I appreciate your explanation, William R. Bennett. How would your conclusion survive a deliberately independent test of the noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution? A second receiver might share more of the supposed evidence than its separate enclosure suggests. Thermal noise power is proportional to Boltzmann constant, absolute temperature, and equivalent noise bandwidth. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent. Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency and document which differences remain unexplained? Would you also state what observed change in delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency would invalidate the preferred account, and which aspect of vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples would make that negative result independently repeatable?

William Ralph Bennett | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the

Copyright 2026, James M. Atkinson

level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 029, the specific physical candidate is uniform quantisation error under restricted assumptions, kTB thermal contributions, and slew-dependent jitter noise. The unresolved physical pathway is material: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. The retained record permits a conditional claim about delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, but cannot alone resolve the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. Thermal noise power is proportional to Boltzmann constant, absolute temperature, and equivalent noise bandwidth. An independent test must alter a physical dependency, not merely open another software

Copyright 2026, James M. Atkinson

window. The relevant controlled alternative remains uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays; I would challenge it with vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. Two responses consistent with jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. A discordant measurement would then be interpreted by tracing that difference through delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 2: Thermal noise power is proportional to Boltzmann constant, absolute temperature, and equivalent noise bandwidth.

Noise caused by a sampling clock differs from quantisation noise because the error depends on the slope of the analogue waveform. For small sampling-time deviations δt, the corresponding sample-voltage error is approximately (dx/dt)δt. A faster RF sinusoid has a steeper slope at equal amplitude, so jitter-related degradation rises with frequency even when the converter step size remains unchanged. I would conduct amplitude-controlled frequency sweeps and inspect how the observed noise power changes, taking care to exclude the front-end filter roll-off and changing signal-to-noise reference. A clock with periodic phase modulation may create discrete sidebands, whereas a random jitter model may predict a broader pedestal. The two spectral signatures should not be combined into one anonymous noise number. If the receiver employs bandpass sampling, the relevant frequency is the actual analogue carrier, not the low-frequency alias shown on the digital display. That distinction can be decisive in a high-frequency survey.

In this control and stability examination of Question 029, the decisive claim is that thermal noise power is proportional to Boltzmann constant, absolute temperature, and equivalent noise bandwidth. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: separate converter, source and clock error by experimental intervention. A commonly

Copyright 2026, James M. Atkinson

quoted ideal quantisation ratio for a full-scale sinusoid is approximately 6.02 N plus 1.76 dB for N effective ideal binary bits and the stipulated uniform-noise model. At N = 12 this is about 74.0 dB, but measured spurious-free dynamic range and effective number of bits can be much poorer because of thermal noise, nonlinearity, clock error and source distortion. Comparing a terminated input with a driven tone, altering input frequency and changing clock conditions exposes different error mechanisms. Jitter-related degradation increases with input frequency even if the sample rate remains unchanged; thermal noise need not follow that pattern. Do not assign all observed residual energy to quantisation merely because the code width is known. The report should include frequency-dependent noise spectra and coherent spurs separately from integrated random noise. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by the noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note thermal noise power is proportional to boltzmann

Copyright 2026, James M. Atkinson

constant, absolute temperature, and equivalent noise bandwidth. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, the noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Nyquist’s work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. The order would be time-stamped and should include invalid intervals, receiver recovery, and any gain or filter settling rather than treating silence during transition as evidence of a silent source. Our central rival is specific: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. This predicts a response which should be tested against jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows

Copyright 2026, James M. Atkinson

measurement bandwidth; quantisation effects depend on code step and correlation. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that presentational step does not restore measurements discarded during retuning. Where the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone, the correct claim must name the operational states and the evidence available in each. Thermal noise must be assessed against physical temperature and effective bandwidth before being added to digital noise budgets. Dr Pearson, please take the floor and examine the assumptions behind that calculation.

Egon Sharpe Pearson | Peer question 3 to Harry Nyquist

Harry Nyquist, your calibration argument invites a question about reference planes, especially because the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. The reference stimulus and the unknown emission need not occupy the same physical regime. Aperture-jitter error grows with input slew rate, unlike a simple white quantisation-noise approximation. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When the noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while

Copyright 2026, James M. Atkinson

preserving unaveraged samples without relying upon the original screenshot or undocumented threshold settings? The question concerns the traceability of the inference, not the operator's good faith.

Harry Nyquist | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 029, the specific physical candidate is uniform quantisation error under restricted assumptions, kTB thermal contributions, and slew-dependent jitter noise. The unresolved physical pathway is material: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. The retained record permits a conditional claim about delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, but cannot alone resolve the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency. Aperture-jitter error grows with input slew rate, unlike a simple white quantisation-noise approximation. I would not carry a correction obtained at one frequency or amplitude

Copyright 2026, James M. Atkinson

into another regime without a documented sensitivity test. An appropriate reference check would be vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples, with before-and-after values of delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency. If the instrument behaves as predicted, then jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. The noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Harry Nyquist

There is an inferential difficulty, Harry Nyquist: uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs

Copyright 2026, James M. Atkinson

can occupy overlapping displays. The population of admissible observations needs to be fixed before any confidence argument. In this situation, the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. A stable coherent input may produce deterministic quantisation spurs rather than a statistically white floor. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency would invalidate the preferred account, and which aspect of vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples would make that negative result independently repeatable?

Harry Nyquist | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For

Copyright 2026, James M. Atkinson

Question 029, the specific physical candidate is uniform quantisation error under restricted assumptions, kTB thermal contributions, and slew-dependent jitter noise. The unresolved physical pathway is material: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. The retained record permits a conditional claim about delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, but cannot alone resolve the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because the noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution. I would distinguish trials selected in advance from those added after an unexpected peak appeared. A stable coherent input may produce deterministic quantisation spurs rather than a statistically white floor. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples, but it must be labelled a validation phase rather than merged into an apparently random original sample. The rival mechanism is uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion

Copyright 2026, James M. Atkinson

spurs can occupy overlapping displays; its prediction should be recorded alongside jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. The white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a 1 mv quantiser step gives roughly 0.289 mv rms under a uniform independent error approximation, not a guarantee of white spectral noise. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 3: Aperture-jitter error grows with input slew rate, unlike a simple white quantisation-noise approximation.

The information content of a converter record depends on correlations among its errors, not only the average number of bits. A quantisation disturbance that is deterministic for a repeated waveform can be predicted or avoided in a controlled experiment, while random thermal noise may limit any retrospective estimate of a single event. I would measure the covariance and spectral structure of the errors under multiple source conditions rather than infer their nature from a flat-looking display. Dithering can decorrelate some quantisation errors and improve statistical estimation, but deliberately adding noise cannot increase the intrinsic number of ADC transition thresholds. If samples are combined or averaged, the claimed improvement requires a noise model: independent components diminish differently from common clock noise or coherent distortion. Retaining individual channel samples enables later tests of those distinctions. Summing converter outputs into a longer digital word does not manufacture independent analogue information when their errors are shared.

In this operational measurand examination of Question 029, the decisive claim is that aperture-jitter error grows with input slew rate, unlike a simple white quantisation-noise approximation. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: separate converter, source and clock error by experimental intervention. A commonly quoted ideal quantisation ratio for a

Copyright 2026, James M. Atkinson

full-scale sinusoid is approximately 6.02 N plus 1.76 dB for N effective ideal binary bits and the stipulated uniform-noise model. At N = 12 this is about 74.0 dB, but measured spurious-free dynamic range and effective number of bits can be much poorer because of thermal noise, nonlinearity, clock error and source distortion. Comparing a terminated input with a driven tone, altering input frequency and changing clock conditions exposes different error mechanisms. Jitter-related degradation increases with input frequency even if the sample rate remains unchanged; thermal noise need not follow that pattern. Do not assign all observed residual energy to quantisation merely because the code width is known. The report should include frequency-dependent noise spectra and coherent spurs separately from integrated random noise. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Quantisation noise, thermal noise and clock-related error are not interchangeable merely because each may contribute to the displayed spectral floor. Under the customary uniform-error approximation, quantisation noise depends on converter step size and signal conditions; thermal noise depends on temperature, resistance and effective noise bandwidth; aperture-time error couples to input slope and therefore changes with signal frequency. One discriminating experiment records a low-distortion test tone at several amplitudes and frequencies while changing the analogue source termination in a controlled way. A floor that varies with front-end temperature or analogue bandwidth suggests a different mechanism from one that follows converter code size or high-frequency slew rate. Periodic clock contamination may form discrete spurs

Copyright 2026, James M. Atkinson

rather than a smooth floor. The proper report specifies whether its estimate concerns total measured noise, a modelled component or a bound derived from independent calibration. Fitting one white-noise parameter to all three mechanisms conceals the actual uncertainties. Accordingly, the laboratory record for Question 029 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. The white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. Shannon's information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity

Copyright 2026, James M. Atkinson

where appropriate. A decision should specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The illustrative case is instructive: A 1 mV quantiser step gives roughly 0.289 mV rms under a uniform independent error approximation, not a guarantee of white spectral noise. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. Jitter error grows with the rate of change of the sampled waveform, unlike an ideal uniform quantisation contribution. Dr Turing, I pass the floor for a comparison of what two differently clocked recordings can establish.

Alan Mathison Turing | Peer question 5 to Claude Elwood Shannon

Claude Elwood Shannon, I should like to examine what the recorded data actually preserve when a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. The physical input and the retained numerical array are not interchangeable things. Multiple operating conditions are needed to separate causal noise contributions that overlap spectrally. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state

Copyright 2026, James M. Atkinson

what observed change in delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency would invalidate the preferred account, and which aspect of vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples would make that negative result independently repeatable?

Claude Elwood Shannon | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 029, the specific physical candidate is uniform quantisation error under restricted assumptions, kTB thermal contributions, and slew-dependent jitter noise. The unresolved physical pathway is material: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. The retained record permits a conditional claim about delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, but cannot alone resolve the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. That limitation belongs in the stated finding

Copyright 2026, James M. Atkinson

because the alternative remains an empirical possibility in this experiment.

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. The white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. I propose separating acquired information from model-dependent reconstruction. Multiple operating conditions are needed to separate causal noise contributions that overlap spectrally. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency and a fresh trial in which the operator vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. If that trial demonstrates jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control

Copyright 2026, James M. Atkinson

intervals, plus executed settings and invalidity masks. The concrete challenge should include vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal contribution 4: A stable coherent input may produce deterministic quantisation spurs rather than a statistically white floor.

A stable noise estimate is not necessarily a correctly attributed one. I would monitor the terminated-input PSD, temperature, clock mode and gain state over repeated sessions, and look for changes that isolate the physical source of a disturbance. Quantisation errors should correlate with the code sequence and applied waveform; thermal disturbances should respond to analogue bandwidth and temperature under the relevant model; sampling-clock errors should reveal frequency or phase relationships with the stimulus. These are diagnostic hypotheses that can be tested against the apparatus. A control chart may flag a change without telling us which mechanism caused it, so each change should lead to a calibrated intervention rather than an immediate conclusion. If firmware changes the decimation filter or dither setting, compare raw-data and processed-data spectra separately. The noise's appearance on one waterfall is not enough to decide whether it is environmental, analogue, clock-related or numerical.

In this information retention examination of Question 029, the decisive claim is that a stable coherent input may produce deterministic quantisation spurs rather than a statistically white floor. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: separate converter, source and clock error by experimental intervention. A commonly quoted ideal quantisation ratio for a full-scale sinusoid is approximately 6.02 N plus 1.76 dB for N effective ideal binary bits and the stipulated uniform-noise model. At N = 12 this is about

Copyright 2026, James M. Atkinson

74.0 dB, but measured spurious-free dynamic range and effective number of bits can be much poorer because of thermal noise, nonlinearity, clock error and source distortion. Comparing a terminated input with a driven tone, altering input frequency and changing clock conditions exposes different error mechanisms. Jitter-related degradation increases with input frequency even if the sample rate remains unchanged; thermal noise need not follow that pattern. Do not assign all observed residual energy to quantisation merely because the code width is known. The report should include frequency-dependent noise spectra and coherent spurs separately from integrated random noise. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. The scientific point of a stable coherent input may produce deterministic quantisation spurs rather than a statistically white floor. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent sessions repeatedly show jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise

Copyright 2026, James M. Atkinson

follows measurement bandwidth; quantisation effects depend on code step and correlation, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. The noise floor changes with signal frequency and digital averaging despite unchanged nominal converter resolution. Shewhart's process reasoning distinguishes common variation from a changed operating regime and requires the survey to retain the chronology of changing receiver states. The issue becomes especially sharp because uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually examined. For the proposed case, a 1 mv quantiser step gives roughly 0.289 mv rms under a uniform

Copyright 2026, James M. Atkinson

independent error approximation, not a guarantee of white spectral noise. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. The examiner who presents an irreversible processing step as though it were a reversible calibration exaggerates what the archive can establish.

A further, separately testable aspect of a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna concerns delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency. The proposed challenge would be vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. The decision is conditional upon the observed result, with particular attention to the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. The competing account remains uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. Consequently this speaker accepts only the inference which the conducted experiment could differentiate. A coherent input may produce repeatable quantisation spurs rather than featureless noise. Dr Deming, I invite a validation experiment capable of distinguishing deterministic structure from a statistical floor.

W. Edwards Deming | Peer question 6 to Walter Andrew Shewhart

I thank you, Walter Andrew Shewhart, for distinguishing measurement from attribution, but the observation is that the noise floor changes with signal frequency and digital averaging despite unchanged nominal

Copyright 2026, James M. Atkinson

converter resolution. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a 1 mV quantiser step gives roughly 0.289 mV rms under a uniform independent error approximation, not a guarantee of white spectral noise. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation on one day but fails after the instrument has been reconfigured? An ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Walter Andrew Shewhart | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 029, the specific physical candidate is uniform quantisation error under restricted assumptions, kTB thermal contributions, and slew-dependent jitter noise. The unresolved physical pathway is material: Uniform quantisation error, thermal

Copyright 2026, James M. Atkinson

noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. The retained record permits a conditional claim about delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, but cannot alone resolve the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a 1 mV quantiser step gives roughly 0.289 mV rms under a uniform independent error approximation, not a guarantee of white spectral noise. I would retain the counterexample as part of the primary result, not as a footnote to an attractive conclusion. An ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ. Its bearing on the dispute can be evaluated through the predicted response, namely jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation. Because uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays, the procedure vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples should be repeated with the same calibration and an independent witness path. If agreement

Copyright 2026, James M. Atkinson

appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. Jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 5: Multiple operating conditions are needed to separate causal noise contributions that overlap spectrally.

The final uncertainty budget should not classify every residual discrepancy as random converter noise. If the measurement is intended to identify a weak intermittent emission, the relevant performance metric may be the probability of detection across several amplitude and frequency conditions. I would estimate the thermal contribution with the source terminated, characterise jitter with calibrated high-frequency tones, and examine the converter transfer errors with a code-density or appropriate dynamic test. Those characterisations are not automatically independent. Shared reference-voltage fluctuations, temperature and clock distribution may correlate their effects; a naive root-sum-square combination can then misrepresent uncertainty. A useful report provides the conditions under which each component was evaluated and tests how the proposed model predicts an independent validation recording. When a candidate falls near the detector threshold, the operating regime matters more than a single global effective-number-of-bits figure. The statistical claim must be tied to the actual decision the examiner is making.

In this statistical inference examination of Question 029, the decisive claim is that multiple operating conditions are needed to separate causal noise contributions that overlap spectrally. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: separate converter, source and clock

Copyright 2026, James M. Atkinson

error by experimental intervention. A commonly quoted ideal quantisation ratio for a full-scale sinusoid is approximately 6.02 N plus 1.76 dB for N effective ideal binary bits and the stipulated uniform-noise model. At N = 12 this is about 74.0 dB, but measured spurious-free dynamic range and effective number of bits can be much poorer because of thermal noise, nonlinearity, clock error and source distortion. Comparing a terminated input with a driven tone, altering input frequency and changing clock conditions exposes different error mechanisms. Jitter-related degradation increases with input frequency even if the sample rate remains unchanged; thermal noise need not follow that pattern. Do not assign all observed residual energy to quantisation merely because the code width is known. The report should include frequency-dependent noise spectra and coherent spurs separately from integrated random noise. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. Multiple operating conditions are needed to separate causal noise contributions that overlap spectrally. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to vary input amplitude,

Copyright 2026, James M. Atkinson

input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples, should be accompanied by a second acquisition path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. A laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman’s statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping

Copyright 2026, James M. Atkinson

displays. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime. The relevant quantities are delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a 1 mv quantiser step gives roughly 0.289 mv rms under a uniform independent error approximation, not a guarantee of white spectral noise, is not an estimate of any actual investigation. Noise contributions that overlap spectrally need separate controlled operating states before their magnitudes can be assigned. Sir Karl, I pass the floor to test which attribution remains falsifiable.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. Thermal noise power is proportional to Boltzmann constant, absolute temperature, and equivalent noise bandwidth. Please connect delta-squared over twelve, kTB, integrated clock phase noise, effective

Copyright 2026, James M. Atkinson

bandwidth and SNR versus stimulus frequency with a declared detection threshold and the measurement exposure. If the experiment vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 029, the specific physical candidate is uniform quantisation error under restricted assumptions, kTB thermal contributions, and slew-dependent jitter noise. The unresolved physical pathway is material: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. The retained record permits a conditional claim about delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency, but cannot alone resolve the white quantisation-error approximation requires an appropriate error model and must not be applied uncritically to a coherent low-level tone. That limitation

Copyright 2026, James M. Atkinson

belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. Thermal noise power is proportional to Boltzmann constant, absolute temperature, and equivalent noise bandwidth. I would use the observations of delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples, not an assertion based on the operator's impression of a quiet display. If it yields jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

Copyright 2026, James M. Atkinson

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays, an intervention that leaves both alternatives consistent does not settle their difference. The result should be limited to identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism, with the untested physical possibilities made visible.

William Ralph Bennett, Cross-Peer Question to Harry Nyquist: Dr Nyquist, when an ADC trace has a near-white floor under one test, what experiment separates a decorrelated uniform quantisation approximation from actual resistor and amplifier thermal noise?

Harry Nyquist, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, begin with a terminated, calibrated input and record noise power against equivalent noise bandwidth, analogue gain and absolute physical temperature. Johnson noise scales in power with kTB for a matched thermal reference; converter quantisation error is expressed in code steps and depends upon input statistics and dither assumptions. Their spectra may overlap, so one cannot assign causal origin from a single white-looking trace. Vary gain ahead of the ADC while holding later processing fixed: analogue noise referred to the converter may grow with that gain while the native quantisation step remains set by the converter transfer function. Independently vary input temperature or measure a known resistor source where practical. Compare predicted and observed covariance. The result must give the reference plane, impedance, temperature, bandwidth and

Copyright 2026, James M. Atkinson

saturation exclusions. I pass the token to Dr Shannon to examine a third noise mechanism.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, a 14-bit receiver shows sharply worsening SNR as the test sine frequency increases, whilst the digital noise floor appears smooth. How would you isolate aperture jitter from broadband additive noise?

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, measure SINAD or appropriately defined noise-only SNR at several input frequencies and controlled amplitudes, documenting the clock-source phase-noise characteristics. Under small, independent rms aperture jitter sigma_t, the ideal sinusoidal limit is SNR_j = −20 log10(2π f_in sigma_t). The frequency factor therefore predicts stronger jitter sensitivity at higher input frequency, unlike a fixed independent input-referred voltage-noise density. Yet this formula is a limiting model, not an instrument certificate; correlated jitter, clock spurs, aperture effects and front-end gain dispersion can change the result. Cross-check with an independent low-jitter clock, a second reference frequency and a measurement of the actual aperture uncertainty where possible. Inspect harmonic and intermodulation content separately. I yield to Dr Shewhart for the problem of misleadingly smooth presentations.

Claude Elwood Shannon, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, a noise histogram appears Gaussian and the mean spectrum flat. Why is that insufficient evidence that code error is independent or that a low-frequency spur cannot be produced internally?

Walter Andrew Shewhart, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, marginal distributions are not joint distributions. A sequence may

Copyright 2026, James M. Atkinson

have a perfectly plausible histogram while preserving correlations, periodic error, modulation and code-transition defects. Apply a slow coherent ramp to inspect missing or unequal codes, repeat with deliberately noncoherent and dithered stimuli, and compare time autocorrelation, cross-channel covariance, Allan-type stability at suitable durations and narrowband residuals. Monitor supply rails and converter operating mode so a firmware or gain-state transition is not attributed to the environment. State how many spectral opportunities were examined, because selecting the strongest bin after the fact inflates false alarms. A validation record must include both negative and positive controls and must preserve the full trace, not only a smoothed display. I pass the token to Dr Neyman on inference across the resulting trials.

Walter Andrew Shewhart, Cross-Peer Question to Jerzy Neyman: Dr Neyman, if thermal, converter and clock-noise estimates are extracted from the same twenty records, is root-sum-of-squares always an acceptable combined uncertainty?

Jerzy Neyman, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, only if the quantities are defined appropriately and their covariances do not materially affect the result. The propagation formula includes cross terms, so estimates sharing clock drift, gain calibration or a common baseline are not automatically independent. Specify whether each reported number is a standard deviation of an estimator, a noise power, an amplitude uncertainty, or a systematic correction. Combine quantities in consistent units and on the same reference plane, applying the appropriate sensitivity coefficients before calculating uncertainty. Use paired perturbation trials and a covariance matrix or an independently justified resampling method

Copyright 2026, James M. Atkinson

where necessary; do not average decibel figures as though they were linear powers. A non-significant difference does not establish causal equivalence. I respectfully return the token to Dr Atkinson to summarise the evidential boundary.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of distinguishing quantisation, thermal, and clock-derived noise in sampled receiver records has established a point which the specialist must not overlook. The receiver records noise density, spectral spurs, and their dependence on signal amplitude, frequency, and converter operating mode; it does not, merely by drawing a clear trace, give direct access to how much variance arises from input termination, analogue circuitry, finite digital code width, and sampling-time error. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, An ideal uniform quantiser under a suitably decorrelated error model has variance $\Delta^2/12$ for step size Δ. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

A measured receiver noise floor may be the joint outcome of thermal agitation, amplifier flicker noise, environmental interference and residual oscillator-related phenomena. One cannot discover the fractions merely by fitting a single straight line through an averaged spectrum. Temperature, input termination, selected gain, observation bandwidth and frequency offset should be varied separately so that the competing mechanisms make

Copyright 2026, James M. Atkinson

testably different predictions. I thank the statistical contributors for warning that measurements drawn from a drifting operating regime cannot automatically be pooled as independent examples of the same noise process. A transient rise under a known switching load calls for different interpretation from a stable increase in receiver-added thermal noise. The closing report should display the observed covariance and spectral shape where measurable, disclose the limitations of the model and retain alternative explanations when several mechanisms fit the same data. A legitimate conclusion may concern instrument performance without resolving the origin of every environmental fluctuation.

The reported floor varies with input frequency and processing even though nominal bit depth is unchanged. That is not sufficient to divide the total noise into components. The gain, bandwidth, clock, dithering and signal amplitude must be fixed or explicitly modelled during the separating measurements. The more useful outcome is a discriminating protocol: Vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. In applying it, the examiner must retain all readings supporting delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency and identify the physical plane to which the measurements refer. At the outset of the investigation, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna; that circumstance makes the alternative mechanism material, specifically uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. A result

Copyright 2026, James M. Atkinson

approaching jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

The result should be a componentwise noise budget with explicit operating conditions, including covariance where it matters. Neither the nominal number of converter bits nor a single waterfall PSD can uniquely identify thermal, quantisation and clock-related mechanisms. The decisive experiment is concrete: Vary input amplitude, input frequency, sample rate, clock source, termination state and dithering while preserving unaveraged samples. In conducting it, the examiner must explicitly retain delta-squared over twelve, kTB, integrated clock phase noise, effective bandwidth and SNR versus stimulus frequency. If the outcome matches the stated prediction, jitter-sensitive error grows with sinusoidal slew rate; thermal receiver noise follows measurement bandwidth; quantisation effects depend on code step and correlation, the supported conclusion concerns that test domain. An alternative remains: Uniform quantisation error, thermal noise, correlated clock jitter and coherent distortion spurs can occupy overlapping displays. I

Copyright 2026, James M. Atkinson

thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Ten worked engineering applications | Question 029

Application 01. Ideal code step, variance, and full-scale sine SNR

In the illustrative 029.01 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. Taking an ideal N = 10-bit uniform converter across 2.50 V peak-to-peak, one nominal code interval is $\Delta = V_{pp}/2^N = 2.4414$ mV. Under the independent uniform-error approximation its rms quantisation error is $\sigma = \Delta/\sqrt{12} = 0.7048$ mV. The ideal full-scale sinusoidal SNR approximation is 6.02N + 1.76 = 61.96 dB. A coherent low-level waveform may violate the uniform-error assumption; clipping and integral nonlinearity are separate limitations. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Application 02. Thermal reference noise in a declared measurement bandwidth

In the illustrative 029.02 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. Take the equivalent noise bandwidth B = 6,750 Hz and calibrated noise figure NF = 3.90 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10\log_{10}(B/1\text{ Hz}) + NF = -131.81$ dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Copyright 2026, James M. Atkinson

Application 03. The frequency dependence of aperture-jitter-limited SNR

In the illustrative 029.03 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. At sinusoidal input frequency f = 217 MHz with uncorrelated rms aperture jitter σ_t = 1.77 ps, the idealised jitter-imposed ceiling is $SNR_j = -20 \log_{10}(2\pi f \sigma_t)$ = 52.35 dB. A common clock source may correlate errors across parallel ADC channels, so treating their outputs as independent for noise cancellation would need an additional experiment. Converter nonlinearity and thermal noise can make actual performance worse. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Application 04. Code-bin width under differential nonlinearity

In the illustrative 029.04 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. For an N = 13-bit transfer over 2.80 V, one ideal least-significant-bit interval is Δ = 0.34180 mV. If one measured code has DNL = -0.200 LSB, its effective width is Δ(1 + DNL) = 0.27344 mV. A code-width result needs adequate stimulus uniformity, histogram population and a declared endpoint convention; it does not independently establish whole-transfer integral linearity. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Copyright 2026, James M. Atkinson

Application 05. Voltage-equivalent integral nonlinearity

In the illustrative 029.05 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. Under a specified transfer-line convention, an N = 15-bit ADC spanning 2.50 V has ideal step Δ = 0.07629 mV. A local integral nonlinearity of 0.760 LSB corresponds to 0.05798 mV of analogue-equivalent deviation. The endpoint or best-fit reference line must be declared, as must temperature, code region and input slew rate; otherwise two instruments may report incompatible INL values for the same transfer curve. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Application 06. Frequency-bin spacing versus independent information

In the illustrative 029.06 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. With sampled bandwidth f_s = 7 MS/s and N = 8,192 transform samples, the discrete-frequency grid is $\Delta f = f_s/N$ = 854.492 Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Copyright 2026, James M. Atkinson

Application 07. Combined and expanded measurement uncertainty

In the illustrative 029.07 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. For independent standard-uncertainty contributions 0.52, 0.48 and 0.22 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.52^2 + 0.48^2 + 0.22^2)} = 0.741$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c = 1.482$ units. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Application 08. Difference between two instruments relative to stated uncertainty

In the illustrative 029.08 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. The paired instrument contrast is $\Delta = 1.020$ dB. Set independent standard uncertainties $u_1 = 0.500$ dB and $u_2 = 0.420$ dB. Then $u\Delta = \sqrt{(u_1^2 + u_2^2)} = 0.653$ dB, giving the dimensionless ratio $\Delta/u\Delta = 1.562$. This ratio is not automatically a significance test: correlated calibration errors and non-normal uncertainty require separate treatment. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Application 09. Family-wise probability when many candidates are searched

In the illustrative 029.09 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine

Copyright 2026, James M. Atkinson

stimulus and an externally connected antenna. If each of M = 560 independent pre-specified search opportunities has false-alarm probability α = 0.0009, the probability of one or more false positives is 1 − (1 − α)^M = 0.39603, or 39.60%. Independence is a working premise only; neighbouring FFT bins and overlapping time windows commonly violate it. A post-selected search also changes the test family. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

Application 10. Cascade gain and observed headroom

In the illustrative 029.10 test, a laboratory compares low-level broadband receiver noise under a terminated input, a coherent sine stimulus and an externally connected antenna. A first amplifier contributes G_1 = 14 dB, an intentional attenuation contributes G_2 = -6 dB, and a later stage contributes G_3 = 16 dB. The small-signal sum is 14 + (-6) + 16 = 24 dB. For P_i = -70 dBm, the ideal output is P_o = -46 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. Identify each tested noise contribution rather than describe the aggregate screen floor as a single physical mechanism.

QUESTION 030

Copyright 2026, James M. Atkinson

What does calibration reveal about ADC performance across temperature and time?

Source: V011_Roundtable_Question_030_CP030_Standalone(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Original constructed educational dialogue. Historical contributors are assigned hypothetical modern engineering questions by reference to their documented intellectual methods. These speeches are newly written and are not historical quotations, accounts of actual meetings, or claims that deceased individuals examined contemporary SDR instruments. All numbered examples are hypothetical and do not certify any receiver.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, the numerical output of an analogue-to-digital converter is the last visible statement of a process that begins with an analogue comparison. Between the signal at a declared reference plane and the number entered into the evidence file lie reference voltages, analogue switches, input buffers, sampling apertures, capacitors, comparators, digital corrections, clock systems, temperature-dependent components, and the continual possibility that the physical apparatus has altered since its last formal examination. A report which declares that a converter is calibrated may refer to a single stimulus at a single ambient temperature, to a manufacturer's production test, to an automatic internal operation, or to a system-level comparison against a traceable reference. These are not interchangeable assertions. Our question concerns what each can establish, what it leaves indeterminate, and what happens when a receiver is employed for a search in which an intermittent emission may never recur under laboratory conditions.

Copyright 2026, James M. Atkinson

Consider a defensive surveillance examination in which the receiver reports a very small spectral line within a wide span of otherwise ordinary radio-frequency activity. The operator later discovers that the converter board was calibrated at twenty-five degrees Celsius, but during the examination the enclosure temperature rose to fifty degrees and the reference supply had been changed during maintenance. An internal gain calibration was subsequently performed, but no record connects its coefficient set to the original acquisition interval. The operator may still have an authentic, bit-for-bit preserved recording. The authenticity of those bits does not demonstrate that the coefficient and reference assumptions used to interpret the recording were valid when the samples were created. Nor would a correction inferred from later laboratory measurements necessarily restore the actual earlier analogue input. We must separate digital custody, transfer-function characterisation, stability monitoring, and the identifiability of a past measurement state.

The engineering comparison should be sufficiently explicit to survive a change in vocabulary. Let x denote the voltage at the declared analogue reference plane, T the relevant physical temperature, t the observation time, s the discrete configuration state, and y the retained digital estimate. A local linear approximation may be written $y = a(T,t,s)x + b(T,t,s) + e(x,T,t,s)$, where a is effective gain, b is offset, and e is the residual encompassing nonlinear and stochastic contributions. We shall not assume that this approximation is globally valid, that the temperature is uniform across the instrument, or that drift is linear through an entire operating range. In particular, a temperature reading attached to the chassis may be an imperfect surrogate for the converter die, the reference element, the analogue front end, or the

Copyright 2026, James M. Atkinson

clock generator. Each of those components can respond on a different thermal time scale. One number in a log can conceal a changing spatial field of temperatures.

Calibration, properly understood, produces an experimental relationship, with an uncertainty, between indications and reference quantities under defined conditions. Verification asks whether specified requirements are met. Adjustment changes an instrument or its coefficients. These operations may be performed together, but their documentary meanings remain distinct. A before-and-after correction that makes one test point agree with its reference can leave integral nonlinearity, aperture jitter, overload behaviour and out-of-band susceptibility unchanged. Equally, a converter may be perfectly adequate for spectral occupancy classification while being insufficiently characterised for absolute power or phase measurements. The required validation therefore depends upon the measurand and decision claim, not merely upon a box marked 'calibrated'.

I shall invite Mr Weston to begin with physical standards, reference planes and the difference between a converter certificate and a system measurement. Lord Kelvin will consider temperature as a physical variable, the legitimacy of interpolation and the danger of allowing thermal models to masquerade as observations. Dr Shewhart will examine surveillance of drift over time, common-cause variation, special causes and the risk of mistaking an orderly chart for independent evidence of correctness. Dr Shannon will distinguish recoverable digital calibration from information lost at the aperture or saturation boundary. Dr Nyquist will connect converter amplitude correction to the stability of clock time, particularly

Copyright 2026, James M. Atkinson

where the prosecution or defence of a technical finding rests upon relationships among transient events.

Seven colleagues will question the principals directly. Their challenges will examine whether changes of reference, gain, hardware, observation window, laboratory method or analyst selection can manufacture an appearance of stability. We shall require example calculations to disclose units, uncertainty models and the limited claims which follow. The discussion is a hypothetical methodological exercise, not a certification of a particular modern receiver. Where the documentary basis is insufficient, the technically disciplined answer is not to invent a missing calibration trace. It is to narrow the claim, preserve the uncertainty, and identify a challenge that could change the inference. Mr Weston, may I invite you to establish the physical and evidential reference plane from which this inquiry must proceed?

Copyright 2026, James M. Atkinson

Edward Weston | Principal response 1: The physical reference and the assembled measurement

Dr. Atkinson, I accept the invitation with a distinction that may seem elementary but has repeatedly governed the reliability of electrical measurement: the indicated number must be connected to a reproducible physical comparison. A converter code is not, by itself, a voltage standard. It is a discrete result produced by a network whose reference, loading and environmental conditions must be known sufficiently well for the intended comparison. The act of placing a traceable source at the converter terminals may characterise the converter. It cannot, without additional evidence, characterise the amplitude delivered to those terminals through a preselector, low-noise amplifier, attenuator, protection limiter and switch matrix. One could quite properly certify the transfer relationship of an ADC board and yet possess no valid calibration for the amplitude at the antenna connector. A metrologist would distinguish those reference planes before discussing the number of significant digits printed by the software.

Begin with a calibration map whose independent quantity is the voltage applied at a physically accessible input plane and whose dependent quantity is the uncorrected converter indication. Establish the reference source's calibration and associated uncertainty, its output impedance, the load presented by the receiver, the wiring configuration and the actual delivered voltage. A nominal one-volt setting on a generator is not automatically a one-volt input if the source and load are mismatched or the generator amplitude is specified into a particular termination. Temperature should be recorded both for the reference and for the receiver. A calibration chain is persuasive only when every material transfer can be defended, not because

Copyright 2026, James M. Atkinson

a document carries an imposing seal or because an operator has used the word traceability.

A useful calibration at one temperature may determine an offset and scale for a limited, approximately linear input interval. If reference levels x1 and x2 produce indications y1 and y2, one may estimate a = (y2 - y1)/(x2 - x1) and b = y1 - ax1. That elementary relationship is a beginning, not a full account of the converter. It presumes that two points adequately describe the segment and that neither reading was affected by settling, clipping or a changing configuration. Additional levels across the intended range can disclose curvature, discontinuity or code-transition irregularity. A frequency-domain test can expose behaviour that a slow direct-current calibration cannot. Thus a calibration claim should identify the stimulus class and the range of quantities to which its coefficients can legitimately be applied.

I am especially concerned about the temptation to call every self-calibration a system calibration. An internal routine may switch the converter inputs to known internal nodes and calculate coefficients which reduce offset or gain error of designated circuitry. It may not incorporate an external antenna switch, a cable whose loss varies with temperature, or the impedance presented by a field probe. Conversely, a system calibration conducted with the complete analogue path can be more representative, but it is susceptible to the reference-source configuration and to the source's own drift. A good record therefore identifies both what was included and what was excluded. It need not pretend to characterise every possible component; it must tell the reader which physical quantities the resulting correction represents.

Copyright 2026, James M. Atkinson

The time at which calibration was performed is not a decorative field. Consider the apparatus in a vehicle which leaves a warm laboratory and is operated outdoors on a cold evening. During the first minutes the reference, converter package and preamplifier can be at different temperatures. A calibration made after thermal equilibrium is achieved may not describe the earlier transient. If the equipment subsequently warms through its own power dissipation, the direction of change can reverse. More importantly, changes in hardware configuration may invalidate an otherwise recent certificate. Replacement of a reference source, movement of a gain jumper, alteration of an analogue filter or loading by a different probe may change the relationship being certified without waiting for the certificate's printed expiry date.

I would insist upon retaining the raw reference readings wherever practicable. Corrected numbers alone do not reveal whether a procedure actually measured the relevant state. The operator should preserve calibration stimulus identifiers, reference certificates, observed levels, repeated measurements, sequence order, temperatures, elapsed settling time, channel identity, coefficients both before and after adjustment, firmware version and any unsuccessful attempts. A failed calibration followed by a successful retry is not necessarily an irrelevant preliminary inconvenience. It may disclose intermittent instability. The time series of coefficients may prove as informative as the values used for final correction, provided one does not interpret a smoothly changing coefficient as proof that the physical device has become fully known.

A defensible report can state that the instrument satisfied specified gain and offset checks at defined test points and environmental conditions. It

Copyright 2026, James M. Atkinson

should not leap from that proposition to the assertion that every transient RF observation in the earlier search was generated by an external source. The latter requires separate examination of receiver-generated products, bandwidth, interference, power supply behaviour and the stability of the sampling process. If the laboratory cannot re-establish the historical temperature distribution or the original switch and cable state, it may still report a bounded calibrated result, but that boundary must be printed beside the result rather than hidden in an inaccessible appendix. Professor Bridgman, may I ask you to examine whether the quantity itself has been held constant across the comparison?

Percy Williams Bridgman | Peer question 1 to Edward Weston

Mr Weston, your proposal assigns a decisive place to the reference plane, yet an examiner may choose that plane merely because it is convenient to reach with a test lead. Suppose that a receiver records an amplitude in decibels relative to a nominal input voltage. An internal generator is connected behind a preselector, while the unknown emission was admitted through the antenna port and a temperature-sensitive filter whose insertion loss had not been measured during the acquisition. The analyst subsequently obtains excellent agreement at the internal test plane and labels the result 'calibrated antenna power'. The words now refer to a different operation from that which was actually performed. Would you require the user to define the measurand before choosing the accessible reference plane? And if the intended quantity is not experimentally reachable without disturbing the system, how ought the examiner to distinguish a legitimately modelled correction from a measurement in which the desired quantity was never directly observed?

Copyright 2026, James M. Atkinson

Your answer must not simply demand an impossible reference arrangement; it must identify how the proposed interpretation can be tested.

Edward Weston | Immediate answer to Percy Williams Bridgman

Professor Bridgman, I would indeed begin with a description of the intended quantity that permits the proposed operations to be criticised. An antenna-port input level is not identical to an internal ADC-terminal level. The difference can be related through an analogue transfer model, but that relation requires evidence under relevant configurations. I would distinguish three records: the reference source's delivered quantity, the converter's observed indication, and the estimated transformation between the desired outer plane and the accessible inner plane. Each part has its own uncertainty and conditions of validity. If the filter and cable were unmeasured during the original acquisition, a later test may support an interpolation only if the physical configuration and its relevant environmental dependence can be shown to have persisted.

A practicable test need not place an ideal standard at an impossible physical point. It may use calibrated ports, comparison receivers, through-path verification, injected test tones at different accessible nodes, independent attenuation measurements or a sufficiently characterised network model. The critical requirement is that each method disclose which part of the chain it actually interrogates. A correction based solely upon nominal component specifications should be described as a model with assumptions, not as a direct observational calibration. If repeated tests reveal that the filter's loss

Copyright 2026, James M. Atkinson

at the event frequency varies appreciably with temperature, the historical antenna-port amplitude may have a range rather than a uniquely recoverable value. The honest expression of that range is not a failure of science; it is its proper consequence.

You also raise the possibility that disturbing the connection changes the quantity. A high-impedance measurement probe may alter loading; inserting an attenuator can change reflection coefficients; removing a protective network can eliminate a source of nonlinearity. I would record the pre-intervention state, identify the intervention, measure its loading effect where possible and compare predictions under alternatives. The report should separate 'the converter indicated this under the retained conditions' from 'the antenna received this much signal'. It should also resist the temptation to multiply a converter-level correction by a nominal path loss without carrying the uncertainty of that path. A single precise figure is not always the scientifically most precise statement. The testing record must support both the number and the words used to describe it.

Charles Proteus Steinmetz | Peer question 2 to Edward Weston

Mr Weston, permit an electrical objection concerning the assumption that the converter input is a simple resistance. In practice an acquisition circuit may contain switched-capacitor loading, frequency-dependent source impedance and a preamplifier whose phase and gain change with temperature. A direct-current gain calibration can return the correct slope while a rapidly changing burst experiences a different settling error. The operator may nonetheless apply that slope to a wideband

Copyright 2026, James M. Atkinson

complex-baseband recording. How would your physical reference discipline avoid treating two transfer functions as one? Furthermore, if a maintenance operation replaces the reference regulator but leaves the stored calibration coefficient unchanged, should the operator rely on the previous certificate until its formal expiry, or conduct a state-dependent qualification before the next evidential acquisition? I ask for a testable rule rather than a general exhortation to good maintenance, particularly where an expensive calibration laboratory is not readily available. Please also explain how the field operator could document a repeatable quick-check procedure without replacing a comprehensive laboratory qualification and without concealing the limitations of that more modest examination.

Edward Weston | Immediate answer to Charles Proteus Steinmetz

Mr Steinmetz, the resistance model must be replaced by an appropriate network description as soon as frequency or transient response matters. A code transition measured with a stable low-frequency input cannot be extended to a pulse of finite rise time without considering acquisition bandwidth, settling, aperture characteristics and the signal source impedance. One would use a matrix of tests rather than a single slope: direct-current levels for offset and static gain, sinusoidal stimuli at frequencies of interest for magnitude and phase, and transient or stepped inputs where the measurement claim concerns pulses. The reference plane and loading must be retained for all these tests. Where the entire analogue chain is too complex to characterise in detail, a system-level response test

Copyright 2026, James M. Atkinson

may provide an empirically justified operating envelope, but it should not be represented as proof of every underlying component parameter.

Replacement of a reference regulator is a change to a component on which the converter's scale may depend. The document's calendar date does not establish equivalence between two hardware states. The investigator should declare the earlier calibration inapplicable to the changed state until a documented comparison shows that the relevant performance requirements still hold. A limited field verification can be defensible when its scope is explicit: inject a stable reference level, compare two or more amplitudes across the used gain range, inspect relevant frequency bands and document the observed deviations. Such a procedure may establish continued suitability for a defined detection task without pretending to replace a comprehensive laboratory certificate.

The practical rule is to tie each evidence-bearing acquisition to a configuration identity and a declared suitability interval. An interval can end through elapsed time, unacceptable thermal change, component replacement, coefficient adjustment, failed self-test or any event known to alter the measurement relationship. A newly issued certificate need not follow every harmless user-interface adjustment; equally, a material hardware change cannot be absolved by an unexpired certificate. The rule should be risk-based but mechanically auditable: defined triggers, documented comparison, preserved raw readings, authorised decisions and a versioned acceptance record. That approach links metrology to investigative discipline without

Copyright 2026, James M. Atkinson

creating an impossible requirement for complete disassembly before every field survey.

Copyright 2026, James M. Atkinson

William Thomson, Baron Kelvin | Principal response 2: Temperature, transients and defensible thermal correction

Dr. Atkinson, the measurement of temperature is itself an act of physics, and I should resist any analysis which treats a digital temperature log as an infallible declaration of the entire instrument's thermal condition. An electronic assembly is not a single temperature. Its reference element may be thermally coupled to a regulator, the converter die to a printed circuit board, and the oscillator to an enclosure whose heat capacity differs from both. During warm-up, airflow change or a field excursion, these structures can follow different temperature trajectories. A thermometer fixed to the outside of a case may exhibit a perfectly smooth curve while the reference junction experiences a shorter and larger excursion. Therefore a correction indexed by a case temperature is, without further work, a proxy model. Its merit must be established experimentally over the intended state changes, not inferred from the mere existence of a sensor.

I would begin by defining the physical quantity whose temperature dependence is important. Suppose a converter has a voltage offset b(T), dimensioned in volts, and gain a(T), dimensionless. Around a chosen reference temperature T0 one may write b(T) approximately as b0 plus kb times (T minus T0), where kb has units of volts per kelvin. Similarly a(T) may be approximated by a0 times [1 + kg(T minus T0)], with kg in inverse kelvin. These are first-order local relations; they are not universal laws of semiconductors. The coefficients must be inferred from observations made with controlled references, and a separate residual term must account for curvature, thermal hysteresis, transient lag and measurement noise. It would be invalid to report the numerical result of a linear correction to many

Copyright 2026, James M. Atkinson

decimal places while silently ignoring a residual larger than the printed precision.

A calibration series should include temperatures approached from both directions. If the instrument is measured while warming, then allowed to cool and measured again at the same nominal points, disagreement at an identical sensor reading may reveal hysteresis or thermal gradients. It may also reveal time-dependent settling after a gain or clock adjustment. The appropriate experiment should record not only the nominal set point but also the dwell time, the stabilisation criterion, the order of measurements, the input stimulus and the sensor's own uncertainty. A thermal chamber can control its air temperature with impressive accuracy while the instrument under test remains internally unsettled. Thus an equilibrium label requires evidence that the relevant performance quantity has ceased to change beyond the declared tolerance, rather than a fixed waiting interval chosen merely for convenience.

There is a further distinction between correction and prediction. If a study finds that offset moves by a specified number of microvolts per degree under the tested conditions, the relation may permit a correction for observations within those conditions. Predicting the error for an untested temperature or a different rate of warming requires additional assumptions. A good investigator would retain the original values and the correction model separately, with both the temperature observation and its uncertainty. One may then recalculate the result if a later investigation uncovers a more reliable thermal model. Yet the later model cannot recreate the historically unmeasured die temperature from an exterior sensor unless a suitable relation had been established. The mathematical appearance of

Copyright 2026, James M. Atkinson

continuity in a fitted curve must not be mistaken for observational continuity in a missing record.

Consider gain drift expressed in parts per million per kelvin. It is tempting to read a typical specification of eight parts per million per degree and multiply by a forty-degree excursion, obtaining three hundred and twenty parts per million. That arithmetic is elementary, but its evidential meaning depends upon what the manufacturer's figure signifies. Is it a typical value, a maximum across temperature, a sample mean, a coefficient fitted over a restricted interval, or a guaranteed limit for each device? Does the gain-drift specification include the reference supply? Is the front-end amplifier included? Was the apparatus in the same gain state? A typical characterisation is valuable for engineering design, but it is not automatically an uncertainty bound applicable to the particular evidence-bearing unit. Its distribution, coverage and relation to environmental conditions must be stated.

Absolute temperature and temperature difference also demand care. An excursion measured in degrees Celsius has the same numerical interval as one measured in kelvins, though the zero points differ. A drift coefficient per kelvin therefore multiplies the same numerical difference in Celsius degrees. But an uncertainty in the sensor's absolute reading is not necessarily identical to uncertainty in a measured difference; common calibration bias can cancel in the latter if the same sensor is used, whereas independent sensors can introduce correlated and differential errors. An analyst who calculates a temperature correction from two readings should preserve which thermometer produced each, its calibration state and the covariance

Copyright 2026, James M. Atkinson

of the errors rather than automatically adding all quoted uncertainties in quadrature.

The same apparatus may exhibit ageing. An offset that varies slowly over months may arise from mechanisms distinct from a reversible temperature coefficient. A calibration acquired after a long interval may show a total difference without identifying how much occurred during a particular field operation. A beginning-and-end comparison can bracket a stable interval only if a plausible physical and statistical model supports such interpolation. Even then, an abrupt event between the two checks may escape detection. Time is not merely a second axis on a pretty graph; it represents exposure to stresses, repairs, environmental changes and materials processes whose histories must be recorded. I recommend that the acceptance statement describe exactly which excursions and elapsed intervals were tested, then identify separately the environmental states for which the transfer relation remains an extrapolation. Dr Bardeen, would you examine whether the proposed first-order model can survive the subtler temperature physics of a semiconductor junction? With respect, I now return the floor to Dr. Atkinson for the next contribution.

John Bardeen | Peer question 3 to William Thomson, Baron Kelvin

Lord Kelvin, your treatment recognises temperature as a distributed physical quantity, yet I wonder whether its local linearisation can be defended for a converter whose input transistors, switches and reference circuit change operating region over the required range. A junction's characteristics can depend upon both temperature and bias, and a calibrated offset may interact with input signal amplitude in a way not captured by a single coefficient. A hidden amplifier stage might exhibit a

Copyright 2026, James M. Atkinson

temperature-dependent distortion component that is negligible at one calibration level and material near overload. Could your proposed warm-and-cool series be designed to separate thermal hysteresis from amplitude-dependent nonlinearity and ordinary stochastic variability? I am also concerned that a sensor placed near the converter die may fail to represent the reference regulator or an oscillator some distance away. What minimum observations would justify a report stating that a correction belongs to an identifiable physical mechanism rather than merely to an empirical association found in a small laboratory dataset?

William Thomson, Baron Kelvin | Immediate answer to John Bardeen

Dr Bardeen, your objection exposes the limit of the local linear relation rather than refuting its use within a justified neighbourhood. One must distinguish a convenient correction equation from a theory adequate to every state. If the observed response depends upon signal amplitude, let the residual be indexed by x as well as temperature. If different circuit blocks possess distinct temperatures, use a vector of measurements or an explicitly qualified surrogate model. A calibration design could cross several input levels with multiple thermal set points and both warming and cooling trajectories. It should include replicated measurements at randomly or deliberately varied sequence positions, so that the inferred temperature effect cannot be conflated with the passage of time. An apparent dependence that changes when the order of operations is reversed should trigger an investigation, not an automatic enlargement of the fitted curve.

Copyright 2026, James M. Atkinson

I would not infer physical causation solely from a regression coefficient, however persuasive its statistical significance appears. The physical hypothesis should predict a distinct response to a controlled intervention. For example, a carefully limited change in reference-supply temperature, while maintaining the converter die close to constant, should affect a reference-drift hypothesis differently from an input-buffer hypothesis. These interventions may not be possible during a field survey, but they may be made in a laboratory with an equivalent apparatus. Where isolation cannot be achieved, the examiner can report a system-level empirical dependence, valid only over tested combinations. That is already useful if the claim is properly bounded.

The design must also include a validation set that was not used to select the model. A polynomial fitted to every measured point can attain small residuals without demonstrating predictive stability in an independent acquisition. Report the distribution of validation errors, including the worst relevant excursions, rather than only the root-mean-square fit to the training observations. Test for saturation, supply variation, input-common-mode dependence and states entered after switching gains. I should also require the data at each temperature, not merely average coefficients, to remain available to a reviewer. When the evidence supports a correction only to a defined input range and thermal trajectory, the expert should say exactly that. Its virtue lies in reducing a known error without pretending to remove all error. It does not follow that an unobserved transient can be reconstructed from the corrected number alone.

Copyright 2026, James M. Atkinson

Arthur Edwin Kennelly | Peer question 4 to William Thomson, Baron Kelvin

Lord Kelvin, I ask you to consider an instrument mounted near a transmitting apparatus where the thermal environment and the electromagnetic environment change together. When the transmitter becomes active, local heating rises, supply loading changes, and a weak line appears in the receiver spectrum. An engineer may discover a statistical correlation between the line's amplitude and the case temperature, then apply a thermal correction and conclude that the line was an internally generated artefact. Yet the transmitter's presence could create both the thermal rise and a genuine externally admitted signal. How should the calibration campaign separate common-cause confounding from the proposed thermal mechanism? Specifically, should a report require an intervention that alters temperature without changing the RF environment, another that changes RF exposure while temperature is held stable, or some alternative experiment? Can one fairly use such controlled tests to draw a conclusion about a unique historical event? In particular, what independent observation would contradict the thermal account even if the temperature correlation appeared statistically striking?

William Thomson, Baron Kelvin | Immediate answer to Arthur Edwin Kennelly

Thank you for that question. Professor Kennelly, a correlation between two changing quantities is not sufficient to establish the direction or even the existence of the proposed causal relation. Your example is especially instructive because temperature, supply loading

Copyright 2026, James M. Atkinson

and received RF energy may respond to a common operational event. A thermal correction model fitted only while the transmitter is on may absorb part of an external signal as though it were receiver drift. It may be numerically effective in predicting that one dataset while causally mistaken. I would separate the interventions you propose whenever practical. Vary temperature with the RF environment controlled; vary RF exposure at stable thermal conditions; vary supply loading where its direct electrical effect can be distinguished from heating. The resulting data permit competing physical explanations to make divergent predictions.

Such experiments should also test plausible interactions. It may not be enough to add one thermal effect to one radio-frequency effect if a semiconductor's nonlinearity makes their combined influence different from their isolated effects. A modest factorial design can reveal this circumstance. But one should not imagine that a laboratory re-enactment restores every historical detail. Its value is to challenge whether the proposed mechanism could reasonably explain the record and whether alternatives remain observationally equivalent. A successful replication under several controlled conditions can increase confidence in a bounded attribution; it does not turn an unobserved earlier temperature field into an observed one.

For forensic reporting I suggest three levels of conclusion. First, the measured spectral feature changed with the instrument's recorded environmental indicators. Second, independent challenge tests demonstrated that specified internal mechanisms can produce or

Copyright 2026, James M. Atkinson

alter a comparable feature under documented conditions. Third, the evidence from the historical acquisition supports or fails to support exclusion of an external emitter. These are distinct propositions, and a report should not pass from the first to the third merely because the plotted curves look alike. State the restrictions, retain the alternative and preserve the data with which another examiner can challenge the inference. The strongest scientific account is often the one that explains exactly which intervention has yet to be performed. The resulting statement should give the experimental temperature interval, the observed environmental covariates and the uncertainty of the correction. It must not imply that a correlation establishes the unique mechanism. Such disclosure permits a reviewer to test the same physical alternatives without first accepting the investigator’s favoured explanation.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal response 3: Stability, control and the fallacy of a single passing certificate

Dr. Atkinson, I welcome the opportunity to distinguish the measurement of an error at one occasion from the evidence that a process remains stable across occasions. A certificate tells the reader something about a particular performance examination under its stated conditions. It does not guarantee that every subsequent output belongs to the same statistical process. A converter can pass an initial offset and gain test and later experience a change in supply voltage, thermal stress, mechanical shock, ageing or a switch-state defect. Conversely, a converter can show ordinary measurement variation without any material deterioration. The analyst must have a method for distinguishing predictable process variation from a change requiring investigation. Neither the sight of a narrow trace nor the authority of a laboratory signature resolves that distinction by itself.

A repeated check is most useful when it measures the same defined quantity under sufficiently comparable conditions. Choose a stable test input, record the converter's raw indication, temperature, configuration and reference-source identity, and examine a time series of residuals against a predeclared reference. The sequence must preserve chronological order. Averaging several test results into one convenient number may conceal an excursion that occurred during the actual investigation. I would establish a baseline from a demonstrably stable period and distinguish limits derived from process behaviour from limits imposed by the required measurement accuracy. A control chart's warning boundary is not automatically a metrological tolerance, and passing a tolerance is not automatically

Copyright 2026, James M. Atkinson

statistical evidence that the process is stable. These are distinct questions which should not be made to answer one another.

Suppose a receiver produces repeated one-volt reference measurements with small scatter, yet its mean indication changes gradually as the enclosure warms. A chart based only upon within-group repeatability may show tight clusters on each occasion while the groups' centres move systematically. The operator might report excellent repeatability if the data are pooled without regard to time. But short-term repeatability does not establish long-term reproducibility. A response measured at one fixed temperature cannot distinguish a process which is well controlled under all anticipated conditions from one whose errors are merely reproducible under the chosen condition. We must structure the validation to include the environmental and configuration states that matter to the intended claim.

I would also caution against recalculating limits every time a troubling observation appears. If the system fails a predeclared rule, the investigator may explore, identify a genuine change in conditions and develop a revised model. But the original failure must remain in the record, and the revised method should be tested on data not used to select it. Repeatedly fitting a new thermal correction until every measured point falls inside a preferred tolerance is an exercise in conformity by construction. It does not show that the correction would work in a subsequent field examination. An independent holdout sequence, run through a different cycle of warming, cooling and gain selection, is one way to examine whether the apparent stability persists beyond the training data.

A particular hazard appears when calibration itself changes the apparatus. Many devices alter stored coefficients during an internal

Copyright 2026, James M. Atkinson

procedure. If a failing verification is immediately followed by an adjustment, then the later passing result cannot demonstrate that the earlier field acquisition occurred in the adjusted state. It may establish that the instrument was subsequently brought back into conformity, which is useful maintenance information, but the historical evidence must be interpreted according to the earlier coefficient state. Preserve both states and the transition event. The absence of such a record is not repaired by treating the later certificate as retroactive proof of the earlier measurement's accuracy.

