spurious-free dynamic range and effective number of bits can be much poorer because of thermal noise, nonlinearity, clock error and source distortion. Comparing a terminated input with a driven tone, altering input frequency and changing clock conditions exposes different error mechanisms. Jitter-related degradation increases with input frequency even if the sample rate remains unchanged; thermal noise need not follow that pattern. Do not assign all observed residual energy to quantisation merely because the code width is known. The report should include frequency-dependent noise spectra and coherent spurs separately from integrated random noise. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns noise density, spectral spurs, and their dependence on signal amplitude, frequency, and converter operating mode; it is not interchangeable with how much variance arises from input termination, analogue circuitry, finite digital code width, and sampling-time error. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is terminated-input, bit-depth, sample-rate, amplitude, and sine-frequency comparisons with raw-sample retention. A claim drawn from that comparison has to carry its actual uncertainties: quantisation step, nominal SNR, effective noise bandwidth, noise factor, rms jitter, and correlation. An ideal uniform quantiser under a suitably decorrelated error

Copyright 2026, James M. Atkinson

model has variance $\Delta^2/12$ for step size Δ. Thermal noise power is proportional to Boltzmann constant, absolute temperature, and equivalent noise bandwidth. Aperture-jitter error grows with input slew rate, unlike a simple white quantisation-noise approximation. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal contribution 1: An ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ.

A converter's quantisation-error model begins with a step size Δ and, under sufficiently decorrelated conditions, a variance $\Delta^2/12$. That assumption is not the same as a guarantee that every recorded error resembles stationary white noise. An undithered low-amplitude sine wave can yield periodic code patterns and narrow spectral spurs instead of a smooth quantisation pedestal. A thermal input may randomise the transition decisions, making the textbook model more useful, but it introduces genuine analogue noise that must not then be counted as quantisation alone. I would examine a shorted or terminated input, a calibrated coherent tone, and an intentionally dithered tone with identical gain settings. The change in spectral shape across those conditions is informative about the error mechanism. A single noise-floor number cannot identify which mechanism dominates. The archive should include code histograms and raw samples so an examiner can distinguish coherent quantisation artefacts from environmental radio signals.

In this physical path examination of Question 029, the decisive claim is that an ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ. A receiver noise spectrum can mix several mechanisms which respond differently to experimental conditions. Thermal noise changes with physical temperature and resistance; ideal quantisation noise depends on step size and assumptions about decorrelation; aperture jitter grows more damaging at high input-frequency slew rates. A constant displayed floor under one test does not prove these contributions have been

Copyright 2026, James M. Atkinson

separated. Nor does simple averaging necessarily increase effective resolution where noise is correlated, deterministic or dominated by converter nonlinearity. The panel should design multiple experiments that vary one hypothesised source without silently changing the others. A useful falsification proceeds from the actual controversy: separate converter, source and clock error by experimental intervention. A commonly quoted ideal quantisation ratio for a full-scale sinusoid is approximately 6.02 N plus 1.76 dB for N effective ideal binary bits and the stipulated uniform-noise model. At N = 12 this is about 74.0 dB, but measured spurious-free dynamic range and effective number of bits can be much poorer because of thermal noise, nonlinearity, clock error and source distortion. Comparing a terminated input with a driven tone, altering input frequency and changing clock conditions exposes different error mechanisms. Jitter-related degradation increases with input frequency even if the sample rate remains unchanged; thermal noise need not follow that pattern. Do not assign all observed residual energy to quantisation merely because the code width is known. The report should include frequency-dependent noise spectra and coherent spurs separately from integrated random noise. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Use a shielded termination at several controlled temperatures to characterise the input-referred noise floor, then introduce an accurately calibrated sine at increasing frequencies while holding its amplitude fixed. Vary converter step size, dither amplitude and sample-clock source separately. Compare histograms and PSDs before and after digital

averaging, documenting the analogue bandwidth and correlations among channels. A thermal-noise explanation predicts a different dependence upon temperature from the phase-error behaviour of a high-frequency sine. I would take delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: An ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ. A response consistent with jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. A laboratory compares low-level broadband receiver noise under a terminated input, a

Copyright 2026, James M. Atkinson

coherent sine stimulus and an externally connected antenna. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays, and measure their behaviour separately before reconnecting the assembled system. Bennett's communications engineering perspective distinguishes stochastic noise models from deterministic signal-dependent converter errors and distortion products. It is therefore material to establish delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency rather than infer them from a single scalar output. The limiting test is concrete: Vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. If the intervention produces jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret the noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution as a new transmitter before challenging the most economical instrumental explanation. The familiar quantisation variance of delta squared over twelve depends on a particular error model, not a universal property of every coherent tone. Professor Tukey, I invite you to interrogate how that model was selected.

John Wilder Tukey | Peer question 1 to William Ralph Bennett

William R. Bennett, may I test the exact physical inference in your account of a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna? The proposed mechanism appears plausible only if changes after vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples are compared with a stable reference condition. An ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency which would settle that narrower claim, rather than a visual impression of improvement.

William Ralph Bennett | Immediate answer to John Wilder Tukey

Dr Tukey, a lower floor after averaging could be consistent with reduced independent quantisation error, suppression of broadband thermal noise, or merely a narrower effective measurement bandwidth. I would report the output bandwidth and record correlations before crediting a converter with additional effective bits. Input-frequency sweeps and clock substitution provide separate tests of aperture error rather than relying on one composite SINAD

Copyright 2026, James M. Atkinson

measurement. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 029, the specific physical candidate is uniform quantisation error under restricted assumptions, kTB thermal contributions, and slew-dependent jitter noise. The unresolved physical pathway is material: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. The retained record permits a conditional claim about delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, but cannot alone resolve the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are delta-squared over twelve, kTB, integrated

Copyright 2026, James M. Atkinson

clock phase noise, effective bandwidth and SNR versus stimulus frequency; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. An ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples, and only a response matching jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, not a conjecture about the operator's intentions.