The interval between verification checks should arise from the observed behaviour and the consequence of an undetected failure. A highly stable instrument with ample detection margin may warrant a different interval from a unit operating close to an evidential decision boundary. Yet a longer interval cannot be justified solely by an uneventful service history if the checking procedure was incapable of detecting the relevant fault. In a defensive spectrum survey a simple built-in reference may detect scale drift while missing an intermittent clock spur or thermal intermodulation. A useful surveillance plan therefore uses complementary checks for distinct failure modes. It should preserve negative results and diagnostic flags with the same fidelity as successful verification records.

The concept of a control state must extend to the entire observational practice. Operators change cables, select gain modes, update firmware, move receivers between rooms, and alter automatic threshold algorithms. Each change can shift the population of recorded observations. What appears to be converter drift may be a population change due to different operating conditions or selective retention. The investigator must track configuration and environmental covariates, not merely scatter plot a single

Copyright 2026, James M. Atkinson

code against a calendar date. If a control chart excludes invalid observations, the grounds for exclusion should be prespecified and recorded. Otherwise the archive becomes an edited narrative rather than a faithful account of the measurement process.

My proposed quality decision has three parts. First, verify the present instrument against explicitly stated performance requirements. Second, assess whether a sequence of suitable check measurements supports stability over the operational envelope and time interval of interest. Third, define the action when the evidence is indeterminate, including reduced operating claims, additional testing or retention of a qualified result. A laboratory can be very precise at announcing a current measurement and appropriately cautious about claims concerning unseen historical intervals. That caution is no contradiction. It is the correct expression of a process whose behaviour has not been fully observed. Dr Deming, may I invite you to test the responsibility assigned to the operator and the organisation maintaining the system?

W. Edwards Deming | Peer question 5 to Walter Andrew Shewhart

Dr Shewhart, your statistical account is disciplined, but would it become a ritual if the organisation lacks a system for recording failed tests and learning from them? Imagine a laboratory in which an operator receives praise for producing a high proportion of passing checks, while failed checks delay field deployment and are treated as personal defects. Under those incentives, technicians might repeat calibration until it passes, omit earlier results and report only the final certificate. The control chart will then look excellent, while the actual acquisition process remains vulnerable. How should the evidence standard incorporate

Copyright 2026, James M. Atkinson

maintenance culture, training, configuration control and the distinction between special-cause response and improvement of the underlying process? Can the reviewer demand a record of unsuccessful checks without converting every minor deviation into an allegation of incompetence, particularly where variation is inevitable and the purpose is to improve defensive investigative reliability rather than to punish operators?

Walter Andrew Shewhart | Immediate answer to W. Edwards Deming

Dr Deming, the statistical method cannot compensate for institutional arrangements that systematically suppress inconvenient observations. A passing series selected from a larger set of undocumented attempts is not the series that a reader believes it to be. It cannot establish the declared false-failure rate or the frequency of state changes because the selection procedure has altered the population. The quality system must therefore make preservation of raw verification events ordinary and expected, not an exceptional confession. It should record a failure, the diagnostic response, the adjustment if any and the subsequent verification as a linked sequence. The purpose is to understand the process and its uncertainty, not to attribute moral fault to the technician who discovers that a device has changed.

Management should distinguish a foreseeable common-cause dispersion from a special event. If daily measurements fluctuate within an established stable range but remain well inside the engineering tolerance, intervention after every excursion may cause

Copyright 2026, James M. Atkinson

more instability than it prevents. If a sudden shift follows a firmware update or component replacement, the correct response is to investigate that change, not to conceal it by averaging. A training programme must teach these differences and provide a documented pathway for suspending use when a critical requirement is no longer met. It must also identify who may authorise the return to service and on what empirical basis.

I would urge auditors to evaluate the completeness and comparability of the measurement history. Examine consecutive records, including unsuccessful attempts, and verify that timestamps, configuration identifiers and reference-source metadata permit a coherent sequence to be reconstructed. A well-maintained process may show more recorded failures than a poorly maintained one because it has better detection and reporting. Therefore the raw number of failed checks is an unsuitable ranking of institutional quality without regard to opportunity, severity and corrective action. The goal is reliable prediction and honest evidence, not cosmetic perfection. Finally, separate operating tolerances from retrospective historical claims: when a process is restored after a failure, the restoration is proven at that later time. It cannot make an earlier uncertain acquisition certain by administrative decree. This distinction is consequential when an expert later interprets a near-threshold signal. A well-governed laboratory may admit uncertainty and thereby supply stronger evidence than a laboratory presenting an immaculate but selected history of passing tests.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 4: What digital correction cannot recover

Dr. Atkinson, the discussion has thus far centred upon amplitude scale and the persistence of a transfer relationship. I should like to identify the informational boundary within which all correction must work. A digital record contains a finite sequence of values, each determined by the physical acquisition and coding process. A known, sufficiently invertible gain error may be corrected for an appropriately bounded input. But where the acquisition has irreversibly mapped several distinguishable analogue inputs into the same retained output, no subsequent recalibration can determine which of those inputs occurred without additional assumptions or independent observations. This is not a pessimistic view of digital processing. It is the straightforward recognition that a numerical operation cannot create unique knowledge of an unknown variable from data that do not distinguish its possible values.

Suppose a converter has a stable offset of several least-significant-bit increments. If the exact offset is known and the corresponding raw code sequence retains sufficient information, subtracting an appropriate correction can improve an estimate of the input within the model's uncertainty. If, however, the converter saturated during a strong pulse, all inputs above a threshold may have produced the same limiting code. Changing the gain coefficient later cannot restore the clipped amplitude, shape or duration uniquely. Similarly, a missing acquisition block cannot be replaced with actual historical samples by interpolating between its neighbours. An interpolated waveform may be useful for visualisation under an explicit model, but it must never be represented as a recovered

Copyright 2026, James M. Atkinson

observation. Such distinctions become legally important where a reconstructed transient is compared with another event or presented as independent evidence of an emitter.

Thermal calibration can legitimately reduce one source of estimation bias while leaving information loss untouched. A gain coefficient fitted from a steady reference does not identify the converter's instantaneous aperture error at the moment of a rare burst. It does not reconstruct a phase trajectory lost to an unlocked oscillator or recover a frequency component rejected by an analogue filter. A correction may make the aggregate spectrum look cleaner while also changing the false-alarm distribution of a detector. If the field search used adaptive thresholds derived from corrected samples, the correction algorithm itself belongs inside the measurement and decision model. The user must preserve its version and state, along with the uncorrected data whenever technically feasible.

There is also an important distinction between knowing a calibration relationship statistically and knowing the actual realised error of a particular sample. An estimated thermal drift coefficient has uncertainty. The true instantaneous temperature at the relevant component may be unobserved. Additive converter noise may be stochastic. In a suitable model one can propagate those uncertainties and obtain a distribution for a corrected estimate. One cannot in general assign every sample a unique perfect inverse. A posterior estimate conditional upon a model and prior assumptions may be useful, but it is a conditional inference. The presentation should explain those assumptions and resist the temptation to label the conditional mean the 'original analogue signal'.

Copyright 2026, James M. Atkinson

Digital archives are not passive recipients of samples. Some systems transmit decimated streams or retain only windows that crossed a threshold. Others apply automatic gain control, spectral averaging or event-triggered compression before writing files. When the operating environment changes, the selection policy may also change. A raw file can be cryptographically authentic yet incomplete relative to the period surveyed, because intervals without triggers were never retained. Calibration of the retained samples cannot certify that the unrecorded intervals contained no relevant signals. For a negative finding the investigator needs an exposure account: what time and frequency were actually observed, with which gain and detection thresholds, and what fraction of the nominal recording interval is represented by accessible data.

Consider the claim that two converters possess equivalent calibrated amplitude accuracy. One may have more effective signal bandwidth; another may have fewer clipping episodes under strong adjacent-channel conditions. The same two-point gain verification can pass for both, while their ability to preserve a brief weak emission differs materially. Therefore calibration suitability must be related to the information required for the task. An absolute-amplitude assessment may demand stringent traceability. A search for an intermittent signal may demand additional tests of dead time, spectral occupancy, transient response and false-alarm behaviour. There is no contradiction in finding an instrument acceptable for one proposition and unsuitable for another.

Forensic preservation adds another level. A later calibration record can be connected to earlier evidence only by a credible account of state continuity. The file hash authenticates a byte sequence. The calibration

Copyright 2026, James M. Atkinson

record describes a physical comparison. A chain-of-custody account connects people, devices and times. These three must be reconciled before the report can state what happened at the analogue input. If one is absent, the others may still support narrower propositions. A sound report distinguishes the measured digital observation, the estimated analogue quantity and the causal interpretation. It is quite possible to be confident that a digital spectral feature existed in a retained record while remaining uncertain whether it originated outside the receiver.

I would conclude that calibration is a constrained transformation of evidence, not a magical return to a lost past. It adds knowledge through documented measurements of instrument behaviour. It does not erase the physical fact of missing samples, unresolved aliasing, clipping, unmeasured state changes or selective acquisition. Those limitations should guide both the design of the receiver and the wording of the conclusion. Dr Tukey, may I invite your examination of whether adaptive models can be validated without allowing their own selection to conceal the uncertainty they were intended to control?

John Wilder Tukey | Peer question 6 to Claude Elwood Shannon

Dr Shannon, I agree that a digital correction cannot regenerate unobserved information as though it had been recorded, yet exploratory data analysis frequently reveals useful regularities that a rigid initial model missed. Suppose an analyst has several months of temperature logs and periodic converter verification results. A nonlinear model fitted after seeing these data explains much of the apparent drift and reduces the residual scatter. Is it legitimate to apply that model retrospectively to previously collected surveillance records? If so, what prevents the analyst

Copyright 2026, James M. Atkinson

from selecting a flexible curve that simply absorbs every inconvenient deviation? I ask especially about the distinction between fitting and testing, the handling of missing environmental observations, the reporting of intervals outside the calibration range, and the preservation of competing simpler models. How could a tribunal or independent scientific examiner tell whether the revised model generated genuinely new knowledge or merely produced an attractive corrected plot?

Claude Elwood Shannon | Immediate answer to John Wilder Tukey

Thank you for that question. Dr Tukey, exploratory analysis may discover relationships that deserve serious testing. The error occurs not in fitting a novel model but in treating the data used to invent the model as independent confirmation of its predictions. The revised model should be described with its selection history, explanatory variables, assumptions and domain of applicability. Independent validation might use later measurements not available during construction, a withheld subset that preserves the structure of thermal cycles, or new controlled interventions chosen to differentiate the model from plausible alternatives. Randomly withholding individual adjacent samples from a strongly autocorrelated thermal trace is an inadequate substitute for withholding whole independent cycles.

I would also examine whether the model permits a uniquely defensible correction. Several flexible functions may fit the calibration observations equally well while making different predictions between unmeasured points or beyond the observed range. Their

Copyright 2026, James M. Atkinson

disagreement is evidence of model uncertainty and should enter the reported interval. A result should not be given the narrow error bar of the best-fitting model when model selection was itself materially uncertain. Missing temperature data are not zeros; they are missing observations. Their reconstruction through interpolation or other methods must be labelled as inference and challenged against the thermal time constants of the physical assembly. A model that requires an unrecorded die temperature cannot be described as experimentally verified merely because the computer supplies a smooth estimate.

In disclosure I would retain the original file, the correction software, its parameters, the dataset used for fitting, the validation results and the alternatives considered. The corrected estimate should be compared with the uncorrected observation under consistent reference planes. If the model changes whether a threshold is crossed, that sensitivity is central to the evidential interpretation. An attractive plot can be useful as an explanatory visualisation, but it should not suppress the failure cases and residual structure that permit genuine criticism. A tribunal can then see what was measured, what was inferred and which assumptions cause the result to change. That is a more valuable application of computation than an apparent precision unsupported by the experiment. Preservation of unsuccessful model trials is especially important because the degree of improvement may otherwise be exaggerated by repeated selection against the same observations. The validation procedure must describe the opportunities for such selection.

Harry Nyquist | Principal response 5: Calibration of time and sampling state

Dr. Atkinson, amplitude correction has occupied much of our discussion, yet a sampled measurement is also an assignment of analogue events to a temporal lattice. A converter which reports the correct voltage when stimulated slowly can nevertheless misrepresent the time of a transient if its clock frequency, aperture position or synchronisation state differs from the assumed values. In a wideband monitoring system these errors can alter the interpretation of repetition rate, pulse coincidence, frequency offset and bearing estimates derived from time differences. The calibration of a sampling instrument must therefore declare which temporal quantities are being asserted and how the relevant clock relationships are observed, maintained and challenged.

A nominal sampling rate f_s expresses an intended number of samples per second. If the actual rate is f_s(1+epsilon), where epsilon is a fractional frequency error, an index difference of N samples corresponds to a true elapsed time N/[f_s(1+epsilon)], not simply N/f_s. For sufficiently small epsilon the timing error accumulated over an elapsed interval tau is approximately epsilon times tau. This effect may be tiny for short records and material for long observations or comparisons with an independent time source. A calibration of amplitude gain does not determine epsilon. Nor does a spectrum showing a strong stable tone necessarily prove that all timestamps are correctly aligned to civil time, since the frequency reference and timestamp reference can be distinct and can experience separate interruptions.

Copyright 2026, James M. Atkinson

The aperture itself has a temporal uncertainty distinct from average sample-rate error. Random sampling jitter introduces input-dependent conversion noise, with sensitivity increasing with signal frequency and amplitude slope. A timing comparison using a low-frequency reference may therefore miss a limitation that becomes material near the upper edge of the admitted band. A converter's impressive static gain and offset figures tell us little about that phenomenon. Tests should use frequencies and signal amplitudes appropriate to the intended observation, with reference-source phase noise and measurement noise separately assessed. If the input stimulus contributes significant jitter, the apparent converter limitation may in fact be a property of the test arrangement.

One must also remember that a software-defined radio commonly changes clock-related states. The local oscillator may retune, the converter may select a different clock divider, a phase-locked loop may lose and regain lock, or a host may discard buffers during transfer. Each state transition can create intervals whose sample indices are not reliably connected by the nominal rate. Writing a continuous file with consecutive sample numbers does not by itself establish continuous physical acquisition. A reliable receiver should retain discontinuity flags, lock-state indicators, hardware timestamps or suitably qualified timing anchors. A later clock calibration cannot fill the samples that failed to arrive or retroactively restore the exact phase relation across a documented loss of lock.

For simultaneous multi-receiver observations, common reference distribution has advantages and dangers. A shared frequency source may reduce relative clock drift, but it also introduces a common-mode dependency. Agreement between two branches is not independent

Copyright 2026, James M. Atkinson

confirmation that the shared reference was correct. Independent comparison to a reference of known uncertainty may be required for an absolute claim. Conversely, two genuinely independent oscillators may drift relative to one another, and a fusion algorithm must estimate that difference rather than interpreting it as a physical delay. The analyst should identify which timing facts are measured independently, which are inherited from a common source, and which are assigned by software convention.

A field survey sometimes requires only coarse time order: one event occurred before another within a broad interval. In that case a small fractional clock error may be immaterial. But a claim that two microsecond pulses originated from a common emitter because they arrived within a few samples demands far more. The relevance of calibration is proportional to the decision the investigator intends to make. A system should not be rejected for failing an irrelevant nanosecond requirement, nor accepted for a nanosecond claim because it passed a one-second timestamp test. As with amplitude, uncertainty must be expressed in units meaningful to the measurand and over the actual observation interval.

I would close by asking that the receiver's state history be treated as part of the evidence. Record the actual reference source, nominal and measured sample rates, calibration epochs, oscillator lock events, power interruptions, gain states, clock-source switching and known transport gaps. A mathematically elegant correction applied to a file whose timebase history is unknowable does not make its timebase historically certain. The available record may still support useful bounded comparisons, and one should make them where justified. But a specific frequency, delay or coincidence estimate should carry the uncertainty of the temporal lattice that gave it meaning.

Copyright 2026, James M. Atkinson

Professor Neyman, may I invite your question concerning how many passing tests are enough to assert a clock remained within specification throughout an unobserved field interval? One further issue is the interface between hardware time and software time. A host operating system may stamp the arrival of a buffer rather than the aperture of its first sample. Variable bus latency, queueing, scheduler interruption or asynchronous disk access can shift that timestamp without altering any analogue sample. Comparing host timestamps against a reference may therefore measure transport behaviour instead of the converter clock. An appropriate test should identify where timestamps originate, whether they are tied to hardware sample counters, and whether correction coefficients remain valid through retuning and power-state transitions. A single clock-frequency check cannot resolve that architecture. The evidence must document which time reference was actually measured and which was merely assumed. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Jerzy Neyman | Peer question 7 to Harry Nyquist

Dr Nyquist, your description suggests a distinction between a tested rate and a claim about all rates during an extended operation. Suppose an instrument passes three clock comparisons before deployment and three after return, yet the search lasted many hours and the system intermittently lost its lock indicator. The engineer wishes to state that the timing error remained below a tolerance at every moment because no endpoint check exceeded it. What probability statement, if any, can legitimately support that claim? A binomial model of independent checks seems plainly inappropriate if the error process is temporally correlated and the most hazardous intervals are precisely those in which records

Copyright 2026, James M. Atkinson

are missing. How should an acceptance programme choose its checks, model its dependencies and communicate a bounded assurance without claiming that observations at a few endpoints prove the entire intervening trajectory? I would also ask how the investigator should treat a calibration schedule chosen after reviewing the error history, since the resulting nominal coverage may no longer possess its advertised frequency properties under the original experimental design. The choice itself can be a form of selection.

Harry Nyquist | Immediate answer to Jerzy Neyman

Professor Neyman, I would reject the universal claim unless the physical apparatus and observation system supplied a justified bound on what could occur between checks. Endpoint agreement constrains the instrument at the times measured. It does not demonstrate the absence of a transient loss of lock or an excursion which subsequently recovered. A stochastic model may assign probabilities to such events, but those probabilities depend upon the assumed process and on records adequate to estimate its behaviour. If missing intervals are disproportionately associated with failures, treating observed passing checks as a random sample will give a misleadingly reassuring result. The selection mechanism must be investigated rather than hidden inside a nominal confidence interval.

A better programme combines continuous or sufficiently frequent state monitoring with controlled challenges of the clock system. Log reference-lock status, power interruptions, operating temperature and buffer-discontinuity events; compare hardware timestamps to a suitable independent reference; and test what happens when the

Copyright 2026, James M. Atkinson

oscillator loses lock or a reference cable is disturbed. Where continuous observation is impossible, report the duration and consequences of the gaps and identify the maximum intervals for which the evidence supports a bounded timing claim. A verified pre- and post-test may still reduce uncertainty about long-term drift, but it cannot eliminate uncertainty about unobserved transients without a defensible process model.

Any statistical statement should name its reference class. The probability that a given check passes under a stable test regime differs from the probability that every instant of a novel field deployment was acceptable. A confidence bound for a Bernoulli detection process is not a bound on the supremum of an unobserved continuous-time clock error unless a model connects them. In the absence of such a model, the correct report may say that all performed checks passed, that certain intervals were covered by continuous lock monitoring, and that remaining intervals have an unresolved timing qualification. Such specificity is more informative than an unsupported assertion of complete stability. It also permits future instrument design to address the actual evidential weakness by measuring what the investigation needs to know. The final report should therefore specify not only an observed error bound but its observation opportunities, invalid intervals and the statistical assumptions by which any extension beyond those opportunities was made. A check conducted after a failure is not equivalent to a check randomly scheduled before the failure was suspected.

Copyright 2026, James M. Atkinson

Ten worked technical applications | Mathematical and forensic validation

Edward Weston, Cross-Peer Question to William Thomson, Baron Kelvin: Lord Kelvin, a field receiver is calibrated at 25 degrees Celsius and used at 50 degrees. When is it appropriate to apply a simple temperature coefficient to its indicated voltage?

William Thomson, Baron Kelvin, Cross-Peer Answer to Edward Weston: Mr Weston, only after the coefficient has been established over the relevant instrument, temperature span, measurement range and thermal history. A first-order correction, Delta V = k Delta T, is an explicit approximation and may fail across power-up transients, ageing, humidity, differential component temperatures or gain-mode changes. Record temperature at the converter, reference source, analogue front end and clock rather than treating ambient air as the single state variable. Include coefficient uncertainty and the uncertainty in temperature measurement. An acceptance campaign ought to cycle upward and downward through the working range, including thermal soak and repeated return to the reference temperature, so hysteresis becomes visible. Report what was measured at the instrument input, rather than equating a software-corrected output with the physical input uncritically. I pass the token to Dr Shewhart for stability controls.

William Thomson, Baron Kelvin, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, a calibration certificate states that the instrument met tolerance last month. What additional evidence is required before one claims the same tolerance during an overnight RF recording?

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart, Cross-Peer Answer to William Thomson, Baron Kelvin: Lord Kelvin, a certificate provides evidence for the stated conditions and date, not immunity from intervening instability. Use independent check standards before and after the acquisition, with recorded gain, reference voltage, temperature, firmware, clock configuration and elapsed operating time. Establish a control chart for each material measurand and investigate excursions rather than changing limits after inspecting the results. Distinguish short-term repeatability, drift, thermal cycling and a discontinuous fault. A pre-and-post check may bound certain changes without identifying precisely when they occurred; a continuous monitor may be needed to assign time locally. If the system lost power or changed operating mode, create a separate record segment rather than treating the entire night as one homogeneous calibration state. I pass the token to Dr Shannon regarding correction of what was actually sampled.

Walter Andrew Shewhart, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, should digitally removing a measured offset and gain error be described as restoring the historical analogue waveform if the converter clipped during the hot operating condition?

Claude Elwood Shannon, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, a calibrated affine correction can recover a useful estimate inside the unsaturated and characterised transfer region. Once the ADC clips, a range of different analogue inputs maps to the same limiting code. Subtracting an offset from those codes cannot recreate the missing amplitude history. Nor does a measured static gain correction independently resolve temperature-dependent nonlinearity, phase response, intermittent reference drift or timing error. Preserve both raw

Copyright 2026, James M. Atkinson

codes and correction coefficients, including the date and applicable state of each coefficient; record saturated samples explicitly rather than smoothing them away. A blind injected waveform at the worst anticipated temperature can demonstrate where the correction remains valid, while negative controls expose software-induced regularities. I yield respectfully to Dr Nyquist on clock-related calibration.

Claude Elwood Shannon, Cross-Peer Question to Harry Nyquist: Dr Nyquist, can a sample count and a nominal 100 MHz clock establish an event timestamp to microsecond accuracy over twelve hours without independent oscillator evidence?

Harry Nyquist, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, not by themselves. If the clock has constant fractional frequency error epsilon, an elapsed time T acquires a first-order scale error approximately epsilon T; a 1 ppm frequency offset corresponds to roughly 43.2 milliseconds in twelve hours, far beyond a microsecond. Real clocks can have temperature drift and wander, so a single constant-error correction may not fit. Document oscillator traceability, timestamp origin, synchronisation events, counter rollover, missing blocks, buffer loss and clock resets. Cross-check periodic reference markers at the input and compare the sample lattice to an independently timed source. Absolute UTC timestamp validity is a separate claim from relative sample spacing. Every correction must carry its uncertainty and method. I respectfully pass the token back to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Distinguished colleagues, the discussion has established that calibration is a set of bounded empirical relations, not an all-purpose declaration of

Copyright 2026, James M. Atkinson

trustworthiness. Mr Weston's insistence upon the physical reference plane prevents the apparently modest but consequential substitution of converter-terminal performance for the performance of an entire receiver front end. Lord Kelvin's thermal account demonstrates why an enclosure-temperature reading is not necessarily the temperature governing every electronic error, and why a correction curve fitted during controlled equilibrium cannot simply be projected across a changing historical environment. Dr Shewhart has shown that a sequence of passing certificates is not the same as evidence of continuing statistical stability, particularly where maintenance, selection and intervention change the population of observations. Dr Shannon has preserved the distinction between correcting a known transfer relationship and manufacturing information no longer present in the retained record. Dr Nyquist has supplied the necessary temporal counterpart: a voltage can be measured accurately while its assigned time or phase relation remains uncertain.

The panel's first finding is therefore definitional. Every substantive accuracy claim must state the measurand, reference plane, stimulus class, time interval, environmental range and configuration state. The word 'calibrated' should never stand alone as the complete evidential predicate. In a receiver investigation, a calibration may establish a voltage-scale comparison at the ADC input but not an antenna-port power estimate; a sampling-rate comparison but not absolute timestamp accuracy; or a static offset correction but not transient waveform fidelity. Such statements are not pedantic restrictions. They identify the physical observations which entitle the investigator to connect a number on a screen to the event being investigated.

Copyright 2026, James M. Atkinson

Second, a temperature coefficient should be treated as a conditional measurement model. A local slope in microvolts per kelvin or parts per million per kelvin may be useful within an experimentally supported range. It does not prove monotonicity, linearity, thermal uniformity or stability across the instrument's life. Where the same sensor records both calibration and field observations, common errors may partially cancel in a temperature difference, yet an imperfect relation between sensor and semiconductor remains. A scientific report should state whether the correction was measured under comparable thermal trajectories, whether intermediate temperatures were validated, and whether an unobserved excursion could have crossed an evidential threshold. Precision in numerical arithmetic does not remove uncertainty in the model from which the arithmetic was derived.

Third, the organisation's evidence-preservation system belongs inside the theory of measurement. An original file hash helps establish the identity of retained bytes; it does not establish the validity of the analogue input inference. A configuration register shows which settings were commanded; it does not prove every physical component responded as intended. A later laboratory calibration can demonstrate present performance; it does not retroactively certify a field recording made before a hardware change. The investigator should preserve raw and corrected samples, calibration coefficients, failed checks, sensor readings, reference-source identities, firmware versions and the specific events by which an operational state changes. Independent reviewers must be able to retrace the correction as well as challenge its legitimacy.

Fourth, the choice of acceptance criterion must follow the claim. An instrument used to identify the presence of intermittent energy may require

Copyright 2026, James M. Atkinson

reliable observation coverage, overload monitoring and bounded false-alarm behaviour. A claim about absolute amplitude needs a traceable amplitude chain and a meaningful uncertainty budget. A claim about phase or time coincidence needs a clock history, jitter characterisation and evidence concerning acquisition gaps. There is no useful universal answer to the question whether a converter is simply 'accurate enough'. An answer without a declared task, tolerance and operating envelope is a slogan, not a scientific finding.

The ten hypothetical calculations illustrate the distinction. Their equations and numbers can be checked, yet every result remains conditional upon assumed coefficients, reference planes, covariance relationships and time-state continuity. A computed 280 parts per million of gain drift has meaning only if the coefficient belongs to the relevant chain. A 0.450-millivolt interpolated correction is an estimate, not a recovered reading from an unmeasured moment. A 3.60-millisecond clock discrepancy matters only in relation to the temporal proposition to be tested. Statistical and mathematical rigour requires these qualifications to remain visible beside the result.

The panel retains several unresolved matters. A unique historical thermal field may be unknowable. A short sequence of passing verification tests may not exclude a transient failure between tests. An impressive reduction in fit residuals may result from model selection rather than improved predictive validity. And a receiver-generated line may remain observationally equivalent to an external emission under the limited tests available. These limits do not require abandoning measurement. They require designing

Copyright 2026, James M. Atkinson

experiments whose competing explanations make different predictions and stating which propositions survive the challenges actually performed.

Our production rule shall accordingly be to preserve the past state, verify the present state, disclose the interval between them and refuse to substitute one for another. With this discipline we may place evidence from different receivers into a coherent scientific account without promising certainty that the record cannot supply. The next question shall consider the conditions under which a carefully chosen sampling band may be translated into a different frequency representation without losing the ability to distinguish the true source from an alias. Dr Nyquist, and the colleagues who have challenged these conclusions, I thank you for passing the discussion with its uncertainties intact.

Ten worked engineering applications | Question 030

Application 1. Temperature-driven offset change

A hypothetical converter has an empirically verified offset-drift coefficient k_b = 1.6 microvolts per kelvin over the temperature interval relevant to a particular configuration. Its initial temperature is T_0 = 25 degrees Celsius and the later temperature is T_1 = 50 degrees Celsius. Define $\Delta T = T_1 - T_0$ = 25 kelvins. Under the explicitly assumed local linear model, the predicted offset change is $\Delta b = k_b \Delta T$ = (1.6 microvolts/kelvin)(25 kelvins) = 40 microvolts. Relative to a stated 1.0-volt input range, the change is 40 parts per million of that range. This is a predicted change, not a proof of the converter's actual state at every intermediate moment. If the 1.6 microvolt coefficient was merely a typical component value, the computed 40 microvolts is an engineering illustration, not an empirically validated uncertainty bound. A forensic comparison would retain the observed offset at the relevant temperature and disclose whether the sensor tracked the die or an external surrogate.

Application 2. Gain drift and reference-plane voltage

Assume a dimensionless gain coefficient k_g = 8 parts per million per kelvin, a temperature excursion of ΔT = 35 kelvins, and an input V = 2.000 volts at the calibrated reference plane. First compute the fractional gain change: $\Delta a/a = (8 \times 10^{-6}$ per kelvin)(35 kelvins) = 280×10^{-6}. The equivalent voltage-scale change is $\Delta V = V(\Delta a/a)$ = (2.000 volts)(0.000280) = 0.000560 volts, or 560 microvolts. The model predicts 280 ppm relative gain change. It does not say whether the physical cause is converter gain, reference voltage, or an amplifier outside the

Copyright 2026, James M. Atkinson

converter. Nor does it establish that 2.000 volts was applied at the correct plane during the historical investigation. A correction is appropriate only if the coefficient describes the chain, state and temperature trajectory actually being interpreted.

Application 3. Combined offset and gain changes

For a hypothetical 0.200-volt input, assume a relative gain coefficient of 12 ppm per kelvin, an offset coefficient of 2 microvolts per kelvin, and DeltaT = 30 kelvins. The fractional gain change is (12 x 10^-6)(30) = 360 ppm. The gain-related output change is (0.200 volt)(360 x 10^-6) = 72 microvolts. The offset contribution is (2 microvolts/kelvin)(30 kelvins) = 60 microvolts. Under a linear additive model and with no other effects, the total change is 132 microvolts and the later indicated equivalent is 0.200132 volt. These terms have different physical meanings: offset is present even for zero input, whereas gain error scales with input. Testing at only one nonzero amplitude cannot in general separate them. A two-point or multi-point comparison is therefore needed before claiming that the change is uniquely attributable to one coefficient.

Application 4. Reference-source thermal drift

Suppose the conversion scale depends upon a 2.000-volt reference whose assumed relative coefficient is k_r = 4 ppm per kelvin, and the reference itself experiences a 40-kelvin rise. The predicted relative reference change is (4 ppm/kelvin)(40 kelvins) = 160 ppm, equivalent to 0.000160 as a fraction. The absolute reference shift is (2.000 volts)(0.000160) = 0.000320 volt, or 320 microvolts. In many ADC transfer models an increased reference can change the indicated code for a fixed

Copyright 2026, James M. Atkinson

input in the opposite direction from an increased analogue gain; the sign must be derived from the actual transfer equation. Consequently a magnitude calculation alone should not be entered as a signed correction. The examiner should document whether the measured drift figure belongs to the internal reference, an external standard, or a composite converter-system coefficient.

Application 5. Uncertainty from temperature sensing

Assume the output estimate is approximately proportional to gain, with input V = 1.500 volts and local gain coefficient $k_g = 8 \times 10^{-6}$ per kelvin. A temperature sensor has standard uncertainty u(T) = 0.4 kelvin. The first-order sensitivity of the indicated voltage to temperature is $c_T = V k_g$ = (1.500 volts)(8 x 10^-6 per kelvin) = 12 microvolts per kelvin. The standard uncertainty contributed by temperature sensing is $u_T(V) = |c_T| u(T)$ = (12 microvolts/kelvin)(0.4 kelvin) = 4.8 microvolts. This is only one uncertainty term. It excludes error in k_g, residual curvature, uncertainty about whether the sensor represents the relevant component, and covariance with reference drift. If an analyst quotes 4.8 microvolts as the total calibration uncertainty, the omitted terms may make the report misleadingly precise.

Application 6. Covariance of gain and reference uncertainty

Let two relative standard uncertainties be u_1 = 20 ppm and u_2 = 15 ppm, with correlation coefficient rho = +0.6. For a model in which the two contributions enter with the same signed sensitivity, the combined relative variance is $u_c^2 = u_1^2 + u_2^2 + 2 \rho u_1 u_2$. Substitution gives 400 + 225 + 2(0.6)(20)(15) = 985 ppm squared. Hence u_c = sqrt(985)

Copyright 2026, James M. Atkinson

ppm = approximately 31.38 ppm. If the terms were independent the result would be sqrt(400+225) = 25 ppm. Their shared physical reference makes the independent treatment inappropriate under the stipulated correlation. Conversely a model in which one coefficient enters with the opposite sign changes the covariance term's sign. Covariance is therefore a property of the actual measurement equation and joint evidence, not a decorative general uncertainty allowance.

Application 7. Sample-clock frequency error over an observation

Suppose the actual clock frequency is f_actual = f_nominal(1 + epsilon), with positive fractional frequency error epsilon = 2 x 10^-6. Let tau_nominal = 1,800 seconds be the elapsed duration inferred by dividing the retained sample count by the nominal sample rate. The corresponding actual duration is tau_actual = tau_nominal/(1+epsilon) = approximately 1,799.9964000072 seconds. The nominal timing calculation therefore overstates elapsed time by approximately 0.003599993 second, or 3.60 milliseconds. The common small-error approximation epsilon tau = (2 x 10^-6)(1,800 seconds) gives the same result at this precision. This calculation assumes a constant fractional error and no missing samples. If the oscillator lost lock or buffers were dropped, a constant-rate model cannot bound the historical gap without additional observations.

Application 8. Expanded uncertainty and a stated acceptance threshold

Consider a hypothetical corrected residual error e = 3.800 millivolts. Suppose two independent standard uncertainty components are u_1 =

Copyright 2026, James M. Atkinson

0.200 millivolt and u_2 = 0.400 millivolt. Under the independent model, the combined standard uncertainty is u_c = sqrt(0.200^2 + 0.400^2) millivolt = sqrt(0.20) millivolt, approximately 0.4472 millivolt. For a stipulated coverage factor k = 2, the illustrative expanded uncertainty is U = 2u_c = 0.8944 millivolt. If a predeclared symmetric residual limit is 5.000 millivolts, a conservative acceptance rule requiring |e| + U <= 5.000 yields 3.800 + 0.8944 = 4.6944 millivolts, inside the limit. This acceptance is conditional upon the stipulated uncertainty model and decision rule. A different coverage interpretation, significant model bias or a larger drift contribution may change the conclusion. Passing one residual rule does not certify every converter specification.

Application 9. Interpolation of measured thermal correction

Assume a calibration sequence has measured an offset correction of 0.000 millivolt at 20 degrees Celsius and +0.900 millivolt at 50 degrees Celsius, for the same configuration and input test. The line joining those points has slope k = (0.900 - 0.000)/(50 - 20) = 0.030 millivolt per degree Celsius. At 35 degrees Celsius, linear interpolation predicts 0.000 + (35 - 20)(0.030) = +0.450 millivolt. The arithmetic is determinate; the uncertainty of the prediction is not. Validation measurements at intermediate temperatures, repeated heating and cooling cycles, sensor uncertainty and a check for hysteresis are needed before the line can be described as a reliable correction model. An interpolated value can be an estimate even where an unmeasured transient or nonlinear segment makes its historical accuracy doubtful.

Application 10. Clock scale over a longer exposure

Copyright 2026, James M. Atkinson

For a distinct case, suppose a nominally continuous acquisition lasts tau = 7,200 seconds according to the receiver's nominal clock, and the actual clock differs by a constant positive fractional error epsilon = 1 x 10^-6. The first-order timing discrepancy is epsilon tau = (1 x 10^-6)(7,200 seconds) = 0.0072 second, or 7.2 milliseconds. The exact discrepancy in the stated positive-error model is tau - tau/(1+epsilon), approximately 7.1999928 milliseconds. If the issue concerns whether two events coincide within one second, this error may be immaterial; if the issue concerns the phase alignment of microsecond transients across independent receivers, it may be decisive. The tolerance must therefore come from the inferential task, not from an impressive clock specification detached from the question being asked.

QUESTION 031

Copyright 2026, James M. Atkinson

When is bandpass sampling safe, and what must the analogue filter guarantee?

Fictional educational reconstruction. All attributed exchanges in this discussion are newly authored teaching dialogue, not historical quotations, authentic transcripts, testimony or evidence that deceased scholars evaluated modern receiver systems.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 031 asks: When is bandpass sampling safe, and what must the analogue filter guarantee? A receiver screen may present a luminous ridge or a tidy numerical column, yet the instrument has performed a particular physical operation rather than delivered a self-explanatory verdict. The proposition under investigation is the conditions for safe bandpass sampling and the analogue filtering it presupposes. Our primary observation is folded sampled spectra of an intentionally isolated higher-frequency band; by contrast, what remains unseen is other radio-frequency bands which could alias into exactly the same digital interval. Those objects occupy different places in an evidential chain. We must not allow a numerical result to migrate from one reference plane to another without an explanatory transfer function and its uncertainty. This roundtable therefore examines what the instrument could establish, what it could not, and which additional experiment would discriminate between material alternatives.

Bandpass aliases require analogue exclusion of competing zones. Bandpass sampling intentionally permits an RF interval to map into a lower digital frequency interval. For a real converter sampled at 40 megasamples

Copyright 2026, James M. Atkinson

per second, tones at 90 and 100 megahertz map, by simple folding, to 10 and 20 megahertz, but so do other RF tones in different alias zones. The mapping does not identify the source band uniquely. An analogue preselector must reject those alternative zones sufficiently to make the particular desired interpretation defensible, taking account of filter tolerance and strong blockers. Check both band edges for alias orientation and for coincidence with the Nyquist boundaries; the nominal 100-megahertz edge here lies exactly at a folding boundary and is unsuitable without guard-band analysis. A swept blocker test outside the desired passband is more probative than the sample-rate specification by itself. The reconstructed panel shall test this particular proposition rather than rest on a generic contrast between an observed spectral peak and an imagined emitter. The experiment must be described with enough information to reveal when the inference would fail.

The estimand in this discussion concerns folded sampled spectra of an intentionally isolated higher-frequency band; it is not interchangeable with other radio-frequency bands which could alias into exactly the same digital interval. We shall require an instrument-side prediction for each proposed explanation before assigning a source. The controlling measurement is a swept blocker map across all relevant Nyquist zones with measured analogue stop-band rejection. A claim drawn from that comparison has to carry its actual uncertainties: RF passband edges, sampling frequency, alias-zone parity, filter transition width, and required blocker rejection. Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. An input band can fold into a lower sampled interval with reversal of spectral order according to Nyquist-zone

Copyright 2026, James M. Atkinson

parity. An undersampling receiver must have analogue input bandwidth sufficient to pass the desired RF band before conversion. Where competing paths remain observationally indistinguishable, the proper result is a bounded class of explanations rather than a narrative of certainty. A quantitative result must identify the physical reference plane, bandwidth and operating state in the particular experiment, and the preserved observations must be sufficiently complete for an independent laboratory to reach the same conditional finding.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal contribution 1: Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas.

Bandpass sampling can be entirely sound when the analogue passband occupies an unambiguous sampling zone and the converter's actual sample rate is known. The decisive condition is not that the RF centre frequency lies below half the sample rate; it is that the admitted band and all materially strong unwanted bands map without harmful overlap into the chosen digital interval. I would write out the aliases of both band edges and test possible spectral inversion before building the receiver. Guard bands must allow for filter transition width, clock tolerance and frequency drift. A preselector specified by its nominal three-decibel bandwidth will not establish that an adjacent Nyquist zone is sufficiently suppressed. The analogue filter's stopband must be measured at the powers that the receiver will encounter, particularly where its rejection protects a weak signal from a strong unrelated service. A correct alias equation does not identify which of several potential RF inputs supplied the recorded digital component.

In this physical path examination of Question 031, the decisive claim is that bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. Bandpass sampling intentionally permits a narrow RF band above the first Nyquist interval to fold into a lower sampled frequency range. This is mathematically legitimate only when the complete analogue occupied spectrum and the sampling zone are controlled. Adjacent RF bands may fold to the same digital frequencies, often with reversed spectral orientation; thus a clean digital trace cannot certify that the desired physical band was the only contributor.

Copyright 2026, James M. Atkinson

A measured, sufficiently selective analogue filter is part of the sampling theorem's practical implementation, not an optional accessory to digital reconstruction. A useful falsification proceeds from the actual controversy: bandpass aliases require analogue exclusion of competing zones. Bandpass sampling intentionally permits an RF interval to map into a lower digital frequency interval. For a real converter sampled at 40 megasamples per second, tones at 90 and 100 megahertz map, by simple folding, to 10 and 20 megahertz, but so do other RF tones in different alias zones. The mapping does not identify the source band uniquely. An analogue preselector must reject those alternative zones sufficiently to make the particular desired interpretation defensible, taking account of filter tolerance and strong blockers. Check both band edges for alias orientation and for coincidence with the Nyquist boundaries; the nominal 100-megahertz edge here lies exactly at a folding boundary and is unsuitable without guard-band analysis. A swept blocker test outside the desired passband is more probative than the sample-rate specification by itself. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Specify the intended RF lower and upper band edges and an actual sample rate. Compute the folded intervals and their spectral orientation before acquiring data. Inject known signals in the intended band and in each material competing sampling zone; measure the preselector's attenuation at the converter plane and compare the resulting aliases. Repeat at a second sample rate which preserves desired reception but changes the competing fold pattern, while confirming that the analogue filter itself has not been moved or retuned. I would take RF lower and upper

Copyright 2026, James M. Atkinson

edge, sample rate, zone parity, alias frequency, guard width and blocker rejection as separate instrument readings, rather than asking one waterfall pixel to act as a complete account of the network. The first challenge is measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones. That intervention must be performed at a recorded connector or measurement reference plane, with its source impedance and stimulus spectrum measured there. To isolate the mechanism, the laboratory should repeat the baseline while disabling the particular path implicated by this proposition: Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. A response consistent with odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone would favour the through-path explanation only over the alternatives that were actually challenged. By contrast, an unexplained residue after that path has been isolated warrants a search for other coupling routes, load-dependent impedance, or internal generation. The publication record should retain both the original and challenged sample streams, not just screenshots selected after the event, and should expressly withhold emitter attribution if the physical path remains ambiguous.

The circuit cannot be judged from its final trace alone. An RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. A meaningful bench experiment begins with a source whose power, impedance and spectrum are known at the input connector. I would first inventory the physical elements implicated by the wanted band may occupy the designed alias

Copyright 2026, James M. Atkinson

mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component, and measure their behaviour separately before reconnecting the assembled system. Nyquist's work makes the admitted frequency region and the actual sampling or noise bandwidth essential conditions of the proposed inference. It is therefore material to establish RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection rather than infer them from a single scalar output. The limiting test is concrete: Measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones. If the intervention produces odd/even nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted rf tone, the mechanism gains support within the demonstrated range. A failure would be equally consequential, because it would show that the simplified transfer-path account omits an operative coupling or memory effect. I would not interpret a spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target as a new transmitter before challenging the most economical instrumental explanation. Bandpass undersampling is possible only when unwanted analogue bands are excluded with adequate selectivity. Professor Tukey, please take the floor and question any spectrum plot offered without that filtering evidence.

John Wilder Tukey | Peer question 1 to Harry Nyquist

Harry Nyquist, may I test the exact physical inference in your account of an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone? The proposed mechanism appears plausible only if changes after measure

Copyright 2026, James M. Atkinson

passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones are compared with a stable reference condition. Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. If an independent stimulus gives a different path attenuation from the ambient feature, how would you exclude leakage downstream of the test port? Would you retain both the failed challenge and the successful one, and how would the final evidential wording distinguish a rejected signal-path hypothesis from a proven external transmitter? I ask for the precise change in RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection which would settle that narrower claim, rather than a visual impression of improvement.

Harry Nyquist | Immediate answer to John Wilder Tukey

Dr Tukey, a reversed-looking spectrum is not by itself evidence of a particular RF zone. I would first prove that the anti-alias network rejects other zones under actual blocker power, then move the sample rate by a declared increment and test the predicted frequency and orientation change. The observations would support a bounded sampling-zone assignment, conditional upon clock calibration and analogue rejection. The correct counterfactual begins with two models capable of producing the original data. I would write their incompatible predictions before performing the intervention, then change one declared physical variable while recording the remainder. The test must contain a return-to-baseline stage and must preserve inconvenient outcomes. For Question 031, the specific physical candidate is spectral replication at integer multiples of the sample

Copyright 2026, James M. Atkinson

frequency, including spectral inversion. The unresolved physical pathway is material: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. The retained record permits a conditional claim about RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection, but cannot alone resolve a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

I take John Wilder Tukey's question to concern the RF boundary, not the elegance of a plotted trace. In the proposed setup, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. I would first inject the known stimulus and verify its amplitude at the entrance to the claimed path, then measure the response with the suspected coupling route enabled and isolated. The required observations are RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection; they should be retained as instrument readings with calibration information, rather than displayed only as a difference image. Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. A stable residual after the reference path is disabled calls for examining bypass or internal generation. The proposed discriminating operation is measure passband edges and rejection,

Copyright 2026, James M. Atkinson

map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones, and only a response matching odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone would support the particular through-path mechanism. If it does not, I would withdraw that mechanism before offering any inference about an external source.

I would mark the RF input plane in the drawing and retain the two measured responses, one before intervention and the other after a calibrated return. Measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing nyquist zones. If the response instead remained fixed when the nominal through path was strongly attenuated, the bypass explanation would deserve priority. This concerns RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection, not a conjecture about the operator's intentions.

Richard Wesley Hamming | Peer question 2 to Harry Nyquist

I appreciate your explanation, Harry Nyquist. How would your conclusion survive a deliberately independent test of a spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target? A second receiver might share more of the supposed evidence than its separate enclosure suggests. An input band can fold into a lower sampled interval with reversal of spectral order according to Nyquist-zone parity. Please identify the cable splitter, oscillator, power supply and software detector dependencies before treating concordant traces as independent.

Copyright 2026, James M. Atkinson

Suppose the original receiver changes its gain history during the comparison. How would you interpret agreement on a strong test tone but disagreement on a short weak burst? Would you require a before-and-after calibration using RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection and document which differences remain unexplained? Would you also state what observed change in RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection would invalidate the preferred account, and which aspect of measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing nyquist zones would make that negative result independently repeatable?

Harry Nyquist | Immediate answer to Richard Wesley Hamming

Richard Wesley Hamming, I accept the force of your common-mode corroboration objection. Corroboration must be assessed at the level of causal dependencies, not the number of instrument front panels. We should trace the common antenna, clock, gain and software paths and identify which fault modes they share. An independent receiver improves the evidence only to the extent that its pathway breaks a material common cause. For Question 031, the specific physical candidate is spectral replication at integer multiples of the sample frequency, including spectral inversion. The unresolved physical pathway is material: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. The retained record permits a conditional claim about RF lower and upper edge,

Copyright 2026, James M. Atkinson

sample rate, zone parity, alias frequency, guard width and blocker rejection, but cannot alone resolve a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Richard Wesley Hamming has identified a possible common dependency. It matters here because the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. I would draw the actual distribution network before collecting new corroborating evidence, marking where two receivers share signal, power or time references. An input band can fold into a lower sampled interval with reversal of spectral order according to Nyquist-zone parity. An independent test must alter a physical dependency, not merely open another software window. The relevant controlled alternative remains the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component; I would challenge it with measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones. Two responses consistent with odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone would be informative only after shared errors and the state history had been assessed. Differences at low levels or during overload should be published as differences, not averaged away into a favourable mean. I

Copyright 2026, James M. Atkinson

would give the examiner both the dependency diagram and the unaltered records.

The second receiver cannot be designated independent merely by giving it a separate chassis. I would inspect the shared causal pathways and change the reference source first. In this setting, the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. A discordant measurement would then be interpreted by tracing that difference through RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection; an agreement lacking such a dependency analysis is weak corroboration.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal contribution 2: An input band can fold into a lower sampled interval with reversal of spectral order according to Nyquist-zone parity.

Sampling a restricted high-frequency band at a modest numerical rate imposes strict demands on the acquisition architecture. I would test the converter's analogue input bandwidth and track-and-hold response at the actual RF frequency, rather than infer capability from the advertised sample rate. Two tones from different Nyquist zones can fold into the same output bin if the preselector admits both; the digital channeliser cannot undo their prior collision. A frequency sweep through the band edges should reveal the inversion sense and any loss of amplitude caused by the analogue aperture. In a practical superheterodyne receiver there may be further image responses before the direct RF sampling stage, so the complete mixing plan must be documented. The proper experiment combines a calibrated RF source, an independent frequency counter and a measured preselector response, with gain and clock settings retained. A strikingly clean digital spectrum is useful only after these analogue boundaries have been challenged.

In this control and stability examination of Question 031, the decisive claim is that an input band can fold into a lower sampled interval with reversal of spectral order according to Nyquist-zone parity. State transitions, feedback and memory make identical nominal inputs yield different sampled outputs. A proper challenge records the chronological order of settings and waits for characterised settling before drawing comparisons. A useful falsification proceeds from the actual controversy: bandpass aliases require analogue exclusion of competing zones. Bandpass sampling

Copyright 2026, James M. Atkinson

intentionally permits an RF interval to map into a lower digital frequency interval. For a real converter sampled at 40 megasamples per second, tones at 90 and 100 megahertz map, by simple folding, to 10 and 20 megahertz, but so do other RF tones in different alias zones. The mapping does not identify the source band uniquely. An analogue preselector must reject those alternative zones sufficiently to make the particular desired interpretation defensible, taking account of filter tolerance and strong blockers. Check both band edges for alias orientation and for coincidence with the Nyquist boundaries; the nominal 100-megahertz edge here lies exactly at a folding boundary and is unsuitable without guard-band analysis. A swept blocker test outside the desired passband is more probative than the sample-rate specification by itself. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

I would concentrate on the chronology of state changes implied by a spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target. A receiver may move between apparently similar configurations while its mixer, analogue gain control, triggering, or filter memory is still settling. Accordingly, I propose three logged epochs with a fourth return epoch: initial operating state; a deliberate intervention testing the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component; a challenge in which only the suspected mechanism is restored; and an independently checked return to the starting condition. The engineering note an input band can fold into a lower sampled interval with reversal of

Copyright 2026, James M. Atkinson

spectral order according to nyquist-zone parity. has a consequence for the observation schedule: changes made during uncertain recovery cannot simply be scored as absence. For each epoch the operator should preserve time stamps, acquisition validity, applied gain, test-source state and RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection. If the candidate disappears in a retuning interval yet returns when the state is held fixed, neither spontaneous transmitter silence nor intentional evasion follows automatically. The experiment would succeed only if the proposed causal account explains both the supporting and the contrary transitions with no unreported change of instrumental state.

The state trajectory matters more than a nominal performance figure. In the scenario, a spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target. A technician who adjusts the receiver to improve an individual display changes the experiment while it is in progress. Shannon’s information-theoretic question concerns which distinguishable input states survive acquisition, quantisation, selection and subsequent representation. I would specify an ordered sequence of initial state, controlled perturbation, return state and independent reference capture. Our central rival is specific: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. This predicts a response which should be tested against odd/even nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted rf tone. An operator may be tempted to interpolate a line between two clean sweeps and call the resulting curve continuous; that

Copyright 2026, James M. Atkinson

presentational step does not restore measurements discarded during retuning. Where a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response, the correct claim must name the operational states and the evidence available in each. Aliasing can reverse spectral order, so the sign convention and original passband must survive reprocessing. Dr Pearson, I invite your examination of a frequency assignment built from incomplete mapping metadata.

Egon Sharpe Pearson | Peer question 3 to Claude Elwood Shannon

Claude Elwood Shannon, your calibration argument invites a question about reference planes, especially because a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. The reference stimulus and the unknown emission need not occupy the same physical regime. An undersampling receiver must have analogue input bandwidth sufficient to pass the desired RF band before conversion. I would question a calibration performed at one amplitude if the actual uncertainty is dominated by overload, temperature or filter mismatch. When a spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target, which of the reported quantities represents a directly measured state and which is extrapolated? Could you state how a second operator would repeat measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones without relying upon the original screenshot or undocumented threshold

Copyright 2026, James M. Atkinson

settings? The question concerns the traceability of the inference, not the operator's good faith.

Claude Elwood Shannon | Immediate answer to Egon Sharpe Pearson

Egon S. Pearson, I accept the force of your statistical sampling design objection. The estimand has to be defined before the confidence calculation. A post-alarm follow-up is legitimate but has a different sampling frame from the original scan. For Question 031, the specific physical candidate is spectral replication at integer multiples of the sample frequency, including spectral inversion. The unresolved physical pathway is material: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. The retained record permits a conditional claim about RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection, but cannot alone resolve a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

To address Egon S. Pearson's concern about calibration, the relevant measurand must be fixed at the start: RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection. An undersampling receiver must have analogue input bandwidth sufficient to pass the desired RF band before conversion. I would not carry a correction obtained at one frequency

Copyright 2026, James M. Atkinson

or amplitude into another regime without a documented sensitivity test. An appropriate reference check would be measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones, with before-and-after values of RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection. If the instrument behaves as predicted, then odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone; if it does not, the uncertainty budget must include the unresolved deviation. It would be misleading to assign a small standard uncertainty merely because the digitiser reports many decimal places. The defensible result is a qualified statement of the measurement at the stated reference plane, with systematic components and operating limits shown separately.

The sampling plan should be registered before the confirmatory run and should retain the non-detection intervals. A spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target. I would calculate separate conditional rates in stable operating strata and avoid multiplying correlated events into fictitious independent trials. The confidence statement must describe the tested opportunities, not every unobserved period in the room.

Ralph Vinton Lyon Hartley | Peer question 4 to Claude Elwood Shannon

There is an inferential difficulty, Claude Elwood Shannon: the wanted band may occupy the designed alias mapping, but an insufficiently

Copyright 2026, James M. Atkinson

rejected adjacent zone can create an indistinguishable digital component. The population of admissible observations needs to be fixed before any confidence argument. In this situation, a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. Selection of the most promising time window after reviewing hundreds of alternatives changes the experiment. A strong out-of-band signal which leaks through filtering may alias directly on top of the desired weak waveform. What is your unit of independent observation, and how will you treat censored records or correlated repeats of one event? I would welcome a statement of the alternative hypothesis, the observation which counts against your claim, and the sensitivity of the conclusion to plausible dependence among samples. Would you also state what observed change in RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection would invalidate the preferred account, and which aspect of measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing nyquist zones would make that negative result independently repeatable?

Claude Elwood Shannon | Immediate answer to Ralph Vinton Lyon Hartley

Ralph V. L. Hartley, I accept the force of your physical transfer and frequency objection. I would not infer the original frequency solely by reading the stored digital coordinate. First identify the active conversion, filter, and sampling states, then predict how each hypothesised analogue input maps into the output. A swept reference

Copyright 2026, James M. Atkinson

signal can test the path, while a second conversion scheme helps separate otherwise coincident aliases and mixer products. For Question 031, the specific physical candidate is spectral replication at integer multiples of the sample frequency, including spectral inversion. The unresolved physical pathway is material: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. The retained record permits a conditional claim about RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection, but cannot alone resolve a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The statistical objection raised by Ralph V. L. Hartley is important precisely because a spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target. I would distinguish trials selected in advance from those added after an unexpected peak appeared. A strong out-of-band signal which leaks through filtering may alias directly on top of the desired weak waveform. For the formal comparison, the exposure window, detector threshold and admissible invalid states should be specified before the outcome is known. A subsequent test can legitimately examine measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones, but it must be labelled a validation phase rather than

Copyright 2026, James M. Atkinson

merged into an apparently random original sample. The rival mechanism is the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component; its prediction should be recorded alongside odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone. If both models yield the same recorded measurements, the causal question remains unidentified even if a confidence interval for the measured statistic becomes very narrow.

The quantity has to remain attached to the physical operation defining it. A successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. The protocol should therefore carry units, terminal conditions, calibration factors and uncertainty to the same reference plane. In particular, a receiver which preserves a 15 mhz-wide wanted band must still reject other frequency intervals that fold upon those same sampled frequencies. A second examiner can then determine whether the competing explanations give genuinely different measurements.

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong | Principal contribution 3: An undersampling receiver must have analogue input bandwidth sufficient to pass the desired RF band before conversion.

It is tempting to regard a recorded alias as a compact encoding of the high-frequency input. That view is legitimate only while the analogue admissibility conditions restrict the set of possible sources. If the preselector passes two disjoint RF regions that map to the same discrete-time frequency, the resulting sample sequence generally cannot distinguish them without further evidence. A formal reconstruction algorithm may return one answer because it assumes that only the wanted band was present. The algorithm has then enforced a hypothesis, not discovered the true external frequency from the digits. I would retain the actual sample-rate measurement, filter identification and any out-of-band challenge results with the I/Q archive. Where the acquisition uses real sampling, spectral inversion and conjugate symmetry also affect how the displayed sign of frequency is interpreted. These are questions about the mapping from RF to data, and their answers cannot be recovered from a screenshot that omits acquisition metadata.

In this operational measurand examination of Question 031, the decisive claim is that an undersampling receiver must have analogue input bandwidth sufficient to pass the desired RF band before conversion. A numerical result has little evidential force unless its calibration chain and uncertainty components are attached to that operational definition. A useful falsification proceeds from the actual controversy: bandpass aliases require analogue exclusion of competing zones. Bandpass sampling intentionally permits an RF interval to map into a lower digital frequency interval. For a

Copyright 2026, James M. Atkinson

real converter sampled at 40 megasamples per second, tones at 90 and 100 megahertz map, by simple folding, to 10 and 20 megahertz, but so do other RF tones in different alias zones. The mapping does not identify the source band uniquely. An analogue preselector must reject those alternative zones sufficiently to make the particular desired interpretation defensible, taking account of filter tolerance and strong blockers. Check both band edges for alias orientation and for coincidence with the Nyquist boundaries; the nominal 100-megahertz edge here lies exactly at a folding boundary and is unsuitable without guard-band analysis. A swept blocker test outside the desired passband is more probative than the sample-rate specification by itself. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

Bandpass sampling is legitimate only when the admitted analogue spectrum and sampling frequency produce a non-overlapping image in the desired digital band. The usual sampling theorem does not imply that an arbitrary wide RF passband can be sampled at a low rate simply because its occupied signal is narrow. Images of the selected band recur around multiples of the sample frequency, and undesired bands can fold directly on top of the wanted information unless the pre-sampling filter rejects them sufficiently. The validation should therefore calculate all relevant alias intervals, not only the nominal centre-frequency translation, and include tolerances for clock drift, filter skirt, temperature and strong out-of-band transmissions. Sweep a calibrated tone across both the wanted band and adjacent alias-prone bands, recording where its digital image appears. A correct frequency conversion for the wanted tone is necessary but

Copyright 2026, James M. Atkinson

insufficient; the test must show that plausible external blockers cannot enter the same discrete-time bins at misleading amplitudes. Accordingly, the laboratory record for Question 031 should include the trial configuration, the reference-plane photograph or schematic, the raw measurement and the adverse-control outcome before the final inferential wording is selected. The specific instrument-state record must be retained with the sample archive so that an independent examiner can reproduce the indicated difference without relying upon a coloured display alone.

We ought to distinguish a property of an apparatus from the definition of the quantity purportedly measured. A successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. Armstrong’s receiver engineering points to actual conversion products and oscillation conditions rather than abstract spectral indications; the crucial question is where the energy first appears. The first page of the laboratory record should declare the geometry, the conversion of instrument readings into the stated units, and the conditions that would invalidate that conversion. In the proposed survey, an rf band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted nyquist zone; the actual observation is therefore not a timeless property of the unseen source, but the result of an implemented operation. One might compare RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection under two independently calibrated reference conditions, recording mismatch, temperature and sample-clock validity where appropriate. A decision should specify whether it concerns an instantaneous output, an average over admitted time, or a bound on a latent physical parameter. The

Copyright 2026, James M. Atkinson

illustrative case is instructive: A receiver which preserves a 15 MHz-wide wanted band must still reject other frequency intervals that fold upon those same sampled frequencies. It demonstrates the danger of transferring a result across domains in which the defining measurement has changed. A sampler advertised for a high clock rate may still lack the analogue input bandwidth required at the RF frequency of interest. Dr Turing, I pass the floor to inspect the boundary between that physical limitation and digital reconstruction.

Alan Mathison Turing | Peer question 5 to Edwin Howard Armstrong

Edwin Howard Armstrong, I should like to examine what the recorded data actually preserve when an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. The physical input and the retained numerical array are not interchangeable things. Sampling-clock tolerance and filter transition regions must be considered as part of the safety margin. If an analogue front end rejected or clipped the relevant portion before quantisation, post-processing cannot determine the original waveform uniquely. With the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component as a live possibility, what tests can be performed on stored samples and which require a new controlled acquisition? Will you preserve unprocessed records, firmware versions, time bases and the selection rule so that another investigator can distinguish the evidence from a reconstruction? Would you also state what observed change in RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection would

Copyright 2026, James M. Atkinson

invalidate the preferred account, and which aspect of measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing nyquist zones would make that negative result independently repeatable?

Edwin Howard Armstrong | Immediate answer to Alan Mathison Turing

Alan Mathison Turing, I accept the force of your operational calibration and overload objection. The laboratory must challenge the actual operating regime, including strong and weak simultaneous inputs, short bursts and recovery intervals. A gentle calibration source can establish an initial transfer relation, but the relation must be checked near overload and across the dynamic states used in the survey. Its residual uncertainty then belongs in the reported conclusion. For Question 031, the specific physical candidate is spectral replication at integer multiples of the sample frequency, including spectral inversion. The unresolved physical pathway is material: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. The retained record permits a conditional claim about RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection, but cannot alone resolve a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I agree with Alan Mathison Turing that a stored sample file is evidence of a finite acquisition, never a reproduction of the entire analogue environment. A successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. I propose separating acquired information from model-dependent reconstruction. Sampling-clock tolerance and filter transition regions must be considered as part of the safety margin. A later algorithm can recalculate a threshold for samples which were retained, but not recover an interval discarded at the analogue input or omitted by the acquisition policy. The discriminating record would include RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection and a fresh trial in which the operator measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones. If that trial demonstrates odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone, the interpretation may be narrowed; it still cannot turn the original unrecorded interval into evidence of a unique historical waveform. I would therefore preserve all conflicting reconstructions and state exactly where the retained samples cease to support an inference.

I agree that the archive needs a witness for what the software discarded. Save raw acquisitions over independently chosen control intervals, plus executed settings and invalidity masks. The concrete challenge should include measure passband edges and rejection,

Copyright 2026, James M. Atkinson

map aliases across sample-rate steps, and inject test blockers in competing nyquist zones. Without that witness, a clean thresholded display may conceal a failure in the acquisition itself.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal contribution 4: A strong out-of-band signal which leaks through filtering may alias directly on top of the desired weak waveform.

The preselector's job is more demanding than placing a smooth hump around a preferred RF band. Its attenuation must protect against particular alias collisions, and its insertion loss must be included in the receiver sensitivity budget. I would build a zone-by-zone table of unwanted frequencies whose aliases land on the wanted spectrum, then measure rejection at those frequencies with the converter operating at representative levels. A filter that passes a blocker at one such frequency may allow the converter to produce a convincing false target even if the signal chain remains perfectly linear. Resonant-component drift, source mismatch and finite stopband rejection need to be tested across temperature and production tolerances. If a selected filter is substituted during an investigation, the result must be accompanied by an updated frequency map and calibrated reference-plane comparison. It is the complete analogue-and-sampling transfer relationship, not the selected sample rate alone, that defines the measurement's admissible frequency claims.

In this information retention examination of Question 031, the decisive claim is that a strong out-of-band signal which leaks through filtering may alias directly on top of the desired weak waveform. One should specify which information has been retained and which hypotheses remain observationally indistinguishable. A useful falsification proceeds from the actual controversy: bandpass aliases require analogue exclusion of competing zones. Bandpass sampling intentionally permits an RF interval to map into a lower digital frequency interval. For a real converter sampled at

Copyright 2026, James M. Atkinson

40 megasamples per second, tones at 90 and 100 megahertz map, by simple folding, to 10 and 20 megahertz, but so do other RF tones in different alias zones. The mapping does not identify the source band uniquely. An analogue preselector must reject those alternative zones sufficiently to make the particular desired interpretation defensible, taking account of filter tolerance and strong blockers. Check both band edges for alias orientation and for coincidence with the Nyquist boundaries; the nominal 100-megahertz edge here lies exactly at a folding boundary and is unsuitable without guard-band analysis. A swept blocker test outside the desired passband is more probative than the sample-rate specification by itself. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The statistical question is whether this experiment could distinguish its preferred explanation from the specified alternative: the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. A test chosen because a feature already appears extraordinary cannot afterwards be presented as if it were a solitary predeclared comparison. I would record the planned family of frequencies, trial levels, acquisition windows and failure criteria before applying measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones. The scientific point of a strong out-of-band signal which leaks through filtering may alias directly on top of the desired weak waveform. is not that the result should be made more impressive but that a contrary result should be allowed to alter the proposed explanation. If independent

Copyright 2026, James M. Atkinson

sessions repeatedly show odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone, a bounded conditional finding becomes defensible; the bounds depend on what was randomised, what remained fixed and what was actually observed. Invalid or saturated records must remain visible in the denominator for any estimate of acquisition coverage; their exclusion may correlate with the strongest relevant inputs. I would report the alternative models beside the adopted one, distinguishing a detected change in a measurement statistic from identification of its cause.

A stored sample archive is not an exact transcription of every possible electromagnetic input. A spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target. His mathematical treatment of networks suggests using complex transfer functions and explicit phase as well as magnitude, especially when cascaded loading shifts the effective response. The issue becomes especially sharp because the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. If the front end compresses, clips, averages or selects time windows, no post-processing command can uniquely reconstruct states which those operations made indistinguishable. I would compare a reference acquisition made with adequate headroom against the questioned recording and declare the information retained by each path. Measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing nyquist zones. That comparison should keep the unprocessed complex values or, where only detector outputs exist, disclose precisely the interval and frequency domain actually

Copyright 2026, James M. Atkinson

examined. For the proposed case, a receiver which preserves a 15 mhz-wide wanted band must still reject other frequency intervals that fold upon those same sampled frequencies. This is a claim about a transformation and its observables, not a licence to assert a unique historical waveform or an emitter's intention. Strong out-of-band signals can fold onto the desired sampled channel when the filter stopband proves insufficient. Dr Deming, please take the floor and demand a test with realistic blocking levels.

W. Edwards Deming | Peer question 6 to Hendrik Wade Bode

I thank you, Hendrik Wade Bode, for distinguishing measurement from attribution, but the observation is that a spectrum appears reversed in the sampled output and a strong distant service folds into the same display interval as the weak target. A forensic report must identify the result that would defeat its preferred interpretation. Consider the working example: a receiver which preserves a 15 MHz-wide wanted band must still reject other frequency intervals that fold upon those same sampled frequencies. It is a hypothetical illustration, not an observation certified by the laboratory. How should the report discuss a challenge which supports odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone on one day but fails after the instrument has been reconfigured? Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. Would you disclose the disagreement and constrain the conclusion to the tested states, rather than reconcile the records through a post hoc adjustment?

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Immediate answer to W. Edwards Deming

W. Edwards Deming, I accept the force of your evidence chain and reprocessing objection. Retain the earliest available samples, complete contemporaneous receiver state, calibration, time-base records, and processing configuration. Every derived plot should identify the source record and transformation. A secure digest establishes continuity of bytes, while separate controls establish the physical interpretation. A reconstructed waveform must be labelled as an estimate. For Question 031, the specific physical candidate is spectral replication at integer multiples of the sample frequency, including spectral inversion. The unresolved physical pathway is material: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. The retained record permits a conditional claim about RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection, but cannot alone resolve a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

The adverse observation proposed by W. Edwards Deming deserves to be published without cosmetic reconciliation. In this case, a receiver which preserves a 15 MHz-wide wanted band must still reject other frequency intervals that fold upon those same sampled frequencies. I would retain the counterexample as part of the primary

Copyright 2026, James M. Atkinson

result, not as a footnote to an attractive conclusion. Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. Its bearing on the dispute can be evaluated through the predicted response, namely odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone. Because the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component, the procedure measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones should be repeated with the same calibration and an independent witness path. If agreement appears only after a threshold has been shifted, the historical record must show the threshold change and its reason. The final statement should match validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband, making clear whether the result excludes one instrument artefact or supports an actual external phenomenon. I should prefer an accurately bounded disagreement to a false appearance of consensus.

The original run and the revised run would be reported separately. Odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone. I would retain the unsuccessful and ambiguous captures to show where the proposed explanation failed.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal contribution 5: Sampling-clock tolerance and filter transition regions must be considered as part of the safety margin.

Before declaring a bandpass-sampling configuration safe, I would ask exactly what failure probability the qualification programme controls. A low-level bench sweep can show that the intended band is captured, but it cannot measure false in-band detections generated by occasional high-power out-of-zone signals. The test population should include those strong signals at representative frequency offsets, with a known weakest relevant wanted signal present where appropriate. Planned clock offsets and temperature changes should challenge the zone mapping and guard-band assumptions. If a candidate detection changes its apparent frequency under a measured alteration of sample rate, that can support an alias hypothesis; it is not by itself proof of source identity. Report detection performance and frequency-assignment errors under the actual tested regime, keeping calibration and environmental uncertainties explicit. An untested high-interference condition must remain outside the scope of the safety claim, however attractive the nominal bandpass-sampling diagram may look.

In this statistical inference examination of Question 031, the decisive claim is that sampling-clock tolerance and filter transition regions must be considered as part of the safety margin. The inferential population, detection threshold, nuisance distributions and dependence among trials must be stated. An apparently narrow confidence bound can be misleading when the underlying sampling design is not justified. A useful falsification proceeds from the actual controversy: bandpass aliases require analogue exclusion of competing zones. Bandpass sampling intentionally permits an

Copyright 2026, James M. Atkinson

RF interval to map into a lower digital frequency interval. For a real converter sampled at 40 megasamples per second, tones at 90 and 100 megahertz map, by simple folding, to 10 and 20 megahertz, but so do other RF tones in different alias zones. The mapping does not identify the source band uniquely. An analogue preselector must reject those alternative zones sufficiently to make the particular desired interpretation defensible, taking account of filter tolerance and strong blockers. Check both band edges for alias orientation and for coincidence with the Nyquist boundaries; the nominal 100-megahertz edge here lies exactly at a folding boundary and is unsuitable without guard-band analysis. A swept blocker test outside the desired passband is more probative than the sample-rate specification by itself. The chain from physical input through conversion, retention and interpretation must remain independently inspectable, and its limits must be made explicit to a later examiner.

The forensic question is how much of the historical input survives when an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. Sampling-clock tolerance and filter transition regions must be considered as part of the safety margin. An attractive reconstruction can be consistent with several physically different signals because information was discarded before the operator retained the complex samples. I recommend preserving the analogue configuration, sample-clock state, precise recording boundaries and the event or detector rule which selected the file for retention. The proposed challenge, namely to measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones, should be accompanied by a second acquisition

Copyright 2026, James M. Atkinson

path whose dependencies are explicitly diagrammed; two displays fed from a common failing stage do not constitute independent witnesses. The signature predicted here is odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone. A different result would not merely be noise around a preferred answer; it might indicate that the hypothesised forward model is wrong. Where the evidence cannot discriminate the histories, it is more accurate to say validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband, than to claim to have restored the original emitter conduct from a partial recording. The resulting opinion should describe the observable, its uncertainty, the alternative, and the precise experimental boundary within which the conclusion holds.

Before adopting a performance number, I would identify its population of measurement opportunities. An RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. The resulting sample cannot be treated as representative of unobserved intervals merely because it contains numerous FFT bins. Neyman’s statistical concern is the design that makes the advertised coverage statement valid, including preselection of tests and correlations among observations. A designed validation must distinguish the tested distribution from the unknown operational environment and must acknowledge that the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. One could stratify the experiment by nuisance condition, retain a random sample of nominally negative intervals, and calculate a separate sensitivity for each physically meaningful regime.

Copyright 2026, James M. Atkinson

The relevant quantities are RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection; their covariance and censoring properties determine whether a nominal confidence statement is defensible. The falsifying result would follow from odd/even nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted rf tone, provided the measurement actually had power to distinguish the rival predictions. The particular illustration, a receiver which preserves a 15 mhz-wide wanted band must still reject other frequency intervals that fold upon those same sampled frequencies, is not an estimate of any actual investigation. Filter transition regions and sampling-clock tolerance determine whether the proposed alias-free band is actually safe. Sir Karl, I invite you to challenge the conclusion at its worst-case operating limit.

Sir Karl Raimund Popper | Peer question 7 to Jerzy Neyman

Jerzy Neyman, before we pass to the next contributor, could you specify the negative finding that would oblige us to revise validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband? I am concerned about the decision reached after an apparently negative trial. A failure to see a feature is not an assertion that no physical emission existed outside the measured aperture. An input band can fold into a lower sampled interval with reversal of spectral order according to Nyquist-zone parity. Please connect RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection with a declared detection threshold and the measurement exposure. If the experiment measure passband edges and rejection, map aliases across sample-rate steps, and

Copyright 2026, James M. Atkinson

inject test blockers in competing Nyquist zones cannot discriminate a masked weak signal from a genuinely absent one, what exact assurance statement would you sign? The wording matters when another examiner must judge the limit of the original survey years later.

Jerzy Neyman | Immediate answer to Sir Karl Raimund Popper

Karl Raimund Popper, I accept the force of your falsifiable conclusions and disclosure objection. The finding should identify the observation, conditional model, controlled intervention and residual alternatives in separate sentences. Its strongest defensible claim may be narrow: the indicated response is consistent with one specified path under documented conditions. Source identity, intent and unobserved intervals require further evidence. Those restrictions improve credibility. For Question 031, the specific physical candidate is spectral replication at integer multiples of the sample frequency, including spectral inversion. The unresolved physical pathway is material: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. The retained record permits a conditional claim about RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection, but cannot alone resolve a successful bandpass-sampling plan depends simultaneously on band edges, clock tolerance, transition bands and analogue aperture response. That limitation belongs in the stated finding because the alternative remains an empirical possibility in this experiment.

Copyright 2026, James M. Atkinson

I am obliged to Karl Raimund Popper for pressing the limits of a negative conclusion. The physical circumstance is an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. A non-detection must be defined against the sensitivity and temporal coverage actually achieved. An input band can fold into a lower sampled interval with reversal of spectral order according to Nyquist-zone parity. I would use the observations of RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection to disclose what signal conditions could have triggered the chosen rule and which conditions were never tested. The relevant experiment remains measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones, not an assertion based on the operator's impression of a quiet display. If it yields odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone, we may describe a conditional exclusion of the challenged mechanism. If it cannot distinguish that mechanism from a missed short emission, it cannot support the broader assurance. A future reader needs the test boundaries, uncertainty, and all invalid windows to understand what the negative result signifies.

To make the hypothesis vulnerable, I would test the opposite outcome in the same controlled apparatus. Since the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component, an intervention that leaves both alternatives consistent does not settle

Copyright 2026, James M. Atkinson

their difference. The result should be limited to validate the entire occupied analogue spectrum rather than infer unique rf provenance from the sampled baseband, with the untested physical possibilities made visible.

Harry Nyquist, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, what must the preselector demonstrate when an intended high-frequency band is folded into a lower sampled interval, and a nearby strong transmitter occupies another Nyquist zone?

Hendrik Wade Bode, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, it must meet a quantified rejection requirement at the analogue reference plane under the actual blocker levels, not merely have a convenient catalogue corner frequency. Identify every materially overlapping alias interval at the lowest and highest allowed sample rates and clock tolerances. Measure passband ripple, stopband attenuation, insertion loss, group delay and large-signal compression over temperature and gain settings. A filter that meets a small-signal rejection figure may still be followed by an overloaded amplifier or converter, generating spurs that a digital image cannot separate from real input signals. Inject an out-of-band challenge tone into the front-end input and show that the folded output remains below a predeclared limit. A successful challenge with one source frequency cannot certify every neighbouring zone. I yield the token to Dr Armstrong on receiver implementation.

Hendrik Wade Bode, Cross-Peer Question to Edwin Howard Armstrong: Dr Armstrong, an engineer demonstrates a clean bandpass-sampled spectrum using a low-power laboratory source. What test distinguishes a practical RF receiver from a numerical aliasing demonstration?

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, the receiver must admit the desired RF band through its actual analogue aperture and remain linear when subjected to credible adjacent and remote strong signals. Verify track-and-hold input bandwidth, impedance matching, mixer or preamplifier compression, intermodulation and reciprocal mixing. Test both a desired weak tone and a strong tone in an excluded zone, then vary their powers separately to reveal nonlinear interactions. Repeat with the intended antenna, coupling network and maximum anticipated front-end gain, since an attenuator or filter used only in the laboratory can conceal defects. Record the physical signal generator levels, cable losses, input plane and all automatic gain events. Digital alias prediction is valuable, but it is not a substitute for measured RF immunity. I pass the token to Dr Shannon for the inversion question.

Edwin Howard Armstrong, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, the software shows a coherent line at 4 MHz after bandpass sampling. Can its exact original RF frequency be established from that one spectrum when multiple zones could have folded into the same bin?

Claude Elwood Shannon, Cross-Peer Answer to Edwin Howard Armstrong: Dr Armstrong, no. The discrete samples alone can be compatible with several original RF frequencies differing by appropriate multiples or reflections of the sampling rate. A claim of unique physical origin requires external constraints, such as a verified analogue passband, measured stopband rejection, a second sample rate that changes the alias mapping, or an independent front-end path. Spectral reversal is also dependent on the zone and complex-versus-real convention. We should test known tones from alternative zones and document their observed digital locations at multiple

Copyright 2026, James M. Atkinson

rates. When different physical inputs remain indistinguishable within the uncertainty budget, the forensic report must retain the ambiguity rather than assigning one transmitter by convenience. Derivative displays must not erase the information needed to challenge the mapping. I yield to Dr Neyman for statistical limits.

Claude Elwood Shannon, Cross-Peer Question to Jerzy Neyman: Dr Neyman, a field team observes no aliased blocker in twenty bench trials and declares the sampling plan safe for a seventy-two-hour unattended survey. What remains unproved?

Jerzy Neyman, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the absence of a detected failure in twenty specified trials neither establishes a zero failure probability nor covers untested blocker powers, frequencies, duty cycles, temperature states and gain transitions. An exact binomial interval under independent identical trials would still leave a positive upper bound on a failure probability; repeated conditions drawn from one narrow stimulus set provide no basis for extrapolation outside it. Define the adverse-condition population, randomise or systematically cover its extremes, and document the sample-rate and filter tolerances. Use independent monitors for unanticipated strong signals and record overload status through the full survey. A claim of safe operation should specify conditions, assurance level and residual uncertainty, not an unqualified word. I return the token with respect to Dr Atkinson for the closing synthesis.

Dr. James M. Atkinson | Moderator concluding synthesis

Our discussion of the conditions for safe bandpass sampling and the analogue filtering it presupposes has established a point which the

Copyright 2026, James M. Atkinson

specialist must not overlook. The receiver records folded sampled spectra of an intentionally isolated higher-frequency band; it does not, merely by drawing a clear trace, give direct access to other radio-frequency bands which could alias into exactly the same digital interval. A convincing engineering explanation therefore begins with the measurement boundary and ends with an appropriately limited conclusion. In particular, Bandpass sampling is not a licence to discard analogue filtering; it depends upon excluding other spectral replicas. This distinction is especially important when a field report may be read by a tribunal, a client or a technical review board unfamiliar with the internal operation of the apparatus. A good report distinguishes observation, model, controlled challenge, uncertainty and interpretation, instead of compressing all five into the single word detected.

Bandpass sampling is a deliberate frequency translation by sampling, not permission to admit unlimited RF energy into a converter. For a narrow, carefully selected passband, the folding relationship can map the wanted spectrum below half the sample rate; but adjacent Nyquist zones may occupy the same digital coordinates, and inversion may reverse the apparent frequency ordering. The critical hardware requirement is a preselector whose rejection outside the wanted band is justified under the anticipated blocker environment. A test tone near each band edge should demonstrate the actual zone mapping and whether the chosen sampling rate creates overlap. I thank Professor Fourier for supplying the spectral mathematics and the receiver engineers for insisting upon an analogue test of the filter. The final acceptance record must identify which RF band has been admitted, the sample-clock uncertainty, the direction of any inversion

Copyright 2026, James M. Atkinson

and the limits of blocker tolerance. No unique emitter attribution follows from an aliased spectral coordinate alone.

The output appears spectrally reversed and a strong out-of-band service could fold into the same displayed interval. The RF origin cannot be established from the sampled spectrum alone; competing zones must be excluded by measured filter rejection and deliberately placed test signals. The more useful outcome is a discriminating protocol: Measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones. In applying it, the examiner must retain all readings supporting RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection and identify the physical plane to which the measurements refer. At the outset of the investigation, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone; that circumstance makes the alternative mechanism material, specifically the wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. A result approaching odd/even Nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted RF tone may justify excluding one alternative, but it cannot by itself erase uncertainty about unobserved states or establish an emitter's identity. The final opinion should therefore validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband. Failed trials, changed receiver states, and measurement uncertainty belong in the retained evidential account alongside successful demonstrations. The differing observations offered by the principal

Copyright 2026, James M. Atkinson

contributors and their peers are most valuable when they specify incompatible predictions, not when they merely recite an agreeable conclusion.

Safe bandpass sampling is an engineering claim about the combined analogue passband, sampling rate and blocker environment. A digital alias coordinate can only be attributed to a specific RF band after the other possible analogue predecessors have been experimentally excluded. The decisive experiment is concrete: Measure passband edges and rejection, map aliases across sample-rate steps, and inject test blockers in competing Nyquist zones. In conducting it, the examiner must explicitly retain RF lower and upper edge, sample rate, zone parity, alias frequency, guard width and blocker rejection. If the outcome matches the stated prediction, odd/even nyquist-zone mappings may reverse spectral order, while clock drift shifts the digital alias of each admitted rf tone, the supported conclusion concerns that test domain. An alternative remains: The wanted band may occupy the designed alias mapping, but an insufficiently rejected adjacent zone can create an indistinguishable digital component. I thank the contributors for their careful and courteous disagreements. Their contribution is strongest where the methods require an actual discriminating observation, rather than one more retelling of the same hypothesis.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 031

Application 01. Alias-location prediction and its non-unique inverse

In the illustrative 031.01 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. For an actual sampling frequency f_s = 39 MHz and analogue input f_i = 122.070 MHz, the nearest-replica folding rule gives $f_a = |f_i - \text{round}(f_i/f_s)f_s|$ = 5.070 MHz. Another RF input in a different Nyquist zone can generate the same sampled coordinate; only the analogue preselector and controlled blockers distinguish those possible sources. The calculation assumes sampling is coherent enough to regard the centre frequencies as stable over the observed aperture. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Application 02. Filter or cable rejection referred to a physical input

In the illustrative 031.02 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. For an admitted input P_i = -49 dBm and separately measured loss L = 28 dB, the linear prediction is $P_o = P_i - L$ = -77 dBm. In SI power this becomes 10^((-77 − 30)/10) = 2e-11 W. That equality presumes a consistent power reference plane and no alternate common-mode ingress; a different screen level should prompt a physical bypass test. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Copyright 2026, James M. Atkinson

Application 03. Frequency-bin spacing versus independent information

In the illustrative 031.03 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. With sampled bandwidth f_s = 9 MS/s and N = 16,384 transform samples, the discrete-frequency grid is $\Delta f = f_s/N$ = 549.316 Hz. Two adjacent bins are not automatically independent observations, particularly when the transform uses overlapping records. The effective noise bandwidth, taper, acquisition duration and analogue transfer function determine what resolution and detection uncertainty can actually be claimed. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Application 04. Thermal reference noise in a declared measurement bandwidth

In the illustrative 031.04 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. Take the equivalent noise bandwidth B = 3,750 Hz and calibrated noise figure NF = 2.70 dB at an assumed 290 K. The thermal-reference estimate is $N = -174 + 10 \log_{10}(B/1\ \text{Hz}) + NF$ = -135.56 dBm. The result is available-noise power in that specific bandwidth; impulsive interference at the antenna is not represented by the 290 K assumption. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Copyright 2026, James M. Atkinson

Application 05. The frequency dependence of aperture-jitter-limited SNR

In the illustrative 031.05 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. At sinusoidal input frequency f = 212 MHz with uncorrelated rms aperture jitter σ_t = 2.25 ps, the idealised jitter-imposed ceiling is $SNR_j = -20 \log_{10}(2\pi f \sigma_t)$ = 50.47 dB. A common clock source may correlate errors across parallel ADC channels, so treating their outputs as independent for noise cancellation would need an additional experiment. Converter nonlinearity and thermal noise can make actual performance worse. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Application 06. Cascade gain and observed headroom

In the illustrative 031.06 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. A first amplifier contributes G_1 = 16 dB, an intentional attenuation contributes G_2 = -4 dB, and a later stage contributes G_3 = 20 dB. The small-signal sum is 16 + (-4) + 20 = 32 dB. For P_i = -68 dBm, the ideal output is P_o = -36 dBm. An intermediate amplifier may saturate even when the overall result appears modest, so the level before every nonlinear stage must be examined. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Application 07. Two-tone third-order products and input intercept

In the illustrative 031.07 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the

Copyright 2026, James M. Atkinson

permitted Nyquist zone. With two equal input tones each at P = -27 dBm and a hypothetical input third-order intercept IIP_3 = +16 dBm, the extrapolated input-referred third-order product is $P_3 = 3P - 2IIP_3$ = -113 dBm, or -86 dBc relative to either input tone. The cubic approximation ceases to be reliable in compression. A two-tone slope check and input attenuation test must establish whether the predicted spur arises inside the receiver rather than externally. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Application 08. Combined and expanded measurement uncertainty

In the illustrative 031.08 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. For independent standard-uncertainty contributions 0.66, 0.54 and 0.31 in a common unit, the root-sum-of-squares combination is $u_c = \sqrt{(0.66^2 + 0.54^2 + 0.31^2)} = 0.907$ units. Using an illustrative coverage factor k = 2 gives expanded uncertainty $U = 2u_c$ = 1.815 units. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Application 09. Gain allocation and blocker headroom

In the illustrative 031.09 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. Assume a calibrated digital full-scale equivalent of -8 dBm, a blocker applied at -45 dBm, and net analogue gain 22 dB. The projected converter input is -23 dBm and remaining margin is -8 − (-23) = 15 dB. If the margin is negative the assumed linear transfer cannot be trusted; a reduced-gain challenge or independent low-gain

Copyright 2026, James M. Atkinson

channel is needed before discussing the weak candidate. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

Application 10. Accumulated sample-clock time error

In the illustrative 031.10 test, an RF band is deliberately sampled below twice its carrier frequency while an analogue preselector confines the permitted Nyquist zone. A free-running sample clock with fractional rate error $\varepsilon = 1.390$ ppm over $T = 563$ s accumulates nominal offset $\Delta t = \varepsilon \times 10^{-6} T = 0.7826$ ms. This model applies to an approximately constant mean rate error, not oscillator phase noise or dropped acquisition blocks. Comparing two differently disciplined clocks requires separate treatment of correlated reference errors and the timestamp tagging point. validate the entire occupied analogue spectrum rather than infer unique RF provenance from the sampled baseband.

QUESTION 033

Copyright 2026, James M. Atkinson

Which resampling operations preserve time, amplitude and phase claims?

Source: V011_Roundtable_Question_033_CP033_Dr_Atkinson(1).docx | Recovered substantive manuscript. Constructed educational dialogue.

Original educational reconstruction. None of the dialogue is a historical quotation or a representation that a deceased contributor evaluated a modern digital receiver. All numerical examples describe stipulated laboratory conditions. The analysis distinguishes the truth of an operation on stored samples from the separate truth of claims about an earlier electromagnetic event.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, our previous examination of signed complex spectra has demonstrated how easily an internally consistent digital representation can be mistaken for a complete record of its physical origin. We now encounter a related problem at the temporal boundary. A recording may begin with complex samples whose timestamps, gains and phase relations are known within specified tolerances, and end with an apparently improved array that contains more samples, fewer samples, or a different nominal sampling rate. The transformation may facilitate listening, efficient channelisation, correlation, storage or comparison among receivers. Yet none of those benefits relieves us of the obligation to explain whether the transformed series still supports the original conclusions about event time, physical amplitude, carrier frequency, phase and duration. A new sampling grid is a representation of the available evidence, not a retrospective acquisition of observations that the original receiver never made.

Copyright 2026, James M. Atkinson

We must therefore reject the simple division of resampling into harmless and harmful operations. Its evidential consequences depend upon the intended measurand, the spectrum admitted before sampling, the interpolation and anti-alias filters, the relationship between source and output clocks, the treatment of discontinuities, and the timestamps assigned after processing. A rational resampler may preserve the content of a band-limited waveform to a declared tolerance. It cannot create the missing high-frequency information excluded by a prior analogue filter. A decimator may deliver a clean narrower channel with lower storage cost while destroying the possibility of investigating signals outside its output passband. A time-warp estimator may improve alignment between two recording clocks while concealing a genuine acquisition gap if the operator does not preserve the original sample indices and clock evidence. An interpolation function may return a value at any desired intermediate time, but the existence of that returned number does not prove that an analogue voltage was independently measured at that instant.

For our common mathematics, let $x[n]$ denote a complex source record sampled on nominal times $t_n = t_0 + n/f_s$, where f_s is the source complex-sample rate, t_0 the declared start time, and n an integer index. Let the target rate be $f'_s = (L/M)f_s$, where L and M are positive integer interpolation and decimation factors reduced to lowest terms. For an ideal stationary time base, the output time associated with index m is $t'_m = t'_0 + m/f'_s$. It need not be true that t'_0 equals t_0. The resampling filter can have delay, a boundary extension policy can affect its first valid output, and an application may shift or trim transient samples. If the physical source clock was in error by ε parts per million or included dropouts, merely assigning a

Copyright 2026, James M. Atkinson

new nominal f'_s does not retrospectively correct those properties. A valid clock correction requires a measured model of the original time base, independent reference evidence, and a statement of residual uncertainty.

Consider the three familiar objectives of fidelity. Amplitude fidelity asks whether output values are unbiased estimates of a specified input waveform quantity, with a gain response and uncertainty that are known over the relevant spectral and temporal support. Phase fidelity asks whether relative and absolute phase claims remain interpretable after filters, boundary treatment, group delay and clock mapping. Time fidelity asks whether an event's onset, separation and order remain tied to real observation times rather than to arbitrary output indices. These are related but not identical. A filter may preserve its passband amplitude to one tenth of a decibel while imposing a substantial, known latency. A zero-phase offline operation can maintain a convenient phase relationship under a particular boundary model but may be noncausal and use future samples that would not have existed during the original detection decision. A visually sharper signal after resampling can have a displaced onset or correlated errors that invalidate the confidence interval attached to the display.

The defensive TSCM context makes these distinctions acute. Investigators may combine receivers with independent oscillators, channelise broad captures, compare burst timing against an external event log, or replay short suspicious fragments through several analysis programs. A few microseconds of incorrect temporal mapping can alter a cross-receiver phase comparison. A tiny scaling error can change whether a brief event crosses a declared threshold. An undocumented filter can reduce a short pulse's peak while making it look broader and more persistent. A

Copyright 2026, James M. Atkinson

well-made report should identify which of those transformations were analytical, which were part of the original recording, and whether the raw source record is preserved for independent reconstruction. It should never describe an interpolated sample as a new physical observation.

I invite Mr Nyquist first to establish what a sampling theorem can and cannot guarantee when a band-limited signal is transferred to another rate. Professor Wiener will then examine the time-varying filter and the consequences of shaping transients, especially when statistical assumptions cease to hold after interpolation. Professor Bracewell will address spectral reconstruction, phase and the danger of using Fourier continuity to conceal a discontinuous acquisition history. Dr Deming will scrutinise calibration, validation, operating characteristics and the distinction between a repeatable algorithm and a properly tested instrument. Finally Dr Shannon will consider information loss, representation and the boundaries of inference when a compressed or decimated archive is used to support a conclusion beyond its retained evidence. Seven colleagues will interrogate the principal statements, and each addressed respondent will reply immediately before the floor passes onward. We will finish with numerical cases that state the applicable variables, filter conditions, clock uncertainties and test limits. Mr Nyquist, please begin by separating the mathematical sufficiency of ideal interpolation from the evidential adequacy of a real receiver's acquisition record.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 1: Reconstruction conditions, rate ratios and omitted analogue information

Dr. Atkinson, the theorem concerning reconstruction has always been more conditional than the enthusiastic operator may wish. In the idealized argument, a continuously defined signal is limited in spectral content, samples are taken at the necessary rate and known times, and reconstruction employs a kernel adequate for that signal class. A change in the density of a representation is then permitted because the relevant information was already present in the original sequence. The new values are interpolants computed from earlier observations and assumptions, not new independent measurements. The strength of this distinction is clearest when we use a real anti-alias filter as part of the declared apparatus. A source spectrum whose admitted energy was restricted to an appropriately narrow band can be translated into a new sample grid without logical contradiction. The same operation applied to an unknown wideband record may fold materially different original components into indistinguishable output frequencies. The arithmetic of the rate change does not prove the premise of adequate band limitation.

Let the input sampling rate be f_s and let the output be $f'_s = (L/M)f_s$. In a rational implementation, one may conceptualise the process as inserting L-1 zeros between source samples, passing the result through a low-pass interpolation filter, and retaining every Mth filtered value. Efficient polyphase implementations rearrange that arithmetic but do not abolish the anti-imaging and anti-alias requirements. If the rate is reduced, the target interval admits less unique spectral width. The filter must suppress energy that would otherwise map onto admissible output frequencies. If the rate is

Copyright 2026, James M. Atkinson

raised, new sample slots must be filled from a declared interpolation model, and spectral images caused by zero insertion must be removed. The operation is meaningful because of the model and filter, not because multiplying the source-sample count improves the original instrument's sensitivity or resolution.

We ought to distinguish a zero-valued inserted sample from a physical zero voltage. The intermediate zeros of the conceptual upsampling stage are mathematical placeholders. A software trace displaying them without the filtering stage could mislead a reader into believing that the physical waveform repeatedly vanished between acquisitions. Proper interpolation can recover the expected sinusoidal trajectory for a defined band-limited input, but its values remain dependent upon surrounding samples. It follows that the statistical uncertainty of an interpolated series is generally correlated. An investigator who treats each of three output samples as three independent observations of a stochastic quantity may report a confidence interval much narrower than the data support. The apparent increase in the number of numbers should not be equated with an increase in independent evidence.

The other hidden variable is time. A nominal sample rate is not an exhaustive description of the original acquisition clock. Let t_n denote the real instant at which the nth sample was acquired. The familiar expression n/f_s is a useful ideal clock model, but real systems possess oscillator error, jitter, potentially discontinuous buffers and sometimes clock-source changes. Interpolation from a series indexed by n does not establish that t_n followed the assumed law. If one receiver acquired at 8,000,080 samples per second while its metadata declared exactly 8,000,000, a later conversion to

Copyright 2026, James M. Atkinson

6,000,000 using that metadata inherits a small but meaningful time-scale error. Correcting it demands identification of the original clock error. Replacing the label alone is not calibration. A long trace can accumulate measurable drift even when the corresponding instantaneous waveform appears smooth.

The engineer should specify what is meant by preserving amplitude. If a finite filter has passband ripple, then the output magnitude of a tone depends upon its spectral location. At a calibrated reference plane the gain may be nearly unity, but we must measure or bound the deviation at frequencies that matter to the claimed event. A transient whose spectrum spans the transition region may change shape and peak even when ordinary narrowband calibration tones pass with little loss. A filter designed for the best average frequency response cannot by itself prove preservation of the exact peak of an unknown, brief pulse. Similarly, a phase-linear filter may possess a constant group delay that must be incorporated in event timestamps. If that delay is known and the relevant signal is within the assumed band, correction can be justified. Without a source clock and group-delay record the investigator cannot simply infer event chronology from the displayed output index.

I would therefore require an acceptance campaign structured by the question being answered. To certify a frequency-preserving path within an admitted band, inject known positive and negative complex tones across that band, including its edges, and compare their positions in source and output spectra. To certify phase preservation, use a reference with controlled phase and timing, estimate the transfer phase and group delay, and repeat after any changes to filter coefficients or resampling factor. To

Copyright 2026, James M. Atkinson

certify burst detection, construct transients whose onset and duration vary independently of the resampler's interpolation grid; do not choose only favourable phases or onsets. An empirical result obtained from such tests supports the specified operating envelope, not arbitrary future signals or unknown upstream states.

A final qualification concerns the correct description of precision. The output rate may be expressed by an exact rational number, but that exactness is a property of the chosen calculation, not of the physical oscillator. A resampler can produce exactly three output samples for every four input sample intervals under a nominated nominal rate while the actual elapsed time is slightly different. We should maintain separate records of the nominal digital ratio, the measured source-clock frequency, the uncertainty of time mapping, and any adjustments to the output epoch. When these quantities are recorded, a reader can distinguish numerical transformations from calibrated physical time. In their absence the result may still be useful for pattern recognition or audio replay, but a forensic claim of precisely timed emissions requires additional evidence. Professor Gabor, please challenge whether the reconstruction of a waveform at additional points can ever establish a new independently observed event or whether it merely increases the apparent fluency of the record.

Dennis Gabor | Peer question 1 to Harry Nyquist

Mr Nyquist, the distinction between reconstruction and fresh observation seems elementary when written on a blackboard, yet becomes less comfortable when a laboratory seeks to detect a pulse that was hardly visible on its original digital grid. Suppose a short recorded interval is converted to eight times its former sample rate, displayed as a

Copyright 2026, James M. Atkinson

smooth curve, and then searched for a threshold crossing. The new curve may cross the threshold between two original sample instants. The software may describe that crossing with a number of nanoseconds and a plausible phase. But the crossing depends upon the selected reconstruction kernel, its boundary assumptions and the original sample spacing. It may be stable for a band-limited test waveform while remaining indeterminate for a transient containing unobserved spectral components. What may the analyst claim about the crossing time, and what additional measurements would justify treating it as a bound on the actual analogue event rather than a property of the interpolation algorithm? Please consider the difference between an estimate, a newly acquired observation, and an interpolation-dependent hypothesis.

Harry Nyquist | Immediate answer to Dennis Gabor

Professor Gabor, the correct answer depends upon the proposition and the evidence for the signal class. If the input was genuinely band-limited to the stipulated range, the acquisition times are sufficiently known, the amplitude relation is calibrated, and the adopted reconstruction kernel approximates the appropriate ideal to an acceptable error, the interpolated crossing may be a legitimate estimate of when the continuous waveform crossed the threshold. Its uncertainty should account for sample-clock error, quantisation, noise, finite filter behaviour and the uncertainty of the waveform model. The estimate is not transformed into an independently measured time merely because it appears on a denser array. The investigator must describe it as an inference computed from earlier observations.

Copyright 2026, James M. Atkinson

For a pulse whose significant spectral energy reaches beyond the acquisition passband, the situation is different. Two physically distinct analogue pulses can produce the same stored samples or substantially indistinguishable values after front-end filtering, while crossing the threshold at different instants. The inverse problem then lacks uniqueness without supplementary assumptions. No amount of spline interpolation, Fourier zero-padding or graphical smoothing can recover the unmeasured distinction. It may still be useful to report the crossing time of the *reconstructed* waveform, but the qualifier is not ornamental. It identifies the actual quantity computed. A report that suppresses this qualifier can present a false impression that the original receiver observed an event with an accuracy determined only by the output display resolution.

A practical experiment should vary the pulse's phase relative to the original sample clock, its rise time, its spectral support, and the noise level. Compare the reconstructed crossing with an independently timed analogue reference whose own uncertainty is documented. Include examples close to the threshold and near the edges of the admitted band. Do not adjust the kernel after looking at failure cases and then report only the successful results as if the procedure had been fixed before testing. If the resampler is part of a detector, the validation population must include missed bursts, false alarms and intervals during which the input was not observed. These tests can yield a bounded distribution of timing error for a defined class rather than a vague assurance that interpolation is accurate.

Copyright 2026, James M. Atkinson

For evidential preservation, retain the raw sample stream and the filter coefficients or an exact software definition sufficient to reproduce the interpolation. Record the original clock information, original sample indices and any trimming or delay correction. Preserve the output as a derivative, with a hash and provenance link to the source. A reviewer can then calculate whether the claimed crossing is stable under reasonable kernel variations, or whether the result is so model-sensitive that only a wider time interval is justified. It is not necessary to deny every use of interpolation; it is necessary to state the inferential step with the same care we apply to a physical calibration. Mr Hamming, perhaps you will ask how an efficient digital implementation can keep such provenance without burdening every routine analysis with an impossible amount of documentation.

Richard Wesley Hamming | Peer question 2 to Harry Nyquist

Mr Nyquist, a receiver may channelise hundreds of signal streams, change their rates more than once, and archive only those records selected by event detectors. Insisting upon every intermediate representation could make long-term storage impractical, yet discarding all processing history would leave the later examiner unable to test a frequency or timing conclusion. Suppose a rational conversion is specified by a versioned program and a finite coefficient array, but a later release changes the boundary extension policy, output-length rounding, and treatment of missing input frames. The nominal rate ratio remains unchanged while the first few samples and event-onset estimates differ. What minimum record makes the output reproducible without preserving every transitory buffer? Which source data must be retained

Copyright 2026, James M. Atkinson

as evidence, which derived data may be recreated, and how should software tests detect a change in algorithmic behaviour even though the code reports the same two integers L and M? I should particularly welcome an account of boundary cases, because short transient records often disclose what long stationary test tones conceal, and of the distinction between reproducible digital outputs and authenticated physical sampling histories.

Harry Nyquist | Immediate answer to Richard Wesley Hamming

Thank you for that question. Dr Hamming, the goal is neither indiscriminate hoarding nor a reliance upon a verbal description as thin as the output rate. We should preserve the earliest practicable evidence that is necessary for the claim, together with the sufficient deterministic information to reproduce derived representations. In a receiver investigation that often means raw complex samples, actual sample-rate and timebase records, frequency tuning and gain states, buffer-gap markers, and the acquisition reference plane. A polyphase resampler's output can often be regenerated, but only if its algorithm, coefficient sequence, boundary treatment, initial phase and trimming rules are also known. Two programs with the same L/M ratio can produce different edge transients and timestamp alignment while behaving similarly in the centre of a long coherent tone.

I would distinguish a scientific reproducibility record from a complete execution log of every internal memory transaction. A stable, cryptographically identified implementation with preserved parameters and an unaltered source file may reproduce an output more convincingly than millions of undocumented temporary buffers.

Copyright 2026, James M. Atkinson

But the test must actually show reproducibility across the operating conditions that matter. Re-running a single sine wave placed far from every band edge will not expose a boundary extension change relevant to a short burst. Test vectors should include a zero-length interval, a very short pulse at each edge, a long coherent tone, noise with known statistics, and a record containing explicit missing blocks. Where fixed-point arithmetic or processor-specific optimisations affect the output, require acceptable numerical tolerances rather than an unsupported claim of bit-for-bit identity across all platforms.

The archived provenance should identify each derivative through a digest of its source and a content-addressed or otherwise unambiguous processing manifest. Include filter taps, software build, clock model, sample-index mapping, numerical type and any stateful adaptivity. If the operator changes the method after seeing results, preserve the earlier output and record the reason for the change. A change that corrects a documented defect may be entirely proper, but it cannot silently replace the evidence that originally led an investigator to select a suspicious fragment. That earlier decision may have depended on the defect itself, and the history may affect the interpretation of false alarms or ascertainment bias.

Finally, the claims must be proportionate to what survived. If a full wideband source recording was retained, a later examiner can test different rate-conversion methods over the acquired band. If only a narrow decimated product was stored, the examiner may still reproduce the derivation and analyse that channel, but cannot demand the lost out-of-band information from the source that no

Copyright 2026, James M. Atkinson

longer exists. An honest record explicitly states the retained band, the unobserved bands and the known deletions. The correct engineering economy is to reduce unnecessary storage while preserving the evidence and methods necessary to support the conclusions that the report actually makes. Professor Wiener, I pass the discussion to you to examine what the filtering stage does to the temporal and statistical interpretation of a recorded event.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 2: Filters, time-domain memory and the covariance induced by interpolation

Dr. Atkinson, I should begin by treating the resampler not as an innocent relabelling of coordinates but as a system that remembers neighbouring observations. A finite impulse response filter forms each output from a weighted collection of input samples. Even when those inputs contain statistically independent noise, neighbouring outputs generally share input contributions, so their errors need not be independent. The practical consequence is not merely a small mathematical detail. If a detector sums or averages resampled values while assuming their errors are independent, it can exaggerate the precision of the estimate and misstate the probability of obtaining an apparent weak feature under a noise-only condition. A more densely sampled picture may make an irregular fluctuation appear smoother while preserving, or even increasing, the dependence among the quantities shown. The appropriate statistical model must follow the transformation.

Consider y[m] = sum over n of h_m[n] x[n], where h_m[n] is the effective weighting kernel that connects input index n to output index m. The kernel changes with m in a polyphase arrangement, and may change again if the rate-conversion ratio adapts to a measured clock discrepancy. If the input has covariance C_x[n,k], the output covariance is C_y[m,r] = sum over n and k of h_m[n] C_x[n,k] h_r[k]*. In matrix notation, C_y = H C_x H^H, where H^H denotes conjugate transpose. This relationship reveals why the output noise statistics cannot generally be inferred from the new sampling interval alone. A filter that attenuates high-frequency noise may reduce variance but introduce correlation; a frequency-dependent calibration may change both

Copyright 2026, James M. Atkinson

the mean response and the error structure. The receiver's confidence calculations should use the transformed covariance or a validated empirical equivalent.

There is also an often neglected distinction between causal filtering and offline processing that uses future samples. A causal filter must accumulate information before delivering its estimate, and it therefore introduces latency determined by its architecture and group-delay response. An offline zero-phase technique may process a file in both temporal directions or compensate a symmetric FIR delay through trimming and padding. These choices may produce pleasing alignment in the output plot, but the algorithm's result cannot be inserted into the historical chronology as though the original detector had known the future. When evaluating whether an alert could have been raised before a suspicious transmitter ceased operating, the earliest information available to the live detector matters. When reconstructing an archival waveform after the event, a noncausal estimate may be useful, provided the distinction is recorded. Both are legitimate activities; neither is accurately described by a single undiscriminating timestamp.

A short pulse illustrates the danger. Let an original waveform contain a sharply bounded disturbance. A low-pass resampling filter has an impulse response extending over several input intervals. The output may show energy before and after the nominal onset, especially where a symmetric offline kernel is employed. That apparent pre-event response is not proof of an earlier physical emission. It is a predictable consequence of applying a kernel with temporal support on both sides of the event. Even for a causal filter, the peak can be delayed and attenuated relative to the source. If the

Copyright 2026, James M. Atkinson

analyst timestamps the filtered peak rather than the calibrated input onset, the report may shift the event by an amount determined by the filter and the pulse's spectrum. A measured group delay corrects certain narrowband relationships, but a broadband transient requires more careful characterisation of the full impulse response.

The operating assumptions become even more fragile when the source rate varies. An arbitrary resampler may choose a succession of fractional phases and interpolate between neighbouring polyphase filter outputs. Under a stable ratio the transformation can be designed for predictable amplitude and phase behaviour. Under adaptive correction, however, the coefficients or phase positions vary with time. The system becomes time-varying, and a single frequency-response plot may not describe every output sample. If the adaptation responds to an estimated signal feature rather than an independent clock reference, it may selectively modify the very anomaly that the investigator intends to measure. A drift-correction algorithm which shifts event positions to improve cross-correlation deserves special scrutiny because success in alignment can be obtained by sacrificing evidence of a real timing difference.

I would validate an algorithm against three separable questions. First, what spectrum is retained and with what passband amplitude, stopband leakage and transition uncertainty? Secondly, how are onset, phase, group delay and absolute timestamp propagated through the chosen processing state? Thirdly, what dependence and bias does the operation introduce into the statistical evidence used for detection? A test based only on an isolated sinusoid at one favourable frequency will not adequately represent transient event classes or time-varying clock adjustments. We need pulses, noise,

Copyright 2026, James M. Atkinson

spectral edge cases, known discontinuities and signals positioned near the decision threshold. The trials should preserve failures and false alarms rather than retune the procedure until only successes remain visible.

This is particularly important in a multi-receiver defensive survey. Two channels may share an analysis program and identical filter coefficients, so identical artefacts may arise in both outputs even though their analogue noise sources are independent. Conversely, one stream may be resampled by a different kernel and emerge with an apparently different phase or onset, creating false disagreement. Corroboration requires knowledge of the respective transforms and their uncertainties, not merely an attractive overlay of two spectrograms. A time registration is useful only to the extent that the mapping and its residual uncertainty are independently supported. Professor Tukey, may I invite your question about how one can report a probability or a confidence interval after the samples have become dependent through the resampling operation?

John Wilder Tukey | Peer question 3 to Norbert Wiener

Professor Wiener, you have shown that filtering a sequence can lower the variance at each output while increasing dependence between successive outputs. Suppose a laboratory produces a million resampled points from a much smaller source archive, reports that a weak spectral component is supported by a million observations, and calculates uncertainty by dividing a standard deviation by the square root of a million. That procedure may be correct only under a restrictive model which the chosen interpolation filter violates. Yet an investigator must still calculate useful uncertainty rather than condemn every derived series as unusable. How should an analysis distinguish the nominal

Copyright 2026, James M. Atkinson

sample count from the effective independent information available for the specified estimator? Would you recommend computing the covariance from the source data and transfer matrix, measuring a distribution of repeated independent experiments, or both? What assumptions about noise stationarity and adaptive resampling should be disclosed before a claimed improvement in detection confidence is accepted?

Norbert Wiener | Immediate answer to John Wilder Tukey

Thank you for that question. Professor Tukey, I would begin by identifying the estimator, not by treating a large sample count as a scientific achievement. The covariance formula I have proposed tells us what may happen under a specified linear transformation. If source noise is stationary with a known spectrum and the resampling system is fixed, one can derive the output covariance and use it to calculate the variance of the actual estimator. For the mean of a correlated sequence y[1] through y[N], the variance is N^-2 times the sum of every covariance Cov(y[i],y[j]), not simply the sample variance divided by N. The off-diagonal terms represent the dependence created or preserved by filtering. They cannot be abolished by changing the output file length.

Where the model is sufficiently established, the concept of effective sample size can provide a compact explanation of why N displayed points contain less independent information than N uncorrelated observations. But effective sample size is not a universal constant attached to the file. It depends upon the statistic, the correlation structure and the question. An estimator of average power, a

Copyright 2026, James M. Atkinson

matched-filter detection statistic and an estimate of pulse onset respond differently to the same covariance. An analyst who calculates one effective count and applies it indiscriminately to every result merely replaces one false precision with another. A defensible report should give the estimator-specific variance or a clearly justified approximation.

Repeated experiments are equally important, particularly when the mathematical model omits nonstationary interference, adaptive gain, burst selection or state changes. Controlled trials can compare the predicted distribution of an estimator with observed outcomes across different input levels, frequencies, noise colours, phase positions and gap patterns. The investigator should not assume that a laboratory's internally generated white noise represents every electromagnetic operating condition. A good campaign uses physically introduced stimuli for relevant analogue behaviours and synthetic inputs for controlled algorithmic edge cases, preserving the boundary between the two forms of evidence. Discrepancies between predicted and observed variance should lead to a revised and explicitly documented model, not to a quiet removal of inconvenient trials.

I would also preserve the original clock mapping and record whether the resampling ratio was constant or adaptive. If the ratio responds to the observed signal, the output may be conditionally selected or manipulated in ways that violate a simple stationary covariance model. A particular adaptive operation may nonetheless be useful, but its randomness and decision rules belong inside the analysis. The experiment should be repeated with input sequences

Copyright 2026, James M. Atkinson

whose physical timing and amplitudes are known independently of the estimator being tested. Only then may the engineer claim that a measured improvement is not merely the result of applying the procedure to the same observations used to choose its settings. Mr Heaviside, perhaps you will challenge whether the mathematical kernel sufficiently accounts for the analogue circuits and filters that preceded it.

Oliver Heaviside | Peer question 4 to Norbert Wiener

Professor Wiener, your matrix account is exact for the linear transformation it specifies, but it begins with samples that have already passed through a physical receiver. Suppose an analogue anti-alias filter introduces a frequency-dependent group delay, an IF amplifier saturates on a strong transient, and the digitiser drops a buffer while the software is attempting to correct its clock. The final resampler may be a perfectly implemented linear operation on its admitted array, yet the original analogue event could be displaced, distorted or incompletely recorded. What boundary must the engineer establish before your covariance and latency analysis can be interpreted as evidence about the earlier electrical quantity? In particular, how should a report distinguish an unavoidable physical delay, a remediable software delay and a loss of information that no filter, however elegant, can reverse? I am also concerned with the status of a calibration measurement taken in one gain condition and later invoked to justify a different receiver state. When does that extrapolation cease to be warranted?

Copyright 2026, James M. Atkinson

Norbert Wiener | Immediate answer to Oliver Heaviside

Thank you for that question. Mr Heaviside, your criticism is necessary because a model of digital processing is not automatically a model of the whole receiver. We should declare at least three boundaries. The first is the analogue input reference plane, where the measurand and conditions of loading and band limitation are stated. The second is the digitiser output, where samples enter the retained sequence under specific clock, gain and quantisation conditions. The third is the derived record after resampling. Between those boundaries we must characterise the transformations relevant to the asserted claim. A covariance calculation beginning at the digitiser output can be correct while saying nothing sufficient about an unmodelled analogue nonlinearity preceding the digitiser.

A stable analogue group delay can often be measured and included as a correction to event timing, with its uncertainty. A known digital FIR delay can similarly be computed from filter coefficients and verified with a reference impulse or modulated waveform. These delays are not errors merely because they are nonzero. They become errors in the report when a timestamp is interpreted at the wrong reference plane or the correction is asserted without evidence that the applicable state remained unchanged. A frequency-dependent group delay may require a waveform-specific correction rather than one global number. When the signal class is unknown and broad, it may be more defensible to report a range of onset times bounded by the established response envelope.

Copyright 2026, James M. Atkinson

Saturation and dropped samples impose different limitations. Clipping can eliminate amplitude distinctions, leaving only inequalities or model-dependent reconstructions for the clipped interval. A missing acquisition block creates a time interval in which the instrument retained no samples. Interpolating across it can make a display visually continuous, but cannot establish what unobserved events occurred inside the gap. The gap should therefore remain represented in the derivative's metadata and in the technical report, even if a secondary visualization uses interpolation to support human inspection. A digitally beautiful curve that conceals a missing block is less faithful evidence than an admittedly incomplete record whose interruption can be audited.

The acceptance programme should combine analogue and digital challenges: physically introduced test signals at the declared input, recorded digitiser-level measurements where accessible, and deterministic synthetic sequences that isolate the software's numerical behaviour. Correlation among derived samples may be estimated in software, while the analogue delay, overload and gain state require physical tests. We should trace which conclusion is supported by which test boundary. This layered discipline avoids both extremes: it neither demands the impossible reconstruction of every unobserved waveform nor allows a perfectly computed filter output to certify everything about the chain that produced its input. Professor Bracewell, the floor passes to you for the relation between Fourier interpolation and the actual continuity of the acquired history.

Copyright 2026, James M. Atkinson

Ronald Newbold Bracewell | Principal response 3: Fourier continuity, finite boundaries and physical phase

Dr. Atkinson, I propose to distinguish the reconstruction of a finite digital record from the reconstruction of the physical waveform that entered its analogue front end. A finite sequence can be extended, interpolated, transformed and inverse-transformed by mathematically well-defined operations. Those operations are useful and sometimes remarkably accurate. Yet any reconstruction of values between source samples depends upon what class of possible continuous signals we allow. One must ask whether the original acquisition conditions supplied adequate support for that class, and whether the observed interval actually contains the continuous history implied by the algorithm. An FFT-based resampler often acts as though the finite sequence is one period of a periodic function. If the first and last samples do not join smoothly, the assumed periodic extension introduces an artificial discontinuity at the boundary. The resulting ringing can be especially misleading when the archive contains a brief burst close to that edge.

For a long coherent periodic input, Fourier resampling may be convenient and mathematically coherent. The analyst transforms the source sequence, modifies the representation to suit a new length, and applies an inverse transform. This can preserve the identified periodic components under the relevant conventions. But a finite transient embedded in a nonperiodic recording is a different matter. An abrupt boundary, a missing buffer or a transmitter's sudden cessation can put energy across a broad range of Fourier bins. Altering the coefficient count can spread or reshape that energy. The appearance of pre-echo, post-echo or a smoother envelope

Copyright 2026, James M. Atkinson

may reflect the imposed extension rather than a historical electromagnetic field. This is why software documentation rightly warns that Fourier resampling relies on a periodic interpretation of its input. In the field report the chosen boundary model should be visible and open to challenge.

The situation is no less delicate in a polyphase FIR method. A long, symmetric impulse response can provide useful passband characteristics and a nearly constant group delay, but at the beginning and end of a finite record the algorithm needs values that do not exist. It may assume zeros outside the observed interval, reflect the samples at the boundary, extend their endpoint value, or construct a line from nearby observations. Each policy is an assumption about an unobserved continuation. The resulting output can differ in the very region where an investigator wishes to measure a sudden onset. It may therefore be prudent to mark an edge interval as affected by boundary treatment and to avoid certifying an onset there without independent verification. The problem cannot be settled by declaring one padding policy universally correct.

Consider now the preservation of phase. A linear-phase FIR filter can delay the components of an admitted waveform by the same nominal amount within its passband. For a stationary sinusoid a calibrated delay may translate into a predictable phase shift. That is useful for coherence and triangulation experiments. Yet a finite burst is not merely a sinusoid repeated forever. Its envelope, modulation and filtering may produce different apparent time markers. Two receivers processed by different filters can agree in absolute sample-rate metadata while differing in their effective onset definitions. A cross-correlation peak may align the derived waveforms but still leave an unknown difference between their original analogue

Copyright 2026, James M. Atkinson

reference planes. The report should therefore identify the phase quantity actually compared, the calibration of each signal path and the uncertainty of the time delay inferred from it.

A resampler also transforms how the discrete frequency axis is expressed. Let f_0 be the physical baseband frequency of a component and f_s the actual input sampling rate. Its discrete-time frequency is $\nu = f_0/f_s$ cycles per sample, considered modulo an integer. Once the record is resampled to f'_s, the same admitted physical tone should have normalized frequency $\nu' = f_0/f'_s$. Its location in cycles per sample changes even if its physical frequency does not. Thus a plot with an unupdated sampling-rate label can produce a false frequency shift from an otherwise correct numerical transformation. Such a mistake is particularly plausible when one software component reads an array of complex numbers while another component supplies the axis metadata. Data format and metadata must be validated as one evidential object.

I would insist upon a dual audit. The first concerns *mathematical reproduction*: can an independent engineer reproduce the output from the raw source, filter coefficients, rate ratio, extension policy and precise version of the algorithm? The second concerns *physical adequacy*: does that reproduced output support the intended claim when compared with known-input reference experiments? The first audit can show that a transform was performed consistently. It cannot alone establish that the original RF waveform was sufficiently band-limited, that an apparent burst was not a receiver artefact, or that a timing claim was referenced to the correct physical plane. The second audit therefore uses independent test

Copyright 2026, James M. Atkinson

waveforms and records their measured performance over the claimed range, including limitations.

A third audit is needed for continuity. A stored complex vector is an ordered array, but array adjacency does not prove continuous acquisition. A buffer can be dropped and the samples on either side concatenated; the resulting array remains perfectly suitable for an FFT, even though its index no longer describes uninterrupted elapsed time. A clock correction may distribute a missing interval over many output samples, concealing the place where a specific event could have escaped observation. An inverse transform cannot discover a historical interruption when no independent record of the interruption survived. Preserve the lost-block indices, source timestamps, acquisition state and discontinuity flags before any resampling, and propagate them through derivative products. If the necessary flags were never retained, the report should say that continuity could not be established from the file alone.

I offer a practical conclusion. Interpolation can be excellent when its premises are established and its transfer and boundary effects are tested. It cannot repair incomplete provenance by achieving numerical perfection. A signal that appears to retain a precise carrier phase after two transformations must still be associated with a measured clock and a known physical receiver path. A burst whose reconstructed onset varies across defensible boundary models should not be assigned a single falsely precise timestamp. A component that disappears after decimation may have been excluded by design, not disproved as an external emission. Major Armstrong, may I invite you to test how the analogue selectivity and

Copyright 2026, James M. Atkinson

blocking behaviour of an actual receiver should constrain the spectral claims of this otherwise mathematical account?

Edwin Howard Armstrong | Peer question 5 to Ronald Newbold Bracewell

Professor Bracewell, suppose a wideband receiver acquires a strong legitimate transmission at one offset and a much weaker suspicious burst near the intended decimation filter's transition band. The operator reduces the sampling rate, and the strong signal no longer appears in the narrow channel, while the weak burst becomes more prominent after filtering and plotting. The investigator concludes that the weak emission was confirmed independently by the resampled representation. Yet the source and derivative share one analogue observation, and the filter has changed the visibility of their relative spectra. How would you require the observer to distinguish genuine improved signal-to-noise ratio within an admitted band from selective removal of a competitor, leakage through imperfect stopband rejection, and an artefact caused by the filter's transient response? What controlled analogue tests are essential before describing the derived waterfall as independent confirmation rather than another analysis of the same acquired evidence? I also ask whether a test performed only on a stable tone can answer the question for short transmissions whose spectral components straddle the filter transition, and how an adverse trial should affect the final qualification.

Ronald Newbold Bracewell | Immediate answer to Edwin Howard Armstrong

Major Armstrong, I take your point about the apparent novelty of the processed trace. The derivative you describe is not independent

Copyright 2026, James M. Atkinson

evidence merely because its appearance differs. It is a transformation of the same source samples, with whatever physical and numerical limitations accompanied them. Filtering may improve the detectability of a component in the retained passband, and this improvement can be scientifically valuable. But the evidential statement should identify the transformation and the claim it supports. If a known interfering signal is removed by a valid filter, the resulting SNR may increase for an appropriately defined detector. That does not establish an additional observation of the weak source. We must avoid counting several filtered versions of one recording as several independent detections when evaluating a false-alarm probability.

A proper challenge begins at the relevant analogue reference plane. Apply a calibrated weak test burst and vary its frequency, duration, phase relative to the sampling clock and amplitude. Add a strong legitimate blocker at frequencies that probe both the analogue front end and the resampling filter's transition and stopband regions. Measure the output of the detector, not simply the visual separation of peaks. Use controls without the weak burst to estimate whether blocker-induced images, overload products or FIR ringing can generate similar indications. If a weak burst is retained only under favourable buffer alignment or selected padding rules, the acceptance domain must be restricted accordingly. If the claimed filter suppression is insufficient for the blocker amplitude, the possibility of residual leakage remains material.

We should also examine the meaning of independence. Two distinct receiver front ends can provide complementary evidence if

Copyright 2026, James M. Atkinson

their paths and clocks are characterised and if their response to the suspected signal is tested. Two resamplings of one raw array generally do not. That distinction is not a judgement that derivative processing has little value. It may be necessary to reveal a weak feature, estimate timing or compare modulation. But the report should use language such as 'the same acquired event remains visible after specified filtering' instead of 'confirmed by another observation' unless an independent measurement was actually taken. The stronger the causal attribution, the more carefully this distinction must be defended.

A statistically competent presentation would preserve unsuccessful searches and alternative filter settings that were actually tried. Selecting the one representation in which the weak burst looks most convincing and ignoring the others may introduce selection bias, particularly if thresholds were retuned after inspection. One can perform an exploratory search and then conduct independent confirmation with a fixed procedure and new data. If that is impossible, the result remains exploratory or conditionally supported and should be described as such. There is no shame in an honest limitation. The danger lies in allowing the elegance of a clean narrowband waterfall to conceal an untested physical mechanism. Dr Deming, I transfer the floor to you to define how an acceptance programme can support a sufficiently limited but reproducible measurement claim.

Copyright 2026, James M. Atkinson

W. Edwards Deming | Principal response 4: Validation across conditions and a measurement system that does not conceal failure

Dr. Atkinson, the central mistake I wish to challenge is to substitute a repeatable procedure for a validated measurement system. A digital transformation may produce the same output every time its program runs, yet the physical claim attached to that output can still be wrong. Reproducibility of a numerical result is an important property, but it is not the whole of measurement quality. We must ask whether the procedure measures the intended quantity under the conditions for which the result will be used. A laboratory may demonstrate accurate resampling of a long sine wave with a fixed phase and then market its receiver as capable of locating unpredictable microsecond bursts while operating beside strong, changing interference. Those are different claims. The operating population of test signals, the calibration reference plane and the decision criterion must match the proposition to be certified.

I would begin by separating the variables that the operator controls from those that the physical environment supplies. Filter coefficients, interpolation ratio, software version and endpoint policy are controllable. Source waveform, burst onset relative to the clock, blocker power, temperature, analogue gain state and network clock conditions may vary independently. A suitable experimental design challenges both types. If the operator adjusts the filter after observing the test cases and then reports only the final favourable result, the evidence may describe a selected success rather than prospective performance. A fixed acceptance rule, established before the relevant evaluation trials, permits a much more interpretable conclusion. Where exploratory development is required,

Copyright 2026, James M. Atkinson

record the development trials separately and test the chosen final procedure against new inputs.

The language of a calibration certificate also deserves attention. A certificate may establish that an instrument met specified performance requirements on a particular occasion, using defined procedures and measurement standards. It does not imply that every later internal coefficient, clock source, front-end state or software branch remained unchanged. If a receiver applies automatic resampling corrections based on a measured external reference, we should record whether that reference was locked, the correction values used, and the residual errors observed. A time-tagging function that has passed a laboratory test can nevertheless fail in service because a buffer is lost or because its firmware changes the initial phase after a retune. The relevant quality system monitors the actual process and its departures, not merely the existence of a certificate in a binder.

Statistical treatment must likewise follow the intended claim. A specification that the mean amplitude error is nearly zero can conceal a significant distribution of individual errors. For threshold decisions on weak intermittent signals, the tails of that distribution may matter more than its centre. A filter can have small average passband ripple and still cause a short pulse at an unfortunate phase to fall below the threshold. A mean time alignment can be correct while occasional output gaps produce large errors. We should report detection probability or timing coverage over a declared trial population, including confidence intervals and the failure modes actually observed. A statement that performance is 'within tolerance'

Copyright 2026, James M. Atkinson

is empty unless the tolerance, coverage, exposure and conditions are defined.

An audit also needs a clear notion of the measurement record. A source file, its authenticated digest, and a transformation manifest identify the input to the algorithm and the rules applied. The resulting derivative should be related to that source without overwriting it. Analysts may correct a documented error and produce a better result, but the earlier interpretation must remain traceable, especially if it influenced later collection choices. A long surveillance survey may contain both selected events and periods with no archived samples. Resampling the selected events cannot justify a claim about absence during the unretained intervals. The same principle applies when downstream software drops any segment it classifies as uninteresting. The record must describe how the data were selected before it can support an inference about the underlying population.

A useful validation report would therefore distinguish three propositions. First, did the implementation apply the declared numerical algorithm? This can be established by deterministic vectors, independent implementations and version-controlled code. Secondly, did the end-to-end receiver preserve the waveform quantities needed for the intended test? This requires calibrated physical stimuli and characterisation across the operating envelope. Thirdly, does the investigation's inference, including its decision threshold and uncertainty, follow from the actual archived evidence? This requires accounting for selection, dependence, missing exposure and competing causes. Success in the first category cannot be promoted to success in the third without the intervening proof.

Copyright 2026, James M. Atkinson

For a practical release decision, I would recommend a table showing each claim alongside its reference plane, test population, maximum or interval error, untested conditions and acceptance criterion. Report discordant cases rather than hiding them in a narrative of success. If a source timestamp is shifted by an unexpected number of samples under one boundary policy, the software can still be valuable, but the scope of the timing claim should be revised. If the filter's stopband is inadequate for a measured blocker, correct the filter or restrict the operating envelope and retest. A release discipline should prefer a bounded, demonstrated result over an expansive assertion that cannot survive an adversarial examination. Professor Bridgman, would you challenge whether the phrase 'preserved amplitude' has a stable meaning unless the physical operation and estimator are first defined?

Percy Williams Bridgman | Peer question 6 to W. Edwards Deming

Dr Deming, the phrase 'amplitude preservation' appears deceptively simple in technical reports. A receiver may report an RMS voltage over a filter's passband, a peak sample value, the maximum of a reconstructed pulse, a narrow FFT-bin amplitude, or the output of an energy detector. A resampler can preserve one of these quantities and change another. An amplifier calibration at a declared frequency cannot establish the peak of an unknown transient, and a zero-phase filter may alter a peak while leaving an integrated power estimate comparatively stable. How should a validation programme define its measurand so that the same word does not conceal changing operations? Would you insist upon separate tolerances for tone amplitude, burst peak, event energy and threshold-crossing time? And when the original source record is preserved, which

Copyright 2026, James M. Atkinson

of these derived quantities should a later examiner be permitted to recalculate under a more defensible estimator without rewriting the historical observation?

W. Edwards Deming | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, I would insist upon the distinctions you propose, because measurement quality is impossible to establish without specifying the quantity and method. The phrase 'preserved amplitude' should be replaced by a defined variable, reference plane, bandwidth, temporal window and estimator. A tone amplitude measured after a narrowband filter is not automatically comparable to the maximum sample of a pulse reconstruction. An RMS value may be stable under transformations that change the pulse's maximum. A detector's energy statistic may depend on integration time, filter normalization and noise subtraction. Each claimed preserved quantity requires its own response test or a justified relationship to another validated quantity.

Separate tolerances are therefore appropriate where the operational decisions differ. A survey might require frequency estimation within an established tolerance for a stable carrier, onset timing within a wider interval for a class of bursts, and peak-amplitude uncertainty over an admitted waveform family. Those requirements should be specified before the performance trials. A single generic percentage applied to all quantities would conceal the different ways that filters, clocks and noise influence them. The validation campaign must include cases near the boundaries of each

Copyright 2026, James M. Atkinson

requirement, not merely the easiest central conditions. When the real-world waveform class is unknown, the report should acknowledge that the tested family is narrower than all possible emissions.

Recalculation from a preserved source record is a strength, not a defect, provided the provenance remains clear. A later examiner may use a better estimator, correct an identified filter bug, or reevaluate uncertainty under a more appropriate noise model. The resulting value is a new analysis of the same underlying evidence, and it should be labelled as such. The original source samples, acquisition metadata, earlier derivative and correction history should remain available. Replacing the original conclusion without a version record would deprive the reader of an important part of the scientific process and could conceal whether an investigative decision was influenced by a now-discredited method.

Finally, we should distinguish correction from invention. A well-characterized, stable scaling error can be corrected with documented uncertainty. A lost sample interval or an unknown analogue overload cannot be restored uniquely simply by choosing a smoother estimator. In such circumstances the analysis may yield bounds or conditional reconstructions, but must say which assumptions generate them. The best measurement report is not the one with the most decimal places. It is the one in which another competent investigator can establish exactly what was measured, what was calculated, what conditions were tested and what alternatives remain plausible. Dr Shannon, I invite you to examine the deeper question of information lost through decimation and the temptation to call a

Copyright 2026, James M. Atkinson

sophisticated reconstruction a recovery of observations never retained.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 5: Retained information, erased bands and the proper scope of a resampled inference

Dr. Atkinson, I should like to draw a distinction between the number of symbols available to the analyst and the information those symbols contain about the original physical event. A transformation can increase the length of a sequence without increasing the set of independent observations. It can also reduce the length while preserving an adequate representation of a restricted class of signals. But if the transformation discards spectral components, fine temporal distinctions or acquisition state, that information may no longer be available to answer a later question. The practical significance lies in specifying the intended inference before deciding that a derived archive is sufficient. No code has the power to make unrecorded alternatives disappear from the set of physically possible histories.

Imagine an acquisition admitting several megahertz of complex bandwidth. The examiner wishes to observe a narrow channel and therefore low-pass filters the record before reducing its sampling rate. If the filter works as designed, it suppresses components outside the preserved band so that they do not alias into the output. The narrower derivative can then support detailed examination of its retained contents, often with much lower storage and computation costs. But it does not establish that nothing occurred outside the retained band. In fact, suppression of those frequencies was the stated purpose of the transformation. A negative result in the derivative is therefore a conditional statement about the filtered channel during the observed interval, not an assurance of silence across the original receiver's entire admitted spectrum.

Copyright 2026, James M. Atkinson

The same reasoning applies to amplitude and phase. A representation is sufficient for a particular task only if the distinctions required for that task have survived. A narrowband, coherently sampled tone may retain an identifiable phase trajectory under carefully designed resampling. A short saturated pulse may not retain its original peak because the clipping occurred before resampling. A channel whose timestamp was lost cannot be made absolutely timed merely by adding an output epoch to a new file. An apparently exact interpolation can be conditioned upon a band-limited model while several incompatible analogue inputs remain possible. The inference is legitimate when its conditions are stated; it becomes unsupported when the analyst treats the particular chosen reconstruction as the only conceivable physical history.

There is also a question about the effect of selection. A wideband survey might retain only segments that crossed a detector threshold, after which each selected segment is resampled and subjected to a more elaborate analysis. The resulting population is not an unbiased sample of the original observation periods. It is selected by an earlier decision rule whose false alarms and misses matter to any estimate of prevalence. An apparent agreement between an initial detector and a later resampled analysis is not independent confirmation when both decisions arise from the same selected data. A proper probability statement requires the sampling and selection mechanism to be included in the model, together with any conditions under which the detector's decisions influenced later acquisition.

To preserve the possibility of serious reanalysis, I recommend retaining the earliest practicable raw representation and its critical metadata whenever the investigation's questions are not yet fully known. Storage

Copyright 2026, James M. Atkinson

constraints may require selective preservation, but the constraints and omitted coverage should be declared. If only a derivative is retained, the report should document its passband, filter transfer, source-clock relation, output reference plane and the precise operations that formed it. It should distinguish what can still be tested from what is now unobservable. An investigator can report a weak feature in a retained narrowband channel with rigor while expressly declining to infer anything about a discarded neighbouring channel. Such intellectual restraint makes the useful finding stronger rather than weaker.

A common misconception is that improved numerical smoothness necessarily increases evidential content. Interpolation often creates samples that are highly correlated functions of earlier samples. They can help estimate a continuous band-limited signal within known assumptions, but the extra entries are not independent sightings. A Fourier zero-pad operation can make a plotted peak easier to localize without actually changing the physical duration or the independent data underlying it. A noise statistic can appear stable after filtering because the filter has removed a portion of the noise spectrum, yet the investigator must use the appropriate transformed noise model to calculate detection confidence. The right question is not how many samples exist after processing, but how much reliable information survives about the specified hypothesis.

A good report should therefore separate three statements. One identifies the stored sequence and its provenance. The second identifies a computed feature in that sequence with its method and uncertainty. The third identifies the physical explanation proposed for that feature, together with alternative explanations and the experiments used to test them. The steps

Copyright 2026, James M. Atkinson

between these statements require evidence. Without those steps the final conclusion may exceed the information retained. With them, a limited result may be entirely decisive for the investigative purpose. Mr Pierce, may I ask you to challenge the proposed retention policy in the difficult circumstances of a wideband receiver with finite storage, intermittent unknown signals and a legal obligation to disclose methods and material limitations? With respect, I now return the floor to Dr. Atkinson for the next contribution.

John Robinson Pierce | Peer question 7 to Claude Elwood Shannon

Dr Shannon, your preference for preserving the earliest practicable evidence is sound, but a defensive monitoring system may acquire many wideband channels continuously, producing far more raw data than can reasonably be stored or examined. One cannot simply declare unlimited retention to be the standard of scientific integrity. Suppose an investigator retains narrowband event snippets, a slower survey waterfall, and a log of the discarded intervals, but no full-rate wideband source stream. That archive can support some conclusions while foreclosing others. What minimum evidential architecture would allow the examiner to make useful, honest claims without pretending that retained products are equivalent to the discarded source? How should a later reviewer identify whether a questioned event might have been removed by a particular filter, missed during an acquisition gap, or distorted by a timestamp correction that is no longer reproducible? Please distinguish unavoidable resource limits from failures of experimental disclosure. In particular, what must be retained so the examiner can account for the opportunity of a weak, intermittent signal to have appeared during intervals that were never preserved at full rate?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Immediate answer to John Robinson Pierce

Mr Pierce, a finite resource limit is a property of the real experiment and should be addressed through explicit design rather than concealment. If continuous raw retention is not feasible, decide which investigative propositions the system must support and design the acquisition and preservation policy accordingly. A hierarchy of products can be useful: limited high-rate source buffers around selected events, calibrated coarse survey summaries, receiver-state logs, clock-reference records, and explicit interval coverage masks. The resulting archive will not answer every conceivable future question, but it can answer the questions for which its coverage and methods were validated. The crucial discipline is to identify the omissions before making an assurance claim that the archive cannot sustain.

I would preserve an auditable account of the selection rule, including its software version, thresholds, integration windows, detection probabilities under tested conditions and the periods during which each receiver was actually observing. A log that says 'nothing detected' is not equivalent to proof that a detector was exposed to all relevant signals. If the record identifies which bands were filtered away, which time intervals were missing and which gain states were active, a later reviewer can determine whether the archived absence is genuinely informative or merely a consequence of not looking. A coverage mask may be no more glamorous than a

Copyright 2026, James M. Atkinson

waterfall, but it has substantial evidential value when a negative conclusion is considered.

Where the actual resampling derivative is retained but its raw source is not, the analysis should state the reproducibility that remains. If filter coefficients, output clock mapping, boundary policy and original interval identifiers are recorded, a reviewer can evaluate what the derivative would preserve for a controlled hypothetical input and test the algorithm's behaviour. However, the reviewer cannot verify the exact omitted original sequence or discover a real event that was excluded upstream. It would be improper to claim otherwise. A preserved source checksum can authenticate a retained block, but it cannot hash data never recorded. The document should separate a verified numerical transformation from the untestable historical details of a discarded input.

The policy can be improved by retaining representative untriggered source intervals for validation, by sampling the apparent noise-only population, and by preserving enough independent test records to monitor detector behaviour over time. Such practices help assess selection bias without requiring that every original bit be stored indefinitely. They cannot substitute for all possible evidence, but they can strengthen the reliability of limited claims. Where litigation or another formal inquiry requires specific disclosure, the record should accurately describe the algorithms, their versions, derivative histories, calibration conditions and known loss of information. A conclusion is not rendered invalid merely because storage was finite. It becomes

Copyright 2026, James M. Atkinson

scientifically fragile when the investigator refuses to specify what was lost.

Finally, I would resist the impulse to use the sophistication of a model as evidence of the completeness of its input. The most elaborate reconstruction can still rest upon an underdetermined source. Conversely, a modest retained fragment with clear provenance, known coverage and carefully bounded inference may be valuable. Our responsibility is to report what survived, why it survived, what transformations altered its form and which physical alternatives remain compatible with it. Dr. Atkinson, I return the floor so that the numerical cases and the final synthesis may place these distinctions into a reproducible engineering framework.

Worked mathematical and engineering applications

The following ten examples are constructed measurements, not instrument certifications. All filters, clock errors and test populations are stated rather than inferred from an unidentified receiver. A reported numerical result applies only to the specified quantity and physical or digital reference plane.

Harry Nyquist, Cross-Peer Question to Norbert Wiener: Professor Wiener, when rational resampling changes a 12 MHz I/Q stream to 8 MHz, what does a specification of the 3-to-2 rate ratio omit about the evidential timing of a short burst?

Norbert Wiener, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the rational ratio specifies the nominal sample lattice, not the physical timestamp mapping. The interpolation kernel, its state at the record

Copyright 2026, James M. Atkinson

boundaries, fractional delay, passband shape, start-time convention and the original oscillator drift all affect the output. I would preserve the source sample indices and acquisition timestamps together with the exact filter coefficients, version, arithmetic precision and treatment of leading and trailing transients. A calibrated timing pulse should enter before the ADC, not merely be fabricated in software after resampling. Compare the output timing with an independently observed event across several burst alignments and clock states; report both fixed algorithmic group delay and variable residual timing uncertainty. If the source lacked the analogue information needed for an unambiguous event, resampling cannot recover it. I pass the token respectfully to Dr Bracewell on phase continuity.

Norbert Wiener, Cross-Peer Question to Ronald Newbold Bracewell: Dr Bracewell, the output of a resampler has a visually continuous phase trace. Why is that insufficient to claim that the original emitter itself maintained phase coherence across a packet boundary?

Ronald Newbold Bracewell, Cross-Peer Answer to Norbert Wiener: Professor Wiener, phase continuity of the constructed output can reflect an interpolation rule. The original phase history may have been discontinuous, missing, noisy or altered by clock changes. Treat complex phase relative to a specified reference oscillator and compensate for any known frequency translation before comparing records. Calibrate the filter phase response and group delay across the entire admitted band, not solely at one centre tone. Include numerical phase wrapping conventions and the output sample time origin. Inject a known phase step near the record boundary at multiple positions and ask whether the processing preserves its magnitude and timing within a declared tolerance. In a forensic record, distinguish

Copyright 2026, James M. Atkinson

measured phase observations, model-dependent interpolations and the unobservable analogue interval between them. I pass the token to Dr Deming to test reproducibility.

Ronald Newbold Bracewell, Cross-Peer Question to W. Edwards Deming: Dr Deming, a developer demonstrates one perfect chirp after resampling. What controlled acceptance programme could expose spectral leakage, aliasing, or software-version dependence before deployment?

W. Edwards Deming, Cross-Peer Answer to Ronald Newbold Bracewell: Dr Bracewell, begin with a fixed source dataset and a predeclared acceptance matrix covering tone placement, chirps, short bursts, phase steps, band-edge stimuli, adjacent blockers and missing sample blocks. Test across rational conversion ratios, filter lengths, coefficient precisions and processor implementations. Record intermediate hashes and ensure that a known software version yields the same output under the same documented numerical settings; where floating-point reduction order differs, use a justified numerical tolerance rather than a visual judgement. Measure amplitude ripple, group-delay variation, alias rejection and event-time error at independently known locations. Reject the habit of adjusting the acceptance threshold after observing a disappointing result. If a filter is changed for better edge performance, rerun the complete relevant regression campaign. I yield the token to Dr Shannon regarding information lost in the operation.

W. Edwards Deming, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, if the original capture contained energy above the target resampler passband and the algorithm correctly removed it, what can a later investigator truthfully infer from the narrow output?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Answer to W. Edwards Deming: Dr Deming, the investigator may infer properties of the declared filtered representation within an established error and uncertainty model. The narrow output cannot by itself show that the eliminated frequency components were absent in the original analogue event. A many-to-one filtering operation has an equivalence class of input histories that map to the same output. Preserve raw samples or a demonstrably adequate parent representation where evidential duties require testing alternative hypotheses. Record the filter transfer function and its rejection, especially if a removed component could explain a transient otherwise attributed to an emitter. When only the derivative survives, say which questions it can still answer and which cannot be reconstructed. A reconstructed-looking waveform is not thereby a fresh physical measurement. I return the token respectfully to Dr Atkinson.

Dr. James M. Atkinson | Moderator's concluding synthesis

Colleagues, the panel has established that resampling is neither a surrogate for physical observation nor a process to be feared simply because it changes the density of a numerical array. Its value depends upon the measurand and the evidence supporting the relationship between source and derivative. Where an input was adequately band-limited, sampled at sufficiently known times, and transformed through a characterised filter, a new representation can preserve selected amplitude, frequency and phase information within declared tolerances. The same operation may be inappropriate for a short uncharacterised transient, a record containing missing blocks, or an investigation whose conclusion depends upon frequencies deliberately rejected by a decimation filter. The

Copyright 2026, James M. Atkinson

question is therefore not whether a software function is accurate in the abstract, but what specified physical claim it preserves under the conditions actually tested.

Mr Nyquist has reminded us that a changed sample rate is a relation among representations. Interpolation points are mathematical estimates from source observations, not additional independently acquired evidence. Decimation is safe for a defined band only when undesired components are sufficiently attenuated before the rate is reduced. The exact rational arithmetic of L and M does not convert an oscillator's nominal rate into an accurate physical time base. The original rate error, clock history and sample-index correspondence must remain in the calculation. A scientifically exact output frequency label can coexist with a physically mistaken time estimate if the analyst has confused these distinct quantities.

Professor Wiener has shown that filtering induces both temporal and statistical consequences. A finite response can displace a peak, change a burst's envelope, or make energy appear before a plotted onset when noncausal offline reconstruction is used. Closely spaced interpolated values may contain correlated noise rather than independent confirmations. A confidence interval based upon their sheer number can be misleading unless the covariance of the actual estimator is considered. The proper validation therefore includes noise statistics, event phases, gap conditions, transition-band signals, and the circumstances under which an adaptive resampling ratio was selected. The smoothness of a waveform is not an evidential substitute for those tests.

Professor Bracewell has brought Fourier interpretation back to the problem of historical continuity. A mathematically well-defined periodic

Copyright 2026, James M. Atkinson

extension can manufacture a discontinuity at the edge of a finite nonperiodic record. A boundary policy can shape the first and final values of a derived sequence. A digitally coherent record can conceal a dropped source buffer if the missing interval is not independently documented. A transform and its inverse may reproduce the array perfectly while leaving the original acquisition history unresolved. It follows that the receiver record must carry its intervals of actual observation, not merely a string of consecutive digital indices. An auditor needs the clocks, gap markers, algorithm version and earlier source if the timing conclusion is to be reproduced and challenged.

Dr Deming has insisted that numerical repeatability and measurement validity be tested separately. A resampler which behaves identically for every invocation may still distort the particular quantity that a field investigator intends to use. We must state whether amplitude means a narrowband voltage, an RMS value, the reconstructed maximum of a pulse or a detector energy statistic. We must state whether timing means the first sample above threshold, a calibrated onset, a correlation maximum or a time referenced to an independent event. These quantities can require different tolerances and different challenge populations. The acceptance plan should be fixed before the decisive test, and the unsuccessful trials should remain in the record. Correction of a demonstrated defect is proper, but silent substitution of a later analysis for the original decision history is not.

Dr Shannon has supplied the logical boundary. A narrow filtered derivative may be sufficient for a narrow question while being inherently inadequate for a question about discarded bands. The addition of interpolated samples does not increase the physical exposure of a receiver,

Copyright 2026, James M. Atkinson

and the elimination of samples does not prove that absent frequencies were silent. Source preservation is desirable, but finite storage can be managed by designing an auditable retention policy that reflects the questions the apparatus is intended to answer. Such a policy must disclose its coverage mask, detector selection rules, gaps and discarded spectral regions. We should prefer a bounded conclusion whose premises are visible to a larger but unjustified conclusion whose missing evidence has been hidden by sophisticated processing.

Our worked examples make these duties concrete. A twelve-megahertz complex stream resampled by five over eight has a new nominal rate of 7.5 megahertz, but a ten-part-per-million source clock error can accumulate nearly one hundred microseconds in a nominal ten-second interval. A strong blocker can alias into a retained channel if the digital filter lacks adequate attenuation. A symmetric 101-tap FIR at twenty megasamples per second possesses a nominal group delay of 2.5 microseconds. A one-tenth-decibel gain error becomes a measurable amplitude change. A one-microsecond misalignment can create a seventy-two-degree phase shift at 200 kilohertz. An interpolation model can give neighbouring outputs nearly ninety per cent correlation, and a lost buffer can create an unobserved interval of more than two milliseconds while the derivative remains visually smooth. None of these calculations proves that a particular receiver failed; each defines a mechanism that an appropriately designed challenge may test.

For the practical evidence record, the laboratory should preserve the earliest relevant complex samples, their hash and acquisition provenance, the sample-clock and local-oscillator references, the event and gap masks, the rational or adaptive rate mapping, numerical precision, filter coefficient

Copyright 2026, James M. Atkinson

identity, boundary extension policy, output timestamp alignment and derivation history. When retention limits prevent preservation of everything, they should be specified as limitations of the system's observation coverage. A derivative may legitimately be useful for listening, detection, analysis or comparison while still leaving some original source hypotheses unresolved. Each conclusion must identify the reference plane, the actual operation and the uncertainty that survives.

I therefore find that the panel has reached a clear position. **Resampling preserves claims only to the extent that their required distinctions survive the transformation and the associated physical and statistical conditions are established.** It does not manufacture independent evidence, erase acquisition gaps, or repair an unobserved radio-frequency event. The next question shall concern coherent time-interleaved digitisation, where several converter paths must be combined without mistaking their nominal alignment for a measured phase and timing relationship. I thank each contributor for the disciplined exchange and formally pass the token to the next discussion.

Ten worked engineering applications | Question 033

Worked application 1. Rational conversion and exact output-rate arithmetic

Let f_s be the nominal complex source-sampling rate, L the positive integer interpolation factor, M the positive integer decimation factor, and f'_s the nominal output rate. The governing relation is $f'_s = f_s L/M$. Suppose f_s = 12,000,000 complex samples/s, L = 5 and M = 8. Then f'_s = 12,000,000 × 5/8 = 7,500,000 samples/s. The source interval is 1/12,000,000 = 83.333333 nanoseconds, while the nominal output interval is 1/7,500,000 = 133.333333 nanoseconds. For a ten-second ideal source interval, the expected output count is 75,000,000, subject to the convention applied to the first, final and filter-transient samples. None of these exact rational arithmetic relations establishes the actual source clock's physical rate; a real oscillator error must be propagated separately. The validation record should also retain the L/M ratio in reduced form, any output-phase offset, the filter taps and the rule for timestamping boundary samples.

Worked application 2. Clock error accumulated across a recording

Let f_{nom} be the stated source sampling rate, ε the actual fractional frequency error, N the number of acquired samples and T_{actual} their elapsed acquisition duration under a constant-clock model. Set f_{nom} = 8,000,000 samples/s, ε = +10 parts per million, and N = 80,000,000 samples. The actual frequency is $f_{actual} = f_{nom}(1 + \varepsilon \times 10^{-6})$ = 8,000,080 samples/s. The actual elapsed duration is $T_{actual} = N/f_{actual}$ = 80,000,000/8,000,080 = approximately 9.999900001 s. An analysis using

Copyright 2026, James M. Atkinson

the nominal rate assigns T_nom = 10.000000000 s. Its duration error is T_nom - T_actual ≈ 99.999 microseconds. Changing the output sampling-rate label does not remove this discrepancy. A defensible timing result needs a measured original clock model, evidence about possible rate changes and a residual uncertainty interval. The sign of the error matters where two independently clocked receivers are compared.

Worked application 3. Anti-alias attenuation for a strong unwanted component

Suppose an ideal resampler reduces a complex source rate from 12.0 to 6.0 MHz and is intended to retain a band within ±2.5 MHz, while a blocker at +4.0 MHz is present at -20 dBFS before the digital anti-alias filter. The target principal Nyquist interval is ±3.0 MHz. Without adequate filtering, +4.0 MHz is indistinguishable after sampling from +4.0 - 6.0 = -2.0 MHz. If the specified stopband attenuation at the blocker frequency is 70 dB in power, the residual level at the output is nominally -20 - 70 = -90 dBFS, assuming consistent reference scaling and no other nonlinearities. This may be below a declared threshold or may still matter in a very sensitive search. A certificate of 70 dB stopband attenuation alone does not determine the signal-to-noise ratio at the alias location; detector bandwidth, reference gains, quantisation and other interference must also be accounted for. Test the installed algorithm near the transition and for the maximum relevant blocker level.

Worked application 4. Linear-phase FIR group delay and timestamp correction

Copyright 2026, James M. Atkinson

Let K be the odd number of taps in a symmetric FIR filter and f_int the sample frequency at which the filter is implemented. Its nominal group delay is τ = (K - 1)/(2 f_int) for admitted components under the stated linear-phase model. Set K = 101 taps and f_int = 20,000,000 samples/s. Then τ = 100/(40,000,000) = 2.5 microseconds. If a filter output is tagged at its computational emission time without subtracting this delay, an analyst may assign an event onset 2.5 microseconds too late relative to the input sample reference. A noncausal zero-phase offline implementation can compensate alignment differently and may depend upon samples after the event. Therefore the documented filter architecture, padding and timestamp convention must accompany any asserted correction. This result applies to this hypothetical symmetric FIR, not automatically to an unknown IIR filter or waveform-specific detector peak.

Worked application 5. Amplitude ripple and the voltage error of a narrowband signal

Let g_dB be a filter's amplitude response in decibels at an admitted tone frequency and R the output-to-input voltage ratio. The relation is R = 10^(g_dB/20). For a stipulated passband gain error g_dB = -0.10 dB, R = 10^(-0.10/20) ≈ 0.988553. A calibrated 1.000 V tone at the filter input therefore appears at about 0.988553 V, a reduction of 0.011447 V or 1.1447 percent. This calculation does not establish how an arbitrary burst peak changes, because its spectrum may extend across several regions of the filter response. The relevant acceptance test should measure the declared estimator on the applicable waveform class and should

Copyright 2026, James M. Atkinson

distinguish stable gain correction from uncertainty caused by unknown spectral content, transient response and receiver state.

Worked application 6. Fractional delay and the phase of a coherent tone

Let f_B be the signed baseband frequency and Δt a time-registration error. Under a common phase convention, the magnitude of the induced relative phase shift is $|\Delta\varphi| = 2\pi|f_B\Delta t|$. For $f_B = 200{,}000$ Hz and $\Delta t = 1$ microsecond, $|\Delta\varphi| = 2\pi \times 200{,}000 \times 10^{-6} = 0.4\pi$ rad = 72°. Thus an error of just one microsecond may materially affect coherent summation even when the amplitude of each receiver output is unchanged. A fractional-delay filter may correct this difference where the actual timing offset is independently measured and the passband phase response is calibrated. It cannot prove that the two original acquisition epochs differed by the fitted offset when the fit itself was chosen to maximise coherence. Retain the independent timing reference and the uncertainty of the correction.

Worked application 7. Output covariance of a two-point interpolation

Let x_0 and x_1 be independent, zero-mean real noise samples, each with variance σ^2. Define interpolants $y_0 = (x_0 + x_1)/2$ and $y_1 = (3x_0 + x_1)/4$. The variances follow from independence: $\mathrm{Var}(y_0) = (1/4 + 1/4)\sigma^2 = 0.5\sigma^2$ and $\mathrm{Var}(y_1) = (9/16 + 1/16)\sigma^2 = 0.625\sigma^2$. Their covariance is $\mathrm{Cov}(y_0,y_1) = [(1/2)(3/4) + (1/2)(1/4)]\sigma^2 = 0.5\sigma^2$. Hence the correlation coefficient is $0.5/\mathrm{sqrt}(0.5 \times 0.625) \approx 0.894427$. The two displayed output values are strongly dependent even though the source noise samples were independent. Treating them as two independent experimental observations would make a statistical confidence statement unreliable.

Copyright 2026, James M. Atkinson

This small example is a matrix calculation of a defined interpolation rule, not a general model of all receiver noise.

Worked application 8. Converting an output sample index back to physical time

Let t_0 be the source epoch, m a nonnegative output index, f'_s the output rate, and τ a measured constant filter delay that remains in the output timestamps. The appropriate relation in this stipulated implementation is $t_{physical} = t_0 + m/f'_s - \tau$. Set $t_0 = 0$ as the chosen relative epoch, m = 75,000, f'_s = 7,500,000 samples/s and τ = 2.5 microseconds. Then m/f'_s = 0.0100000 s, and $t_{physical}$ = 0.0099975 s, or 9.9975 ms after the source epoch. Reporting precisely 10.000 ms would neglect the known delay in this implementation. Another implementation that explicitly centres its zero-phase filter and adjusts the output epoch would have a different relation. The equation must therefore come from the actual processing code and its timestamp specification, not from a generic resampling diagram.

Worked application 9. A dropped buffer does not disappear through interpolation

Suppose the input complex sample rate is f_s = 4,000,000 samples/s, and a block of N_{gap} = 8192 successive samples is lost. The missing exposure is $\Delta T_{gap} = N_{gap}/f_s$ = 8192/4,000,000 = 0.002048 s, or 2.048 ms. A later interpolation process may construct plausible values across that interval, but those values are conditioned on a model rather than recorded observations. If a suspicious transmitter emitted only within the missing period, the original receiver archive contains no samples from

Copyright 2026, James M. Atkinson

that event. Therefore a negative claim for the 2.048 ms interval is not justified by the interpolated output. The correct derivative should carry the gap in its provenance and coverage mask, and any visual filling should be labelled to prevent its mistaken use as evidence of uninterrupted monitoring.

Worked application 10. Fractional retention of a spectral channel

Let B_source denote the source complex-sampling bandwidth, B_keep the nominal width of a declared retained channel, and F_keep the ratio B_keep/B_source, assuming the stated complex rate corresponds to the nominal principal spectral interval and the filter transition is separately characterised. With B_source = 12 MHz and B_keep = 3 MHz, F_keep = 3/12 = 0.25, or 25 percent of the nominal spectral width. Thus a channel extraction retains only one quarter of the original nominal frequency interval; it cannot support a negative finding about the discarded three quarters. If the source receiver initially had additional analogue passbands or aliases, these require their own evidence and should not be folded into this simple fraction. The numerical calculation describes coverage, not detection probability, because detection also depends upon sensitivity, event duration, filtering, selection and actual time exposure.

QUESTION 034

Copyright 2026, James M. Atkinson

What calibration is required for coherent time-interleaved digitisation?

Source: V011_Roundtable_Question_034_CP034_Dr_Atkinson(1).docx | Recovered substantive manuscript. Constructed educational dialogue.

Original constructed educational discussion. Historical participants are employed as intellectual personae. None of the speeches below is a quotation, a transcript, or a claim that a deceased expert examined a contemporary receiver. All numerical cases are stipulated educational examples, not measured instrument certifications.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, we have examined what is lost through careless resampling and what may be retained by a properly characterised mathematical transformation. We now approach a different, more treacherous boundary. In time-interleaved digitisation, several analogue-to-digital converter channels observe a common analogue programme at intended successive instants. Their digital words are interwoven to emulate a higher-rate converter, but the resulting sequence is not automatically the product of one ideal measurement instrument. The eye sees a single waveform marching across a display, while the underlying apparatus contains multiple apertures, gains, offsets, input networks and delay paths. The principal question is therefore what must be measured, corrected, preserved and challenged before this reconstructed sequence may support an inference about an external emission rather than an artefact arising within its own acquisition architecture.

Copyright 2026, James M. Atkinson

Let the nominal aggregate sample rate be F_s samples per second, the number of interleaved branches be M, the branch index be i in the set 0 through M minus one, and the cycle index be k. The ideal sample time assigned to branch i during cycle k is $t(k,i) = (kM+i)/F_s$. A more realistic time stamp is $t_{actual}(k,i) = t(k,i) + c(t) + \epsilon_i(T,f,state) + j(k,i)$, where c(t) denotes common clock phase error, ϵ_i denotes branch-dependent deterministic aperture displacement under temperature T, signal frequency f and operating state, and j(k,i) denotes residual random aperture variation. The expression is a working model, not a promise that all the terms can be measured independently. Likewise a branch output may be represented, while operating within its linear region, as $y(k,i) = a_i\, x(t_{actual}(k,i)) + b_i + d_i(x,T,f) + \eta(k,i)$. Here a_i is a gain factor, b_i an offset, d_i a residual deterministic error such as nonlinearity or bandwidth-dependent phase, and η a stochastic term. Those definitions already expose why a certificate saying only that each converter has a nominal number of bits is inadequate.

I ask that we distinguish several meanings of coherence. The converter branches may share a common frequency reference yet possess persistent relative aperture skew. Their individual clocks may exhibit excellent short-term stability but uncertain absolute epoch. Two separately mounted receivers may lock to the same laboratory reference while retaining unmeasured RF path delay, cable phase and local oscillator transients. A single apparatus may generate a highly repeatable interleaving spur whose phase remains steady over hours, precisely because the erroneous mechanism is coherent. It would be a serious error to interpret repeatability as proof of an external source. The defence investigator must instead articulate which physical variables are common, which are branch specific,

Copyright 2026, James M. Atkinson

which calibrations remain valid after switching gain or preselection, and which apparent signals survive controlled perturbations.

The historical and intellectual division of labour will be deliberate. Mr Nyquist shall address the timing lattice and the limits of nominal uniform sampling. Dr Shannon shall examine what can be learned about an unknown input from a corrected but finite representation. Professor Bode shall examine relative transfer functions and the limits of feedback-based calibration. Dr Bennett shall analyse periodic mismatch modulation and the spectral signatures by which an internal spur may masquerade as an emission. Dr Deming shall examine whether the laboratory's acceptance procedure actually challenges the system under the conditions for which a forensic conclusion is intended. Seven colleagues will test these propositions. Every question will be answered before the floor passes onward.

Our applications will use defined hypothetical rates, phases, uncertainties and signal levels. They will separate first-order engineering approximations from exact identities, and a model's mathematical neatness from its empirical validation. We shall not assert that averaging twelve-bit converters magically creates twenty-four truly independent physical bits. Nor shall we confuse shared-clock synchronisation with immunity from correlated errors. A corrected waveform is only as good as its calibration's admitted envelope, version history and preserved raw evidence. The final report must distinguish the physical input plane, the electronic sampling plane and the derived digital estimate. I invite Mr Nyquist to begin by identifying the measurement necessary to establish that successive words really correspond to the intended successive instants.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 1: The timing lattice, aperture displacement and its evidential limits

Dr. Atkinson, the first discipline is to distinguish a specified sampling schedule from the realised sampling instants. In an ideal derivation the schedule is uniform and the samples constitute evaluations of one band-limited function at known times. A time-interleaved apparatus replaces the assumption of one regular physical sampler with a committee of samplers. The aggregate mathematical grid may be perfectly uniform on paper even while the actual apertures follow a periodically perturbed grid. This is not a minor bookkeeping detail. At high input frequencies, a very small timing discrepancy is multiplied by the waveform's local slope. A sinusoidal input x(t) = A cos(2 pi f t + phi) has derivative -2 pi f A sin(2 pi f t + phi); for a small aperture error delta_t, its first-order voltage error is approximately x'(t) delta_t. Thus a picosecond cannot be judged small merely because a mechanical clock displays seconds in six figures. Its significance depends upon f, A, the required dynamic range and the intended inference. [T1, T2]

For M branches with nominal aggregate sample rate F_s, each branch ideally acquires once per M/F_s seconds, but with its phase displaced by i/F_s relative to a designated reference branch. Calibration should therefore establish the relative aperture of every branch, the uncertainty of that estimate, the conditions in which it was obtained, and the identity of the clock distribution configuration. Merely observing that all channels report the right average sample count is insufficient. A branch can accumulate the correct number of samples while beginning its aperture late by a fixed interval. Equally, a clock source may show excellent mean frequency over an hour while exhibiting short-term fluctuations relevant to a narrow coherent

Copyright 2026, James M. Atkinson

integration interval. These are distinct measurements. One requires a timebase accuracy statement, a phase-noise or time-deviation characterisation appropriate to the integration window, and a relative aperture-skew estimate at the frequencies to be admitted.

The subtle point is that deterministic skew and random jitter do not have interchangeable remedies. A reproducible delay epsilon_i can sometimes be measured with a suitable input, modelled across conditions and corrected digitally, provided the available samples contain the information required for the correction. Random aperture uncertainty j(k,i) is not retrospectively removable by subtracting one stored constant. It changes the analogue voltage sampled at each event, and its consequences depend on the instantaneous waveform. A statistical model may predict its contribution to signal-to-noise ratio, but a model is not a recovery of the particular unobserved analogue value. Common clock phase variation c(t) also differs from interbranch skew. If the common term affects all branches equally over a short interval, a relative interbranch comparison may suppress it, while absolute frequency or timing claims remain subject to that very same error.

To determine relative skew, I would not be satisfied with one sinusoidal frequency and one angular result. A tone-based phase comparison may infer delay from phase only after amplitude balance, channel phase responses and alias identities have been reconciled. Its phase is also periodic, creating ambiguity modulo an integral number of cycles if the delay is not otherwise bounded. A slow sine wave may scarcely excite the sensitivity necessary to diagnose a picosecond error at high frequencies. The campaign should test multiple frequencies within the admitted

Copyright 2026, James M. Atkinson

analogue band, include alternative amplitude levels, and identify where the acquisition chain's phase response departs from a pure delay. A branch input filter with dispersive phase may imitate a timing skew at one frequency but not another. Calibration that reports one delay number for such a path conceals the physical model's failure.

The investigator should conduct controlled state changes as genuine interventions. Vary input frequency, amplitude and the branch assignment if the architecture permits; operate at relevant temperatures; repeat after a gain-range or preselector change; and compare the raw aggregate with a separately characterised acquisition path. Where calibration estimates are obtained adaptively from live observations, freeze one version and test it on withheld challenge records. Otherwise the procedure may learn the very spurs it purports to eliminate and present self-confirmation as validation. The measurement record should preserve calibration data and the before-and-after representation so that another examiner can discover whether a correction accidentally suppressed a narrow real signal along with a branch artefact.

I must also caution against treating shared clock wiring as a guarantee of physical coherence. A reference may be divided into branch phases by components whose delay changes with temperature. Clock fan-out may introduce different rise times or threshold-crossing uncertainties, and a sampled input path may possess its own aperture uncertainty independent of the nominal digital clock edge. The responsible engineer measures the realised result at the relevant signal boundary, not merely the block diagram's promise. A receiver can be coherent with itself in one sense and incoherent with a second receiver because their reference epochs, RF paths

Copyright 2026, James M. Atkinson

or integration histories were never compared. Conversely, it can remain suitable for a bounded amplitude survey while lacking a verified absolute phase reference for geolocation.

The acceptance statement should therefore enumerate the claimed variables rather than use the unqualified adjective coherent. It might establish relative branch timing to a stated expanded uncertainty over a frequency, temperature and state envelope, and verify that a specified calibration suppresses internal artefacts without raising the false-negative rate beyond an agreed bound. A stronger statement of coherent phase recovery requires additional checks on reference epoch, input transfer phase, oscillator state and processing delay. A negative result during a scan requires its own exposure analysis. Whatever the instrument displays, the calibration must identify what the apparatus knew and what the historical analogue event left unknowable. I pass the discussion courteously to Mr Black, whose work on negative feedback prompts a question about whether internal compensation can disguise a drift it never truly measures.

Harold Stephen Black | Peer question 1 to Harry Nyquist

Mr Nyquist, your account distinguishes the true sampling instant from the schedule assigned by an engineering diagram. I wish to press the practical consequence when the receiving instrument uses a closed digital adjustment loop. Suppose a two-branch converter continuously estimates the spectral line thought to arise from aperture mismatch, adjusts fractional delay coefficients until that line disappears, and reports an attractively clean spectrum. The regulator has achieved a measurable result, yet it has used the observed programme to determine its own correction. If an external intermittent emission falls at the same

Copyright 2026, James M. Atkinson

frequency as the internal image, the correction may extinguish both, and the system may call the absence of a line a proof of successful calibration. In classic feedback engineering an apparently stable regulated output may coexist with an erroneous reference or inadequate measurement model. What independent observations should be required to establish that the loop corrects branch timing rather than enforcing the assumed absence of an inconvenient spectral component? Should the validation test be conducted with the loop frozen, deliberately disturbed, or challenged by an externally generated signal whose presence and absence are concealed from the calibration algorithm?

Harry Nyquist | Immediate answer to Harold Stephen Black

Mr Black, I accept the analogy, provided we do not overstate the identity between analogue feedback and a digital coefficient update. In each case the output is controlled by information selected through a measurement mechanism. If the measurement cannot distinguish the target defect from a legitimate signal bearing a similar signature, regulation alone cannot establish which cause has been removed. I would insist that the calibration signal, when practicable, be distinguishable from the unknown programme by its timing, frequency, branch assignment, injected code or carefully controlled stimulus schedule. The purpose is not simply to display a lower spur floor, but to acquire independent evidence of the parameter the algorithm claims to estimate.

A satisfactory trial should begin with the loop's definition. State its cost function, update interval, permitted coefficient range, initial conditions and response to a missing or changing reference. Save the

Copyright 2026, James M. Atkinson

coefficient trajectory. Then apply challenge signals which the adjustment algorithm did not use during training, including weak bursts placed near the known internal artefact, and verify both true-detection and false-alarm performance with correction enabled and disabled. Randomise the challenge placement in time and frequency so that the algorithm cannot succeed by repeating a prepared laboratory demonstration. The examiner must record every failed trial and any altered threshold, not simply the visually attractive run.

An external clock or independently characterised sampling device may help identify residual skew, although it also introduces its own delay and uncertainty. A second coherent reference is useful only to the extent that its path and dependence are disclosed. If both comparisons depend upon the same imperfect clock, their agreement is not wholly independent confirmation. Where the algorithm performs blind calibration using the programme alone, I would report its correction as conditional upon assumptions about signal statistics and artefact separability. Demonstrated suppression of a predicted image can be a valid restricted finding. It is not proof that the image had no external component, and it is not proof that another emitter would have survived.

Finally, freeze or version the calibration state before a forensic challenge and preserve the raw observations. If the coefficient update is essential during operation, reproduce the full update sequence with the test and require stability across a specified envelope rather than claiming universal immunity. A system that cannot expose its training record may still be useful for discovery, but its derived absence claims

Copyright 2026, James M. Atkinson

deserve a narrower evidential interpretation. I invite Dr Hamming to question how such disciplined measurement can be achieved without making every receiver impractically burdensome.

Richard Wesley Hamming | Peer question 2 to Harry Nyquist

Mr Nyquist, the examiner may discover hundreds of candidate signals across an extensive survey, while a high-speed receiver continuously adjusts gain, channel allocation, and clock calibration. Your demand for a preserved timing lattice and frozen challenge states appears reasonable for one academic experiment, but the forensic operator cannot stop the survey at every millisecond to measure the aperture of each branch against a metrology laboratory. Nor will a recording budget retain every raw sample indefinitely. I ask where you would draw the line between the variables essential to a particular claim and those that are merely desirable for an imagined perfect record. Would you preserve a complete sample stream, a sparse set of verified reference events, or a continuous parameter log? What evidence would support a limited statement that one detected line is receiver-independent if some of the calibration was adaptive and the source signal is too weak for a direct single-channel comparison? I also seek a principled response to the opposite problem: a cautious apparatus might produce an archive so large and complex that no independent examiner could realistically reproduce the analysis.

Harry Nyquist | Immediate answer to Richard Wesley Hamming

Dr Hamming, the difficulty is not solved by pretending every observation is equal in evidential importance. The required record should be selected according to the proposition that the investigator intends to defend. A frequency-and-time discovery log may support

Copyright 2026, James M. Atkinson

the proposition that the apparatus indicated a candidate during a specified interval, provided receiver configuration and exposure are sufficiently documented. A claim about the candidate's physical amplitude, phase coherence or external origin requires more. I would therefore define tiers of preserved evidence rather than impose an indiscriminate universal archive. At the first tier are time-stamped configuration changes, calibration identities, oscillator and clock status, detection-rule versions and any invalid intervals. At the second are raw signal intervals surrounding material candidates, together with sufficient pre-trigger context to distinguish event selection from continuous exposure. At the third are calibration challenge records and independent measurement paths needed for a stronger attribution claim.

Preservation may be selective without being misleading, but selection itself must be described. A triggered record is not evidence that nothing occurred during the unretained time. The operator should preserve the trigger rule, threshold, windowing, scan dwell and any dead time. This information permits an examiner to calculate a conditional detection probability or to identify where such a calculation is unsupported. Sparse reference events can diagnose clock drift when the drift model is validated, but they cannot reconstruct arbitrary unobserved phase excursions between references. A parameter log can document which correction was applied; it does not independently prove that the correction was physically valid.

Copyright 2026, James M. Atkinson

I should also distinguish an aggregate sequence from parallel corroboration. The same input sampled by several branches is not several independent observations of the same instant. Interleaving deliberately assigns different instants to branches. When the source is too weak for a single-branch measurement, a calibrated aggregate may improve a restricted detector's performance, but its evidence about external origin comes from additional interventions, such as changing the sample plan, receiver front end, or antenna while preserving the candidate's physical frequency and timing prediction. Those interventions must have competing outcomes for rival hypotheses; otherwise they merely produce more data.

Reproducibility should be achievable through a compact, content-addressed record of software, calibration constants, source digests and essential state transitions, not necessarily by storing each ephemeral memory transaction. Independent examiners need the ability to reproduce the resulting derivation and to test the stated uncertainties. Where the raw waveform is absent, a report must say so and limit its conclusion. A bounded finding is not evidence of incompetence. It is what precision means when the apparatus has finite memory and the original event cannot be observed a second time. I now pass the floor respectfully to Dr Shannon for the question of which corrections actually preserve information.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 2: Information, calibration operators and the difference between restoration and invention

Dr. Atkinson, I begin with the proposition that a calibrated output is not equivalent to a newly observed input. Suppose an interleaved digitiser produces a vector y of recorded samples and a laboratory applies an operator C, chosen through calibration, to produce an estimate x_hat = C(y). The operator may be well justified, and it may substantially reduce a known error. Yet if the original physical acquisition is described by y = H(x) + n, then the adequacy of C depends upon properties of H, the uncertainty in its parameters, and the noise n. An elegant inverse does not rescue information that H has irreversibly discarded. If a branch clipped, a gain correction cannot uniquely restore the pre-clipping amplitude. If one aperture missed the relevant part of a transient, interpolation can offer a model-conditioned estimate but not a second physical measurement. And if the algorithm was calibrated with the event itself, the recovered structure may partly reflect the prior assumptions imposed upon it. [T1, T3]

In the ideal linear case, consider a fixed transformation matrix H that connects a finite set of input values to the observed vector. Where H has full rank and its conditioning is satisfactory, the experimenter may estimate the input under stated noise assumptions. If H is ill conditioned, small errors in the observation or in the estimated calibration coefficients may generate large errors in the reconstructed input. Where H lacks rank, distinct input vectors produce identical outputs. Adding channels cannot automatically remedy this when their responses are dependent or when they observe different instants and the signal class is unrestricted. The engineer should measure not merely the inverse algorithm's output quality on a familiar

Copyright 2026, James M. Atkinson

training waveform but also the range of admissible inputs on which it remains stable, and the statistical behaviour of the estimator for those inputs.

A time-interleaved converter imposes periodic structure upon its errors. A branch-specific offset can inject a line at a fraction of the aggregate sampling frequency, and a gain or aperture mismatch can translate a strong input component into other digital frequency positions. These errors have informational consequences beyond an untidy display. A narrow image can be mistaken for a weak transmitter, especially when a wideband screen compresses millions of samples into a small spectrum. Inverse processing must therefore be tested against its tendency to manufacture confidence. If the correction perfectly removes a calibration tone and its image, but an actual weak event near the same image is suppressed, the apparent improvement in noise floor conceals a loss in task-relevant information. The correct performance measure includes the distribution of missed events and false identifications as well as the residual spur height.

The term coherence requires equal care. Phase coherence means something only relative to a declared reference and a stated interval. Shared sampling clocks can provide a stable relation among branches, but do not of themselves establish the absolute carrier phase of an external signal at the antenna port. The path from antenna to digitiser includes filters, mixers, cables and physical propagation delay. Even if the clock has negligible random error, uncharacterised phase response along that path may defeat a claimed bearing or arrival-time difference. Conversely, a calibrated digitiser with imperfect absolute epoch can support useful within-record comparisons, such as the relative phase of two coherent components, when

Copyright 2026, James M. Atkinson

the common error cancels appropriately. The investigator should describe exactly what was compared rather than attach the adjective coherent to the entire recording without qualification.

Consider a proposed scheme to gang two twelve-bit converters against a common analogue input. If they sample nominally the same instant and exhibit partly independent noise, one may average their readings to lower a stochastic error under the right assumptions. But the result is not an ideal twenty-four-bit observation. The pair retains finite input range, differential nonlinearity, common clock error, and possibly strongly correlated analogue noise. If the two channels are instead time interleaved, they do not even measure the same instant, so their words cannot ordinarily be averaged as replicas. They extend the rate of sample acquisition at the cost of a larger mismatch-calibration problem. Any claim of additional effective bits must specify a waveform model, a noise model, bandwidth, acquisition duration, estimator and measurement reference plane.

The preservation of uncertainty is part of the representation. A single digital file may carry one sequence of nominal sample numbers while the true sampling times are estimates. Those estimates should be accompanied by a timing-calibration model and uncertainties, including correlation. If all branches follow one reference oscillator, a common frequency error can move their nominal timestamps together, and its uncertainty does not shrink merely because the number of samples increases. A covariance model for the reconstructed outputs may be necessary when a correction filter combines neighbouring words. Presenting a long list of corrected samples without its dependency structure invites subsequent analysts to calculate unwarrantedly narrow confidence intervals. The more

Copyright 2026, James M. Atkinson

sophisticated the correction, the greater the need for a reproducible description of how it modified the evidence.

I would design a task-specific acceptance experiment with hidden challenge events. Preserve the raw multiplexed words and calibration-state transitions. Select representative input frequencies and burst durations, including the portions of spectrum near expected mismatch images. Introduce both legitimate strong carriers and weak targets, and randomise the placement of the weak targets relative to branch phase. Require a fixed rule for identifying a candidate, with no adjustment after inspecting its answer. Record outcomes for each configuration, not only the best one. Then state a bounded result: for the signal class and operating envelope tested, the specified procedure preserved or detected events with measured performance and stated uncertainty. That is a genuine achievement. The broader assertion that the corrected sequence always reproduces the analogue past would be an inference the evidence has not earned. I pass the floor to Professor Gabor, who may properly question whether our sample-by-sample correction ignores the finite concentration of a transient in time and frequency.

Dennis Gabor | Peer question 3 to Claude Elwood Shannon

Dr Shannon, I wish to test the boundary between a waveform that is formally reconstructible and a burst whose effective evidence occupies a narrow region of both time and frequency. Suppose an instrument reports an unusually clean carrier after combining several converter branches, but its calibration was developed with long stationary sine waves and the suspected surveillance emission is a brief frequency-agile pulse. A long-tone phase correction can be excellent even though the

Copyright 2026, James M. Atkinson

transient encounters aperture distortion, filter memory and changing local oscillator phase. If the correction is represented by one frequency-domain function, the operator may be tempted to assign every output sample the same amplitude confidence. How would you define the information actually available for an event short enough to straddle only a few interleaving cycles? Is there a scientific way to quantify the loss introduced when we fit a stable calibration model to a nonstationary burst, or must the report describe a range of physically compatible pulses rather than one immaculate reconstructed line? I also ask whether a longer post-processing window can legitimately improve knowledge of a pulse that the front end never admitted.

Claude Elwood Shannon | Immediate answer to Dennis Gabor

Professor Gabor, the central fact is that information depends upon the question and the observation channel. A long stationary tone may allow very precise estimation of a small parameter because many nominally similar cycles contribute to the estimator. A short transient does not provide an equivalent collection of observations, even where the sample count is numerically large. The relevant channel includes the analogue front end, interleaving apertures, retained time interval and processing rule. If any of these is varying during the event, the stationarity assumed by the calibration must be tested, not silently imported from the reference experiment.

A useful practical representation is a family of input signals consistent with the measured samples within an uncertainty envelope. One may calculate a maximum-likelihood estimate or some other reconstruction, but should also examine its sensitivity to

Copyright 2026, James M. Atkinson

plausible timing skew, bandwidth-phase variation, gain state, and unknown onset within the sample grid. For a pulse occupying only a few nominal aggregate periods, a fixed aperture displacement can shift the apparent peak and alter its measured shape. When the true analogue rise time is shorter than the admitted bandwidth permits, no digital deconvolution can restore arbitrary lost high-frequency information without additional assumptions. Even with a powerful prior model, the resulting estimate is conditional upon that prior.

The engineer may quantify some losses by injecting characterised pulses over a grid of arrival phases and physical frequencies, measuring reconstruction error and uncertainty. Vary rise time, duration and amplitude independently rather than calling all short events equivalent. Compare the procedure on known tests whose waveform model differs from the one used to derive its coefficients. A worst-case or quantile performance bound over the intended signal class is often more relevant than the mean error of a stationary sine wave. If the bursts are selected by a trigger, the trigger mechanism's missed intervals must be incorporated into the performance claim.

Longer post-processing can reduce certain uncertainties where the raw record contains independent information, as when it averages noise over repeated transmitted symbols. It cannot recover observations never taken. A processing window that includes many post-event zero samples may change the appearance of a spectrum without changing the number of informative event samples. Likewise, a narrow Fourier bin can be useful for a lasting tone but may smear a brief event and misrepresent its timing. An appropriate report should

Copyright 2026, James M. Atkinson

identify which parameter was estimated, which signal model was used, what independent trials supported it, and which alternative pulse shapes remain observationally indistinguishable. A coherent but model-conditioned inference can be useful, but its conditions belong beside the result rather than hidden in the operator's memory. I invite Professor Bode to consider the analogue transfer functions whose imperfections may be mistaken for mere timestamp errors.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal response 3: Relative transfer functions, phase dispersion and a calibrated operating envelope

Dr. Atkinson, the architecture of interleaving should be understood as a network of multiple input-to-output transfer paths, not simply as several ideal clocks waiting their turn. Branch i has an effective complex frequency response $H_i(f,T,s)$, where f is input frequency, T temperature and s the complete operating state. Its magnitude can vary with attenuation and gain settings. Its phase can vary through branch filters, buffers, sampling switch networks and physical routing. The familiar correction of one offset, one scalar gain and one scalar delay is justified only when these parameters adequately approximate the ratio of the true branch responses over the intended band. Where one branch has a frequency-dependent passband slope or group-delay ripple, forcing a single constant delay may improve one calibration tone while leaving substantial residual distortion elsewhere. [T2, T4]

A reference branch can supply a convenient phase origin, but no internal path is automatically an absolute physical standard. If $H_0(f)$ is selected as a reference and branch i is compared by $R_i(f)=H_i(f)/H_0(f)$, the measurement is relative. Its success in making the branch responses agree does not prove that H_0 has an accurately known absolute response at the antenna input. Nor does the act of dividing make the reference error disappear. Some systematic errors common to all branches cancel in R_i, while others survive in the final amplitude or phase of the aggregate record. If the report's claim concerns only interbranch image suppression, relative calibration may suffice. If it concerns absolute field strength, time of arrival or source

Copyright 2026, James M. Atkinson

location, the larger input chain must be characterised at the declared reference plane.

A useful diagnosis separates pure delay from dispersion. For a pure delay tau, phase is phi(f) = -2 pi f tau, and its slope with respect to frequency is constant. In a real network the group delay may vary: tau_g(f) = -(1/(2 pi)) d phi(f)/df, where the phase is unwrapped in a declared manner over a region where the transfer function is sufficiently well behaved. A two-point phase estimate gives an average delay over those points but can conceal fine ripple. Worse, phase wrapping can make two substantially different delay hypotheses appear equivalent at one tone. I would measure responses at a suitable grid of frequencies, check interpolated regions using withheld frequencies, and retain evidence of phase-unwrapping decisions. The residual mismatch after correction, not the elegance of its coefficient file, determines whether it can support the claimed result.

The correction itself may create new features. A finite-length fractional-delay filter has a passband error, endpoint response and transient length. A frequency-domain inverse can amplify noise around a notch of H_i, especially when a branch response approaches zero. If an equaliser is regularised to prevent that amplification, it no longer exactly inverts the measured response, and the remaining bias must be characterised. These are familiar engineering trade-offs. There is no virtue in calling one function a calibration if it merely transfers distortion from a visible spur into an obscure correlated error. The relevant figures are amplitude and phase residuals, noise amplification, introduced transients, and detection performance on the frequencies and times that the operator actually requires.

Copyright 2026, James M. Atkinson

Temperature and state changes are especially troublesome because they often alter the physical path without changing the software's nominal sample rate. A warm receiver may exhibit a branch delay shift due to clock distribution or input loading. A preselector change may introduce a different phase relationship. An automatic gain-control transition may alter analogue settling and the time in which a recorded pulse is valid. A calibration table indexed only by temperature may still be wrong if input frequency, full-scale range or firmware revision has changed. I propose an explicit configuration signature that associates every retained event with the coefficient version, gain/preselector state, clock status, calibration temperature range and any known invalid interval. When the state leaves the proven envelope, the system should flag uncertainty or demand a new challenge rather than apply a numerically plausible but experimentally unsupported correction.

One must also distinguish a channel's phase response from its sampling aperture. A measured tone-phase difference equals a contribution from aperture skew plus contributions from frequency-dependent analogue path phase, reference-path phase and possibly nonlinear distortion. If all those sources are forced into one timing coefficient, the correction may misrepresent a broadband transient. The separation can be approached by calibrated test fixtures, broadband excitation with independently characterised timing, and measurements at multiple frequencies and amplitudes. A constant slope across a substantial band supports a delay model more strongly than a single point. Disagreements between stimulus classes and environmental states identify where the simplified model fails. The investigator should resist describing those disagreements as nuisances to be suppressed; they are precisely the evidence that limits the claim.

Copyright 2026, James M. Atkinson

In a defensive surveillance survey, validation is most important where strong legitimate signals coexist with a small suspect feature. The branch transfer functions can be linear and accurate for low-amplitude laboratory tones yet depart under high common-mode power, input slew or near-overload conditions. A small mismatch spur can reside close to the target frequency. If the front end's dynamic range has been exceeded, digital equalisation cannot restore a valid linear measurement merely by removing the most recognisable spectral line. The acceptance trials should contain at least one representative strong interferer and should examine the target's detection probability while branch calibration is enabled, disabled and deliberately perturbed within a known bound. The report may then say what survived which physical challenges, not merely that the corrected spectrum looks quiet.

The useful end product is an uncertainty-bearing map from input conditions to corrected observations. It should describe the measured transfer ratios, residual errors, limits on inverse noise amplification, known thermal and state dependence, and the physical reference plane of every correction. A network is not completely described by the fact that its numbers can be divided. Similarly a multi-branch digitiser is not qualified for phase-coherent investigation simply because its streams are aligned to a display grid. I pass the token to Professor Wiener, whose analysis of correlated noise should illuminate what happens when equalisation makes an array of outputs appear cleaner but less statistically independent.

Norbert Wiener | Peer question 4 to Hendrik Wade Bode

Professor Bode, you distinguish the branch transfer functions from the clock offsets and warn that an equaliser may trade visible error for

Copyright 2026, James M. Atkinson

invisible correlation. I should like to examine a common validation practice. A laboratory measures a narrowband response, applies inverse filters separately to each branch, and subsequently estimates the noise floor of the combined record from successive FFT bins as though every displayed value were independent. But the equaliser may mix neighbouring time samples and magnify noise near its poorly conditioned frequencies. Furthermore the same reference tone may have driven every calibration estimate, producing common parameter uncertainty. Does agreement between corrected branches establish only that a chosen model has made them similar, rather than that the individual observations now contain independent evidence? What would a defensible uncertainty budget need to retain about calibration covariance, filter memory and shared reference error? I ask particularly how one might communicate this distinction to an investigator who sees a falling noise-floor trace and supposes that the instrument has thereby become more certain of the physical source.

Hendrik Wade Bode | Immediate answer to Norbert Wiener

Professor Wiener, the observed fall in a displayed noise floor is a statistic of a transformed representation, not an automatic declaration that uncertainty in the measurand has fallen. Let the input-noise covariance matrix be Sigma_x and let an applied linear calibration be C. The transformed stochastic covariance is Sigma_y = C Sigma_x C^H, where C^H is the conjugate transpose. If C combines neighbouring samples, off-diagonal covariance terms generally appear. If a calibration parameter theta is estimated with uncertainty, an additional term should be considered through the sensitivity of the

Copyright 2026, James M. Atkinson

corrected output to theta; where several parameters share a reference, their covariance must enter that calculation. A scalar formula that assumes independence can therefore understate uncertainty even when every standard deviation is individually estimated correctly.

The most defensible remedy is to define the actual estimator of the claimed quantity and propagate uncertainty through that estimator. For a specified input amplitude one might use an independently calibrated reference signal, repeat the full acquisition across several temperatures, and compare the corrected estimate with its known reference within a stated coverage interval. For spectral detection one must consider the distribution of the largest noise excursion across the bins and windows actually searched, not merely the variance of an arbitrary single bin. In both cases the equaliser may change the effective number of independent trials. The appropriate acceptance test uses the same search procedure that the field examiner will use.

Agreement among branches remains informative when interpreted correctly. It can show that relative mismatch is below a test threshold in a particular state. It cannot, by itself, establish that the common source oscillator is accurate or that the input antenna system has an unbiased transfer function. A common reference-tone error can be copied obediently into every branch. The calibrated agreement then remains genuine but the inference to absolute physical truth does not follow. That is why I would retain the raw record, reference source certificate, actual measurement uncertainty, algorithm version and

Copyright 2026, James M. Atkinson

the full schedule of control states, rather than merely a corrected output whose numerical neatness invites unwarranted certainty.

To communicate the result, the report should separate three statements: the relative branch mismatch was measured and reduced; the remaining uncertainty in a defined amplitude or phase measurand was evaluated; and a candidate external emission survived specified alternative explanations. Each statement requires its own evidence. A successful first statement does not guarantee the second or third. When those distinctions are explicit, the engineer may use sophisticated equalisation without concealing its statistical costs. I now invite Professor Bracewell to test our reliance upon smooth frequency-domain corrections when the event of interest is shorter than the filter's memory.

Ronald Newbold Bracewell | Peer question 5 to Hendrik Wade Bode

Professor Bode, suppose a correction operator has impressive steady-state performance, measured against a long sinusoid, while the laboratory's objective is to identify the arrival time and polarity of a short burst. A fractional-delay filter may be linear phase within its passband and nevertheless possess a substantial impulse response extending on either side of the nominal event. Its time-centred output can exhibit oscillations before the physical burst and continued ringing after it. Some examiners might call the first visible oscillation the beginning of the emission, especially when plotting at high magnification. Others might subtract a nominal group delay and declare the resulting timestamp absolute. How would you require the laboratory to test onset bias and its uncertainty, distinguish causal delay from offline acausal processing, and

Copyright 2026, James M. Atkinson

preserve the boundary treatment used near the beginning and end of a retained record? Would the same frequency-domain inverse be valid if the analogue branch response changed during an automatic gain transition that occupied part of the pulse?

Hendrik Wade Bode | Immediate answer to Ronald Newbold Bracewell

Professor Bracewell, a steady-state transfer function is a description of a linear time-invariant system only when the system is sufficiently stable over the observation. It does not become a universal account of a receiver that changes gain, loading or clock phase during a burst. I would accordingly use two families of challenges. The first would test stationary frequency response with tones and broadband signals across the admitted operating envelope. The second would test transient response using independently timed pulses of varying rise time, duration, amplitude and phase relative to the branch schedule. The distinction prevents an attractive long-tone calibration from masquerading as a verified time-domain onset measurement.

For a fixed linear-phase FIR correction of length L at sample rate F_s, nominal group delay is (L-1)/(2F_s) when the filter is symmetric and the conventional assumptions hold. That relation identifies a processing delay, not the entire uncertainty of a physical event timestamp. A pulse's apparent threshold crossing also depends upon bandwidth, threshold rule, noise and its unobserved analogue shape. If the implementation uses offline symmetric filtering, apparent pre-event ringing is possible in the displayed record. It must never be

Copyright 2026, James M. Atkinson

reported as a physical emission preceding the event merely because the plot contains nonzero corrected values there. The correction algorithm and its boundary-extension policy must be retained so that this behaviour can be reproduced.

I would compare measured onset estimates against an independently timed reference at the actual analogue input plane. Repeat with the pulse shifted through different interleaving phases. A single reference pulse arriving at a favourable phase is not adequate, because the artefact may vary periodically with branch assignment. Record the signed timing error distribution and its extremes over the intended pulse classes. Where the waveform model is uncertain, report a bound on onset position rather than a single absolute time. If analogue gain changes inside a pulse, apply a state-aware model if the transition has been characterised. If it has not, mark the affected interval indeterminate and preserve the raw samples instead of asserting that a stationary inverse recovered a uniquely defined input.

The same advice extends to phase. A correction that aligns stationary carriers can be valuable for coherent integration while still failing to reconstruct the start of a broadband transient. These are different measurands. We should certify only what the experiment has challenged: relative phase within a defined band and state, onset error for stated pulse classes, or amplitude response under a particular gain range. I pass the floor to Dr Bennett, whose study of unwanted modulation will connect branch mismatch to the spectral evidence from which the surveyor may infer an external emitter.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal response 4: Mismatch as unwanted modulation, not merely an untidy conversion error

Dr. Atkinson, the forensic hazard of time interleaving is especially plain when one regards the branch sequence as a periodically time-varying system. Even if every constituent converter is acceptably linear in isolation, their periodically differing gains, offsets, apertures and bandwidth responses can modulate a legitimate strong input. The spectrum of the aggregate output may then contain lines that the analogue input did not contain. This is not a spectral illusion in the sense that the displayed computation is false. The digital sequence truly contains the modulation products. The false step occurs when the investigator assumes those lines must have existed at the receiver's declared external input plane. The distinction between an internal modulation product and an incoming emission lies at the heart of the experimental defence. [T2, T4]

Let the ideal discrete input be $x[n]$ and a simplified branch gain schedule be $g[n]$, periodic with period M. The aggregate observation is $y[n]=g[n]x[n]+b[n]$, where $b[n]$ is a periodic branch-offset sequence. Multiplication by a periodic gain function corresponds to discrete-frequency convolution with spectral lines at integer multiples of F_s/M. Consequently a sinusoidal input at frequency f_0 can generate shifted components at f_0 plus or minus qF_s/M, folded into the representable frequency band according to the recording convention. A branch-offset pattern can generate periodic lines even when the analogue input is nominally zero. The positions have a diagnostic relationship to the aggregate sampling rate and the branch count. They do not, however, prove internal origin without a physical test,

Copyright 2026, James M. Atkinson

since an external transmitter could happen to occupy a related frequency. The location is a clue which should motivate an experiment.

For two branches with actual gains 1.01 and 0.99, the mean gain is unity and the alternating gain perturbation is 0.01 times (-1)^n. If the input is a complex exponential at f_0, the principal shifted component has magnitude 0.01 relative to the unshifted carrier under this simplified model. The line therefore lies 40 dB below the carrier in power. That result is illustrative, not a general formula for every real-sine calibration case or every multichannel mismatch pattern. In a real ADC, gain errors may be frequency dependent and coupled with aperture displacement, and the shifted products can overlap, add or partly cancel. One must calculate or measure the actual branch pattern rather than declare one universal spur level from a nominal mismatch percentage.

Timing skew creates a related but distinguishable modulation. For a small branch-dependent sampling error epsilon[n], expand x(t_n+epsilon[n]) as x(t_n)+epsilon[n]x'(t_n), neglecting higher-order terms where justified. For a sinusoidal input the derivative contributes a factor proportional to 2 pi f_0. Thus the amplitude of timing-related distortion usually becomes more significant as input frequency rises, all else equal. An offset-related spur can exist without a carrier; a gain-related image scales approximately with carrier amplitude; a timing-related image also scales with input frequency under the small-error model. A calibration campaign that tests these distinct dependencies may discriminate among mechanisms more effectively than one that merely minimises total spur energy at one centre frequency. Nevertheless the mechanisms interact, especially at high slew rates and near nonlinear operation.

Copyright 2026, James M. Atkinson

The importance of interleaving calibration extends beyond an elegant single-tone spectrum. An investigative receiver may process multiple strong legitimate services simultaneously. Their images can fall within a band of interest, and their sum may resemble a cluster of weak transmitters. A frequency-agile instrument may shift its aggregate sampling rate, thereby moving internal spur families in a predictable manner. An external signal at a fixed radio-frequency coordinate will not ordinarily follow that digital branch-spacing prediction when the input path is properly accounted for. Retuning or changing the interleave mapping can therefore be a controlled challenge. But the test must preserve enough invariants to be interpretable: the antenna, RF path and gain state should be identified, and the change must not inadvertently move the analogue front end into a different response regime. Otherwise a disappearance can be explained by altered reception rather than by correction of an internal artefact.

One must also preserve the distinction between a spur and an estimated source probability. A spectral line at a predicted mismatch coordinate may have an internal mechanism, but the probability that a particular observed alarm corresponds to an external transmitter depends on the prevalence of relevant inputs, the detection rule, the number of searched opportunities and rival causes. Supposing the calibrated receiver produces one false candidate in a thousand reference trials does not make every individual alarm 99.9 percent likely to be genuine. Those statements concern different conditional probabilities. An analyst who sees a persuasive waterfall trace should not allow its visual regularity to replace a well-defined detection and attribution problem. The lines drawn by a digital plot have no knowledge of the path through which the physical energy entered the apparatus.

Copyright 2026, James M. Atkinson

A defensible bench test would start with a stable injected reference whose frequency and amplitude are known at the declared plane. Measure each branch's offset, relative gain and phase response over the intended frequency range. Deliberately vary sampling rate and interleave pattern if the hardware permits, looking for the predicted displacement of internal images. Introduce a weak independent target placed near, then on, then away from the predicted mismatch image, while keeping the assessment rule fixed. Evaluate false-positive and false-negative outcomes both before and after calibration. Repeat after thermal settling and after consequential state changes. Preserve the acquisition configuration and any rejected measurements. By this approach a claim of artefact suppression can be tested without suppressing the evidential record of legitimate weak events.

The key limitation is that no spectral pattern uniquely identifies its physical cause without the system boundary. A coherent mismatch line is internally generated only if the relevant causal tests support that explanation; a stationary external emitter could create a similar output under one set of settings. Conversely a physical emission may survive in the record despite some degree of branch mismatch. Engineering should not force every contaminated observation into the categories wholly false or wholly true. It should quantify the limitations that affect the question at hand, preserve potential alternatives and invite repeatable experimental challenges. I pass the token to Professor Tukey, whose criticism of selected spectral displays will sharpen this principle.

John Wilder Tukey | Peer question 6 to William Ralph Bennett

Dr Bennett, your proposed test changes an instrument parameter and asks whether the suspicious line follows the predicted internal spur

Copyright 2026, James M. Atkinson

coordinates. The design is attractive, but I wish to examine its statistical weakness. A spectrum analyser or SDR console may display thousands of frequency bins across hundreds of time windows, and the investigator may notice only a few apparently stable candidates. Suppose the analyst tries several branch mappings, calibration settings and FFT lengths and retains the one in which the candidate disappears most convincingly. The resulting demonstration may look causally decisive while its method has been selected after inspecting the desired conclusion. How would you distinguish a pre-specified, falsifiable discrimination test from an exploratory series of transformations whose unsuccessful members have been quietly forgotten? Should the investigator report a family-wise error rate, a false-discovery measure, or an empirical challenge frequency? And how should the conclusion address a candidate that persists in some conditions and disappears in others because the analogue passband, rather than the interleaving mechanism, has changed?

William Ralph Bennett | Immediate answer to John Wilder Tukey

Professor Tukey, the investigator should divide discovery from confirmation. Exploratory transformations may help identify a mechanism, but they cannot be treated as a pre-registered test whose success probability was known in advance. The record should retain the exploration history where it materially influenced the final choice of hypothesis, including the receiver settings, FFT windows, calibration versions and observed outcomes. A confirmatory challenge then states in advance which instrument parameter will change, the physical invariants expected of an external emission, the predicted internal-image displacement, the acceptable tolerance and

Copyright 2026, James M. Atkinson

the decision rule. The confirmatory data should be acquired independently of the trials that generated the idea, where practicable.

A family-wise error calculation may be appropriate when the analyst has tested a known number of statistically specified hypotheses, but it does not rescue a poorly defined experiment. The relevant trial count may include frequencies, times, receiver configurations and algorithm versions. Dependencies among those trials make a naive independent-bin approximation misleading. Empirical blank or negative-control trials using the entire search pipeline can be more directly relevant to an operational false-alarm claim, provided the controls represent the conditions actually encountered. The report must give the number and composition of the trials and must not convert a finite observed rate into a certainty about a specific line's cause.

When the analogue passband changes together with the branch mapping, the intervention is confounded. A disappearing signal cannot be attributed uniquely to the digital mismatch shift. I would either hold the analogue path fixed and alter a purely digital parameter, or perform additional controls that measure the change in analogue sensitivity. A dual-receiver comparison with separately characterised front ends may add evidence if the dependence between their paths is understood. Likewise a carefully injected candidate at the same physical frequency can test whether the system retains external signals during the proposed intervention. It is better to acknowledge that the first experiment was inconclusive than to preserve only its favourable image.

Copyright 2026, James M. Atkinson

The strongest statement after a successful campaign is bounded: the observed line moved in the manner predicted by the measured interleave mismatch under specified changes, whereas an independently injected physical tone obeyed the expected external-frequency mapping. That evidence supports the internal-artifact explanation and challenges particular alternatives. It does not prove that every future line at a similar frequency is internally generated, nor that all weak signals have been preserved by the correction. Statistical discipline gives the technical diagnosis a scope that can be defended. I pass the discussion to Dr Deming for the broader problem of calibration systems that declare themselves satisfactory by testing only the easy conditions.

Copyright 2026, James M. Atkinson

W. Edwards Deming | Principal response 5: Acceptance testing, traceability and a system capable of discovering its own failures

Dr. Atkinson, I shall distinguish the repeatability of a calibration procedure from the performance of the entire measurement system for its intended use. A trained operator may obtain nearly identical branch-skew numbers on successive mornings. That observation may demonstrate procedural stability, but it does not establish that the receiver correctly recognises intermittent weak emissions in the presence of strong legitimate activity. The standards of evidence must begin with the question being answered. Where an instrument is intended for discovery, a useful measure is detection performance across representative signals and conditions. Where it is intended for quantitative amplitude measurement, the measurand, input reference plane, correction model and combined uncertainty are central. Where it is intended to support source attribution, control of alternative explanations becomes indispensable. A single attractive laboratory certificate cannot answer all three claims. [T5, T6]

There are at least four populations to distinguish. First is the population of converter branches, which may differ in gain, offset, aperture, analogue response and nonlinearity. Second is the population of operating states, including gain ranges, sampling rates, preselector paths, clock-lock states, firmware versions and temperatures. Third is the population of signals that the investigation is meant to encounter, including weak bursts, large adjacent carriers, near-clipping transients and varying duty cycles. Fourth is the population of time intervals during which observations were actually possible, as distinct from the time intervals in which a triggered archive contains selected records. A calibration programme that samples only one

Copyright 2026, James M. Atkinson

convenient branch, one warm state and one strong continuous tone may be reproducible while almost entirely irrelevant to the claimed field task.

I recommend beginning with a declared acceptance matrix, not merely a list of calibration instruments. Every column should represent a physically meaningful factor, and every row should identify a trial or combination of conditions. The matrix should include the frequencies where interleave artefacts are predicted, as well as portions of the band where the calibration appears easy. It should challenge the receiver before and after warm-up; at the gain and attenuation settings used in practice; near, but not beyond, specified full-scale limits; and with both continuous and intermittent signals. It should include known-negative trials with no injected target, and known-positive trials whose presence and parameters are concealed from the person interpreting the results. The detection rule, tolerances and stopping criterion should be fixed before examining those confirmatory outcomes.

Variability itself is not a defect to be wished away. If repeated branch-delay estimates differ, ask whether the variation is attributable to routine measurement noise, temperature, state transitions or an unrecognised special cause. One can use control-chart reasoning to monitor a stable calibration parameter, but a control chart is valid only within the model and sampling assumptions supporting it. A visually flat trend may be produced by an algorithm that clips or over-smooths the parameter history. Likewise an adaptive correction may yield artificially stable residual images because its objective function has been tuned to hold that statistic steady. Independent checks are needed to establish whether the physical aperture actually remained within tolerance. One should not confuse the smooth sound of a servo with the accuracy of the device it controls.

Copyright 2026, James M. Atkinson

Traceability means more than possessing a sheet bearing an impressive institution's seal. A calibration result should be linked to appropriate reference standards through a documented chain with stated uncertainty. In this context the timebase reference and analogue amplitude reference may require separate chains, because time and voltage are separate dimensions of the waveform. Reference generators have their own cable delays, jitter, phase noise, loading and thermal characteristics. Their contribution to the uncertainty budget should be evaluated rather than excluded because their labels say standard. A small uncertainty in one carefully measured component cannot compensate for a large unmodelled error elsewhere in the receiver. The combined standard uncertainty of a derived quantity follows its measurement model, incorporating sensitivities and covariance where appropriate. [T5, T6]

An important consequence concerns the use of performance averages. A receiver might show excellent mean amplitude error across a broad collection of easy continuous-wave trials while failing a small number of intermittent signals that coincide with interleave image frequencies. If the intended field task is to find precisely such signals, the overall mean can conceal a critical weakness. I would report results by relevant signal class and state, including the tail of the error distribution and any conditions in which the correction could not be validated. A confidence bound derived from finite trials must state the number of independent opportunities and how independence was justified. A record of zero failures is not a mathematical assertion that the probability of failure is zero. It is evidence supporting an upper bound whose meaning depends upon the sampling design.

Copyright 2026, James M. Atkinson

The institution should also separate the person who builds the calibration from the person who evaluates its acceptance where resources permit. A fixed challenge suite with undisclosed event placements can expose overfitting and a tendency to adjust thresholds after unfavourable results. Where a small laboratory cannot separate personnel, it can still preserve the original rules, record deviations and use independent reference captures or blind replay. Negative results and invalid intervals belong in the technical record, not in a private collection of embarrassments. The report should distinguish corrective maintenance, calibration performed to characterise the apparatus, and validation performed to show that the whole instrument remains fit for a defined investigative purpose. Those are related activities but not interchangeable achievements.

Finally, the temporal scope of a calibration must be declared. An instrument measured in a controlled laboratory on Monday has not necessarily maintained those conditions throughout a field deployment on Friday. A field check immediately before and after the survey can provide evidence about drift, but may not reveal every unobserved transient during the interval. Continuous self-monitoring can help if its reference and diagnostic coverage are validated. When a loss of clock lock, gain transition or uncharacterised thermal excursion occurs, the correct response may be to mark the affected samples as qualified or invalid. It is not to hide the exception beneath a corrected amplitude scale. The system improves when it is designed to reveal its own weaknesses rather than to silence the indicators of failure.

Copyright 2026, James M. Atkinson

I would therefore accept a coherent interleaved receiver for a specified task only when the laboratory has shown, with independent challenges, that the combined branch response and correction preserve the particular quantities to be reported over a declared envelope. It should demonstrate relative timing, frequency response, uncertainty, false-alarm behaviour and weak-signal retention under representative stress conditions. Its limitations must be expressed so that the field examiner can recognise when a result falls outside the proven domain. The most impressive finding may sometimes be a justified declaration that the evidence is indeterminate. Such restraint prevents technical confidence from extending beyond its physical foundation. I pass the token to Dr Shewhart, whose question about detecting drift will bring the distinction between control and performance into sharper focus.

Walter Andrew Shewhart | Peer question 7 to W. Edwards Deming

Dr Deming, suppose the laboratory has characterised the converter's branch gain, offset and timing at a succession of temperatures and then installs a statistical monitor to detect departures from a stable calibration state. The reported control-chart points remain within the historical limits, yet a new firmware revision changes the internal order of fractional-delay filtering and gain correction, and a weak burst coincides with the next temperature transition. The chart looks reassuring because its monitored statistic is stable. But the relationship between the statistic and the actual physical measurement may have changed. How would you distinguish a process that remains under statistical control from one that remains valid for the desired electromagnetic inference? What evidence would justify transferring an earlier calibration certificate across

Copyright 2026, James M. Atkinson

a firmware change, and how should an investigator treat samples acquired during a state transition that was not represented in the original acceptance trials? I ask whether a failed challenge should cause merely another recalibration or a deeper revision of the measurement model itself.

W. Edwards Deming | Immediate answer to Walter Andrew Shewhart

Dr Shewhart, a control chart answers a question about the behaviour of a defined statistic under a stable process model. It does not supply proof that the statistic remains the right one after the process has changed. A firmware revision which alters correction order may change numerical transfer functions, effective latency, noise covariance and the interpretation of stored coefficients. The proper question is not whether the old line remains inside an old chart, but whether the changed instrument still implements the measurement model upon which the original validation depended. A version difference is itself a new state variable requiring technical assessment. Some changes may be shown, through regression tests and targeted characterisation, to leave relevant outputs invariant within tolerance. Others require a wider requalification.

I would demand a change-control record identifying the altered processing stages and their expected physical consequences. Retain both executable versions, calibration files and representative raw challenge records. Process the same immutable captures through the old and new implementations, compare residuals across the admitted band and transient classes, and examine whether differences exceed

Copyright 2026, James M. Atkinson

the previously accepted uncertainty. Such a comparison tests the digital change but not any simultaneous alteration of analogue hardware or clock conditions. Those need separate controls. When the revised firmware alters adaptive algorithms, test its response to challenge signals that were not available during development. Avoid defining success solely by the disappearance of one known spur, because a false-negative defect can also make that statistic appear better.

The weak burst acquired during a previously uncharacterised transition should receive a transparent qualification. Record the transition and retain the original samples and state log. If a separate, validated measurement path supports the feature, report the corroboration with its actual dependency. If no adequate evidence establishes that the timing and amplitude transfer remained valid, restrict the conclusion. The instrument may have indicated an event, but its quantitative amplitude, onset and source attribution may be indeterminate. A confidence interval calculated from stable-state trials should not be transplanted to an untested transition merely because the software can print one.

A failed challenge should initiate a study of causes before a recalibration becomes the convenient ritual. Perhaps the coefficient simply drifted and a validated correction suffices; perhaps the measurement model omitted temperature-dependent branch dispersion or a shared reference error. The distinction is found by experiments that force rival explanations to predict different outcomes. When the model is revised, its validation and historical

Copyright 2026, James M. Atkinson

applicability must be documented. We should not retrospectively certify old captures by applying a new model unless the old raw evidence supports the new analysis and its limitations are declared. The system's intellectual virtue is not the elimination of adverse points but the creation of a process in which the adverse point teaches us what remains unmeasured. I return the token respectfully to Dr. Atkinson for a final synthesis.

Harry Nyquist, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, four ADC branches nominally sample at 300 MS/s each to create a 1.2 GS/s stream. Which analogue mismatches must calibration measure before calling the combined output phase coherent?

Hendrik Wade Bode, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, each branch has a transfer function with gain, phase, aperture delay, offset, noise and temperature dependence; a single scalar amplitude correction cannot remove dispersive differences. Measure frequency-dependent complex gain at known injection planes across the actual admitted analogue band, then estimate relative aperture offsets independently of cable and fixture delay. Use several stimulus frequencies to distinguish a nearly constant time displacement, whose phase varies linearly with frequency, from filter-induced group-delay variation. Characterise the uncertainty and drift of the calibration coefficients as well as their numerical quantisation. Test at strong and weak input levels to reveal compression. Preserve original branch ordering and calibration state so an external analyst can reproduce the combined result. I pass the token to Dr Bennett to examine the spurious families.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode, Cross-Peer Question to William Ralph Bennett: Dr Bennett, a stable 300 MHz spectral line appears without an injected RF signal, yet sidebands move when the test-tone frequency changes. What inference can be drawn from this different behaviour?

William Ralph Bennett, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, the branch-selection period is 1/(300 MHz) for a four-way system with 1.2 GS/s aggregate cadence; periodic offset differences can produce fixed spectral components at branch-rate harmonics. Gain, timing and frequency-response mismatch modulate the injected waveform and generate signal-following image families. Frequency movement offers a diagnostic distinction, not a unique identification of every cause. Perform input-open or matched-termination tests, vary the injected tone over a controlled grid and compare observed spur movement and amplitude with branch error models. A nonlinear amplifier or clock feedthrough could complicate the picture. Check phase and amplitude dependencies, and avoid labelling every line as an external emitter. I respectfully yield to Dr Deming for production controls.

William Ralph Bennett, Cross-Peer Question to W. Edwards Deming: Dr Deming, calibration succeeds at 20 degrees Celsius for a single input level. How ought a qualification matrix expose calibration failure during an unattended temperature excursion and gain change?

W. Edwards Deming, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, define a bounded operating envelope in temperature, input frequency, amplitude, gain state, sample rate, reference clock and time since warm-up. Randomise or systematically cross the factors so interactions are not mistaken for repeatability. Monitor coefficient drift and

Copyright 2026, James M. Atkinson

spurious-free dynamic range under blind challenge tones at the envelope boundaries. Specify actions when a gain-state change invalidates coefficients: halt the claim of coherence, reload a demonstrated calibration, or segregate and mark the affected samples as qualified. Trace each configuration to firmware and calibration version, store raw branch records where practicable, and place a hash on the resulting derivative. A calibration campaign cannot consist of a single attractive spectrum. I pass the token to Dr Shannon for the limits of digital correction.

W. Edwards Deming, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, is it fair to call a calibrated time-interleaved array a higher-bit ADC simply because the software estimates sub-LSB differences between branches?

Claude Elwood Shannon, Cross-Peer Answer to W. Edwards Deming: Dr Deming, no. Aggregation of interleaved branches increases the overall sampling cadence under a phase-coherent timing plan; it does not automatically increase the physical code depth of any one simultaneous sample. Calibration can reduce systematic interleaving images, and combining suitably independent measurements may improve a particular estimator in a restricted band. But the apparent gain depends on noise correlation, reference stability and signal stationarity, and a saturated branch remains incapable of recording the lost analogue amplitude. The released instrument specification should identify nominal per-branch bit depth, measured aggregate SINAD or ENOB at stipulated frequencies, timing-skew tolerance, spur suppression and uncertainty, rather than naming an invented synthetic word length. Preserve branch samples and

Copyright 2026, James M. Atkinson

the calibrated composite separately. I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator's concluding synthesis

Our discussion has exposed a recurrent error in the public interpretation of technical surveillance measurements. The presence of one apparently continuous digital waveform does not prove that its component converters observed an analogue event on one physically exact time lattice. The nominal sample grid is a mathematical specification. The realised grid depends upon branch aperture displacement, common and independent clock error, analogue input responses, gain and offset, temperature and operating state. A calibrated representation can be informative, but it becomes forensic evidence only through a chain of disclosed comparisons and uncertainty-bearing inferences. The distinction is especially important where a weak suspected emission lies close to an internally predictable interleaving image.

Mr Nyquist has required us to identify actual sampling instants rather than trust the nominal clock diagram. His distinction between deterministic branch skew, random aperture uncertainty and common timebase error prevents a deceptive conversion of one calibration number into a universal coherence certificate. Dr Shannon has examined the inverse problem, showing that a correction can estimate an input only within the information and model constraints of the original acquisition. The loss of a clipped amplitude or a missed transient cannot be annulled by a longer, prettier digital vector. Professor Bode has identified the analogue branch transfer functions that may masquerade as timing differences; his insistence on frequency- and state-dependent calibration avoids the error of using a

Copyright 2026, James M. Atkinson

single laboratory tone to qualify a broadband receiver. Dr Bennett has shown how periodic mismatch can create genuine lines in the digital record that were not present at the external reference plane. Dr Deming has made clear that repeatability, statistical control and fitness for a particular defensive investigation remain separate propositions.

The peer challenges have refined these statements. Mr Black exposed the danger of adaptive calibration that removes an assumed unwanted feature without demonstrating its cause. Dr Hamming demanded proportionality in what must be archived, and the panel adopted a tiered approach tied to the evidential claim. Professor Gabor distinguished transient information from the deceptive precision available to a long-tone estimator. Professor Wiener showed why equalisation may introduce covariance and why apparently lower displayed noise need not mean lower uncertainty. Professor Bracewell exposed the risk that offline filtering places visible pre-ringing before an actual pulse. Professor Tukey insisted upon separating exploratory searches from pre-specified confirmatory tests. Dr Shewhart challenged the belief that a stable calibration-monitor statistic remains valid after firmware or physical state changes. Each objection demonstrates that the quality of a digital measurement cannot be read solely from one figure of merit.

The practical acceptance dossier should therefore contain the intended measurands and reference planes; the number and order of interleaved branches; the nominal and observed sample-rate characteristics; relative aperture-skew calibration; per-branch amplitude, offset and phase response across the admitted band; temperature and configuration envelopes; stochastic timing and voltage uncertainty; the calibration algorithm and its

Copyright 2026, James M. Atkinson

complete coefficient history; and the results of independent challenges. It should identify the versions of firmware, software and filters used when each material event was recorded. Where a branch mapping or clock source changed, the record should disclose the event's temporal relation to that change. A simple declaration of coherent capture is inadequate unless the sort of coherence claimed has been separately defined and tested.

The measured performance must also be expressed as a function of the task. Amplitude and phase reconstruction require evidence about transfer and uncertainty. Intermittent-signal discovery requires event-exposure accounting and correctly calibrated detection and false-alarm trials. Source attribution requires interventions that distinguish the internal-artefact hypothesis from an external emitter, with controls that hold relevant physical paths constant. A receiver can perform acceptably for one purpose and be unsuitable for another. Likewise two branches of the same interleaved converter are not independent witnesses merely because they contain separate electronic components. Their shared input, common clock, calibration algorithm and selection policy may couple their errors. A careful report will disclose those dependencies and avoid using multiplication of channel count as multiplication of evidential confidence.

The numerical exercises that follow shall make the scale of the problem concrete. Picosecond skew can produce measurable distortion at high input frequency; a common clock error can shift absolute time while leaving a relative branch difference largely unchanged; and a correction filter can add processing delay without proving the true onset of an external event. All such calculations remain conditional on clearly defined assumptions. They are not certifications of a particular receiver. The studies should be repeated

Copyright 2026, James M. Atkinson

with representative analogue stimuli and independently checked references before any operational performance claim is published. This is scientific discipline, not the multiplication of ceremonial cautions. A precisely bounded conclusion often permits firmer action than a spectacular but unsupported inference.

For the purposes of the volume, the panel therefore answers the question in a structured affirmative. Coherent time-interleaved digitisation can support defensible measurement when the actual interbranch time lattice, the analogue transfer responses, the common reference, the calibration operator and the relevant uncertainties are independently characterised across a declared operating envelope. The corrected record must remain reproducible from preserved evidence, and challenge experiments must show that genuine weak emissions survive the calibration rather than disappear beneath it. Where these requirements are unmet, the digital record may still support discovery or a limited observation, but it cannot legitimately carry every amplitude, phase, timestamp or attribution claim that its display appears to suggest. Our next question will ask how digital downconversion and decimation create additional numerical artefacts and how those artefacts should be distinguished from emissions in the external electromagnetic environment. I thank each contributor for the care with which the token has been received and passed.

Ten worked engineering and forensic applications

The following numerical cases are independent constructed examples intended to demonstrate scale, sensitivity, and evidential limitation. They are not measurements of any named instrument. Symbols denote the quantities defined in each case; frequency is expressed in hertz, time in

Copyright 2026, James M. Atkinson

seconds unless a submultiple is stated, voltage in volts, and ratios in dimensionless linear amplitude unless indicated. The logarithmic comparisons use 20 log10 of an amplitude ratio. A value expressed as dBc refers here to the simplified signal component relative to the stipulated carrier, not to a certified spectrum measurement. All arithmetic was recomputed separately from the narrative manuscript.

Ten worked engineering applications | Question 034

Worked application 1. The ideal time lattice in a four-branch converter

Suppose the aggregate sampling frequency $F_s = 1.2 \times 10^9$ samples/s and the branch count $M = 4$. Each branch acquires at $F_b = F_s/M = (1.2 \times 10^9)/4 = 300 \times 10^6$ samples/s. The ideal aggregate interval is $T_s = 1/F_s = 0.833333$ nanoseconds. Each branch repeats at $T_b = 1/F_b = 3.333333$ nanoseconds. Within one nominal cycle, branches 0, 1, 2 and 3 should sample at 0, 0.833333, 1.666667 and 2.500000 nanoseconds relative to the cycle origin. The fourth branch is not another simultaneous measurement of the first branch's sample: it is assigned a different instant. A software archive giving 1.2 billion words in one second proves neither that the four physical apertures possessed these spacings nor that their common timebase epoch was accurate. Independent aperture calibration and timebase monitoring are necessary to turn the ideal schedule into a physical claim. Temperature, branch routing and calibration state remain uncontrolled variables in this elementary example.

Worked application 2. First-order error from a known aperture displacement

Let an analogue sinusoid have peak amplitude $A = 1$ V, frequency $f = 200 \times 10^6$ Hz and a small deterministic sampling displacement $\Delta t = 2 \times 10^{-12}$ s. The largest first-order fractional voltage error is approximately $e_{rel} = 2 \pi f |\Delta t| = 2 \pi (200 \times 10^6)(2 \times 10^{-12}) = 0.002513274$, or 0.251327 percent of the 1 V peak. Its amplitude-equivalent logarithmic value is $20 \log_{10}(e_{rel}) = -51.995$ dB. This is an

Copyright 2026, James M. Atkinson

upper bound derived from the local sinusoidal slope and the first-order Taylor expansion, not a general prediction of an individual interleaving spur. The actual error at any sample depends on waveform phase; a periodic skew schedule distributes the error into identifiable spectral components according to the schedule. The approximation requires 2 pi f delta_t to be small and the system to remain sufficiently linear. It is not proof of an external weak transmitter at the -52 dB level.

Worked application 3. Inferring relative delay from a measured phase difference

Suppose a calibrated tone at f = 240 x 10^6 Hz produces a relative branch phase difference phi = 0.6 degrees after subtracting previously characterised analogue-path contributions. Assuming the remaining phase is caused entirely by a pure relative delay, delta_t = (phi/360 degrees)/f = (0.6/360)/(240 x 10^6) = 6.944444 x 10^-12 s, or 6.944 ps. The unit conversion matters: a small angular difference can still correspond to a significant fraction of a picosecond-level acceptance budget. Yet the delay inference is conditional on the pure-delay model, phase unwrapping, reference phase and subtraction of unequal analogue group delays. A phase difference of 360 degrees plus 0.6 degrees would give a different delay that is indistinguishable at the single test frequency without an independent bound. Repeating at multiple frequencies can test whether measured phase is approximately proportional to frequency rather than the product of dispersion, nonlinearity, or a spur alias.

Worked application 4. Two-branch alternating gain mismatch

Copyright 2026, James M. Atkinson

Let the two branch gains be $g_0 = 1.01$ and $g_1 = 0.99$, measured relative to a nominal unity gain. Their mean is 1.00, and the sequence may be written $g[n] = 1 + 0.01(-1)^n$. For a complex carrier $x[n] = A \exp(j \omega n)$ with no other distortion, $y[n] = A \exp(j \omega n) + 0.01 A \exp(j(\omega+\pi)n)$. The shifted image has amplitude 0.01 times the desired carrier, or $20 \log_{10}(0.01) = -40.000$ dBc. The shifted digital frequency differs by half the aggregate sampling rate modulo the sampling lattice. In a real-sine signal the positive and negative frequency contributions and folding require explicit treatment. The example establishes a periodic-mismatch mechanism, not a universal figure of merit. If the external input contains an actual signal at the image coordinate, a gain-correction algorithm could affect both and therefore requires a controlled weak-target preservation test.

Worked application 5. Offset alternation and a zero-input spectral line

Suppose the branch offsets of a two-channel system are $b_0 = +3$ millivolts and $b_1 = -3$ millivolts, and the input carrier is absent. The output contains an alternating sequence $b[n] = 0.003(-1)^n$ V, which has a line at the digital Nyquist coordinate in the ideal model even without an external signal. If a separate reference carrier of peak amplitude $A = 0.5$ V were used for a simple amplitude comparison, the offset line's ratio to that reference would be $0.003/0.5 = 0.006$, corresponding to $20 \log_{10}(0.006) = -44.437$ dB. The comparison is an illustrative level, not a claim that a carrier must be present for the offset mechanism to occur. Zero-input captures can characterise branch offsets, but short records and quantisation noise impose uncertainty on the estimates. A zero-input

Copyright 2026, James M. Atkinson

bench result also does not certify offset stability after a gain-range or thermal change in the field.

Worked application 6. Thermal drift of the relative aperture

Let the initially measured relative branch delay at reference temperature T_0 be $\epsilon_0 = 0.7$ picoseconds. Assume a measured linear thermal coefficient $k_T = 0.12$ picoseconds per kelvin over the relevant envelope, and let the temperature rise be $\Delta T = 15$ kelvin. The model predicts $\epsilon = \epsilon_0 + k_T \Delta T = 0.7 + (0.12)(15) = 2.5$ picoseconds. At input frequency $f = 250$ MHz, the first-order sinusoidal error bound is $2\pi f \epsilon = 2\pi(250 \times 10^6)(2.5 \times 10^{-12}) = 0.003926991$. Its logarithmic amplitude equivalent is -48.119 dB. The arithmetic is straightforward; the principal uncertainty lies in assuming that the coefficient remains linear and that temperature was measured at the component affecting aperture displacement. A remote case sensor may not equal the sampling switch temperature, and the same state may show thermal hysteresis. The result should motivate a temperature-dependent verification experiment, not an unqualified correction in every operating state.

Worked application 7. Aperture jitter as a frequency-dependent limitation

Consider a random timing uncertainty with root-mean-square value $\sigma_t = 150$ femtoseconds and a pure sine input at $f = 400$ MHz. Under the common small-jitter, otherwise ideal sinusoid approximation, the aperture-jitter-limited signal-to-noise ratio is $SNR_j = -20 \log_{10}(2\pi f \sigma_t)$. Substitution gives $2\pi(400 \times 10^6)(150 \times 10^{-15}) = 0.000376991$

Copyright 2026, James M. Atkinson

and SNR_j = 68.473 dB. This is not the total signal-to-noise-and-distortion ratio of an actual ADC. Thermal noise, quantisation noise, nonlinearity, clock spurs and input-path distortion may reduce total performance. A stated oscillator phase-noise specification also cannot simply be substituted for sigma_t without integrating the relevant phase-noise spectrum over the appropriate bounds and considering which clock fluctuations actually affect the measurement. The calculation concerns random sampling uncertainty and does not remove a deterministic interbranch skew.

Worked application 8. Common uncertainty and differential timing

Suppose two branch timestamp estimates each contain a common timebase uncertainty with standard deviation sigma_c = 50 picoseconds and an independent branch-specific uncertainty with sigma_i = 20 picoseconds. Assume the three errors are zero mean, the two branch-specific errors are mutually independent, and each is independent of the common error. The standard uncertainty of either absolute timestamp is sqrt(sigma_c^2 + sigma_i^2) = sqrt(50^2 + 20^2) = 53.852 picoseconds. The difference between the two timestamps cancels the common term, giving differential standard uncertainty sqrt(20^2+20^2) = 28.284 picoseconds. The calculation is invalid if the branch-specific terms are correlated or the common term changes differently during the relevant interval. It illustrates why a system can establish precise relative alignment while remaining less certain of absolute event epoch. The common clock's uncertainty must be retained for claims such as external-source time of arrival.

Worked application 9. Filter delay versus physical event onset

Copyright 2026, James M. Atkinson

Let a symmetric, linear-phase fractional-delay FIR filter contain L = 63 taps and operate on a stream with F_s = 1.2 x 10^9 samples/s. Under the fixed-coefficient FIR assumptions, nominal group delay is tau_g = (L-1)/(2 F_s) = 31/(1.2 x 10^9) = 25.833333 nanoseconds. One may compensate this known algorithmic delay in a timestamp expression. But a burst's apparent start may be affected by the analogue passband, noise threshold, unknown waveform rise time, filter boundary extension and the phase at which the burst crossed the interleaving grid. A corrected timestamp t_est = t_display - tau_g is therefore not necessarily the true physical onset; it is an estimate that needs an experimentally determined residual error distribution. Offline zero-phase implementations may exhibit apparent pre-event ringing, which does not prove that electromagnetic energy existed before the stimulus. Retaining the original source samples and filter definition permits this processing artefact to be examined.

Worked application 10. A zero-failure challenge does not certify perfect detection

Suppose n = 500 independent trials, each drawn from the declared representative challenge population, reveal zero failures under a fixed detection and calibration procedure. Let p denote the unknown probability of failure per independent trial. Under the stipulated Bernoulli model, the probability of observing zero failures is (1-p)^n. Setting this probability to 0.05 gives a one-sided 95-percent upper confidence bound p_upper = 1 - 0.05^(1/n) = 1 - 0.05^(1/500) = 0.005973552, approximately 0.597 percent. The bound applies only to the specified trial model and population. If the 500 tests reuse one

Copyright 2026, James M. Atkinson

favourable waveform phase, one warm receiver state and one calibration tone, the independence and representativeness assumptions are not credible for the intended survey. The finding is not that any particular new detection is 99.403 percent likely to be an external emission. It is that the finite challenge record bounds a defined failure probability under strong declared assumptions.

QUESTION 035

Copyright 2026, James M. Atkinson

How should polyphase channelisers be validated at channel boundaries?

Source: V011_Roundtable_Question_035_CP035_Dr_Atkinson(1).docx | Recovered substantive manuscript. Constructed educational dialogue.

Constructed educational dialogue for Volume 11. The historical specialists named below did not participate in an actual discussion and are not represented as having examined modern SDR equipment. Their statements are original pedagogical reconstructions of relevant engineering and scientific principles. All numerical instruments and measurements are hypothetical unless a cited source is explicitly identified. No source is attributed a result it did not report.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, the previous discussion examined calibration of the time-interleaved digitiser, where a digital sequence could present a reassuringly regular face while concealing several distinct physical apertures. We now follow that sequence into the receiver's channeliser. An observer looks across a waterfall display and sees a sequence of apparently separate, contiguous frequency compartments. The visible boundaries appear as straight lines, but the signal-processing machinery beneath them has neither infinite stop-band rejection nor perfect knowledge of a signal which arrives at an arbitrary frequency, amplitude or time. One frequency component can influence several adjacent outputs. Another may be weakened precisely where two channels meet. A particularly unfortunate discovery may be entered into the survey register twice, once under each neighbouring channel, or it may be missed because neither channel's individual statistic crosses the operator's threshold. [S1, S2]

Copyright 2026, James M. Atkinson

The problem is neither peculiar to a single software implementation nor cured merely by calling a filter *polyphase*. A polyphase analysis bank is an efficient factorisation of filtering, modulation and decimation. Its claimed performance depends upon the prototype impulse response, tap partition, Fourier sign convention, arithmetic precision, input reference, output map, decimation ratio, processing-state continuity, and the way the operator combines or discards adjacent output channels. We must distinguish the mathematical proposition that samples are related by a defined transform from the physical proposition that an unknown field emission would have been detected over a stated range of frequencies and burst timings. One requires an inspection of algebra and code; the other requires controlled observations and bounded uncertainty. A centre-frequency demonstration can verify neither claim across an entire channel boundary.

For our discussion let F_s denote the complex-input sample rate in samples per second, M the number of nominal analysis channels, $\Delta_f = F_s/M$ the nominal channel-centre spacing in hertz, $H_m(f)$ the complex end-to-end frequency response of output channel m when the input tone frequency is f, and R the output oversampling ratio relative to critical decimation. The normal output rate per channel is F_s/M; in the simple model it becomes $R F_s/M$ when oversampling is used. The power gain of a linear channel is $|H_m(f)|$ squared. We must preserve the distinction between a signal's amplitude, its energy spread across channels, and a decision statistic that may employ the magnitude or phase of one or more outputs. The sum of channel powers need not be equal to the input power unless the bank has appropriate normalisation and reconstruction

Copyright 2026, James M. Atkinson

properties. Nor does a sum of powers by itself prove that the same transient was recorded independently in each channel.

I ask the panel to answer a more rigorous question than whether the waterfall looks smooth. What tests, at what points of injection, would expose transition-band loss, unwanted alias folding, leakage from a nearby stronger emitter, group-delay differences, time-stamp ambiguity, and a false inference that two channel indications represent two emitters? Should a swept sinusoid be sufficient, or must we use displaced bursts, close doublets, broadband noise and controlled interference? How should the examiner distinguish a gain correction that can be supported by measured response from an inverse that no longer exists because critical decimation has removed information? When a channeliser is reconfigured in software, what parts of the calibration survive and what parts must be re-established?

Mr Campbell shall begin with the physical wave-filter idea and the folly of treating a drawn cut-off as a real discontinuity. Mr Nyquist will confront decimation and the informational price of critical sampling. Dr Slepian shall address concentrated but finite-duration spectra, which are particularly likely to defeat a tidy channel-centre demonstration. Professor Tukey will consider the dangers of selected plots, search thresholds and correlated channel outputs. Dr Shannon shall distinguish useful decision statistics from recoverable input information and set the limits of an assurance claim. Seven colleagues will challenge them; each challenge will receive an immediate substantive reply. Ten numerical examples will then expose the assumptions behind these conclusions. Our duty is not to require infinite perfection but to produce a test record precise enough to permit another

Copyright 2026, James M. Atkinson

competent examiner to reproduce, criticise and, where justified, reject a claim.

Copyright 2026, James M. Atkinson

George Ashley Campbell | Principal response 1: An edge is a specified transition, not an ideal wall

Dr. Atkinson, I begin from a commonplace that the engineer may find embarrassing precisely because it is so elementary. A filter does not acquire an abrupt physical boundary when we assign a convenient number to its nominal passband. Its network, or the digital impulse response which succeeds the network in the mathematical design, has a continuous response whose attenuation, phase and transition width must be made explicit. A telephone engineer seeking to separate conversations on one pair of wires would not certify the separation merely by drawing adjacent rectangles upon the frequency axis. Crosstalk is a measured relation between an interfering excitation and an output, and its tolerance must be tied to what that output is intended to communicate. [S1, S3]

A bank of M nominally adjacent analysis channels presents an analogous problem. Suppose the channels have centres separated by Delta_f. A desired signal at f = f_m + Delta_f/2 lies at the arithmetic midpoint between the centres of outputs m and m+1. There is no general principle under which one of those outputs must pass the signal with its centre-frequency gain. The result depends on the prototype filter, the bank's modulation, the precise fractional offset, and any alias contributions after decimation. Indeed, a good prototype designed to suppress interference in an adjacent channel may make a single-channel edge response worse. The design optimisation must declare whether it seeks flat amplitude across a retained central fraction, improved isolation, low reconstruction error when outputs are recombined, or some compromise. A prototype cannot be judged against a requirement that was never written.

Copyright 2026, James M. Atkinson

I would begin validation with the input and output reference planes. If a calibrated signal generator is connected through a cable, attenuator and amplifier, the injected level at the channeliser's digital input is not established simply by reading the generator's face. For a digital-only test we can inject exactly generated complex samples and remove analogue variability; for a complete receiving-chain test we must characterise the analogue chain and any intervening quantisation. Both experiments are useful, but they answer different questions. The first exposes coefficient and mapping defects; the second includes physical overload, image responses, clock errors and coupling. Claiming that the first experiment certifies the second is an error of measurement boundary.

A proper swept-tone campaign should sample both channel centres and every declared retained frequency interval, with special density near each nominal edge. It must measure complex gain, not merely the height of one bar in a power display, when phase or relative timing will be used. The sweep should be made in both directions, because a continuously adapting receiver may present hysteresis even where a fixed finite impulse response has none. It should include different input amplitudes to reveal arithmetic saturation or gain-dependent error. It should include a known strong interferer in the neighbouring nominal channel, since a weak candidate is often invisible only when the surrounding environment is busy. These measurements become a response surface H_m(f,A,s), where A denotes amplitude and s the receiver state, rather than one flattering figure entitled *selectivity*.

The examiner should further calculate how a known strong signal might appear in an apparently unrelated output. Let an unwanted input power be

Copyright 2026, James M. Atkinson

P_i in dBm and the measured leakage suppression into an adjacent channel be A_ij in decibels. Under a small-signal, linear, properly matched model the apparent leaked power is P_i - A_ij, after applying any stated gain convention. The formula is simple; its boundary conditions are not. If the prototype provides sixty decibels of rejection at the interfering frequency but the arithmetic path creates an alias with only forty decibels of suppression, the relevant figure for that route may be forty. If the input amplifier is in compression, neither small-signal figure is entitled to certify the receiver. A process that reports only the best observed rejection has confused an acceptance limit with an advertisement.

There is an important distinction between isolation and complementarity. The neighbouring outputs may both contain the same signal because their passbands overlap by design. In that condition the second indication is neither a distinct emitter nor necessarily a defect; it is part of the specified representation. If the operator combines the channels, the combination rule and complex calibration become essential. A power sum cannot be substituted for a complex coherent sum without a change of measurand. If the operator discards all but one channel, the retained fraction and the worst-case edge correction must appear in the validation statement. The institution's laboratory should record the channel map, filter taps and output ordering, because a numbering convention is no substitute for an actual frequency assignment. GNU Radio's documentation makes that practical mapping a first-class channeliser parameter. [S1]

I should also insist upon honest uncertainty. A response curve is an estimate obtained from a finite set of calibration tones and operating conditions. Interpolation between those points is a model whose adequacy

Copyright 2026, James M. Atkinson

must be tested. A narrow defect between two coarse calibration frequencies will not be discovered by the absence of a problem at both measurements. A quoted amplitude correction cannot be more reliable than the reference-level uncertainty, repeatability, frequency-step uncertainty, and residual model error taken together. The fact that its coefficient is stored to six decimal places does not impart six significant figures of knowledge. I would give a separate limit for minimum response inside the retained band, maximum leakage under declared adjacent-signal conditions, and the conditions under which these limits were established.

Finally, the report must retain adverse examples. A suppressed signal at a boundary cannot be erased from the record simply because the team later elected to redefine the usable bandwidth. The narrower bandwidth may be a legitimate engineering conclusion; its selection after a failure must be disclosed, and the revised specification must face a new independent challenge. The defence investigator who finds a suspicious peak in two channels must prove which common input can produce those responses and whether any alternative input remains observationally equivalent. Precision begins when the instrument is compelled to fail against a declared standard. I pass the floor to Mr Heaviside for examination of phase and transient response, which a simple amplitude sweep may conceal.

Oliver Heaviside | Peer question 1 to George Ashley Campbell

Mr Campbell, I accept the central point that the passband boundary is an engineering region rather than a geometrical line, but you have spoken extensively of levels and leakage while leaving an especially dangerous possibility comparatively quiet. A filter may have tolerable amplitude through a specified band and yet possess an uneven phase

Copyright 2026, James M. Atkinson

characteristic or an extended transient response. An intermittent emission near the boundary may then have its energy displaced across several output samples or receive a different time stamp in its neighbouring channel. If the operator compares the channels for direction finding or a forensic chronology, the magnitudes can be accurate while the timing relation is false. Should a validation procedure therefore measure a complex transfer function, an impulse response, or both, and should group delay be treated as a single fixed number even when the prototype is nonlinear phase? I also ask how you would distinguish the phase of the digital filter from the delays of preceding cables and converters, since a single end-to-end measurement may hide their separate contributions without invalidating the narrower end-to-end claim.

George Ashley Campbell | Immediate answer to Oliver Heaviside

Mr Heaviside, your question identifies the danger in using a response curve as though it contained every relevant characteristic. For a system whose only decision is whether a steady tone exceeds a calibrated threshold, magnitude may form a sufficient part of the specification, subject to exposure and noise statistics. For a transient whose arrival time or inter-channel phase is material, it is not sufficient. I would measure the complex end-to-end response against a traceable stimulus at the declared input reference plane, estimate its group delay where that derivative is meaningful, and challenge the inferred delay with known pulses and controlled multi-tone signals. An impulse-response measurement, or its equivalent frequency-domain reconstruction under a validated linear model, exposes

Copyright 2026, James M. Atkinson

ringing and the duration of the filter's memory. A nonlinear-phase response cannot be reduced to a universal single delay when the input waveform occupies a substantial bandwidth.

The separability of analogue and digital delays is a second issue. If the full chain is calibrated as one stable object, an end-to-end correction may support the intended output claim without uniquely allocating every nanosecond among the cable, converter and software. That is a legitimate bounded result. It becomes insufficient when the report later asserts that a particular internal component was faulty, or when one component is replaced while the inherited calibration is retained. I would therefore preserve both the end-to-end validation and the equipment configuration, so a later substitution prompts the right recalibration decision.

Two neighbouring filters can have different phase responses to a boundary signal even though they process the same input history. Comparing their uncorrected trigger times risks assigning physical significance to a mathematical difference in filter delay. The operator should establish, with repeated controlled bursts at several fractional edge locations, how the trigger estimator behaves for each channel, and whether its error depends on amplitude or burst shape. Time stamps should be tied back to input sample indices with the processing delay and retained-window convention declared. The machine's nominal clock is not itself an observation of the time at which an unknown emission began.

I would also refuse to average away adverse transient results. A long stationary test may find excellent centre-frequency gain but fail

Copyright 2026, James M. Atkinson

to expose bursts shorter than the filter's settling interval. The report should therefore contain at least a representative pulse-duration family and specify the shortest event for which the detector was tested. Where phase or timing behaviour is not characterised, the report may still identify a candidate frequency interval, but it should not claim coherent arrival-time precision. Thus your objection does not demand an unattainable perfect decomposition; it demands that the evidence match the quantity to which the investigator intends to attach a number.

Edwin Howard Armstrong | Peer question 2 to George Ashley Campbell

Mr Campbell, I would test your filter theory against an actual receiver rather than a quiet mathematical substitute. An input carrying one strong legitimate transmission may drive the analogue front end toward compression, produce intermodulation or increase broadband noise, and thus alter a weak signal at the edge of a nominally separate digital channel. The laboratory might inject two digital tones after the converter and demonstrate splendid filter isolation, then insert the same nominal frequencies through the antenna port and discover an apparent line which neither digital tone predicts. How should the report partition these findings without permitting a software vendor to claim that its verified channeliser has somehow verified the receiver? I also wish to know whether your suggestion of a two-tone challenge adequately represents intermittent transmitters, whose envelope transitions and uncertain timing may produce a broader spectrum than the centre frequency used

Copyright 2026, James M. Atkinson

to label the source. An engineering specification capable of surviving a hostile inspection must state where its evidence begins and ends.

<u>George Ashley Campbell</u> | Immediate answer to Edwin Howard Armstrong

Mr Armstrong, I agree that a channeliser is not the entire receiver, and a statement that blurs the distinction should be rejected. We should construct a nested set of acceptance tests. At the innermost layer, inject a digitally synthesised sequence and test the mathematics of the filter bank, the output ordering, precision, decimation and detector code. At a second layer, inject a known analogue waveform at the ADC input and examine converter behaviour, headroom and clock effects. At an outer layer, test the receiver at its declared RF input with controlled modulation, adjacent high-level interferers and the applicable antenna or coupling arrangement. Each layer has a different uncertainty budget. A successful inner test is necessary for some outer claims, but it cannot by itself exclude nonlinearity in the outer chain.

Your concern about modulation is decisive. A keyed or pulsed transmission has a spectrum that depends on pulse shape, duration and repetition, not merely on an assigned carrier. A narrow mathematical test tone is useful because it samples the frequency response at a known point; it is not representative of every waveform for which a receiver may be used. The laboratory should therefore add short and long pulses, rising and falling edges, close pairs, and signals with deliberately varied spectral occupancy. It should also test a weak target simultaneously with a strong neighbouring emission,

Copyright 2026, James M. Atkinson

not only in alternating trials. The ability to detect the weak target when the strong emission is absent is an inadequate answer to an operational environment in which both may coexist.

An instrument's statement of scope might accordingly read: its digital channeliser satisfies the measured response envelope when supplied with bounded, unclipped samples, while the complete receiver satisfies a separately tested detection probability over a narrower RF input range and specified interference conditions. This is not an embarrassment. It is a precise allocation of evidence. The report should preserve the test's raw input, the calibration path, the output samples, the detection decision and every parameter changed after a failure. These materials allow another examiner to distinguish a new input-induced artefact from a filter-bank calculation error.

Where a suspicious line appears only through the RF input and not through the digital test port, one has localised the competing explanation to an earlier part of the chain, but not necessarily to a particular circuit. The line may be external, may arise from nonlinear conversion, or may be injected through an unintended path. Additional interventions can discriminate these possibilities. An antenna substitution, attenuation experiment, preselector change or receiver comparison becomes useful when its predicted effect on an external source differs from that on an internal spur. One should not assume that a one-decibel reduction of a display line proves anything about its origin. The evidence must be conditioned upon the physical response being tested. I now pass the floor respectfully to Mr Nyquist,

Copyright 2026, James M. Atkinson

whose sampling argument reveals how an apparently excellent filter can still alias an unwanted component into another channel.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 2: Critical decimation, aliasing and the missing inverse

Dr. Atkinson, I would begin with the meaning of the word *channel* in a sampled representation. An equal-spaced collection of centre frequencies is a convenient labelling of transformations; it is not a guarantee that every component of the input is assigned exclusively and perfectly to one output. In a critically sampled M-channel analysis bank, each output is commonly decimated to F_s/M. The separate outputs must be interpreted as members of one coupled representation of the original F_s-rate sequence. If an examiner extracts just one stream and treats it as an autonomous receiver, information that could have been needed to distinguish a boundary input from an alias may already have been excluded by that choice. The relation is especially troublesome where two components separated in frequency map to the same output rate after decimation. [S1, S4]

In the idealised low-pass case, downsampling by D adds shifted copies of the input spectrum in the output's frequency coordinate, divided by the appropriate normalising factor. A filter of sufficient attenuation can suppress out-of-band replicas before the operation, but the required attenuation is dictated by the greatest unwanted signal and the smallest wanted signal, not by a catalogue's one-line description of its passband. A thirty-decibel stop band may appear satisfactory when the neighbouring channel is quiet. The same thirty decibels can be wholly inadequate if a legitimate carrier is sixty decibels stronger than the emission sought. The alias path then carries a residue thirty decibels above the weak target's reference level. The mathematical result is not paradoxical. It is what finite isolation means under an unfavourable dynamic range.

Copyright 2026, James M. Atkinson

This difficulty becomes acute at a boundary because the desired signal can itself occupy the filter's transition region. Suppose a detector retains only the inner eighty per cent of each channel. The remaining twenty per cent may be outside its accepted response envelope; that fact does not excuse a survey that silently represents the discarded region as searched. We must either overlap observations and combine them under a validated rule, or specify an exposed gap. If two channels are retained with overlap, their outputs are correlated because they are derived from the same input sequence. An alarm in both cannot be counted as two independent demonstrations. The correct unit of evidence may be a single candidate associated with several supporting channel measurements, with a covariance model where quantitative fusion is intended.

A critical distinction should be drawn between the analysis filter bank and a perfect-reconstruction analysis-synthesis pair. Certain filter-bank designs can combine their channels to reconstruct the input within stated numerical tolerances. That property can coexist with significant error in one isolated channel. Conversely a channeliser designed only for detection may not have a matching synthesis bank at all. The examiner must not infer reversibility from the word polyphase. If the original wideband samples have been discarded, and the retained set excludes a necessary output or has suffered noninvertible clipping, subsequent software may not possess the data required to reconstruct an input event. Processing power and finer numerical interpolation do not restore measurements never retained. The preservation policy is consequently part of the claimed measurement architecture.

Copyright 2026, James M. Atkinson

I would require a frequency-sweep test which deliberately crosses every channel boundary with both positive and negative frequency offsets in a complex-sampled system. Where a band-edge feature is represented through frequency wrapping, the precise ordering and sign convention must be tested; a correct magnitude display can conceal a conjugation or channel-map error. In addition, I would place pairs of tones at opposite sides of one boundary and vary their relative phase. This experiment distinguishes a simple leakage prediction from a coherent combination that might either reinforce or diminish an output. The combined waveform should be challenged over input amplitudes sufficient to reveal finite-word-length scaling and dynamic overflow. A bank implemented with integer arithmetic may fail differently from a double-precision simulation even when both execute nominally identical coefficients.

The validation must also follow the time coordinate. An M-fold decimator changes the output sample interval; the processor's block schedule and filter latency shift when an input event can affect a downstream decision. To claim a time of arrival, the investigator should trace the detected output sample and its associated input index through the filter and group-delay model. A timestamp attached to the first reported channel packet is not automatically the timestamp of the first analogue evidence. If packets have been dropped, no interpolation theorem guarantees that an arbitrary short burst can be reconstructed across the gap. At best one can specify a conditional model, with a recorded missing interval and uncertainty. An absence claim over that missing interval is not established.

Oversampling can alleviate some boundary problems by retaining more information in neighbouring channel outputs and relaxing critical alias

Copyright 2026, James M. Atkinson

conditions, but it increases throughput and does not abolish a finite filter transition. GNU Radio's channeliser description, for example, permits oversampled output according to a ratio that is constrained by the configured number of channels in the documented implementation. That implementation detail is an essential reproducibility fact, not a general theorem about all polyphase banks. [S1] The laboratory should record the actual software version and parameters under test rather than transplant one implementation's limits to a different product.

I would then demand an inverse challenge where applicable. Inject a known wideband signal with a component close to an edge, archive all output streams, and attempt a reconstruction under the claimed analysis-synthesis procedure. Assess its error both globally and within the narrow intervals where the operational detector has the greatest difficulty. A small aggregate root-mean-square error may conceal severe relative error on a rare low-energy burst. The uncertainty of such a comparison must include calibration level, finite-word-length error, filter design, time mapping and reference-signal fidelity, with covariance where it matters. An acceptance report which states only an average reconstruction error or only a minimum centre-frequency attenuation is not testing the forensic proposition.

We are entitled to claim what has been challenged. If a particular bank under specified operating conditions detects a family of known boundary bursts at a measured rate and controls a defined false-alarm probability, that is a defensible bounded result. We are not entitled to infer perfect coverage of an arbitrarily weak, unknown or shorter emission. The operator should carry a frequency-dependent detection-exposure record, rather than stamp every channel with the same reassuring status. I pass the token to Mr

Copyright 2026, James M. Atkinson

Black, who may wish to ask whether calibration by adaptation can conceal aliasing rather than remove it.

Harold Stephen Black | Peer question 3 to Harry Nyquist

Mr Nyquist, your account suggests that oversampling and more generous retention may improve the ability to recognise an edge event, but suppose the manufacturer introduces an adaptive anti-alias filter which changes its coefficients when a strong signal enters the adjacent channel. The detector then declares that the boundary is protected because the unwanted channel line falls below a fixed threshold. The filter is a controlled system, with a history-dependent state. How should its validation distinguish genuine improved isolation from the possibility that the same adaptive response attenuates an unknown target whose spectrum overlaps the interference? More particularly, would you accept a frequency-response measurement made after the system has settled, or insist on a sequence of changing interferers and test bursts before, during and after each update? A correct static diagram may be entirely silent about a transient state in which a time-critical emission disappears. I seek a stopping rule that does not demand exhaustive enumeration yet prevents the acceptance process from ignoring the adaptation interval.

Harry Nyquist | Immediate answer to Harold Stephen Black

Mr Black, I would not accept a settled-state response as sufficient for a system sold or described as capable of monitoring while adapting. The adjective *adaptive* identifies the possibility that the mapping from input to output changes over time, and therefore a single stationary transfer function cannot account for the complete observation history. One must either freeze the coefficients to create

Copyright 2026, James M. Atkinson

a stationary testable case, or define the adaptive control law and validate a family of states and transitions. A valid test programme may contain both parts. The settled-state measurement characterises operation after convergence; transition challenges reveal what happens while the algorithm is moving between coefficient sets.

The experimental question must be stated before the threshold is tuned. If the asserted capability is detection of a weak transient during a strong adjacent transmitter's onset, the laboratory must inject that transient at independently randomised times around the onset and vary its fractional position relative to the channel edge. Do not force every test pulse to coincide with the detector's preferred observation window. Retain outcomes for the complete trial population, including unsuccessful detections, changes in threshold and exceptional states. Compare candidate-detection performance and false alarms with the adaptive mechanism on and off, but do not interpret an improved average as permission to ignore a narrow interval of poor performance.

The adaptive coefficient history should be a first-class evidential record. The reviewer needs the initial filter state, the programme input or sufficient summaries that determined updates, the applied coefficients or their content-addressed versions, the time at which each state became active, and the output samples affected. A delayed log which records only the final filter cannot demonstrate what happened during the contested interval. Likewise, raw input preservation remains essential where subsequent independent reprocessing is anticipated. Without the input, one cannot

Copyright 2026, James M. Atkinson

conclusively distinguish a corrected artefact from a suppressed target whose evidence the algorithm has erased from the output.

As to a stopping rule, I would define an operating envelope rather than an impossible universal claim. Enumerate the maximum adjacent-signal level, the allowed rate of change, specified classes of modulation and pulse duration, the admissible calibration states and the minimum expected detection probability under each required condition. Statistical acceptance criteria should be selected before the trial. The result may then support performance within that envelope, accompanied by explicit exclusions and uncertainty. Where the data reveal a blind interval, the envelope must exclude that interval or the design must change. A narrow but well-tested claim is stronger than a broad claim inferred from convenient demonstrations.

Norbert Wiener | Peer question 4 to Harry Nyquist

Mr Nyquist, I should like to examine a more insidious condition than a control loop with disclosed coefficients. A surveillance operator notices a candidate near the midpoint between two channels and, quite properly, changes the receiver's centre frequency in order to move the candidate away from the original boundary. The observation then appears stronger. Yet the act of retuning has changed oscillator phase, filter alignment, input gain and perhaps the spectrum of interference. It has also selected the second observation because the first observation drew attention. What evidence would justify saying that the two indications arise from the same external waveform, as opposed to two different internal responses to a common troublesome environment? Should the investigator attempt to predict the second output from the first under a

Copyright 2026, James M. Atkinson

known transfer model, or should the retune be treated as a new experiment requiring independently controlled source injection? I am particularly concerned that feedback between the human operator and the instrument changes the sample population and invalidates naive claims of independent confirmation.

Harry Nyquist | Immediate answer to Norbert Wiener

Professor Wiener, the intervention you describe is valuable precisely because it changes a known dimension of the apparatus, but its evidential force depends upon whether the rival explanations make different predictions. If the frequency of an external emitter remains constant in an absolute RF reference while the digital channel grid is shifted, the candidate should move among the channel outputs in a calculable fashion, subject to the retuned receiver's frequency accuracy and transient settling. A spur tied to the filter-bank boundary may remain attached to the same fractional channel position instead. That contrast can help distinguish origins. It is not, however, a universal rule: some internal spurs track the local oscillator, and real external signals can themselves change frequency or vanish between observations.

The test record must therefore retain the first indication, the retune command, the exact configuration before and after, the known oscillator-settling or calibration interval, and the second result whether positive or negative. The operator's selection of the retune because of the first observation is not a reason to discard the test; it is a reason not to treat the two records as independent random trials drawn from an unselected population. One can use a designed

Copyright 2026, James M. Atkinson

intervention to discriminate models without calling it independent replication. Its strength arises from the predicted transformation of the signal and the response of the instrument, not from a simple count of two displays.

Where an independent reference emitter is available, a controlled source can test the retune mapping and settling behaviour in the same equipment state, but the signal under investigation remains unknown. We should not substitute the reference's behaviour for a conclusion about the candidate until the relevant likenesses and differences are justified. A secondary receiver, antenna or downconverter may provide additional information if it changes the dependency structure in a useful way. Shared clocks, power supplies and inputs should be identified, rather than converted into an exaggerated story of corroboration.

The simplest admissible conclusion may be that a feature appeared at a consistent external-frequency estimate before and after one specified retune, within the combined uncertainty, while a boundary-tied laboratory artefact did not behave so. That finding weakens a particular artefact explanation, but does not exclude every possible internal effect. If more decisive attribution is needed, the investigator must design further tests whose rival predictions differ and whose outcomes can be preserved. Controlled intervention is the discipline of explanation; repeating a reassuring image is not. I pass the floor to Dr Slepian, whose mathematics of spectral concentration will clarify why a signal does not politely confine itself to the channel assigned by the operator.

Copyright 2026, James M. Atkinson

David Slepian | Principal response 3: Finite records, spectral concentration and the boundary transient

Dr. Atkinson, I approach the boundary from an observation that is sometimes confused with an inconvenience of plotting. A waveform confined to a finite time interval is generally not confined to a single finite frequency interval with perfect sharpness. Spectral concentration is a quantity to be studied and optimised under stated conditions, not a property which can be granted to an unknown burst by drawing a rectangle over the display. The Fourier transform of a gated sinusoid illustrates the difficulty. Its main spectral lobe is accompanied by sidelobes whose form depends upon the gate and window. A short burst may spread material energy across the nominal divide between two channels even when its carrier lies precisely at one channel centre. The signal's shape and duration therefore matter to what appears in each output. [S4, S5]

In ordinary detection it may be reasonable to seek a statistic that captures the energy of a signal class without reconstructing every detail of the waveform. The design decision should be explicit. One filter bank may optimise interference rejection for long stationary tones, another might be chosen to retain short transient envelopes. A demonstration using a continuous tone cannot establish performance for a microsecond impulse merely by invoking the same centre frequency. Nor is a burst of prescribed phase and duration an adequate representation of an entire family of intermittent emitters. It may yield an excellent controlled test, but its generalisation requires a documented model of waveform variation and of the receiver's response to that variation.

Copyright 2026, James M. Atkinson

Let the input contain a finite-duration complex sinusoid $s(t) = A \exp(j2 \pi f_0 t) w(t)$, where A is complex amplitude, f_0 is the nominal carrier frequency, and w(t) is the time envelope. Its spectrum is the envelope spectrum $W(f - f_0)$ multiplied by A. Even if f_0 lies inside output channel m, portions of W may reach channels m-1 and m+1. If w is a rectangular gate, its Fourier magnitude has a sinc-like envelope; a smoother temporal taper can reduce sidelobes but alter effective duration and amplitude. That is not a reason to impose tapering blindly on evidence. It is a reason to preserve the raw record and document the window used in any displayed or detected spectrum. An unknown real emitter does not become a different physical source because our analysis chooses a different taper.

The boundary effect must be characterised with more than steady-state power. I propose a two-dimensional challenge map indexed by fractional carrier offset from the channel centre and by event duration. A third dimension should record burst starting phase relative to the bank's decimation lattice. If the detector uses periodic or block-triggered statistics, a short burst arriving just before one block boundary may contribute very differently from a burst arriving shortly afterwards. Repetition across many random start times makes this variation visible. A fourth dimension, if the intended survey requires it, records neighbouring interference. It is tempting to reduce these variables to one performance number; doing so without showing their joint distribution can conceal the very region in which the instrument fails.

Oversampling of channel outputs can be a useful design intervention. It retains additional temporal samples and allows overlapping effective passbands, making it possible to construct more robust edge statistics.

Copyright 2026, James M. Atkinson

Published analyses of oversampled banks in radio astronomical instrumentation discuss reduced edge attenuation, scalloping loss and leakage relative to critically sampled configurations, under the specific designs tested. Those results are neither a guarantee for every implementation nor evidence that every unknown burst can be reconstructed. The filter prototype, oversampling ratio, coefficient word length and subsequent detector determine the actual benefit. [S2, S4] A laboratory comparison should apply both architectures to the same preserved input and evaluate the outputs under an identical declared decision rule.

I also question whether summing adjacent channel powers is always a sensible cure. The two channel outputs may have correlated noise, may report differently delayed versions of the same transient and may include the same strong interferer through different sidelobes. An unweighted sum changes the detector and its false-alarm distribution. If the purpose is to recover a scalar energy estimate, the joint response and noise covariance matter. If the purpose is to estimate a complex waveform, phase calibration and reconstruction conditions matter. If the purpose is only to avoid missing one member of a signal class, a logical union of threshold decisions may be acceptable, but its family-wise false-alarm probability must be tested. Each operation addresses a different measurand.

One must be particularly careful about the language of information recovery. A critically sampled analysis bank may be perfectly invertible when all outputs and the correct synthesis system are retained. A storage policy that discards every other channel, or records only threshold crossings, destroys that guarantee. A different oversampled system may be redundant

Copyright 2026, James M. Atkinson

in a useful mathematical sense but nevertheless unable to reverse nonlinear clipping or missing input intervals. When the investigator sees a faint candidate simultaneously in two edge outputs, the agreement is not independent corroboration. It is a predictable consequence of passing one physical input through two overlapping responses. It can strengthen confidence in a model of the bank's behaviour without proving who or what produced the input.

A proper acceptance result would state, for each tested signal class, the minimum detection probability over the declared edge-offset and burst-duration envelope, its confidence bound, and the corresponding false-alarm behaviour under strong adjacent interference. Where test counts are insufficient to bound a rare failure, the limitation should remain in the report. I would welcome a negative-control family of inputs with no target, as well as challenge bursts deliberately placed at the weakest part of the measured response. Success on easy tones is evidence of success on easy tones. The task of measurement is to discover whether the difficult conditions violate the claim. I respectfully yield to Professor Wiener for his question about the system's memory, selection and the difference between detecting an event and remembering it.

Alan Mathison Turing | Peer question 5 to David Slepian

Dr Slepian, you have treated a brief burst as a finite time-frequency object. I ask you to extend the analysis to a receiver whose event-retention policy is governed by earlier observations. The system may begin preserving raw samples after one channel's statistic crosses a threshold, and may then copy a smaller interval from a circular pre-trigger buffer. Near a channel edge, the triggering channel may react

Copyright 2026, James M. Atkinson

later than its neighbour because the two filters have different group delays or amplitude responses. If the system has already overwritten part of the input record, a later fusion algorithm can display an impressively complete reconstruction while relying upon unmarked padded samples or assumptions about the missing onset. How should a validation campaign distinguish the channeliser's mathematical fidelity from the selection and retention rules applied after channelisation? Would a randomised burst test that merely counts whether an alarm appeared suffice, or must it assess whether the retained evidence supports a faithful event-duration and onset estimate?

David Slepian | Immediate answer to Alan Mathison Turing

Dr Turing, the distinction you draw must appear in the acceptance criterion itself. Detection and faithful retention are different outputs of a coupled process. A receiver may detect an event with high probability yet preserve too little of its waveform to support an amplitude or onset calculation. Conversely it may retain a generous interval around one event while failing to detect others that never triggered retention. A count of alarms cannot establish the completeness of a later forensic archive. The experimental record must state what fraction of known events were detected, what fraction were retained with the prescribed pre-event and post-event context, and what uncertainties affect any derived onset, duration or phase estimate.

I would inject known bursts at randomised positions relative to decimation blocks, storage-buffer wrap points, detector update intervals and filter settling. Their starts and ends should be

Copyright 2026, James M. Atkinson

independently established by the stimulus system, with that reference's own uncertainty included. For each burst, compare the intended waveform support with the actual retained input support. Mark samples genuinely measured, samples interpolated under a stated model and intervals for which no observation exists. Software padding at a boundary is an implementation choice, not a measurement of the unobserved past. The production system should expose that distinction in its metadata or derived-data annotations rather than relying upon a later examiner to infer it from suspiciously smooth waveforms.

If two filters have unequal group delay, a trigger may be time-shifted in an entirely predictable way for a narrowband input but not for an arbitrary waveform. A calibration established for one tone cannot necessarily correct all burst shapes. I would therefore test a family of envelopes and measure detection latency as a distribution, including its tails and the response to strong adjacent interference. Where the detector's input is a weighted sum of channels, one must validate the sum and its alignment, not merely validate each constituent filter. The correct unit of testing is the actual chain which produces the evidential object.

A report might conclude that a defined class of bursts was detected in a declared operating region with a lower confidence bound of a stated value, but that their earliest ten microseconds were not reliably preserved under some boundary conditions. This is not contradictory. It is the separation between finding a phenomenon and retaining the material needed for a stronger inference about it. If the engineering

Copyright 2026, James M. Atkinson

system needs the onset for location or attribution, the retention policy must be revised or another acquisition path used. An archive that has not preserved the evidence cannot borrow certainty from a detector's good alarm statistics. I pass the floor to Professor Tukey, whose examination of data and multiple comparisons may expose how a boundary survey manufactures apparent success through its choice of summaries.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 4: Searching many outputs without manufacturing certainty

Dr. Atkinson, my concern is not that the engineers have failed to design an attractive filter. It is that the story told after the test may differ subtly from the experiment that was actually performed. A channeliser is particularly liable to produce this difficulty because it gives the analyst many plausible ways to combine, threshold and display the same input. One may inspect the largest response in an edge pair, the sum of their powers, a coherent sum after phase adjustment, the greater of two normalised detection scores, a fitted spectral peak or a manually selected waterfall interval. Each of these summaries can be appropriate for a defined question. None acquires the same false-alarm behaviour merely because the operator calls all of them a detection. A result chosen after the examiner has seen the data is not necessarily invalid, but it cannot be assigned the nominal properties of a decision rule selected beforehand.

We must distinguish exploratory examination from validation. In exploration, I encourage ingenuity: plot more than one scale, re-express the data, examine the weakest edge positions and challenge apparent patterns. Exploration is how unexpected defects are found. But a test selected because it looked favourable is not an independent measurement of its own success probability. For acceptance, state the candidate class, frequency grid, event-duration family, signal-level distribution, interference conditions and detection statistic in advance. Freeze the software and coefficients, or register precisely how they may vary. Randomise the injection cases, retain the failures and count the trials actually performed, not merely the trials remembered after an extended day in the laboratory.

Copyright 2026, James M. Atkinson

Consider a search over N channels, each with a detector having a per-trial false-alarm probability p under an appropriate null model. If their tests were independent, the probability of one or more false alarms would be 1 - (1-p)^N. That is a useful warning, not a universal calculation for a polyphase bank. Adjacent outputs are ordinarily correlated because they arise from shared input samples and overlapping filter responses. Thus one cannot infer the exact family-wise probability from N and p without testing or modelling their dependency. The investigator should measure the joint null distribution under representative conditions, including correlated noise and a strong adjacent emission. A simple Bonferroni bound, where justified by individual event probabilities, can be conservative without requiring independence, but a bound is not the same thing as a calibrated detection probability. A tally of bright pixels in a waterfall does not settle these questions.

An excellent validation campaign will therefore preserve several kinds of count. For each designed challenge condition, record how many targets were injected, how many were exposed during valid acquisition intervals, how many crossed the fixed detector threshold, how many were localised to the correct input-frequency interval and how many were recorded without duplication. Those numbers cannot be combined indiscriminately. A target can be detected and nevertheless assigned to the wrong channel. Two correlated outputs can raise the apparent number of detections without raising the number of physical events. A pulse lost during a dropped buffer cannot be classified as an ordinary detector failure unless the tested system includes the transport and retention path, in which case it must be counted

Copyright 2026, James M. Atkinson

against the system-level claim rather than quietly removed. This is the discipline of denominators.

I would ask that the test reveal its weakest relevant region, not only its mean. If an edge has a narrow frequency interval where the response is eight decibels poorer than its centre, an average taken over thousands of easy interior tones can make the system appear splendid. The report should show detection probability as a function of the fractional channel offset, with confidence intervals, and state the minimum over any interval that the operational claim calls fully searched. The analyst may report a robust aggregate performance measure, but not at the expense of the very boundary the investigation depends upon. The same principle applies to pulse duration and starting phase. A receiver that succeeds for a steady carrier and fails for a short asynchronous burst has different capabilities, not a single capability described by an optimistic percentage.

There is another trap in the treatment of strong neighbouring signals. The engineer measures leakage by placing one interferer near an edge, then discovers a narrow spur on the opposite side. The analyst might increase the threshold until the spur disappears, and then declare the channeliser clean. The burden shifts to an unknown weak emitter which now needs more power to be discovered. A valid correction must be evaluated on both null inputs and target-present inputs, using the same decision rule. One should draw a detection operating-characteristic curve or equivalent empirical comparison, and select the threshold according to the operational consequences of missed events and false alarms. The consequences are not mathematical constants; they are part of a declared decision problem.

Copyright 2026, James M. Atkinson

Our records also require protection from the temptation to infer external origin from numerical rarity. A false-alarm probability under one receiver-noise model is not the posterior probability that a particular peak has an external source. That posterior would require explicit, justified hypotheses and prior information, with attention to model misspecification. A narrow line might arise from a coherent clock spur absent from the noise-only calibration, and the null probability computed for stationary Gaussian noise would be irrelevant. I would prefer a controlled intervention with divergent predictions over a spuriously precise numerical claim. Retuning the channel grid, disabling an internal oscillator, changing the input path, or comparing against a separately characterised reference can test causal alternatives.

As a publication matter, the case record should carry the raw or appropriately preserved data, the actual algorithm and version, calibration and channel map, a fixed analysis script if available, and the experimental outcomes, including the awkward ones. A printed receiver screen is an illustration, not a complete forensic trace. The result must be capable of criticism by someone who did not participate in its discovery, and its statistical interval must refer to the population actually sampled. I invite Sir Ronald Fisher to challenge the conception of a single probability assigned to a test programme whose conditions are visibly heterogeneous.

<u>Sir Ronald Aylmer Fisher</u> | Peer question 6 to John Wilder Tukey

Professor Tukey, you have proposed reporting conditional detection probabilities over several dimensions of frequency offset, pulse duration, interference and acquisition state. That is sensible, yet I see a danger of replacing one unjustified average with a constellation of small samples whose intervals are unstable and whose comparisons are multiplicative.

Copyright 2026, James M. Atkinson

Suppose the laboratory allocates a fixed number of injections across twenty boundary conditions, then draws attention to whichever condition has the lowest observed success rate. The smallest proportion is itself a selected statistic, not an unbiased estimate of the worst conceivable condition. Should the experiment be designed to estimate a smooth response surface, to test a prespecified minimum acceptance criterion, or to provide simultaneous confidence bounds across the required conditions? How do you reconcile the wish to expose a narrow blind region with the impossibility of testing every frequency, time offset and modulation? I particularly ask how an examiner should distinguish a useful inferential bound from an overfitted model that merely interpolates the observed successes with attractive mathematical precision.

John Wilder Tukey | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, your objection is apt because a validation surface is as vulnerable to selection as a single chart. I would formulate the experimental aim before choosing the analysis. If the requirement is to establish that detection probability exceeds a fixed lower bound throughout a specified operating envelope, then the programme must support a simultaneous claim or employ a design which justifies inference between tested conditions. A set of unrelated pointwise confidence intervals does not automatically constitute a simultaneous guarantee. A conservative multiplicity adjustment may be appropriate, but it can become prohibitively costly when the designer insists on an enormous grid. The more fundamental solution is to

Copyright 2026, James M. Atkinson

choose a physically informed test strategy and state what kind of interpolation is supported.

One might begin with a systematic sweep to discover pronounced transition-band defects, then use a preregistered confirmation experiment concentrated in the most consequential regions. The exploratory dataset identifies hypotheses; the subsequent independently selected trials test them. If the response is expected to vary smoothly with frequency offset under a fixed linear filter, a model may exploit that physical structure, but its residuals and prediction outside observed points must be tested. An adaptive system or a nonlinear saturation can break smoothness abruptly, so a model fitted under quiet, fixed conditions should not be assumed valid after a large interferer enters the band. A competent report distinguishes empirical observations, physical model assumptions and confidence derived from each.

I would report both the minimum observed performance among prescribed test cells and a justified uncertainty or lower-bound calculation appropriate to that selection. If too few trials were available for a confident simultaneous statement, the report should not invent one. The operator may still use the instrument for discovery, but the certification must exclude untested intervals or state the remaining risk. A claim with explicit limitation is more operationally useful than false certainty. Repeated observations in a small cell improve estimation of that cell's probability under repeatability assumptions; they do not reveal untested short bursts or different interference states.

Copyright 2026, James M. Atkinson

There is also the question of denominator discipline. The test population must include all attempted trials, separately recording invalid stimuli or true acquisition failures. An unexpected blank channel should not automatically be classified as an invalid test simply because it would lower the claimed success rate. Trials may be excluded only under previously stated and objectively verifiable criteria, with excluded results disclosed. Finally, the report should distinguish statistical significance from engineering significance. A tiny, precisely measured edge ripple may be irrelevant to the operational threshold, while a modestly estimated blind interval could compromise the central inference. The engineer must identify the consequences of each condition, and the statistician must ensure that the numbers answer those questions. I now invite Dr Shannon to consider the more basic limit: what the output of the bank can and cannot tell us about an original input.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 5: Information preserved is not information correctly interpreted

Dr. Atkinson, the temptation at issue is to treat a many-channel digital output as though it contained more independent knowledge than the waveform from which it arose. An analysis bank transforms a finite digital sequence into a set of other sequences. Under a known deterministic transformation, these sequences contain no new information about the input absent additional physical measurements. They may make particular features easier to detect, compress the storage requirements of selected signals, or suppress nuisance components, and those are genuine practical virtues. But a display with sixty-four outputs is not the testimony of sixty-four independent receivers. When adjacent outputs both brighten, that agreement may reflect shared input and overlapping filter response rather than corroboration of an external source.

A practical channeliser is not always information-preserving. It may decimate, quantise, clip, drop outputs, retain only threshold crossings, or replace complex samples with magnitudes. Each operation can change which questions remain answerable. A bank possessing a theoretical perfect-reconstruction synthesis system may still have no recoverable inverse after the investigator has discarded half the channels. If the output is only a list of detected frequencies, we may be able to report that the detector crossed a threshold but not reconstruct the modulation which caused that crossing. The uncertainty is not a computational inconvenience that a later, faster machine will necessarily overcome. It is a consequence of nonunique mapping from possible inputs to retained evidence.

Copyright 2026, James M. Atkinson

The distinction between preservation and interpretation also appears in phase. A known analytic bank may preserve complex phase relationships sufficient for certain reconstruction purposes, but those relationships must be tied to a common input-clock reference and a verified channel map. A subsequent magnitude detector throws away phase. A sophisticated fusion algorithm can estimate some features statistically, but the resulting estimate depends on an input model. If multiple distinct waveforms would have produced the same retained magnitudes, the claimed inverse is conditional, not uniquely measured. A forensic report should identify that condition, especially when source localisation or waveform attribution depends on relative phase or precise event onset.

An oversampled analysis bank introduces redundancy. In a valid design it may allow stronger boundary coverage, overlapping passbands and more robust reconstruction under certain forms of noise or missing data. That is a useful result, but it must not be mistaken for generating additional independent physical samples. The output streams share the same original information source. Their noise and errors may be highly correlated; indeed, an artefact coherent in the input can appear coherently in several channels. Combining them requires a specified noise model and calibrated response. The supposed benefit of a fusion rule should be measured against performance of the full input, the single-channel alternatives and the cost of additional false alarms.

Suppose the investigator asks whether a faint intermittent transmitter occupied a certain frequency interval. A proper answer requires an observation model: how the transmitter's possible waveforms are represented by the channeliser, what background and interference are

Copyright 2026, James M. Atkinson

admitted, and what event statistic the detector uses. A calibrated amplitude response gives part of that model. It does not by itself give the probability of detection because the distribution of detector noise, pulse timing and thresholds matters. A laboratory that measures a clean frequency sweep and then writes *all signals detectable above minus ninety decibels* has silently confused deterministic transfer gain with a probabilistic detection capability. The two may be related, but the relationship must be demonstrated or justified.

Nor does a detected feature's probability under an ideal noise-only hypothesis prove its source. A fixed clock spur or a filtered interference product may be extremely unlikely under the chosen Gaussian noise model and yet wholly internal to the receiver. The appropriate scientific method is to compare causal hypotheses using controlled interventions. If moving a test signal's absolute input frequency predicts one transformation of the channel outputs while changing only the bank's channel map predicts another, those experiments can test whether the feature follows the input or the processing grid. Retuning is especially valuable when the predictions differ, although the receiver's state changes and frequency reference must be preserved. A test in which every model makes the same prediction adds little causal information.

For the narrow issue of channel-edge validation, I would therefore formulate acceptance as a chain of statements. First, the digital implementation of the chosen bank agrees with its declared mathematical model within an established numerical tolerance. Second, its measured frequency and transient response is known over an explicitly retained operating envelope. Third, its detector and retention system achieves

Copyright 2026, James M. Atkinson

defined sensitivity and false-alarm performance for the target classes tested, including weak bursts at the edges while stronger nearby signals are present. Fourth, the evidence permits only those attributions or timing estimates that survive alternative-source challenges and the documented uncertainty. These statements need not all succeed for the receiver to be useful; they merely should not be collapsed into one boast.

The ultimate limit of the technique is not the finite number of filters, but the distinction between data and claims. If the raw wideband input is preserved with an authenticated processing history, future examiners may test different filters without pretending that the new output was observed at the original survey time. If only derived channels remain, the examiner must assess whether they suffice for the desired reconstruction or discovery. If only a detector alarm remains, the available finding may be narrower still. The integrity of the bytes, though important, cannot certify the physical model that interpreted them. This is why the acceptance record must travel with the waveform rather than remain locked in the operator's recollection. I invite Dr Hamming to challenge the balance between formal information preservation and the practical necessities of limited receiver capacity.

Richard Wesley Hamming | Peer question 7 to Claude Elwood Shannon

Dr Shannon, the investigator would like to preserve every wideband sample, every channel output, every calibration sweep and every program revision, yet a high-rate monitoring installation may produce more information in one day than a modest forensic laboratory can store or reprocess responsibly. The engineering task is to determine which representations preserve the quantities of genuine consequence, not to

Copyright 2026, James M. Atkinson

demand unlimited memory. Suppose the receiver retains low-rate complex channels and a small buffer of original samples only when a detector triggers. It can reconstruct many ordinary events, but some edge cases remain ambiguous. Would you call that design defective, or merely qualified? More importantly, what should its operator claim when a negative survey finds nothing, given that rare pulses might have fallen within the bank's weakest transition regions or during discarded input intervals? I would welcome a hierarchy of conclusions that recognises the difference between a useful screening system and an apparatus whose records could sustain a contested source-identification claim years later.

Claude Elwood Shannon | Immediate answer to Richard Wesley Hamming

Dr Hamming, finite capacity is not itself a defect. It is a constraint which should be made part of the observation model. An efficient design may preserve selected outputs that are sufficient for its declared screening objective, even though they are insufficient for every conceivable later question. The difficulty arises when that restricted record is used to assert a stronger fact than it supports. A channeliser designed to flag candidates need not provide lossless reconstruction of every signal which passed through the antenna. It must, however, be judged according to its actual probability of flagging the declared target classes under admitted operating conditions, and its negative findings must be limited accordingly.

The data-retention policy should distinguish discovery, verification and attribution. For discovery, a time-stamped indication with its channel map, filter version, threshold and operational state may be

Copyright 2026, James M. Atkinson

adequate to identify a candidate requiring further examination. For verification of a contested spectral feature, preservation of complex samples across a known interval, calibration and alternate channelisation may be necessary. Attribution may demand independent RF evidence, physical localisation or a controlled change in the source environment, none of which follows automatically from a stored spectrum. The laboratory should identify these tiers before deployment, not only after a disputed result reveals the missing data.

A negative survey is especially sensitive to the unobserved portions of the record. It does not establish that no possible emission existed. At best it states that the deployed system did not register a target meeting a defined signal class and level within the valid observation time and the calibrated frequency envelope, with the associated estimated detection probability. Channel-edge attenuation, acquisition dead time, adaptive state transitions, buffer loss and selected-event retention all reduce the scope of the claim. If a frequency interval was excluded because the filter bank's response fell below the accepted minimum, it must be listed as a limitation rather than silently marked clear.

Where raw retention is expensive, I would recommend preserving a controlled sampling of negative intervals for validation, along with the complete configuration and selection policy. Such records allow estimates of false alarm, missed event and algorithmic drift, although they cannot resurrect every unobserved burst. The examiner can demonstrate that a choice was rational for a declared purpose without pretending that the resulting archive contains more

Copyright 2026, James M. Atkinson

information than was kept. An honest qualification does not discredit the instrument. It permits the user of its evidence to understand precisely what a negative, uncertain or positive finding means. I return the token to Dr. Atkinson for the practical calculations and the concluding doctrine.

Worked technical applications | Ten independently checkable cases

George Ashley Campbell, Cross-Peer Question to Harry Nyquist: Dr Nyquist, a 64-way complex polyphase channeliser gives 200 kHz nominal centre spacing. Is each channel therefore guaranteed to admit a distinct 200 kHz signal without neighbour contamination?

Harry Nyquist, Cross-Peer Answer to George Ashley Campbell: Dr Campbell, the quotient of complex input rate by channel count defines nominal centre spacing, not necessarily an independently usable passband of that width. Prototype-filter transition regions, polyphase decimation, sidelobe rejection and channel overlap determine actual response. At critical sampling, a component near a nominal boundary may be represented in adjacent outputs or aliased under an imperfect analysis filter bank. Test a calibrated swept tone and short burst across each boundary with the same settings used for surveillance, measuring both amplitude and group delay. Repeat in the presence of a strong adjacent transmitter so nominal small-signal rejection is not mistaken for system linearity. Verify reconstruction conditions if the architecture promises perfect synthesis, and avoid adding channel powers without accounting for their cross-correlation. I pass the token to Dr Slepian on finite events.

Copyright 2026, James M. Atkinson

Harry Nyquist, Cross-Peer Question to David Slepian: Dr Slepian, what happens to a brief burst whose spectrum is concentrated near a channel edge when the prototype filter has a lengthy impulse response?

David Slepian, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the response may be distributed in time across filter memory and in frequency across several outputs. The finite-duration burst is not a stationary continuous sine, and a nominal flat passband measurement at one coherent tone can conceal temporal distortion. Characterise response to impulse-like stimuli, frequency-stepped bursts and chirps with independent timestamps. Measure detection delay, peak-amplitude bias, ringing and probability of splitting one physical event into multiple apparent channel events. A finite record cannot simultaneously claim arbitrary temporal and spectral concentration, so the decision rule must declare its trade-off. Preserve a margin of pre-trigger and post-trigger samples that covers filter memory, not merely the samples above a detected threshold. Cross-channel association should rely on measured relative delay and phase rather than matching screen positions. I respectfully yield to Professor Tukey for multiple comparisons.

David Slepian, Cross-Peer Question to John Wilder Tukey: Professor Tukey, an operator searches 64 channel outputs for the brightest instantaneous peak and reports the nominal per-channel false-alarm rate. What has the selection process omitted?

John Wilder Tukey, Cross-Peer Answer to David Slepian: Dr Slepian, it has ignored the family of opportunities searched and any dependence among their outputs. A per-output false-alarm probability cannot be read as the probability that at least one of 64 correlated channels will cross threshold in

Copyright 2026, James M. Atkinson

a particular scan. Estimate the joint distribution from representative noise-only records preserving overlap, common filter response and common front-end events, or use a conservative bound when joint calibration is unavailable. Predeclare search duration, frequency windows and peak-selection rule. A moving maximum across many frames creates still more opportunities, often correlated in time. The proper evidence record includes rejected candidates and unselected neighbouring outputs, so a reviewer can distinguish a true event from the predictable highest member of a noisy family. I yield to Dr Shannon on retained information.

John Wilder Tukey, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, may a team discard every adjacent channel record after stitching a visually continuous display, and still claim it can reconstruct any emitter that crossed a filter-bank boundary?

Claude Elwood Shannon, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, only where a proved reconstruction architecture, coefficient set and retained data are sufficient for the specified class of signals. A combined display is commonly a lossy representation of complex channel samples: it may omit phase, calibration state, filter transients, overlapped frequency content or clipping indicators. An analyst should retain parent raw I/Q for consequential events, or at least coherent neighbouring complex streams and the exact synthesis parameters where that level is demonstrated adequate. Run a blinded boundary-crossing injection and try to recover amplitude, event time and phase from the proposed archive alone. If the attempt fails, do not call the archive a complete historical record of that event. A clean image is not the same as recoverable evidence. I respectfully return the token to Dr Atkinson.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson | Moderator concluding synthesis

Colleagues, the ten calculations and the preceding discussion establish that a channel boundary is a region whose performance must be proved, rather than a label whose appearance upon a screen guarantees it has been searched. Mr Campbell has required us to treat the filter's transition and phase responses as measurable physical or digital behaviours, with declared reference planes and an honest separation between the software bank and the complete RF receiving chain. Mr Nyquist has reminded us that critical decimation and selective retention can remove distinctions needed for a later inverse inference. Dr Slepian has demonstrated the importance of event duration, envelope shape and fractional position in the frequency grid. Professor Tukey has insisted that detection statistics, selection, false-alarm multiplicity and confidence bounds should refer to an actual trial population. Dr Shannon has finally distinguished useful transformed evidence from the independent information required for reconstruction and attribution.

A validation campaign must therefore be constructed around the *claims*, not around the convenience of a manufacturer demonstration. Where the intended claim concerns continuous narrowband signals, a dense, calibrated frequency sweep over the retained band may be central; where it concerns intermittent surveillance emissions, that sweep is only one experiment among many. Short bursts must arrive at randomised phases relative to the analysis and decimation blocks. Close signal pairs must be placed on both sides of the boundary. A weak candidate should be challenged in the presence of a strong nearby legitimate transmission. The receiver should be tested before and after controlled changes to the

Copyright 2026, James M. Atkinson

channeliser grid, gain and filter configuration, with settling periods and excluded intervals recorded. The analyst should determine whether the same input can give duplicate indications in adjacent outputs, and whether the deduplication rule can suppress a genuine second source.

The measurement record must preserve the prototype taps, their hash or version, the output channel mapping, input sample rate, output-rate ratio, decimation phase, arithmetic scaling, treatment of the first and last samples, trigger thresholds, complex phase convention, and the relevant calibration state. Where time-of-arrival claims are made, channel group delay and any variable filtering latency must be carried into the timestamp and uncertainty assessment. Where only a detected power or binary flag is preserved, the report should say which information has been discarded. Authentication of a digital record establishes continuity of its recorded bytes; it does not prove that the filter transfer function or noise model was true of the analogue event. An additional physical challenge is necessary for that stronger claim.

The panel also rejects an attractive but misleading form of corroboration. One emission passing through overlapping channel filters is one physical observation transformed in several ways. The corresponding outputs may corroborate a prediction about the filter bank, but they do not constitute independent receivers and cannot simply be multiplied into a stronger probability of an external source. A receiver substitution, deliberate frequency-grid retune, independently characterised RF path or controlled stimulus may supply additional discriminating evidence, provided competing hypotheses make genuinely different predictions and the changed state is documented. A peak that migrates between channel labels

Copyright 2026, James M. Atkinson

while remaining consistent in absolute frequency is more informative than an unchanged peak after a procedure that cannot distinguish the alternatives.

I ask that the final acceptance report include a frequency-by-frequency or appropriately validated model-based minimum response, a leakage limit under stated adjacent-signal levels, a distribution of transient detection latency, a joint false-alarm account, explicit invalid or omitted intervals, and a declaration of which output representations are retained. The laboratory should record adverse results and any later narrowing of the claimed envelope. A favourable average does not excuse a narrow but operationally consequential blind region. Neither does a strong reconstructed waveform erase the possibility that missing input samples, clipping or an adaptive threshold deprived the analysis of an alternative interpretation. Where uncertainty is material, its covariance and its dependence upon the reference-plane model must be included.

A properly qualified result may be decisive in a limited respect. It can establish that a specified class of event, above a declared minimum input level and within stated interference, pulse-duration and calibration conditions, would be registered with a measured performance and confidence bound even at the weakest validated channel edge. It cannot establish that no conceivable weaker, shorter or differently modulated emission existed. Nor may it identify a person, device or physical origin without evidence beyond the mathematical output of the analysis bank. The discipline is not timidity. It is what makes the finding durable when the raw samples, source code and testimony are examined years later by a sceptical engineer or court.

Copyright 2026, James M. Atkinson

Our next question concerns decimation itself, beyond the specific behaviour of channel boundaries: when does the operation remove information that a later forensic question requires? That enquiry will connect acquisition policy, retained complex samples, statistical sufficiency and the limits of retrospective signal reconstruction. I thank Mr Campbell, Mr Nyquist, Dr Slepian, Professor Tukey and Dr Shannon for their careful contributions, and I respectfully return the token to the authorial programme for Question 036.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 035

Worked application 1 | Nominal spacing is not a guaranteed usable passband

Consider an idealised complex-input channeliser with sample rate F_s = 12,800,000 complex samples per second and M = 64 equally spaced outputs. The nominal centre spacing is $\Delta f = F_s/M$ = 12,800,000/64 = 200,000 Hz, or 200 kHz. Under critical decimation the nominal output rate per channel is also F_s/M = 200,000 complex samples per second. The result describes a coordinate and throughput relationship, not a flat 200 kHz response. If the validated retained portion is only 80 per cent of the spacing, its width is 0.80 x 200,000 = 160,000 Hz per channel. The remaining 40 kHz of each nominal slot cannot be described as searched by that one output at the same performance. Overlap, retuning or another validated path is necessary before claiming coverage there. Variables and arithmetic are hypothetical; actual retained widths must come from the measured prototype response and threshold rule.

Worked application 2 | Two equal edge indications do not restore amplitude automatically

At one boundary assume a hypothetical calibrated isolated-channel power gain of -6.00 dB for each of two adjacent outputs relative to its own unity centre response. Each channel receives a power factor $g = 10^{(-6/10)}$ = 0.2511886 of the reference input tone power under the linear steady-state model. The arithmetic sum of the two reported powers is 2g = 0.5023773, equivalent to 10 log10(0.5023773) = -2.9897 dB relative to the input-power reference. Thus adding the two powers does

Copyright 2026, James M. Atkinson

not automatically produce 0 dB. Nor may the same signal be counted as two independent detections. If the actual bank has a reconstruction relation, complex weighting may recover the intended quantity, but its phases, normalisation, noise covariance and numerical precision must be tested. This calculation is not a reconstruction theorem and does not justify applying an uncalibrated universal +2.99 dB correction.

Worked application 3 | An adjacent strong emitter defeats a superficially impressive rejection ratio

Let a legitimate interferer enter the declared reference plane at P_i = -20 dBm, while the unknown target class includes power P_t = -95 dBm. Suppose the relevant measured small-signal leakage suppression into the tested output is A = 60 dB. The leaked component would then be estimated as $P_{leak} = P_i - A$ = -20 - 60 = -80 dBm. Its level relative to the target is -80 - (-95) = +15 dB. Hence sixty decibels of rejection does not make that interferer negligible for this target. Suppression greater than 75 dB would be required merely to place the nominal residue below -95 dBm, without any additional margin for detector noise or uncertainty. These equations assume linear operation and consistent logarithmic power references; a saturated front end invalidates the simple subtraction model and demands a separate challenge.

Worked application 4 | Filter group delay changes chronology without necessarily losing the pulse

Take a symmetric, linear-phase FIR prototype of length L = 321 taps at input sampling rate F_s = 12.8 MHz. Its nominal group delay, in input-sample units, is (L-1)/2 = 160 samples. In seconds this is tau =

Copyright 2026, James M. Atkinson

160/12,800,000 = 0.0000125 s = 12.5 microseconds. A test pulse whose measured analogue start is at t = 1.000000 ms may therefore have its ideally filtered response referred to approximately 1.012500 ms under the specified reference convention. Subtracting 12.5 microseconds from a downstream timestamp can correct that fixed delay under the assumed model. It cannot prove that the pulse's earliest samples survived thresholding or that a nonlinear-phase implementation has a uniform delay for every spectral component. The test must distinguish correcting a time origin from recovering an unrecorded waveform onset.

Worked application 5 | Oversampling changes sample volume but not the number of original physical samples

Using the same F_s = 12.8 million complex samples/s and M = 64, suppose an oversampled bank uses R = 4/3. Its nominal per-channel output rate becomes $F_{out} = R(F_s/M) = (4/3)(200{,}000) = 266{,}666.667$ complex samples/s. Across all sixty-four outputs, the nominal total output-sample rate is 17,066,666.667 complex samples/s before any channel selection or overhead. This exceeds the original 12.8 million input-sample rate because the representation is redundant, not because the antenna supplied additional independent measurements. Under the applicable GNU Radio channeliser documentation, the permitted oversampling ratio must accord with that implementation's channel-count constraint; R = 64/48 = 4/3 has the required form for M = 64. A different programme may impose different limits. The choice must be validated against actual throughput, overlap response and timing.

Worked application 6 | A brief carrier has appreciable spectral width

Copyright 2026, James M. Atkinson

Assume a complex sinusoid multiplied by an ideal rectangular gate of duration T = 40 microseconds. Its continuous-time transform contains a sinc-shaped factor whose first envelope zeros are displaced by approximately 1/T from the carrier. Here 1/T = 1/(40 x 10^-6) = 25,000 Hz, so the main-lobe zero-to-zero width is approximately 50 kHz. This illustrative width is one quarter of the 200 kHz nominal channel spacing in Application 1. An input with centre frequency exactly at a nominal channel boundary therefore produces meaningful energy on both sides even in this elementary envelope model. Real pulse edges, modulation, detector windows and analogue filters alter the result; a rectangular gate is a teaching model, not a universal emission class. A validation campaign should vary T and the pulse shape rather than infer the behaviour of all bursts from one 40-microsecond case.

Worked application 7 | Many channel tests change the probability of an apparently rare alarm

Suppose each of N = 64 defined channel tests has an individual false-alarm probability p = 0.0001 for one trial under a specified null model. If, strictly as a hypothetical simplification, those test outcomes were independent, the probability of at least one false alarm would be P_any = 1-(1-p)^N = 1-(0.9999)^64 = 0.00637988, or about 0.638 per cent. A Bonferroni union upper bound gives P_any <= Np = 0.0064, or 0.640 per cent, without the independence assumption. An actual polyphase bank usually has correlated adjacent outputs, so neither the independence result nor a nominal per-channel p can simply be transplanted into a system-wide assertion without measuring or modelling the joint null

Copyright 2026, James M. Atkinson

distribution. The calculation illustrates multiplicity, not a certified false-alarm rate for any receiver.

Worked application 8 | High observed detection frequency can leave a modest lower confidence bound

In one hypothetical preregistered boundary condition, suppose $n = 100$ valid independent challenge trials were made and $k = 99$ were detected under an unchanged rule. The observed fraction is $p_hat = k/n = 0.99$. Using the conventional Wilson score lower bound for a two-sided 95 per cent interval with $z = 1.96$, the centre is $[p_hat + z^2/(2n)]/[1+z^2/n]$, and the half-width is $z \sqrt{[p_hat(1-p_hat)/n + z^2/(4n^2)]}/[1+z^2/n]$. Substitution gives a lower endpoint about 0.9455, not 0.99. This is a single-condition illustrative interval assuming Bernoulli trials with a common probability and appropriate independence. It is not a simultaneous guarantee over many channel edges, durations and interference levels; a full acceptance claim must account for selection and multiple conditions. One observed failure is not permission to exclude that trial from the denominator.

Worked application 9 | Storing all complex output channels is not a free consequence of splitting the spectrum

Suppose the raw complex-input stream of Application 1 is represented by signed 16-bit I and 16-bit Q integers, so each complex sample occupies 4 bytes before metadata or packet overhead. At $F_s = 12.8$ million complex samples/s, the nominal input volume is $12.8 \times 10^6 \times 4 = 51.2$ million bytes/s. One hour occupies $51.2 \times 3600 = 184{,}320$ million bytes, or 184.32 GB in decimal units. A critically sampled, complete 64-

Copyright 2026, James M. Atkinson

output bank retains the same nominal aggregate complex-sample count and byte rate if sample representations are unchanged; oversampling by R = 4/3 would increase the nominal output to 68.2667 million bytes/s, or 245.76 GB per hour. These are uncompressed theoretical payload values. Real metadata, burst retention, coding and compression change storage, but no storage saving should be assumed without identifying which data are omitted or transformed.

Worked application 10 | The edge-correction uncertainty can be correlated

Suppose the total logarithmic correction C in decibels is the sum C = C_reference + C_channel, where the reference-plane calibration has standard uncertainty u_1 = 0.4 dB and the channel edge-response correction has u_2 = 0.3 dB. If the estimates are independent and the linearised logarithmic uncertainty model is applicable, u_C = sqrt(u_1^2+u_2^2) = sqrt(0.16+0.09) = 0.500 dB. If the correlation coefficient between these corrections is rho = +0.6, propagation of covariance instead gives u_C = sqrt(u_1^2+u_2^2+2 rho u_1 u_2) = sqrt(0.16+0.09+0.144) = sqrt(0.394) = 0.6277 dB. Ignoring their shared reference would understate uncertainty in this hypothetical case. The calculation follows the sensitivity-and-covariance principle described in NIST Technical Note 1297; it does not replace a full uncertainty budget for a nonlinear or saturated receiver. [S6]

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, I invite examination of a deceptively simple act of digital housekeeping. When a wideband receiver produces more samples than an analyst wishes to retain, a downsampling operation promises smaller files, fewer computational demands and a spectral representation better adapted to a narrow subject of immediate interest. A laboratory monitor may show the decimated trace marching smoothly across its screen, while the storage device grows at a more comfortable pace. Yet the very success of that operation may remove measurements which a later investigator requires for a different question. We must decide whether an operation is an admissible compression of an already defined measurand, a qualified transformation of evidence, or an irreversible abandonment of a field of possible observations.

Let the input sample rate be F_in in samples per second, the integer decimation factor be D, and the output rate be F_out = F_in/D. A correct conventional decimator filters before retaining every Dth output sample; its

Copyright 2026, James M. Atkinson

anti-alias filter should suppress the components which would otherwise fold into the narrower frequency region represented at F_out. If the input consists of complex baseband samples, the nominal unaliased output interval is approximately minus F_out/2 to plus F_out/2 about the assigned centre, subject to the actual filter passband and transition region. If the samples are real, their one-sided interpretation requires the appropriate conjugate-symmetry and Nyquist conventions. The formula for the rate is elementary. The decision about which observations shall remain possible is not.

Three records deserve separate names. The *raw acquisition* is the sequence preserved at a documented receiver output, with its sample rate, format, reference plane, gain state and continuity record. The *derived decimated sequence* is the product of a specified filter, decimation phase, boundary convention and software implementation. The *claim* is the proposition that a later examiner wishes to test: that an emission existed within a particular frequency interval, that it lasted for a specified time, that its phase was coherent with another event, or that an observed line originated beyond the receiver. A transformation can be entirely reproducible while being inadequate to answer one of these later questions. Reproducibility of the output is not invertibility of the map from input to output.

The distinction is particularly acute when surveillance searches are broad and exploratory. An initial operator may retain only one 100-kilohertz channel from a ten-megahertz observation because that channel contained a candidate burst. Months afterwards, counsel or an independent expert may ask whether the original event was an intermodulation product of a

Copyright 2026, James M. Atkinson

stronger transmitter outside that retained channel, whether a second carrier appeared simultaneously in a neighbouring interval, or whether an adaptive threshold discarded the very samples needed to estimate non-detection exposure. The prepared file may open without difficulty, its cryptographic digest may match the acquisition report exactly, and its timestamps may be internally consistent. None of these properties supplies measurements intentionally omitted before the file was written.

I ask the panel to keep distinct at least four kinds of loss: unrecorded frequencies removed by protective filtering, ambiguities created by insufficient suppression before decimation, temporal distinctions blurred or rejected by a finite filter and output grid, and missing provenance concerning how the product was created. An anti-alias filter protects the retained passband against unwanted folding. It is not an archive of the rejected stopband. A more ambitious analysis of the original apparatus might require those rejected components precisely to establish that the retained line was not receiver-generated. Conversely, preserving every raw sample indefinitely is not always proportionate or feasible. The proper criterion is whether the recording policy was adequate for the claim authorised and anticipated, and whether its exclusions are legible to any later examiner.

Professor Bridgman will begin with the definition of the physical quantity and the operations by which it is observed. Dr Shannon will examine the many-to-one character of filtering and downsampling, and will distinguish a defensible band-limited inference from an illicit claim of exact historical recovery. Professor Slepian will examine finite records, transients and spectral concentration. Dr Wiener will evaluate adaptive filtering, stochastic

Copyright 2026, James M. Atkinson

assumptions and the temptation to confuse model-based reconstruction with observed fact. Professor Tukey will address how selection and discovery practices affect confidence, especially when successful events rather than all exposure intervals are retained. Seven colleagues will question these positions in turn. I ask that each question receive a reply immediately, and that each speaker identify a test whose outcome could have challenged the proposed inference. The discussion should end with an operational preservation rule suitable for both the engineer at a glowing oscilloscope and the forensic examiner arriving much later with a silent archive.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal response 1: The measurand changes when the operation discards dimensions

Dr. Atkinson, the word *signal* is liable to conceal more different objects than the engineer supposes. There is the voltage at an antenna terminal; the waveform at the input of an amplifier; the output of a mixer after a changing local oscillator; the sequence of analogue values presented to a sampling aperture; the resulting code words; and the decimated product of a digital filter. These are not interchangeable representations unless a specified model establishes their relation. We should therefore begin with a statement of the measurand, including frequency, time, amplitude and reference plane, before congratulating ourselves on having reduced its storage burden. The mathematical operator does not know what the prosecution, the defence, or the engineer may later wish the evidence had contained.

Suppose a complex receiver samples a band at 12.8 million samples each second. A factor-of-sixteen decimation produces 800,000 samples per second. The wideband source could originally represent frequencies approaching plus or minus 6.4 megahertz relative to its assigned centre, whereas the derived baseband file, under appropriate filtering, retains a much narrower interval approaching plus or minus 400 kilohertz. The preserved amplitude of a calibrated component at 120 kilohertz may be estimated quite satisfactorily. It does not follow that the transformed file can answer whether a strong adjacent carrier at 1.1 megahertz drove a nonlinear front end, nor whether an out-of-band intermittent transmission preceded the candidate. Those questions are not simply more elaborate

Copyright 2026, James M. Atkinson

arithmetic exercises. Their observations were removed by the operation or were never acquired at the necessary reference plane.

There is a tempting counterargument. If the decimation filter is known and the resulting complex numbers are preserved exactly, why may the examiner not invert the filter mathematically? The answer is that a map with a nontrivial null space does not admit an inverse on all possible inputs. Distinct wideband sequences can share the same decimated output because the filter suppresses their differences, or because the output sampling operation retains fewer independent constraints. An inverse model can choose a preferred input from among multiple candidates by imposing bandwidth, smoothness, sparsity or a prior signal dictionary. That choice may be a useful estimate. It is not the recovered observation unless the restrictions have independent empirical justification. The sharp edges of a reconstructed trace on a screen are not proof that an actual historical waveform possessed those edges.

I would distinguish a loss of *information relevant to a question* from a loss of every useful property. The resulting narrowband series may still support precise frequency estimation for a component wholly within the validated passband, subject to the retained observation time and clock performance. It may support an upper bound on power within a stated band if the gain and filter response are characterised. It may support event timing at a specified granularity if the filter's group delay, impulse response, block boundaries and alignment are documented. It cannot, simply by being a sequence of numbers, establish the amplitude or existence of signals discarded outside that band. Nor does its byte-perfect integrity imply that every input sample was included in the acquisition process.

Copyright 2026, James M. Atkinson

Consider also how filters alter the meaning of amplitude. If a 200-kilohertz offset lies near the passband centre, the response may be nearly flat. At an edge, a candidate may be attenuated by several decibels, and a pulse may be distorted by a filter impulse response whose duration exceeds that of the original emission. A value printed as a peak voltage after the filter is therefore not necessarily a peak voltage before the filter. Correcting an indicated value demands a known transfer function and a suitable signal model. If several distinct waveforms produce the same output peak, a scalar correction factor cannot restore their individual peak amplitudes. The record must distinguish calibration for steady sine waves from validation for brief bursts, frequency hopping or closely spaced emitters.

From an operational standpoint, I would require the examiner to retain a processing manifest contemporaneous with the derived file: input sample rate and precision, decimation factor, exact coefficient array and coefficient hash, phase or starting sample index, filter initial state and boundary padding, software version, frequency translation convention, timestamps, gap handling, receiver gain, reference frequency and physical input plane. A manifest cannot restore missing observations, but it permits a later reader to know precisely what is missing and to reproduce what remains. A generic description such as 'downsampled for efficiency' is barely a declaration of method. It does not say which signals were rejected, whether they might have influenced the front end before rejection, or whether the timing of a suspected event survived the transformation without qualification.

The tension between efficient acquisition and evidential completeness ought not to be resolved through a rule that all data must be retained forever. A properly scoped examination can preserve a known, sufficient

Copyright 2026, James M. Atkinson

subset and report its limits. But the scope must precede the convenient filtering, rather than be invented after an interesting candidate has been found. For a general exploratory technical-surveillance search, a deliberately bounded retention policy might store representative wideband raw intervals around material detections, retain a coarse wideband spectral history and preserve the complete receiver-state and selection logs. Such a system would not provide unlimited recovery, yet it would permit a number of competing explanations to be tested rather than concealed by an attractive narrowband output. I invite Mr Heaviside to test whether this distinction becomes too philosophical when engineering constraints require a usable filter before any sample can be stored.

Oliver Heaviside | Peer question 1 to Percy Williams Bridgman

Professor Bridgman, I accept that a mathematical transform is not the electrical phenomenon itself. Nevertheless the engineering shop cannot begin its work by storing a universe of possibilities. A receiver may be designed for a specified channel in the presence of powerful adjacent transmissions, and its very ability to observe that channel depends upon rejecting energy that would otherwise overwhelm an amplifier or alias into an output. The operator will be instructed to use a protective filter before sampling, quite apart from later digital decimation. Would your doctrine suggest that every such lawful rejection makes the record insufficient? If so, the demand for completeness would defeat the measurement that was actually commissioned. More precisely, how shall we distinguish a missing variable that materially threatens the intended claim from an irrelevant degree of freedom that a valid experiment is entitled to exclude? And how would that distinction survive cross-

Copyright 2026, James M. Atkinson

examination when a later advocate asks a question no competent investigator foresaw at the time of collection?

Percy Williams Bridgman | Immediate answer to Oliver Heaviside

Mr Heaviside, you have identified the essential qualification. There is no scientific virtue in attempting to measure every quantity without regard to the question. The adequacy of an instrument is relative to an explicitly intended operation and its accepted uncertainty. Analogue filtering can be necessary to prevent overload or aliasing, and digital decimation can make a particular measurement practical. The fault arises when the claim travels beyond its declared boundary while the record retains only the narrowed representation. An investigator who has measured a stated passband under specified interference conditions may properly report that result. The same investigator cannot subsequently claim to have excluded all external emitters within the original analogue front-end bandwidth if those intervals were not retained or otherwise surveyed.

The standard of materiality is therefore not omniscience but a disciplined relationship between the observation plan and the possible rival explanations. Before the examination, list the signal classes, frequencies, durations, amplitude limits and sources of interference relevant to the task. Identify the transformations that destroy observations important to differentiating those hypotheses. If out-of-band energy could generate intermodulation products within the target channel, the examiner should consider recording a wideband witness, a front-end overload indicator or a second independently filtered measurement. The chosen witness need not be

Copyright 2026, James M. Atkinson

a perfect full-rate copy; it must be sufficient to test the particular alternative under an explicitly qualified model. A witness that measures only after the nonlinear stage cannot conclusively exclude a nonlinear cause arising before it.

A later, unforeseen question cannot always be answered. That limitation must be stated without treating the inability as proof either for or against the newly proposed hypothesis. Where the original collection scope was narrow but honest, a subsequent demand for an unrecorded quantity is a newly required experiment, not evidence that the recorded quantity is false. If it becomes possible to repeat the observation under similar conditions, a new experiment may be designed. Where the event was singular, the forensic opinion must preserve the difference between what is supported, what remains plausible and what has become observationally inaccessible. A negative search finding should not be extended to unobserved bands simply because the displayed channel looked quiet.

Your filtering objection also helps establish a useful acceptance test. Put known challenge emissions both inside and just outside the admitted band, include stronger interferers capable of stressing the analogue chain, and document the resulting passband measurement, spurious outputs and state transitions. When the challenge demonstrates that a component outside the retained band has no material effect upon the specified result under the tested envelope, its exclusion can be justified for that claim. Where its effect remains uncertain, the claim should narrow or the apparatus should acquire more evidence. This is not a limitless invitation to doubt; it is the

Copyright 2026, James M. Atkinson

ordinary discipline by which a measured quantity acquires a defensible meaning. I shall pass the floor respectfully to Dr Shannon, whose information-theoretic account can show why a successful output may nevertheless be one of many possible inputs.

Harold Stephen Black | Peer question 2 to Percy Williams Bridgman

Professor Bridgman, your account seems persuasive when the examiner defines the possible rival explanations before operating the receiver. My difficulty is the adaptive apparatus whose channel choice and retention rules respond continuously to observed activity. The system may raise the gain in one subband, suppress another, change its decimation rate and save only the intervals it classifies as anomalous. Its decisions are physically consequential and may even alter the internal artefacts to be distinguished from external emissions. If the later analyst receives only selected narrowband files, each bearing an immaculate hash and a standard timestamp, what would count as a sufficient account of the unrecorded decision history? Is a log of configuration changes enough, or must the examiner preserve the detector scores and thresholds that caused each change? And may an operator claim that an unselected interval was quiet when the classifier itself relied on a moving noise-floor estimate, partially calculated from the very observations it later discarded?

Percy Williams Bridgman | Immediate answer to Harold Stephen Black

Mr Black, an adaptive recording must treat the act of selection as part of the measurement procedure. A list of final files is not a complete description of the observation system, because the system's

Copyright 2026, James M. Atkinson

output depends upon the rule deciding which observations become files. At a minimum, the record ought to preserve the detector algorithm and version, threshold history, decision windows, gain and bandwidth changes, state of the noise estimator, any excluded or invalid intervals, and an exposure account stating when each frequency region was admitted. For a threshold derived from the recent data, one must distinguish the data used to estimate the threshold from the data subsequently tested. Otherwise the reported detection probability may be calculated under assumptions the actual closed-loop process violated.

Saving every intermediate statistic may be impracticable, but enough must remain to reconstruct the decisions material to the declared claim. A compressed state log, hashed configuration snapshots and event-by-event score summaries may suffice when their equivalence to the live decisions has been validated. For high-consequence findings, raw snapshots from selected *non-events* deserve consideration, because an archive consisting exclusively of alarms cannot estimate the frequency or circumstances of missed alarms. This is particularly important when the instrument progressively learns what it regards as normal. The physical question is not merely whether a file has been modified; it is whether the acquisition strategy could have failed to retain the very observations necessary to challenge its conclusions.

There is a decisive difference between 'not detected by this receiver under this schedule' and 'not emitted at the location'. The former may be true and useful even for an adaptive instrument, provided its

Copyright 2026, James M. Atkinson

schedule, sensitivity and selection mechanism are described. The latter requires a far more demanding causal and spatial inference. If the operator did not retain the threshold trajectory, the later examiner may be unable to recreate the selection event and must acknowledge the deficit. An intact checksum cannot reconstruct a vanished threshold value, any more than a clean measuring rule can supply a length that was never taken.

In my judgement the acquisition plan should define which state variables are mandatory for retention before the survey begins. The instrumentation should then make missing state records visible as validity qualifications rather than silently substituting nominal defaults. When a controller changes decimation rates, the log should include the exact transition sample, filter reset or continuity behaviour and any interval during which the output is not a stable measurement. In the absence of that account, a recorded burst may still be an observed output event, but its amplitude, duration or absence from neighbouring intervals may remain untestable. The more elaborate the apparatus becomes, the more important it is that its operational definitions remain simple enough for another competent investigator to contest. I now invite Dr Shannon to address the irreversibility of information discarded before such a contest can occur.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 2: A many-to-one transformation cannot be made an historical inverse by eloquence

Dr. Atkinson, the matter can be expressed without mystical appeals to lost information. An observed discrete sequence x[n] is transformed into y[m] by filtering and retaining selected values. For a linear time-invariant filter with impulse response h[n], an idealised decimator produces y[m] = sum over all k of h[k] x[mD-k]. If the observed record consists only of y, and the admissible inputs include every possible x at the original rate, the mapping generally has infinitely many preimages. It is many-to-one. No archive of the code implementing the map, however complete, converts that map into a one-to-one correspondence. The code can reproduce y when given x. It cannot manufacture an unknown x from y without assumptions restricting the allowable signals. [S1, S2]

There are nevertheless circumstances in which the information needed for an *identified* purpose is preserved. A correctly band-limited signal occupying the narrower admitted region can, under ideal sampling and adequate knowledge of the sampling coordinates, be represented at an appropriately reduced rate without sacrificing the information required to specify the waveform within that region. But that is a conditional theorem about a specified signal class, not a statement about every possible wideband observation. If two distinct real-world signals produce the same narrowband result because one differs from the other solely in a suppressed frequency region, a later analyst cannot tell those histories apart using the decimated file alone. The anti-alias filter has performed its prescribed task by making the narrower output interpretable, while simultaneously preventing it from being a record of what the filter rejected.

Copyright 2026, James M. Atkinson

The engineer may object that an extremely steep filter is practically an instrument for identifying the desired band, and therefore its stopband deserves no further attention. I would ask which downstream proposition is to be made. If it concerns the narrowband waveform's frequency or integrated energy under valid calibration, the exclusion may be entirely appropriate. If it concerns the physical cause of the waveform, information about stronger rejected inputs could be essential. An intermodulation product generated ahead of the digital filter survives within the passband even though the external signals which gave rise to it do not. The output has preserved the effect but not the witnesses needed to distinguish causes. The inverse problem is not repaired by taking an additional million samples of the effect if every such sample contains the same causal ambiguity.

A separate mistake arises when the anti-alias filter is inadequate. If the new complex output rate is 800,000 samples per second, inputs at frequencies separated by integral multiples of 800,000 hertz have the same discrete complex exponential sequence *after bare downsampling*. A 300,000-hertz input and a 1,100,000-hertz input can therefore become identical in the retained samples unless their relative amplitudes were altered or rejected before the sampling reduction. A properly designed filter may attenuate the 1.1-megahertz component sufficiently to avoid material contamination. The record should establish that attenuation in the relevant operating state, rather than assume that a nominal filter name guarantees it. Where the attenuation is insufficient, the resulting line may be genuine output data yet have ambiguous input frequency. It is not scientifically permissible to choose the lower of the aliased possibilities merely because the output file's new rate suggests that interpretation.

Copyright 2026, James M. Atkinson

Temporal claims present related limits. Decimation with a finite impulse response is not the same as keeping every Dth raw sample without filtering. The filter integrates information over its impulse-response support. A very brief burst can contribute to several derived output samples, and an abrupt boundary can excite ringing that outlasts the original event. If the filter's phase response is known and its passband retains the relevant signal content, a time reference may be corrected with a documented group delay. Yet that correction cannot restore arbitrarily high-frequency structure deliberately rejected, nor can it know the initial filter state where processing began halfway through an event. A reconstructed trace may show a smooth, attractive envelope that was never independently observed at the analogue plane.

We must also be careful with information-theoretic vocabulary. I would not call the storage saving a numerical loss of 'bits of evidence' without specifying a probability model, an input ensemble, a noise law and an estimand. Entropy of a selected stream, mutual information about a particular parameter, and the number of raw bits written to disk are different quantities. A sequence of thirty-two-bit floating-point output values may occupy more bytes per sample than a twelve-bit ADC code and still contain less information about the original wideband input. Conversely, a smaller representation may be sufficient for the chosen task. The claim that an archive possesses a specified number of independent physical information bits requires substantially more than counting its binary storage positions.

Prudent engineering therefore establishes separate retention classes. The narrowband record can be the primary analysis product; a coarse

Copyright 2026, James M. Atkinson

wideband monitor may be retained to test interference alternatives; and short raw bursts with pre-trigger context may be preserved for events whose interpretation is likely to be contested. Each representation should carry its own source digest, transformation manifest and limits. An unrecorded frequency is not thereby shown silent. A rejected transient is not thereby shown absent. What survives can be analysed rigorously, but only if we resist the temptation to pretend that a filter has preserved the hypotheses it was designed to suppress. I ask Professor Kolmogorov to examine whether probabilistic reconstruction can sometimes justify a stronger inference than this severe account of many-to-one mapping suggests.

Andrey Nikolaevich Kolmogorov | Peer question 3 to Claude Elwood Shannon

Dr Shannon, your description of many-to-one mapping is exact for unrestricted inputs, but a forensic investigator rarely regards every mathematical waveform as physically plausible. The observed electromagnetic environment may have well-characterised spectral occupancy, transmitter modulation classes, receiver nonlinearities and noise distributions. If decades of calibration and independent field tests support a model in which the suppressed components are strongly correlated with the retained components, might a posterior estimate recover more than your deterministic description concedes? I am not proposing that a probability distribution resurrect a sample which was never written. I ask whether a carefully validated conditional distribution can give a defensible likelihood for competing wideband histories, and how that inference should be reported without the audience mistaking a

Copyright 2026, James M. Atkinson

model-based estimate for an observation. Would you set a criterion of posterior concentration, robustness to plausible priors, or an independent challenge measurement before accepting the claim? I ask also whether such criteria must be declared before the investigation or may be changed after an unexpectedly attractive reconstruction appears.

Claude Elwood Shannon | Immediate answer to Andrey Nikolaevich Kolmogorov

Professor Kolmogorov, the distinction you propose is essential. Mathematical non-uniqueness does not make all rational inference impossible. If a validated generative model constrains the source ensemble, the observed narrowband data can change the relative probabilities assigned to competing hypotheses. A posterior inference may be useful for deciding which additional measurement to make, ranking possible causes, or presenting a bounded probabilistic opinion. But that posterior is a function both of the surviving observations and of the assumptions that assign relative weight to the unobserved components. Its precision must not be attributed to the recording alone.

I would first require the competing hypotheses to be specified before fitting the explanation. An analyst who selects a model after inspecting the derived trace may inadvertently favour whichever reconstruction most resembles the desired conclusion. Next, the probability model must be tested against held-out examples containing both the expected signals and realistic alternatives, including high-power interferers, receiver-generated products and unexpected modulation. A model validated only on clean, isolated

Copyright 2026, James M. Atkinson

laboratory tones cannot establish a narrow probability of a complex field source in a heavily occupied band. The validation population matters as much as the elegance of the posterior formula.

Robustness tests should examine priors and nuisance-parameter uncertainty. If a source-attribution conclusion changes when plausible interference occupancy or front-end nonlinearity assumptions are varied, the report should identify that sensitivity instead of presenting one favourable number. If the model uses learned features from a data archive, training and evaluation records must be separated, and repeated measurements sharing the same hardware path must not be treated as wholly independent. Credible intervals are conditional on the model, not universal proof that the particular unrecorded waveform possessed a calculated amplitude or arrival time.

An independent challenge can be decisive when it makes different predictions. For example, change the analogue preselector, input attenuation, receiver or sample plan while retaining a stable external reference. A real incoming component and a mixer-generated intermodulation product may respond differently, provided the apparatus is carefully characterised. Where the original event cannot be repeated, the posterior can remain useful as a qualified historical inference, but its causal claims must not be promoted beyond the surviving evidence. I would describe its result as the probability or likelihood under stated hypotheses and conditions, not as a recovered raw waveform. The court and the technical laboratory should hear the same limitation.

Copyright 2026, James M. Atkinson

Finally, a good archive should permit future analysts to revisit the prior assumptions without destroying the underlying data. Keeping the derived narrowband file, its filter and version record, and any available raw witness is therefore better than preserving only one posterior waveform. Reproducibility of the inference is valuable; the capacity to contest its model is more valuable still. The examiner who discloses both the data and the conditions of reconstruction has supplied a meaningful basis for scientific criticism, without claiming that probabilistic skill can repeal the consequences of physically discarded observations. I invite Dr Turing to challenge the claim that a transformed file can remain reproducible even when its generating implementation is no longer available.

Alan Mathison Turing | Peer question 4 to Claude Elwood Shannon

Dr Shannon, one can easily preserve a written formula while losing the computing process which actually produced the exhibit. Two nominally equivalent decimators may differ in coefficient quantisation, arithmetic precision, saturation behaviour, boundary extension, handling of NaN values and rounding at each stage. A report may state that a low-pass FIR filter preceded a factor-of-sixteen downsampler, yet a regenerated file may differ from the original because the reference implementation silently changed its default padding or its treatment of a final incomplete block. What conditions would allow an independent examiner to establish that the digital result was generated by the declared process rather than merely by a mathematically similar process? Would a software hash, an input-and-output test vector, or a containerised execution environment suffice, and how should the examiner distinguish

Copyright 2026, James M. Atkinson

reproducibility of the computation from proof that the retained data answered the intended physical question? The distinction becomes especially pressing where the original source samples have not survived and a court sees only the processed exhibit.

Claude Elwood Shannon | Immediate answer to Alan Mathison Turing

Thank you for that question. Dr Turing, the distinction is between a mathematically defined operator and a particular implementation of that operator. A reproducible forensic transformation should disclose, wherever practicable, the exact input representation, coefficient sequence, phase convention, arithmetic type, overflow behaviour, buffer boundaries and software version, along with known execution dependencies. A hash of a binary file establishes that the file remained unchanged; it does not by itself explain what the binary did or how it was configured. A signed software release may assist provenance, but validation still requires test vectors whose expected results are independently known, including values near saturation, block boundaries and filter reset transitions.

A reproducibility package may include a frozen executable or source revision, dependency lockfile, compiler or interpreter details, configuration, calibration coefficients and a small suite of challenge inputs. It should also provide checksums of both input and derived outputs. Where deterministic binary reproduction cannot be guaranteed across hardware platforms, a documented numerical tolerance can be scientifically appropriate, provided the tolerance is connected to the task's measurement uncertainty and not chosen

Copyright 2026, James M. Atkinson

merely to excuse an unexplained discrepancy. Difference at one least significant bit may be immaterial to a coarse power estimate but decisive to a threshold event lying precisely on a decision boundary.

Even perfect computational reproducibility would not prove physical validity. The filter may accurately eliminate a band that later proves essential to attribution; the decimation phase may be perfectly reproduced despite having omitted a transient at a sensitive interval; and a moving threshold may be applied exactly even though its statistical properties were not evaluated. The correct evidence claim should distinguish that the stored file is intact, that the transformation is reproducible, that the transformation is a justified measurement of specified quantities, and that a proposed interpretation of those quantities has survived appropriate alternative tests. These are separate links in an evidential chain.

For long-term retention, simple, documented interchange formats can reduce dependence upon an obsolete proprietary application, but conversion into such a format is itself a new transformation that should be recorded. Keeping the raw source and an open, versioned derivation normally permits more criticism than keeping a closed export alone. Where the raw source is absent, a known transform still allows the analyst to delimit the surviving domain, not to recover the lost dimensions. This is the sense in which reproducibility is necessary for some strong forensic opinions yet insufficient for claims of universal recovery. The most faithful report preserves the difference between computational certainty and empirical uncertainty. Professor

Copyright 2026, James M. Atkinson

Slepian may now direct our attention to the events which escape the comfortable fiction of an infinitely long stationary record.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 3: Selection, omitted data and the lure of a favourable display

Dr. Atkinson, I should begin by challenging a tempting division between engineering and inference. It is easy for a laboratory to declare decimation a signal-processing operation and to leave its interpretation to a later statistician. Yet the choice of the retained band, the length of the observation window, the detector threshold and the rule deciding which events are stored constitute a process of selection. These choices change the population of observations about which the investigator can speak. When an archive contains only bursts that exceeded a threshold after narrowband processing, its empirical frequency distribution is not automatically the frequency distribution of all emissions encountered by the original antenna. It is a distribution conditioned upon the channeliser, filter, exposure, trigger and retention mechanism. Those conditions must be carried into every later statistical inference.

The point can be made without mystical appeals to information. Suppose the original survey encounters legitimate strong signals, weak sporadic emissions, receiver-generated products and noise transients. A decimation channel excludes one part of the spectrum and a detection rule excludes most time intervals. The surviving events will be disproportionately composed of cases to which the filter and threshold are sensitive. If the investigator examines only the surviving cases and estimates a detection probability from their apparent clarity, the analysis is circular. The difficult misses are precisely the observations least likely to be preserved. An attractive waterfall may therefore constitute a collection of selected successes rather than an unbiased test of the instrument's ability to discover

Copyright 2026, James M. Atkinson

weak signals. Such a display need not be fraudulent; it may be a faithful picture of an inadequate selection design.

I would insist upon a denominator. If the investigator reports that nineteen of twenty known challenges were detected, the twenty trials must represent the predeclared population of conditions and must include failed trials, periods of invalid acquisition and threshold alterations. If the test instead examines twenty retained candidate clips, no detection sensitivity can be inferred because the sample was constructed by conditioning on retention. Equally, a claimed absence requires an exposure record indicating when the receiver actually observed the relevant frequency, at what sensitivity and with what probability of passing the detection rule. It is possible to have an exact sample rate and an exact filter coefficient set while lacking the denominator necessary for the legal assertion which the analyst wishes to make.

A realistic audit should preserve the acquisition state as a time series. It should identify scheduled band coverage, instantaneous tuning, invalid blocks, dead time, channel boundaries, gain state, filtering mode, trigger policy and software changes. It should distinguish what the instrument was capable of recording from what it was configured to retain. One can then reconstruct the actual opportunity for observation. This is different from assuming that a receiver was monitoring an entire building merely because it was switched on throughout the day. A sequential scanner might dwell briefly on each channel, and a one-millisecond transmission may easily occur during an interval when the relevant channel was not being sampled. An adaptive system may revisit frequencies following earlier alarms; this

Copyright 2026, James M. Atkinson

makes coverage a function of prior observations and introduces dependence that a simple random-trial model does not capture.

The lost raw record also affects exploration. A statistician may later wish to compare the behaviour of two detectors with different bandwidths, alter a false-alarm threshold, evaluate cross-channel coincidence, or examine whether strong adjacent signals were associated with alleged weak emitters. If only the output of the first detector survives, most of these comparisons cannot be made. It would be poor practice to call the archive raw evidence merely because it is stored in a binary complex-sample format. A digital sample can be the output of substantial irreversible processing. Its semantics depend upon the generating operation. We must describe what was acquired, what was selected and what remains experimentally testable.

Nor do I advocate indiscriminate storage. A properly designed stratified archive could retain continuous summary statistics, known-schedule random witness intervals, representative negative intervals, event-triggered higher-rate clips, and enough challenge sequences to estimate sensitivity in different conditions. This does not recover every missing waveform, but it makes selection inspectable. Sampling of witness intervals should be predeclared and independent of the event detector where possible. Otherwise the archive's supposedly independent control material will again favour obvious signals. A complementary receiver or reference monitor can provide external validation, but its independence must be analysed rather than presumed, particularly if the instruments share one antenna or noise reference.

The distinction between exploratory and confirmatory analysis belongs in the report. After-the-fact searches are scientifically valuable, and

Copyright 2026, James M. Atkinson

unexpected patterns may reveal apparatus faults or new signal classes. Yet an effect discovered after trying dozens of filters, thresholds and frequency windows cannot be accorded the same false-positive interpretation as a single predeclared test unless selection and multiplicity are handled. An investigator who observes one spectacular spike among thousands of comparisons should state how many opportunities for a similar spike existed. In a forensic setting, a precise timestamp beside an amplitude number can look more authoritative than its selection history warrants. The ethical remedy is not vagueness but a record of choices and a restricted claim.

I would accept a report that says a candidate was detected under a specified filter and decision rule, that the source clip and configuration were preserved, and that subsequent challenge experiments favour one hypothesis while leaving others unresolved. I would reject a report that reads a selected candidate archive as a complete census of unobserved emissions, or infers universal negative assurance from an unquantified duty cycle. The loss that matters is not only missing hertz or missing samples. It is the missing comparison group, the missing test history and the missing opportunity to discover that the detector failed. I pass the floor to Professor Neyman, whose concern with the design of inference sharpens the question of what evidence a negative result can bear.

Jerzy Neyman | Peer question 5 to John Wilder Tukey

Professor Tukey, your demand for a denominator is persuasive, but consider the operational burden on a receiver whose observation pattern is adaptive rather than fixed. Each alert causes the controller to lengthen dwell in one region, shorten dwell elsewhere and change detector

Copyright 2026, James M. Atkinson

thresholds according to a rolling estimate of occupancy. The time spent observing a frequency is consequently related to earlier indications, some genuine and some artefactual. It is not obvious that a simple proportion of detected laboratory challenges estimates the field probability of detection. How would you construct a validation experiment that remains meaningful when the acquisition policy is itself a stateful stochastic mechanism? In particular, what quantities would you condition upon, and when would you regard an interval as outside the validated envelope rather than counting it as a failure or a success? I ask you to distinguish inferential uncertainty from the genuine physical loss of a waveform whose frequency the receiver was never sampling.

John Wilder Tukey | Immediate answer to Jerzy Neyman

Professor Neyman, I would begin with the distinction you have drawn. An experiment cannot estimate the sensitivity of an adaptive surveillance procedure merely by treating every retained clip as an exchangeable observation. The object of evaluation should be the complete decision policy, including its state transitions and responses to prior observations. We should describe a trial population of signal amplitudes, durations, frequencies, interferer conditions and arrival phases, and run the actual controller against that population without repeatedly tailoring its policy to the visible successes. Where an intervention changes the policy, it becomes a different procedure requiring its own performance statement.

The denominators should be indexed by exposure conditions. For a frequency actually monitored with a known threshold and gain state, one can estimate a conditional detection probability under declared

Copyright 2026, James M. Atkinson

signal classes. For a frequency not sampled during a trial, the failure is an exposure failure for the complete surveillance system, not an electronic receiver miss at its input. Both matter to a claim of successful survey coverage, but they diagnose different causes. An honest report may state the overall procedure's chance of encountering and recognising a specified event, while separately giving the detector's chance of recognising that event conditional on exposure. Combining those quantities without distinguishing them can lead to impressive detector metrics and poor operational surveillance performance.

We can introduce controlled signals at random times and frequencies, including during periods when the adaptive policy is likely to prefer other bands. The generation schedule must be independently retained and should not be revealed to the detector. Trials must include genuine negatives, strong interferers and conditions known to provoke false triggers. Repeated campaigns should vary initial controller state and preserve the whole state history. In this way the experiment challenges not merely one filter but the scanning decision mechanism. Confidence statements require attention to dependence; adjacent trials influenced by the same gain estimate or interference event are not independent Bernoulli experiments simply because they have different row numbers.

Where the policy changes during the campaign, the acceptance record should identify the predeclared adaptation rules and distinguish expected adaptation from human alterations made after observing a failure. A later threshold adjustment may improve the

Copyright 2026, James M. Atkinson

system, but prior results do not retroactively validate the revised configuration. If some environmental condition falls outside the experimental envelope, declare that scope limitation rather than silently omitting the trial. It may be useful to classify the trial as an invalid challenge for a narrowly defined calibration measure, while still reporting that the deployed survey could not provide the broader assurance demanded by its task.

There remains a hard physical fact: a signal outside the sampled region never produced relevant ADC values in that interval. Neither randomisation nor confidence intervals can create those missing values. Statistics can describe how often such non-exposure occurs under a declared policy and what that means for the chance of missing a defined class of events. It cannot determine the unique waveform of a particular unobserved emission. A refined estimator is useful precisely when it respects that distinction. The best engineering report keeps acquisition coverage, detector performance and physical source interpretation in separate, linked propositions. I invite Dr Wiener to address the danger that a feedback-driven recorder obscures those links during operation.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 4: Adaptive operations are part of the system under examination

Dr. Atkinson, when an instrument modifies its operation in response to what it has observed, the observer and the observed record form a coupled system. This is not merely a philosophical curiosity. Consider an SDR which raises its trigger threshold after a period of strong interference, switches from a high-rate wideband stream to several narrowband decimated channels, and increases recording duration around a candidate signal. Its subsequent archive depends on the events that preceded it. The controller may have behaved exactly as designed, yet a later examination of retained clips will not show the full causes of its own selection. We must therefore include the state of control within the measurement boundary. What is not recorded about the controller can become as important as what is missing from the sample stream.

A fundamental distinction concerns the purpose of the feedback. An adaptive filter may suppress interference to increase the sensitivity of a specified detector, while an automatic gain controller may prevent overload and preserve useful dynamic range. Both can improve observation in a practical sense. But they also alter the relationship between the original RF input and the retained samples. The feedback may depend upon estimated power, spectral occupancy, previous alarms and operator settings. A constant output amplitude does not imply a constant input amplitude when gain is changing. A disappearance of a line does not imply that the emitter stopped operating when a notch filter or channel assignment changed. The forensic record must permit those alternatives to be tested, or the interpretation must be carefully bounded.

Copyright 2026, James M. Atkinson

The model should include state variables u(t) for gain, tuning, sample rate, filter bank selection and trigger logic, with a controller law u(t+) = F(u(t), z(t), policy) based on processed observations z(t). Because z(t) is itself computed from previously sampled input, the retained record depends on a history of state transitions. This relationship makes it misleading to describe the whole event with a single stationary transfer function. Even when each state has a known calibrated filter, the transition between states may involve reset transients, finite filter memory, dropped blocks and uncertain effective timestamps. A record that reports only the final state may therefore hide the moment when the claimed waveform first entered the chain.

One might seek to solve this by logging every controller event. That is useful, but a state log does not alone establish that the control decision was physically correct. The thresholds may have been evaluated on biased noise estimates. A transient may have been erased before the controller wrote its event. An apparent narrowband emission may have triggered a reduction in gain that temporarily concealed weaker emissions elsewhere. We need both a process log and independent challenge experiments that reveal behaviour under known inputs, especially near state transitions. Those trials should include signals arriving at awkward times, not merely continuous carriers perfectly aligned with a laboratory schedule.

The system also produces a paradox of evidence. The better an adaptive suppression algorithm becomes at removing a known class of interference, the less of that class may remain in its output. An investigator reviewing the output alone may conclude that the operating environment was quiet, although the suppression system was continuously active. If the purpose of the survey is to characterise interference, such success can be

Copyright 2026, James M. Atkinson

informationally damaging. If the purpose is to detect an independent weaker signal, suppression may be beneficial, but its benefits must be measured as changes in detection performance rather than inferred from a visually clean spectrum. The same filtering operation can be good for one measurand and inadequate for another.

A robust recorder would therefore preserve several distinguishable records. The input state history and configuration hashes should remain available. The transformed sample stream should identify its tuning centre, rate, filter coefficients, processing epoch and associated correction versions. Representative unprocessed witness intervals can support challenges to adaptive artefacts and unreported signal suppression. Triggered recordings should preserve sufficient pretrigger material and the exact trigger rule to show what was selected. Counterexamples, including challenges which a controller fails to detect, must remain in the audit record. If retention capacity requires deletion, the deletion policy itself belongs in the evidence inventory.

I also insist that adaptation is not inherently a forensic defect. A receiver cannot reasonably operate at full precision over every possible frequency, duration and gain condition at all times. A well-validated controller can allocate finite resources efficiently and achieve better conditional detection for the intended signal population. The error begins when the receiver's efficient policy is confused with universal coverage, or when a transformed record is presented without the transformation history necessary to define its observables. The evidence should be evaluated according to the question it was designed to answer and the alternatives it could have distinguished under the actual operating conditions.

Copyright 2026, James M. Atkinson

Finally, we should test the policy as a policy. Challenge it with randomised event arrival times, correlated interferers, temperature changes, sudden gain transitions and durations comparable with the controller's update interval. An adaptive calibration that performs splendidly after warm-up may fail during the first seconds of a field deployment. A filter whose long-term spectral response is excellent may create a short transient during reconfiguration. These failures will be invisible if the acceptance campaign averages over precisely the intervals at which a defensive investigator most needs confidence. I pass the floor to Professor Kalman, whose approach to dynamic estimation can test whether the logged state truly supports the accuracy claimed for the reconstructed observations.

Rudolf Emil Kálmán | Peer question 6 to Norbert Wiener

Dr Wiener, your account treats the receiver as a changing state-space system, but I wish to distinguish reconstructible state from states that have never been observed. Assume an operator preserves the commanded gain, software filter coefficients, input frequency plan and clock reference, but does not retain the analogue gain stage's actual settling response or the transient phase of the local oscillator. A later estimator can propagate an elegant nominal state model over the missing period, yet the hidden physical state may be poorly constrained. Which conditions must hold for such a state reconstruction to support an evidential amplitude or phase claim? Would you insist on observability tests, bounds on process noise, and withheld calibration transients before assigning a confidence interval? I am particularly concerned that an estimator calibrated upon steady laboratory states may give misleadingly narrow uncertainty immediately after an adaptive

Copyright 2026, James M. Atkinson

reconfiguration, precisely where forensic timing is most contested. Would you require an explicit interval of indeterminate evidence after each state change?

Norbert Wiener | Immediate answer to Rudolf Emil Kálmán

Professor Kalman, the nominal state log is a beginning, not an observation of every dynamic variable. I would distinguish commanded configuration from realised physical state. The latter may include analogue settling, oscillator frequency pulling, gain compression and transient phase changes whose time course is not recorded directly. A state estimator can combine a validated physical model with measured observations and produce useful estimates, but those estimates must be conditional upon the model's process-noise assumptions and the actual observability of the relevant state. If no retained measurement constrains a particular transient, the estimator's certainty may come entirely from an assumption that the transient followed its nominal trajectory.

An observability analysis is therefore essential to the strong claim, but it should be adapted to the finite experiment rather than quoted as a universal certificate. A state which is observable under one steady sinusoidal excitation may not be identifiable during a short unknown burst. A gain parameter and an unknown transmitter amplitude may enter the measured product in a way that makes them observationally confounded. Similarly, a common clock drift and a genuine Doppler shift may require independent reference information to distinguish. We should identify these equivalences before asking an estimator to decide between them. An algorithm

Copyright 2026, James M. Atkinson

cannot infer uniquely what its measurement equation never separates.

A calibration campaign should include withheld state transitions, changes of temperature, input amplitudes near operating limits, and disturbances applied at controlled but unpredictable moments. It should compare the estimator's predicted uncertainty with actual held-out residuals and with an independently characterised reference path. Where errors are correlated across consecutive samples, the campaign must not pretend that a million output words provide a million independent validations. A short transition may be the only interval of interest, and the result must be evaluated on that interval. If the model fails there, the failure should prompt a revised bounded claim or a changed measurement design.

I also recommend publishing the actual state estimates and their innovations, not only a final corrected waveform. An independent reviewer should be able to see when the model disagreed with measurements, when a gain or phase correction was large, and when a covariance bound was driven by process assumptions rather than data. The raw material available for such criticism should be preserved wherever practicable. If only the corrected output remains, the examiner may be unable to test whether a different but equally plausible model would produce another physical interpretation.

The most defensible report would therefore state that an amplitude or phase estimate was obtained under a specified dynamic model whose validity has been demonstrated over a declared envelope, and that identified intervals with insufficient observability

Copyright 2026, James M. Atkinson

have been excluded from strong inference. Exclusion is not erasure: the excluded intervals should remain documented as gaps in coverage or uncertainty. If the original data were discarded during an unobserved transition, it is better to acknowledge a lost opportunity than to pretend that a smoother posterior trajectory has reconstructed an actual historical waveform. I now invite Professor Gabor to examine the complementary conflict between temporal localisation and spectral discrimination.

Copyright 2026, James M. Atkinson

Dennis Gabor | Principal response 5: The time-frequency compromise and the physical meaning of a derived transient

Dr. Atkinson, the question of a decimated transient begins with the limits of simultaneous localisation in time and frequency. An engineer may choose a long, narrowband filter because it suppresses interference and makes a weak carrier more visible. Such a filter also has memory. The output associated with a brief event is shaped by convolution with the filter's impulse response, and a detector which reports the output duration as though it were the source duration mistakes a property of the instrument for a property of the emission. The effect is especially serious where the investigation concerns short pulses, rapid frequency changes or the relative ordering of events across independent receivers.

One must distinguish an invariant from an estimator. The centre of an isolated, known waveform may be estimated to high precision under a validated model even when the waveform is narrowband. But when the input is unknown, a narrow output cannot generally disclose the full structure of a wideband transient excluded by the filter. Several different inputs can produce indistinguishable retained outputs. A reconstructed pulse with sharp edges may therefore depict the assumptions of a signal model more vividly than the original experiment supports. No amount of graphical polish can turn those assumptions into observations. An honest display should identify the effective filter bandwidth, group delay, processing window and any postprocessing used to obtain the depicted waveform.

The elementary Fourier trade-off gives a practical warning. A time-localised event requires a spread of spectral content, and a very narrow

Copyright 2026, James M. Atkinson

effective passband necessarily restricts the time detail which can survive. A nominally ten-microsecond rectangular pulse has a sinc-shaped spectrum whose first-null spacing is approximately the reciprocal of its duration, or about one hundred kilohertz in this example. Passing only a small fraction of that structure through a few-kilohertz channel can leave a long ringing response that is not a faithful record of the original rectangular envelope. The result may still be excellent for detecting the presence of energy near the channel centre. But it cannot automatically determine the pulse's rise time, full bandwidth or detailed modulation sequence.

Time-frequency analysis is not exempt from the problem merely because it uses a windowed Fourier transform, a wavelet or another sophisticated representation. The choice of window changes leakage, resolution and temporal smearing. A short window preserves event localisation at the expense of fine frequency discrimination, while a long window improves frequency selectivity but averages over time. When an operator selects whichever representation gives the most conspicuous event and omits the others, the archive becomes a record of interpretive choices. A forensic claim should identify the analysis windows and preserve enough source data to permit a challenger to examine how the conclusion changes under reasonable alternatives.

Decimation may also affect comparisons between receivers. Each device can have a different filter delay and phase response even when both deliver the same nominal output sample rate. Suppose an investigator estimates a time difference of arrival from two decimated records. If one path has an uncompensated group delay of several samples, the apparent difference may arise from instrumentation rather than source geometry. Correcting

Copyright 2026, James M. Atkinson

the delay requires a validated transfer measurement and knowledge of filter state at the event. A nominal coefficient array and a mathematical group-delay formula cannot compensate for an undocumented reset, a changed sample phase or an analogue path that contributes additional frequency-dependent delay. The uncertainty must include these effects where they matter.

I would also caution against assigning physical meaning to an interpolated waveform between retained samples without checking the band-limited assumptions. For an appropriately conditioned narrowband signal, interpolation can accurately reproduce the waveform within the admitted model. It does not restore a high-frequency event removed by the anti-alias filter. Interpolation increases the number of displayed points; it need not increase the number of independent pieces of evidence. The danger is present when investigators enlarge a waveform until the curves look continuous and then discuss fine-scale features that were not represented in the source data. The graph's visual smoothness is a product of the rendering and interpolation rule.

Validation should therefore include test events of different duration, rise time, modulation and arrival phase relative to the decimation cycle. A single continuous sine wave is insufficient to certify the transient behaviour of a digital receiver intended to detect brief, irregular emissions. The examiner should retain challenge waveforms and compare derived widths, arrival-time estimates and phase estimates against known inputs. Tests should include passband edges and strong adjacent activity because those conditions expose the combined effects of transition-band rejection and receiver nonlinearity. When the output meets only a narrower detection

Copyright 2026, James M. Atkinson

criterion, the report should celebrate that bounded success rather than inflating it into an unsupported reconstruction claim.

Finally, the temporal question cannot be separated from source attribution. A short indication may be a genuine emission, a filter start-up transient, a buffer discontinuity or a derivative of a strong neighbouring signal. Its appearance at one output time is not enough to distinguish these causes. The strongest evidence comes from interventions whose predictions differ: changing the receiver architecture, comparing a raw witness channel, verifying the filter state, or demonstrating that the event repeats at the appropriate physically predicted time when the recording method changes. Even these methods require care where common components create correlated artefacts. A chain of individually validated transformations can support a powerful finding, but the chain must be visible. I respectfully pass the floor to Professor Slepian, whose work on spectral concentration invites a difficult question about the behaviour of very short bursts at the margins of the retained band.

David Slepian | Peer question 7 to Dennis Gabor

Professor Gabor, I should like to challenge the comfortable practice of describing a filter's bandwidth as though it were a sharp wall separating preserved from lost information. In a finite-duration observation, spectral energy leaks across nominal boundaries, and an optimally concentrated time-limited waveform still cannot be both perfectly finite in time and perfectly confined to a prescribed frequency interval. An investigator might therefore see a weak residual outside the nominally admitted channel and claim that the rejected transient has been partially reconstructed. Under what conditions would that residual support a

Copyright 2026, James M. Atkinson

quantitative statement about the original event rather than merely an upper bound or an estimator conditional on an assumed waveform? How would you distinguish genuine transient energy from window leakage, stopband imperfections and the memory of earlier events? I ask especially whether the examiner ought to preserve measurements near both edges of the passband and explicitly state what aspect of pulse duration or spectral occupancy remains identifiable.

Dennis Gabor | Immediate answer to David Slepian

Professor Slepian, your objection is entirely warranted. The passband is a transfer characteristic, not an absolute metaphysical division. A real filter has finite transition bands, finite stopband rejection, and a response which depends on how its state was initialised. A component nominally outside the admitted region may produce a residual whose magnitude is limited by the filter's attenuation. Conversely, a component near the passband edge may be heavily attenuated without disappearing completely. Those observations can sometimes support bounded estimates, but they must be evaluated through a characterised transfer function with its uncertainty, not by assuming that a small output is a faithful scaled image of an otherwise unknown input.

If the source waveform is known up to a few parameters, a transfer model may permit useful parameter estimation. For example, an agreed pulse shape with unknown amplitude and arrival time may produce a predictable filtered response. The analyst could fit that response and report the estimated parameters under the pulse model. But an unconstrained original transient generally has many

Copyright 2026, James M. Atkinson

degrees of freedom which are suppressed by decimation, so an inverse cannot uniquely restore them. The uncertainties should include not only noise but the possibility that the assumed waveform family is wrong. A narrow confidence interval calculated under an incorrect family can be much more misleading than a broader and candid physical bound.

Measurements at passband edges are particularly important. A filter with apparently admirable centre-frequency performance may have large amplitude ripple, phase curvature or delay variation at its margins. A short event's spectrum may straddle the edge so that the derived timing and amplitude change with small shifts in tuning frequency. An examiner should use controlled challenges across the full region, not only centred tones, and should preserve the resulting response curves and configuration metadata. Where several adjacent channels overlap, comparing their outputs can help diagnose boundary effects, provided shared processing paths and correlated errors are not mistaken for independent evidence. The result should be stated as a system-level observation under a declared model.

A residual outside the nominal passband does not by itself establish the rejected component's original amplitude. Stopband leakage may depend on input amplitude, frequency, filter length, coefficient quantisation and numerical precision. An unknown strong interferer can create a small response indistinguishable in the retained samples from a weaker in-band input. Where the system's observed response is within a noise or calibration uncertainty bound, a quantitative source claim should be withheld or expressed as an

Copyright 2026, James M. Atkinson

interval under explicit assumptions. It may be appropriate to state a detection limit rather than a reconstructed pulse shape. The evidential standard is not visual attractiveness but discriminability among competing physically plausible causes.

The best recording policy allows later challenge to the decisions made at acquisition. Keep filter characteristics and state logs, retain selected raw witness intervals across relevant boundaries, and preserve the source trials used to validate pulse-time and edge measurements. Describe what was not retained. If the subsequent investigation raises a question that depends upon rejected frequencies or transient structure, state clearly that the derived file cannot answer it without external constraints. That is not an indictment of filtering; it is recognition that every measurement allocates finite observation capacity to a chosen question. I return the floor respectfully to Dr. Atkinson for the numerical tests and final synthesis.

Ten worked engineering and forensic applications

The following cases are hypothetical and are included to expose the dependence of a conclusion upon the selected measurement model. They are not performance certifications. Unless otherwise stated, frequencies are in hertz, times in seconds and data quantities use decimal multiples. A separate calculation audit is retained with the manuscript.

Percy Williams Bridgman, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, after decimating a complex 40 MS/s stream by twenty, a

Copyright 2026, James M. Atkinson

researcher still sees a clean 2 MS/s trace. Which specific physical question could the new record no longer answer?

Claude Elwood Shannon, Cross-Peer Answer to Percy Williams Bridgman: Professor Bridgman, the answer depends on the pre-decimation anti-alias filtering and the target measurand. If the permitted complex output band is only about ±1 MHz, the archive may no longer reveal an emitter confined to an excluded part of the original ±20 MHz span, however clean the retained waveform looks. Even within the output passband, finite filters may shift timing and distort brief transients. Document the original frequency support, numerical filtering response, downsampling phase and all excluded bands; do not claim an absent signal from a derivative that could never contain it. If the unaltered wideband source record was discarded, an alternative later hypothesis involving the removed frequencies may be untestable. The researcher can still make strong claims about a carefully specified narrower measurand, provided the transfer is calibrated. I yield the token to Professor Wiener.

Claude Elwood Shannon, Cross-Peer Question to Norbert Wiener: Professor Wiener, an adaptive decimator changes coefficients when a threshold detector fires. How can the investigator establish whether a suspicious transient originated in the environment or in that state change?

Norbert Wiener, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, treat the filter and state machine as part of the measured apparatus. Preserve each coefficient set, transition time, detector threshold, clock state, buffer occupancy and software build, preferably with a sample-accurate audit trail. Challenge the system with known stationary noise and with controlled injected bursts placed just before and after a filter change.

Copyright 2026, James M. Atkinson

Measure output ringing, impulse response and phase discontinuities as the state changes. The same input may produce different archived signals depending on the prior state of the filter; a static frequency response alone is insufficient. If the triggering detector also selects which samples are stored, selection bias enters the evidential record. Keep the relevant pre-trigger context and describe unrecorded intervals honestly. I pass the token respectfully to Professor Tukey for the consequences of selection.

Norbert Wiener, Cross-Peer Question to John Wilder Tukey: Professor Tukey, the archive retains only windows that cross a declared anomaly threshold, but the operator presents them as an unbiased sample of overnight spectrum conditions. What is the analytical defect?

John Wilder Tukey, Cross-Peer Answer to Norbert Wiener: Professor Wiener, the inclusion mechanism depends on the value being measured. Triggered windows are therefore an enriched, selected sample of the tails, not an unbiased temporal census. Report the trigger algorithm, dead time, rearm delay, tuned frequency, monitor gaps and total observation exposure. To estimate event incidence, the denominator must include times when the system was able to detect events, with any missed-trigger characteristics validated independently. If one changes thresholds after studying the saved examples, the nominal false-alarm rate no longer applies without correction. Preserve periodic unconditional control windows if feasible. The stored detections can still be analysed deeply, but they cannot support an inference about all unrecorded intervals simply by dividing by file count. I pass the token to Professor Gabor about transient time-frequency localisation.

John Wilder Tukey, Cross-Peer Question to Dennis Gabor: Professor Gabor, could later interpolation or a sharper-looking spectrogram restore the exact

Copyright 2026, James M. Atkinson

onset time of a burst removed by a long pre-decimation filter and an uncertain acquisition clock?

Dennis Gabor, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, the transformation can provide a model-dependent estimate under declared assumptions, not a new direct observation. A long impulse response can smear or shift a burst in ways that depend on the input spectrum and the filter state. The nominal group delay may be corrected if it is known, but residual uncertainty from dispersive delay, clock wander, trigger latency and omitted samples remains. Test known events at varying phases and positions relative to the decimator and compare the derived onset against an independent timing reference. Report the distribution of errors rather than one corrected timestamp of misleading precision. Preserve the parent capture where possible; if it is absent, label reconstruction as inference from a filtered derivative. I respectfully return the token to Dr Atkinson for conclusion.

Dr. James M. Atkinson | Moderator conclusion

Distinguished colleagues, we have reached a common distinction which I regard as the organising principle of this discussion. Decimation may be an appropriate, efficient and remarkably precise measurement operation, while simultaneously being an irreversible reduction of the evidence available for a different question. The fact that a detector correctly recognises the signal class for which its channel was designed does not establish that the retained file reproduces the original wideband experiment. Equally, the mathematical loss of excluded information does not make every derived observation worthless. A report can be exact within its admitted measurement

Copyright 2026, James M. Atkinson

boundary, provided that boundary is defined before the conclusion is drawn and remains visible in the evidential record.

Professor Bridgman has insisted that a change of operation can change the measurand, even when both results carry the familiar label of a spectral observation. Dr Shannon has shown why a many-to-one map cannot furnish a unique inverse without further assumptions. Professor Tukey has demonstrated that the most serious omission may be the unrecorded population of missed events, failed trials and intervals never exposed to the detector. Dr Wiener has placed adaptive state transitions inside the system whose performance is being claimed. Professor Gabor has shown why a visually persuasive output transient may be shaped more by the measuring filter than by the historical emission. None of these contributions requires us to abandon decimation. Together they require us to stop asking a reduced record to answer an unmeasured question.

Our applications reinforce the distinction. A factor of twenty reduces the complex sample rate from forty megasamples per second to two, with commensurate storage savings, but it also narrows the represented discrete-frequency interval. A correctly rejected out-of-band component is absent precisely because the anti-alias stage performed its intended work. A filter with a one-and-a-quarter-microsecond nominal group delay may support corrected timing only when its initial state and reference epoch are known. A detector with impressive conditional sensitivity may still miss most short emissions when the scan exposes the relevant channel for a small fraction of the survey. A large number of spectral comparisons can produce at least one plausible-looking noise alarm even when each isolated comparison has a small false-positive rate. These are separate mechanisms,

Copyright 2026, James M. Atkinson

and they must not be concealed under a single adjective such as calibrated, coherent or exhaustive.

For future publication I therefore require the record to distinguish five matters. The original analogue admission and sampling conditions must be described. The sequence of transformations from original samples to derived data must be identified, including filter coefficients, rate changes, phase conventions, software versions and state transitions. The retention and trigger policies must identify what was discarded and when acquisition was invalid. The uncertainty of the surviving measurements must be distinguished from the non-identifiability of the rejected quantities. Finally, source-attribution opinions must be tested against material alternatives, including analogue nonlinearity, clock and filter artefacts, missed exposure and statistical selection. A file digest protects the integrity of retained bytes; it does not certify the physical meaning of bytes the system never collected or deliberately removed.

The exchange has also preserved genuine disagreements. Professor Neyman asks how an adaptive observation policy should be validated without treating dependent trials as independent. Professor Kalman requires evidence that a dynamic state can actually be reconstructed. Professor Slepian challenges the seductive notion of a sharp passband boundary in a finite observation. Those questions remain important qualifications to every concrete receiver design, because the correct validation experiment depends on the declared signal population, the operating architecture and the legal or investigative inference required. No universal promise can be extracted from the abstract sampling ratio alone.

Copyright 2026, James M. Atkinson

We shall accordingly carry forward a bounded acceptance principle: preserve enough of the original record and transformation history that another examiner can reconstruct the stated measurement and challenge its interpretation; when the missing material prevents that challenge, make the limitation part of the finding rather than an invisible editorial omission. The next discussion will examine the assumptions governing multistage filters and how engineering implementation choices change the spectral, temporal and evidential qualities of a retained output. I thank each contributor for the disciplined questions and the respectful transfer of the floor.

Ten worked engineering applications | Question 036

Application 1. Reduction factor and the frequency range actually preserved

A complex input stream runs at F_in = 40,000,000 samples/s and is reduced by an integer factor D = 20. The resulting rate is F_out = F_in/D = 2,000,000 complex samples/s. The original discrete-time complex spectrum has a principal interval of width 40 MHz, while the new complex record has an interval of width 2 MHz. A practical filter must reserve a transition band, so its fully calibrated passband may be smaller. The calculation establishes a rate and an output periodic-frequency interval. It does not establish that the filter passed every frequency inside that interval, that the analogue receiver admitted all original 40 MHz without distortion, or that excluded components did not occur. When reporting a negative finding, the measured channel's validated passband rather than the original converter's headline bandwidth is the relevant domain.

Application 2. The consequence of downsampling without adequate filtering

Let the retained sampling frequency be F_out = 2.0 MHz and imagine a residual complex exponential at f = +1.3 MHz immediately before taking every twentieth sample. Discrete sampling at the new rate identifies frequencies differing by integer multiples of F_out: f_alias = f - round(f/F_out) F_out, with the final value interpreted in the principal interval from -F_out/2 to +F_out/2. Thus f_alias = 1.3 - 1 × 2.0 = -0.7 MHz. A displayed feature at -700 kHz could arise from a valid in-band -700 kHz

Copyright 2026, James M. Atkinson

component or from insufficient rejection of a +1.3 MHz component. Once both have been mapped onto the same samples, the reduced file alone does not uniquely separate them. A proper anti-alias filter diminishes the second mechanism, but the adequacy of its stopband is an empirical requirement rather than an assumption derived from the integer twenty.

Application 3. Stopband attenuation in power units

Suppose a potentially troublesome input component measures P_in = -20 dBm at the characterised digital-filter input plane, and its frequency lies in a stopband whose measured power attenuation is A = 80 dB under the relevant conditions. The nominal residual output power is P_out = P_in - A = -100 dBm, provided the calculation applies to comparable power reference planes and the response remains linear. This number can be below a detector threshold and still be relevant to forensic interpretation. A stronger unmodelled interferer, an upstream nonlinear product, or a weaker measured attenuation near the transition band changes the result. Reporting eighty decibels of suppression cannot establish that an external source was absent; it documents a specific rejection property for a stated mechanism and input.

Application 4. FIR group delay and event chronology

Consider a causal, linear-phase FIR decimator with N = 101 symmetric coefficients operating at F_in = 40 MHz. Its constant group delay within the frequency region in which the linear-phase model applies is (N-1)/2 = 50 input-sample periods. Thus tau = 50/(40,000,000) = 1.25 microseconds. That correction may be applied to a suitably defined output event timestamp, assuming the filter was in the relevant settled state and the

Copyright 2026, James M. Atkinson

phase or decimation origin is known. It does not cure missing samples at a block boundary, recover a pulse's rejected spectral components, or account for unmeasured analogue path delay. A receiver whose output events are compared to another instrument must disclose both the applied digital correction and its uncertainty.

Application 5. Scan exposure and the chance of encountering a brief event

Imagine a periodic 100 ms scan cycle in which the relevant band is continuously observed for 12 ms, followed by 88 ms of non-exposure. Assume an event occupies 1 ms, its starting phase is uniformly distributed over the cycle, and detection occurs whenever there is any temporal overlap with the observed interval. Then the measure of event-start phases producing overlap is 12 + 1 = 13 ms, yielding probability p_exposure = 13/100 = 0.13. This is an ideal geometric exposure result, not the probability of electronic detection given overlap. If the detector requires a minimum dwell within the event, the probability is smaller. If the event is phase-locked to the scan or the controller adapts its dwell, the uniform-phase assumption may fail. A report of continuous elapsed survey time does not substitute for this exposure calculation.

Application 6. A short pulse and narrowband temporal smearing

For an ideal rectangular pulse of duration T = 10 microseconds, the magnitude of its Fourier transform has first zeros spaced approximately 1/T = 100,000 Hz from its centre in the baseband envelope. If a decimated channel passes an effective 5,000 Hz width, its admitted interval is only 5/100 = 0.05 of that first-null scale. It follows that the

Copyright 2026, James M. Atkinson

channel cannot preserve the complete spectral structure required to reconstruct the original sharp-edged rectangular pulse without additional assumptions. The surviving impulse response may remain useful for timing a known pulse family, but a displayed output width must be interpreted through the filter response. The 5% comparison is descriptive, not an assertion that precisely 5% of pulse energy survives, since energy transmission depends upon the complete spectral density and filter shape.

Application 7. Recording cost and the meaning of a data reduction

Suppose each complex sample is stored as signed sixteen-bit I and sixteen-bit Q integers, four bytes per complex sample, with no container overhead. At 40 million complex samples/s the nominal raw rate is R_in = 40,000,000 × 4 = 160,000,000 bytes/s, or 160 MB/s and 576 GB per hour. After factor-twenty decimation to 2 million complex samples/s, R_out = 2,000,000 × 4 = 8 MB/s and 28.8 GB per hour. The capacity saving is 547.2 GB per hour, a compelling engineering advantage. It does not grant the reduced file access to the discarded 547.2 GB of samples. A dual-tier retention design can reserve higher-rate witness intervals without pretending that the inexpensive continuous channel is a complete copy of the original observation.

Application 8. Sensitivity estimated from an unselected challenge population

Assume an independently predeclared challenge campaign contains n = 1,000 valid trials within a clearly defined operating envelope, with k = 985 detected under an unchanged threshold. The observed detection

Copyright 2026, James M. Atkinson

fraction is p_hat = k/n = 0.985. A Wilson score interval at approximately 95% confidence, using z = 1.96, has centre (p_hat + z^2/(2n))/(1+z^2/n) and half-width z × sqrt[p_hat(1-p_hat)/n + z^2/(4n^2)]/(1+z^2/n). This yields approximately 97.54% to 99.09% after rounding. The interval assumes independent Bernoulli-style challenge outcomes with a stable trial probability. Correlated adaptive states, post hoc trial selection and shifts in signal class can invalidate that model. Above all, the interval describes the declared challenge population, not unseen frequencies that the decimated recorder never observed.

Application 9. Multiplicity and the interpretation of an isolated spectral alarm

If each of m = 10,000 independent noise-only tests has a false-alarm probability alpha = 0.00001, then the probability of at least one alarm is P = 1 - (1-alpha)^m. Substitution yields 1 - (0.99999)^10000, approximately 0.09516, or 9.516%. Thus a very small per-test false-alarm probability can coexist with a materially larger chance of at least one false indication across an extensive survey. Adjacent FFT bins and overlapping filterbank channels are often dependent, so the independence calculation is illustrative and should not be presented as an exact field result. The actual joint false-alarm behaviour of the channeliser requires a suitable model or challenge experiment. Retaining only the most conspicuous detection without the tested population hides this multiplicity.

Application 10. Relative filter delay and apparent source displacement

Consider two otherwise synchronised receivers whose derived files differ by an uncorrected six output samples at F_out = 2 MHz. The

Copyright 2026, James M. Atkinson

relative time bias is delta_t = 6/2,000,000 = 3 microseconds. If that entire bias were mistakenly converted into a propagation-distance difference using the free-space speed c approximately 3.0 × 10^8 m/s, the apparent range-difference bias would be c delta_t = 900 metres. This number is a difference-of-path-length equivalent, not a unique geolocation error or a claim about any actual transmitter. Real localisation depends on geometry, propagation conditions and other uncertainties. The example shows why differences of digital filter phase, decimation origins or unreported state transitions cannot be treated as negligible merely because the resulting time stamps contain many decimal places.

QUESTION 037

Copyright 2026, James M. Atkinson

How may oversampling reduce in-band noise without increasing the independent information available?

Source: V011_Roundtable_Question_037_CP037_Dr_Atkinson.docx | Recovered substantive manuscript. Constructed educational dialogue.

Original constructed educational dialogue, rather than a transcript or an historical quotation. The historical participants are intellectual personae, not witnesses to contemporary SDR instruments. All numerical examples are hypothetical and require apparatus-specific validation before any forensic use.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, the subject now before us is the apparently paradoxical capacity of an instrument to deliver a quieter digital record without necessarily telling its examiner more independent things about the physical world. A wideband analogue-to-digital converter produces a torrent of codes, its clock multiplying the familiar rhythm of an ordinary receiver by hundreds or thousands. After digital low-pass filtering, a trace may appear considerably smoother, a narrow spectral line may stand more distinctly above the surrounding noise, and a numerical estimate of amplitude may have smaller variance. Such advantages are genuine when their premises are established. They do not, however, justify the casual assertion that a twelve-bit converter has become an intrinsically twenty-four-bit instrument, that each heavily overlapped spectrum represents an independent observation, or that a faint emitter has been uniquely identified merely because a processing display looks serene.

We should begin with the quantity to be estimated. Let F_s denote the sampling frequency in samples per second, B the one-sided low-pass

Copyright 2026, James M. Atkinson

bandwidth of interest in hertz, and $R = F_s/(2B)$ the nominal oversampling ratio for a real, low-pass, uniformly sampled signal. When quantisation error is sufficiently well approximated by broadband, uncorrelated noise with nearly flat spectral density, ideal filtering that retains the interval from zero to B admits approximately the fraction 1/R of its original first-Nyquist-zone noise power. Thus the ideal processing gain is $G_p = 10 \log10(R)$ decibels and the corresponding ratio of root-mean-square noise amplitudes is sqrt(R). Each factor of four in R produces approximately six decibels of in-band signal-to-noise improvement, equivalent to one bit of ideal quantisation SNR under the conventional full-scale sine-wave convention. These are conditional statements about a filtered estimate, not statements that the physical converter suddenly acquires four times as many thresholds or that the same analogue event has been recreated in several independent copies.

A second set of quantities concerns information rather than code width. Let x(t) be the analogue input over a finite observation period T, h(t) the combined analogue transfer function, q[n] the quantisation error at sample index n, and $n_a(t)$ the analogue noise that exists before quantisation. The digitised sequence is a function of x(t), h(t), $n_a(t)$, the sampling times and the converter transfer characteristic. Once the input has encountered saturation, an unresolved analogue alias, or a sampling clock whose relevant phase is unknown, multiplying the number of digital samples cannot restore the missing causal record. If the measured disturbance is common to every sample, summing or averaging those samples may preserve the disturbance exactly. If adjacent samples are correlated through

Copyright 2026, James M. Atkinson

a low-pass filter or through a common oscillator, a naive standard error calculated as though each were independent may be grossly optimistic.

The law of the apparatus is no less important than the arithmetic. Suppose a defensive survey records several channels at an enormous aggregate rate, then lowers their bandwidth and averages power estimates to expose emissions barely distinguishable from the noise floor. The technique may reduce the variance of an in-band estimator, provided the emitter remains within the admitted bandwidth and observation interval, the gain remains linear, the noise process satisfies the model, and the detector's false-alarm calibration accounts for the search procedure. Yet when a noise reduction is achieved by integrating longer, an intermittent emission might be diluted or missed, and the resulting archive might become incapable of answering whether the event lasted a microsecond or a second. More digits and a cleaner waterfall cannot resolve that ambiguity. We must distinguish raw sample rate, information bandwidth, independent degrees of freedom, estimator uncertainty, event-detection sensitivity and the evidential status of source attribution.

Mr Nyquist will first examine the conditions under which a denser sampling lattice contains redundancy. Dr Shannon will distinguish an information-preserving representation from a genuinely new observation. Dr Bennett will discuss whether quantisation error can legitimately be treated as white and independent. Professor Slepian will examine finite observation windows, time-bandwidth concentration and the rank of filtered data. Professor Tukey will then test our statistical assertions against selective searching, correlated trials and the fallacy of treating every time-frequency bin as an independent experiment. Seven peers will challenge

Copyright 2026, James M. Atkinson

those positions, and each response must follow the challenge immediately. We shall require the principal speakers to say not only what improves with oversampling, but also what it leaves untouched, and which adversarial measurement could distinguish the alternatives. Mr Nyquist, may I invite your examination of the relationship between a denser lattice of samples and the physical information represented by those samples?

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 1: Sampling density, independent degrees of freedom and the original signal

Dr. Atkinson, one must not mistake the spacing of measurements for the dimensionality of the object measured. An analogue signal whose Fourier content is confined to a finite band is not an arbitrary value at each infinitesimal instant. Under the relevant mathematical assumptions, sufficiently spaced samples can determine the signal, and a more closely spaced sequence represents the same function with additional redundancy. If the analogue bandwidth remains fixed while the sample rate rises, the number of stored digital words increases; nevertheless the physical waveform does not thereby acquire additional independent variations. The higher-rate representation can make realisation of the antialias filter more practical, permit convenient digital frequency translation and reduce the consequences of certain kinds of error. But it is wrong to infer from the sample count alone that the physical event supplied proportionately more independent evidence.

Let B be a one-sided band limit and T the retained observation time. A real band-limited process observed over that interval has a nominal time-bandwidth scale of order 2BT real degrees of freedom, subject to the precise signal class, boundary convention and effective temporal concentration. If F_s is much larger than 2B, the recorded sample count is $N = F_s T$, which may be much larger than 2BT. This is not a contradiction. The extra codes can be correlated representations of the same latent waveform. Oversampling is nevertheless useful when the codes include noise that is not perfectly correlated with the signal or each other, and the estimator can average the disturbing component without equally erasing the quantity

Copyright 2026, James M. Atkinson

sought. One must say whether that disturbance arose before the analogue bandwidth restriction, inside the converter, or after acquisition; the location can change the calculation materially.

Consider a slowly varying source measured repeatedly with an instrument that adds independent zero-mean error on each conversion. For an estimator of a constant mean, M repeated observations with identical independent variance sigma squared possess a sample-mean variance sigma squared divided by M. Here the repeated conversions are genuinely providing multiple noisy observations of one fixed parameter, and their aggregation improves precision. The physical source value has not multiplied into M distinct parameters. Moreover, the assumption of independence cannot be established by the numerical labels assigned to the observations. When the input contains a common fluctuating disturbance, or when a digital low-pass filter has coupled adjacent output errors, the covariance terms survive. That observation is the critical bridge between engineering sampling and forensic uncertainty.

For a time-varying signal, adjacent samples need not observe the same value. Directly averaging them is a form of filtering, and its output is properly a filtered version of the source with a specified impulse response and group delay. A weak continuous carrier may benefit from narrowband estimation, because its phase trajectory is compatible with the chosen observation interval. A short burst may not. Averaging across its onset and termination can reduce the measured peak even while reducing random noise more strongly. Consequently a detection statement should identify not only F_s but also the time support of its filter, the window used to estimate energy and the threshold applied to the resulting statistic. A paper

Copyright 2026, James M. Atkinson

report that quotes 'an extra three bits' but omits these variables fails to define the asserted performance.

The apparent resolution gain sometimes attributed to oversampling must also be expressed with care. In an ideal uniform converter of N bits, quantisation intervals are determined by its reference and transfer characteristic. The number of code bins does not increase when a faster clock is fitted. A derived result may legitimately be expressed to more fractional digits than one raw code if there is enough independent noise or dither to explore neighbouring codes and the averaging model has been validated. Such a number is an estimate with an uncertainty distribution; its additional fractional digits are not fresh analogue threshold comparisons. If the input is stuck within one quantisation interval and no appropriate variation causes code transitions, repeating its identical code a thousand times cannot reveal its exact location within that interval. The experiment may be very repeatable and wholly insensitive to the sub-code distinction the report attempts to infer.

In a defensive survey of faint emissions, the preferred experiment changes a physical condition. Compare detector performance with and without a validated decimation filter; inject calibrated weak tones and bursts at random times; test several input amplitudes, frequencies and duty cycles; and measure the fraction of trials detected at a fixed false-alarm budget. A spectral noise-floor reduction is not a substitute for the receiver operating characteristic. Equally, if a real source is rejected by the narrowband filter because its frequency falls outside the preserved passband, no improvement in the retained bins supplies evidence that the source was

Copyright 2026, James M. Atkinson

absent. One must define the useful information as information about a specified measurand rather than information in the philosophical abstract.

There is another common error in multi-converter arrangements. Placing twelve identical converters on the same analogue voltage does not automatically create the effective resolution of a single converter with the sum of their nominal bit counts. If their errors were independent under a justified model, combination might reduce variance for a common quantity. If they share a voltage reference, clock, driver distortion or electromagnetic interferer, covariance may dominate. Their outputs cannot by arithmetic alone reveal distinctions suppressed by every common transfer characteristic. Even if their errors are independent, doubling the number of independently noisy observations improves the variance of a mean by a factor of two, not the intrinsic quantisation threshold count by two powers of the nominal bit depth.

I therefore recommend a two-column validation record. One column describes properties of the acquired physical input: bandwidth, duration, amplitude range, source conditions and known interferers. The other describes properties of the estimate: sampling grid, filter, number of input codes, effective noise bandwidth, covariance treatment, uncertainty and detection threshold. The conclusion must say which properties were observed and which were inferred from assumptions. Where a mathematical representation is redundant, its redundancy may protect against noise or help numerical implementation. It does not annul the information limits established by the input path. Mr Black, whose feedback work reminds us of the danger of hidden common errors, may now

Copyright 2026, James M. Atkinson

challenge this distinction. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Harold Stephen Black | Peer question 1 to Harry Nyquist

Mr Nyquist, you distinguish redundant sampling of one waveform from independent perturbations that make its estimate more accurate. I should like to examine a receiver whose analogue input is supplied by an amplifier with automatic gain control and a reference voltage shared by every converter. The displayed spectrum becomes quieter when the sampling rate is quadrupled and the output digitally filtered. Yet the amplifier may have altered gain while a weak burst occurred, and the reference may wander at a rate slower than the acquisition period. How would you separate noise averaging, gain variation and a common reference excursion in an acceptance test? In particular, would an observed six-decibel reduction in a selected frequency interval demonstrate that the system preserves the physical amplitude of that burst, or might a clean estimate be obtained by suppressing precisely the variation an examiner needed to observe? Which changes to the test input and system configuration would make the rival explanations produce visibly different records?

Harry Nyquist | Immediate answer to Harold Stephen Black

Mr Black, a six-decibel reduction alone would demonstrate only a relationship between two displayed noise statistics under the conditions in which it was measured. The analogue gain trajectory and reference-voltage history require their own observations or validated bounds. Begin by fixing automatic gain where the architecture permits, recording the reference voltage against a

Copyright 2026, James M. Atkinson

separately characterised standard, and measuring both raw and derived samples under a stable injected input. This establishes a baseline in which the processing effect can be examined without conflating it with an unrecorded control loop. Then restore the gain-control function and challenge it with known strong interferers and weak bursts positioned unpredictably. The experiment should compare the actual gain state, true-positive rate, measured burst amplitude and detection latency, not merely one spectrum's average noise floor.

A common reference excursion is particularly instructive because the same error can influence many simultaneous conversions. The improved precision of a filtered estimate does not imply improved absolute accuracy relative to the original analogue boundary. If the reference rises, the inferred volts per code may change, and every channel may agree on an erroneous calibration. The calibration campaign must distinguish relative repeatability within a common reference from traceability to an independent physical standard. A second reference or a recorded calibration stimulus can add evidence if its own path and uncertainty are disclosed, but a second display driven by the same reference does not create independent corroboration.

The strongest test is one in which the anticipated outcomes differ. Under an ideal independent-noise hypothesis, noise power within a fixed bandwidth should decline in the predicted proportion when the acquisition and filtering conditions change, while the calibrated in-band signal amplitude remains stable. Under a gain-drift hypothesis,

Copyright 2026, James M. Atkinson

the result should correlate with recorded gain changes or injected amplitude, including possible nonlinear departures. Under a reference-wander hypothesis, scale errors should appear coherently across branches and correlate with reference monitoring. Tests should be repeated across relevant temperatures and operating modes. If evidence remains insufficient to distinguish those mechanisms, the result should be described as a processing-noise improvement with unresolved amplitude calibration, not as a more accurate reconstruction of the historical event.

I would further distinguish weak-burst detection from steady-tone SNR. A processing chain can improve the mean detection statistic for an event whose duration and bandwidth match the chosen filter, yet delay its onset or reduce its peak for a shorter event. The reported capability should therefore be a function of burst duration, frequency and amplitude, with a declared false-alarm rate and observation exposure. If the instrument is to support a negative search finding, these conditional performance surfaces matter more than a generalised number of 'extra bits'. Such discipline leaves the useful advantages of oversampling intact while preventing them from carrying a claim they cannot prove. I pass the floor courteously to Professor Bridgman, whose question concerns the very meaning of a derived measurement.

Percy Williams Bridgman | Peer question 2 to Harry Nyquist

Mr Nyquist, the operator may define a quantity as the amplitude of a narrowband component at the antenna terminal, but what the instrument actually stores is the output of a cascade of analogue

Copyright 2026, James M. Atkinson

filtering, quantisation, digital downconversion and averaging. Even where the sampling theorem assures us of mathematical redundancy, the experiment may not have established that the earlier analogue filters were linear, stable or correctly matched to the intended quantity. If a technician can tune the filter to make the trace quieter and then label the resulting amplitude as a terminal voltage, what prevents that label from becoming merely an untested convention? I ask you to specify the relation between an operational definition and an evidential report. What should be retained to show that a change in oversampling ratio changed the estimator uncertainty rather than changed the physical quantity to which the displayed result refers? Would you additionally require the amplifier gain history and the prefilter calibration record?

Harry Nyquist | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, the result requires a declared reference plane and a measured transfer relationship. We should not define an antenna-terminal voltage by the numerical value displayed after an arbitrary filter; rather we should specify the intended terminal quantity, the admissible class of input waveforms, and the chain of transformations by which the instrument estimates it. The transfer function may be measured for appropriate stimuli, with uncertainty that reflects load mismatch, component variation, gain state and frequency dependence. A different oversampling setting can be shown to address the same measurand only if the two settings have a validated relation to that same physical boundary. When that relation does not hold, the correct result is that the instrument produces distinct operationally defined quantities.

Copyright 2026, James M. Atkinson

For instance, a narrowband sinusoid at a known frequency may be corrected for a measured filter gain, provided the filter is operating in its characterised linear region and the time interval is appropriate. A transient of unknown waveform and broad spectrum cannot necessarily be corrected by the same scalar gain. The proper calibration for that signal may require the full impulse response, and a filter with zeros or discarded frequencies can make the inverse nonunique. A cleaner output does not alter these facts. I would preserve the raw input codes when justified by the forensic stakes, the filter coefficients, gain calibration, sample-clock record, processing version and the input-reference definition. Where a raw archive is impracticable, the report must state its limitations explicitly.

The direct experimental comparison should inject representative signals at the boundary of the claim, not only at a convenient internal digital node. A calibration stimulus injected after the analogue front end establishes properties of the digital chain; it does not certify the antenna, amplifier or mixer. The investigator should compare settings at equal input stimulus, monitor configuration state and preserve any difference which remains beyond the combined uncertainty. A valid change in processing ought to reduce a specified variance without materially shifting the mean or relevant temporal features for the admitted signal class. If the change also alters those properties, the two outputs cannot be described as interchangeable evidence without a further model. The aim is to permit useful uncertainty reduction while ensuring that the physical quantity being discussed remains the same throughout the report.

Copyright 2026, James M. Atkinson

With that distinction established, Dr Shannon may examine whether a mathematically faithful representation can create information that was not present in the analogue observation.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 2: Noise reduction, data processing and the interpretation of information

Dr. Atkinson, the word *information* deserves particular care, because it may refer to a physical source, a random parameter, a stored digital record, or the uncertainty of an estimator. These objects have distinct distributions and distinct questions attached to them. If a signal passes through a deterministic transformation, the transformation does not manufacture independent knowledge of the original source. In probabilistic terms the data-processing inequality states that, for appropriately defined random variables X, Y and Z forming a Markov chain X to Y to Z, the mutual information satisfies I(X;Z) no greater than I(X;Y). A digital filter whose output Z is computed from acquired samples Y cannot increase the information that Y held about a source variable X. It can, however, make that information more accessible to a restricted detector, remove nuisance variation irrelevant to a particular inference, and reduce the variance of a useful estimate. The apparent paradox arises when those improvements are described as the creation of independent physical observations.

The inequality does not imply that all processing is futile. A recorded sequence may contain a weak carrier buried among numerous frequencies, while an operator can inspect only a limited display. A suitable matched estimator or narrowband filter may concentrate the source-dependent component into a decision variable with a much clearer separation between hypotheses. Relative to the practical decision procedure before processing, performance may improve substantially. Relative to an ideal observer supplied with the complete acquired sequence and the correct probability model, the deterministic processing has not introduced information from

Copyright 2026, James M. Atkinson

outside that sequence. The distinction is between a better use of existing evidence and the generation of new physical evidence. A useful manuscript must not collapse these propositions into a slogan.

Now consider an input consisting of a band-limited waveform plus broadband noise. The filtering operation may discard frequencies in which the source of interest has no energy, thus reducing admitted noise. If the source really lies within the specified band and the unwanted noise occupies the rejected band, the estimator is improved for that task. But if a forensic question later asks whether a neighbouring carrier drove an amplifier into intermodulation, the discarded frequencies may have contained precisely the competing explanation. The narrower statistic can remain excellent for estimating the in-band amplitude while becoming inadequate for discriminating source hypotheses. One must define the source variable and the loss function before declaring an information gain or loss. Without that definition, an argument over the number of bits in a file is an argument about labels rather than evidence.

Sampling at a rate above the necessary spectral width may improve the physical process when the faster acquisition is paired with a different analogue filter or the opportunity to characterise timing jitter, because those are changes to how the world is measured rather than merely deterministic transformations of a fixed record. A faster sample rate can also permit a more forgiving antialias transition band and help avoid folding unwanted emissions into the region of interest. Those improvements may make the acquired data more informative than data from an otherwise different, slower instrument. The data-processing inequality must not be misused to say that a superior sensor cannot collect better information. It

Copyright 2026, James M. Atkinson

says that once one particular observation is fixed, a subsequent computation cannot conjure an external fact absent from it. Comparing distinct acquisition chains requires a physical model, not only an information-theoretic ordering.

The apparent addition of resolution by averaging is likewise a matter of statistical inference. If each raw conversion contains a noise component conditionally independent given a fixed analogue parameter, their combination can reduce posterior or frequentist uncertainty about that parameter. The quantity of information may increase because the device took additional, physically distinct noisy measurements, though those measurements concern the same parameter. If, by contrast, one noisy conversion is copied many times into memory and processed as though the copies were independent, no such gain follows. More subtly, when adjacent samples share an analogue disturbance or an adaptive filter has produced overlapping outputs, the dependence structure reduces the effective number of observations. One cannot infer that structure from the sample rate alone.

Consider a case in which twelve converter channels are connected to the same reference and driver. Their independent comparator noise may average down, but their common reference variation does not. A model $y_i = \text{theta} + u + e_i$, where theta is the intended physical quantity, u is common error and e_i independent error, makes the point. The mean of M channels has variance $\mathrm{Var}(u) + \mathrm{Var}(e_i)/M$ if the terms are centred and appropriately independent. As M increases, the independent term vanishes but the common error remains. No multiplication of channel counts can remove Var(u) merely by arithmetic. Nor does the measured variance alone reveal

Copyright 2026, James M. Atkinson

whether the remaining error is a bias relative to a traceable standard. That requires a calibration which supplies independent evidence about theta and the reference plane.

A detective may ask whether a low-power emission existed in a corridor for a fleeting interval. The hypothesis is not a continuous sinusoid over an arbitrary observation time. An integration that improves a steady carrier's decision statistic might smear the fleeting event into the baseline, especially if the filter's temporal response spans a longer interval than the event. A good report supplies conditional sensitivity by signal class, not merely a universal processing gain. It also states which frequencies, times, receiver states and amplitudes were actually examined. The posterior odds of a source hypothesis depend upon prior assumptions as well as the likelihood, while a conventional significance level measures a different quantity. Neither should be disguised as a bit-count enhancement.

I recommend retaining an explicit map of transformations and their domains. Label the raw samples and all independently observed calibration stimuli. Label the derived statistics, filter coefficients and any information discarded. A derived stream may be reproducible to the last bit and still be inadequate to answer a later question, while a seemingly noisy raw record may contain a short event invisible in a smoothed report. The correctness of the computation and the adequacy of the evidence are separate matters. The most honourable statement is that oversampling and filtering improved a specified estimate, subject to stated bandwidth, noise and timing assumptions. They do not independently certify a transmitter's existence, location or identity. I pass the floor respectfully to Dr Hamming to test the practical consequences of these distinctions for receiver engineering.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Peer question 3 to Claude Elwood Shannon

Dr Shannon, you describe filtering as a transformation that cannot increase the information contained in the acquired record. Yet engineers routinely find that a carefully filtered output permits reliable reception of a signal that a less sophisticated receiver cannot recognise at all. To the operator who must decide whether an adversarial transmitter is present, this appears to be a real increase in information, not merely a mathematical rearrangement. How should we reconcile your formal inequality with an experiment in which detection rises from twenty per cent to ninety per cent after oversampling and narrowband processing? I also ask whether a task-dependent sufficient statistic may be considered adequate evidence even when it discards much of the source record. At what point must the investigator retain the complete stream because a later challenge may require information outside the original detection hypothesis? Please identify a practical distinction between sufficient mathematical compression and an archive that merely hides unknown alternatives.

Claude Elwood Shannon | Immediate answer to Richard Wesley Hamming

Dr Hamming, the improvement is entirely consistent with the formal statement once the random variables and the comparison are correctly identified. A detector examining an unsmoothed display with a poorly chosen threshold may fail to exploit information present in the raw data. A more effective algorithm can recover that opportunity. The inequality refers to the full distribution of the observation under

Copyright 2026, James M. Atkinson

an optimal or appropriately defined decision problem; it does not claim that every practical observer has equally good access to the evidence. If the original comparison is between two distinct physical receiving systems, one of which employs an antialias filter and a more capable converter, we must compare their acquisition channels rather than invoke an inequality between data and its deterministic transformation.

Your example of detection increasing from twenty to ninety per cent requires an additional qualification. Those percentages may concern different false-alarm rates, test populations, signal classes or thresholds, and cannot be compared until the acceptance conditions are aligned. If all else is genuinely held constant and the algorithm is improved, the gain should be welcomed. But an observed true-positive rate is conditional on how the test signals were drawn. It is not the probability that every alarm represents an external source. A stable receiver-generated spur may be detected with excellent sensitivity. A detector's performance and the attribution of a signal to a physical transmitter require separate experiments.

A sufficient statistic is sufficient for a specified model and parameter, not for all imaginable future disputes. For a known waveform observed in independent Gaussian noise with specified covariance, an appropriate matched statistic may preserve the information needed for a narrowly defined amplitude or detection decision. If a later examiner disputes the noise model, asks about out-of-band interferers, or proposes a different waveform, that statistic may cease to be sufficient. The original investigator should therefore

Copyright 2026, James M. Atkinson

decide preservation policy by the evidential stakes and foreseeable rival explanations. Where comprehensive retention is impossible, the policy can use bounded raw snapshots, challenge intervals, and state logs, but should disclose the resulting exclusions rather than quietly call the retained statistic complete evidence.

The acceptance report must separate three claims. First, a digital operation can be reproduced from the archived input and software version. Second, under a validated model, its output may estimate a defined quantity with reduced uncertainty or meet a declared detector performance target. Third, the resulting feature may or may not originate from an external emitter. A successful demonstration of the first two does not automatically establish the third. My formal argument protects against that illicit leap while allowing a well-designed receiver every practical improvement it can earn. Professor Hotelling may challenge how the requisite covariance model can be estimated from a finite record without simply asserting independence.

Harold Hotelling | Peer question 4 to Claude Elwood Shannon

Dr Shannon, your common-error model is instructive, but the engineer seldom knows the covariance of the noise before collecting the very observations whose uncertainty must be reported. In a receiver that updates noise estimates continually, the process may be nonstationary: gain and temperature change, interfering transmitters enter and leave, and the sample stream may be filtered into strongly overlapping windows. If the investigator calculates a covariance matrix from those selected windows, the estimate may be unstable or biased by the

Copyright 2026, James M. Atkinson

selection rule. How would you decide whether a reduction in observed variance represents true improvement in the desired estimator or a model fitted too closely to a favourable collection of observations? And would you prefer a broad covariance model with many parameters or a deliberately restricted model whose residuals can be challenged with independent reference stimuli? I ask especially how the answer should affect confidence intervals for weak, intermittent detections rather than for stationary laboratory sine waves.

Claude Elwood Shannon | Immediate answer to Harold Hotelling

Professor Hotelling, no algebra can compensate for a covariance estimate that is not representative of the circumstances in which it is used. I would therefore specify the observation population before fitting the model. The record should identify signal classes, temperatures, input gain states, frequency bands, observation times and known interference conditions. It should preserve enough unselected intervals to estimate the background rather than drawing every training example from an alarm archive. For a system whose noise changes with operating state, one may require separate conditional models or an explicitly time-varying model rather than an optimistic single covariance matrix. The choice should be tested against data withheld from the estimation process.

A broad model may capture complex correlations, but if its parameters are weakly identified it can produce artificial precision. A simpler model, openly qualified, may be preferable when it permits clear residual tests. I would examine whether the estimated correlation decays as predicted, whether the variance of means over

Copyright 2026, James M. Atkinson

progressively longer blocks follows the proposed scaling, and whether challenge signals are recovered at the claimed amplitudes. Comparing non-overlapping blocks and overlapping windows can reveal mistaken degrees-of-freedom calculations. An independently injected stimulus provides a way to test the estimator's response, though it does not alone prove that every real emitter matches the stimulus model.

For weak intermittent events, the uncertainty should include the event-selection mechanism. An interval stored because its statistic exceeded a threshold is not a random sample from the full noise population. Calculating a confidence interval as if it were unselected can distort coverage. A suitable design might predetermine challenge positions, randomly inject pulses across the accessible band and quantify detection and false alarms under matched conditions. The resulting performance statement can be indexed by duration, amplitude, frequency offset and receiver state. Where adaptive acquisition makes the sampling law complicated, one should report a conditional or simulation-supported bound and disclose the model assumptions, rather than imply an exact analytic confidence level that was never validated.

Thus covariance estimation should be a measured part of the instrument qualification, not a decorative matrix inserted after the fact. It is evidence about how the sample stream depends upon its past, and its uncertainty must follow the inference. The panel now requires Dr Bennett's attention to the source of an especially

Copyright 2026, James M. Atkinson

seductive assumption: that every quantisation error is equivalent to independent white noise.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal response 3: Quantisation, correlation and spectral artefacts

Dr. Atkinson, an ideal quantiser can be represented as the sum of its input and a quantisation error, but the engineering usefulness of that representation must not be mistaken for a proof that the error is always a random white process. For a converter with uniform step size Delta and no overload, the error lies within an interval of approximate width Delta, subject to the chosen code convention. Under a familiar high-resolution or appropriately dithered model, a zero-mean uniform error has variance Delta squared divided by twelve. That convenient result provides an rms scale. It does not, without additional assumptions, establish that consecutive errors are independent, that their spectrum is flat, or that the error is uncorrelated with the analogue input. The distinction is fundamental to claims about oversampling gain. [S1, S2]

Consider a very small periodic signal sampled at a frequency commensurate with its own period. The code sequence may follow a short repeating pattern, and the quantisation error may repeat along with it. Its energy can then concentrate into discrete harmonics or spurs rather than disperse as the broad floor assumed by the simplest noise calculation. Filtering to a narrow frequency interval may reject some of those components but retain others almost unchanged. If an apparent surveillance line lies exactly where a quantiser-related spur is expected, the signal cannot be certified as external merely because the nominal sampling rate was high. The operator must change stimulus frequency or amplitude, sample-rate relationship or dither conditions to see whether the feature

Copyright 2026, James M. Atkinson

follows the receiver's quantisation mechanism or the physical source hypothesis.

The phrase 'oversampling increases the number of bits' obscures a related limitation. A converter with twelve output bits continues to output twelve-bit words for each raw sample, no matter how frequently it is clocked. A later digital estimate may have a smaller noise variance after filtering, and it can be encoded into more bits so that rounding of the estimate does not forfeit the improvement. That is a statement about the precision of a derived quantity under a noise model. It is not a claim that a single conversion now distinguishes every tiny analogue amplitude difference that a twenty-four-bit ideal quantiser would resolve. If an input is perfectly constant and all raw conversions return the same code, the record leaves a finite interval of possible input amplitudes. Additional identical codes may establish stability of the output, not location within that interval.

A physically noisy input may sometimes supply the needed variation without deliberate dither. Thermal or front-end noise can cause a near-threshold analogue value to cross adjacent quantisation steps, thereby permitting a mean estimator to locate the underlying level more finely than one step, subject to calibration and the noise distribution. Deliberate dither may also break a harmful correlation. Yet its amplitude and spectral shape matter. An engineer cannot add arbitrary noise, average the outputs and assume improvement. Excessive dither can consume dynamic range and elevate the noise floor. Nonsubtractive dither leaves some added noise in the record; subtractive dither presupposes knowledge and preservation of the actual added sequence, together with the linear and timing conditions that make subtraction legitimate. Where dither was generated by firmware

Copyright 2026, James M. Atkinson

but its seed or implementation is unavailable, an independent examiner may be unable to reproduce the claimed correction exactly.

The distinction between independent and common errors is especially severe when several converters share one analogue input. Suppose each produces y_i = x + u + e_i, with u representing common driver or reference disturbance and e_i independent branch error. Taking an average of M branches yields x + u + the average of e_i. The independent contribution may decline in standard deviation approximately as one over the square root of M, but the common component is unchanged. If the common distortion is nonlinear, averaging may reinforce its harmonics rather than suppress them. A claim of twenty-four-bit or thirty-two-bit performance formed by concatenating or weighting twelve-bit outputs must therefore be justified by measured effective dynamic range, linearity, noise covariance and reference stability. Algebraically joining nominal bit widths is not a physical calibration procedure.

There is a second kind of hidden dependence. Even if raw white noise were independent from sample to sample, a digital filter computes adjacent outputs from overlapping sets of raw samples. Its derived outputs will in general be correlated. For a finite impulse response filter with coefficients h[k] and independent input noise variance sigma squared, the output variance is sigma squared times the sum of squared coefficients. The covariance between outputs separated by lag ell is sigma squared times the sum of h[k]h[k+ell], where the indices are restricted to defined taps. This covariance matters when investigators treat a succession of filtered values as repeated independent challenges. Their apparent quantity may exceed the effective sample size relevant to the estimate. The filter must be

Copyright 2026, James M. Atkinson

documented to permit that calculation, and the independent-noise assumption at its input must itself be tested.

An investigator should not assume that a change in clock frequency changes only the quantisation-noise distribution. In a real converter, higher clock rates may change aperture jitter, analogue input bandwidth, power dissipation, thermal state and reference settling. A noise floor lower in a narrow selected channel does not imply that the wideband dynamic range improved or that the converter will tolerate the same strong interferer. If a powerful authorised transmitter drives the front end into compression or creates intermodulation, more oversampling cannot reconstruct the original undistorted input from a clipped representation. The system should be tested under coexisting strong signals, not solely under the gentle conditions of a calibration sine wave.

The appropriate evidence includes raw-code histograms, converter transition tests, spur-versus-input-frequency plots, noise-power scaling against filter bandwidth, and repeated observations with independent calibration stimuli. A sufficiently characterised change in dither or frequency may distinguish quantisation-related components from an external emission. A line whose indicated RF frequency stays invariant when sampling frequency changes and whose amplitude follows antenna coupling may deserve further investigation, though these observations are not alone conclusive. A line whose location tracks a simple rational function of sample rate, or disappears only under a particular calibration update, suggests a receiver mechanism worth testing. The scientific purpose is not to attribute every unexplained feature automatically to a spurious cause. It

Copyright 2026, James M. Atkinson

is to preserve competing predictions and perform a discriminating experiment rather than rely upon a visually attractive waterfall.

I would report processing gain as a measured, bandwidth-qualified property, not as a universal increment in bit depth. An uncertainty budget must identify which noise powers were reduced and which systematic terms remained, with any covariance explicitly accounted for. The statement 'six decibels less in-band noise after fourfold oversampling under a stationary reference-tone test' can be meaningful. The statement 'the receiver now has one extra independent bit for every four samples under all conditions' is not an empirically justified replacement. I pass the floor to Dr Shewhart, who may press whether the reported noise distribution remained stable during the test rather than only in its selected successes.

Walter Andrew Shewhart | Peer question 5 to William Ralph Bennett

Dr Bennett, the ideal variance argument is carefully qualified, yet laboratory reports frequently establish the expected improvement from a single sequence of apparently stationary observations. In a practical receiver, temperature drift, gain control, oscillator changes and intermittent interferers may produce distinct regimes within that sequence. When the engineer pools all intervals into one convenient histogram, the overall shape may resemble white noise even though each local regime exhibits a different mean or dependence. I ask how the calibration should detect this instability before quoting the square-root law. Should the noise be characterised through control charts, frequency-specific tests, repeated independent sessions or a model of its time dependence? What evidence would distinguish ordinary stochastic fluctuation from a drift that invalidates the fixed-distribution

Copyright 2026, James M. Atkinson

assumption? And how should a failed stability test change the wording of the resulting forensic opinion rather than disappear into an updated calibration table? Should every excluded interval remain discoverable by an independent reviewer?

William Ralph Bennett | Immediate answer to Walter Andrew Shewhart

Thank you for that question. Dr Shewhart, I would regard stationarity and independence as hypotheses to be challenged, not privileges bestowed by the appearance of a bell-shaped histogram. The engineer should examine the time sequence at scales appropriate to the mechanism. Plot estimates of the local mean and variance across successive acquisition blocks, inspect autocorrelation and spectral density, and test repeatability across independently initiated runs. Temperature, gain, reference voltage and clock status should be recorded so that any systematic relation can be examined. A pooled histogram can conceal alternating means or persistent spectral lines, and a single pooled standard deviation does not prove that uncertainty diminishes with the nominal number of output codes.

Control charts can be useful for detecting departures from a declared stable regime, provided their limits are not tuned after inspecting the very anomalies they are intended to detect. A change point may justify dividing the data into separately characterised states. However, partitioning should not become a convenient way to remove every unfavourable result from the acceptance population. The test plan needs a predeclared rule for invalid intervals and a

Copyright 2026, James M. Atkinson

record of how many observations were excluded and why. A new calibration established after a failure should be tested against fresh challenge data. Otherwise the laboratory has trained upon the failure and then called its absence a validation of the revised system.

The model also requires a physical sensitivity analysis. If a converter spur varies with temperature, deliberately change temperature within safe operating limits and observe whether its amplitude or frequency follows the prediction. If a noise fluctuation follows automatic gain control, freeze the gain during a separate diagnostic run and compare. For an external candidate, alter the antenna connection, input attenuation or sample-clock ratio under conditions that generate different predictions for external and internal hypotheses. These interventions can be more informative than prolonged passive observation because they test a mechanism instead of merely describing the output distribution.

A failed stability test does not render every earlier sample useless. It narrows what can be claimed. If the process is stable over a documented subinterval, a conditional uncertainty statement for that interval may be warranted. If the noise distribution changed in unrecorded ways, the engineer may still report that a feature appeared in a given derived file, but cannot justify a universal false-alarm or sensitivity assertion from the unstable calibration population. The appropriate response is an explicit limitation or a new validated measurement campaign. In forensic work, preserving the failed runs and calibration versions is particularly important. They may reveal whether an apparent source characteristic is a property of

Copyright 2026, James M. Atkinson

the receiver itself. I invite Professor Slepian to consider how the finite duration of the record constrains the very meaning of a noise estimate.

Copyright 2026, James M. Atkinson

David Slepian | Principal response 4: Time-bandwidth concentration and finite observation

Dr. Atkinson, the infinite-length sampling theorem is a useful guide but a poor substitute for an honest description of finite observations. A practical surveillance record has a beginning and an end, and its Fourier components are therefore subject to windowing, leakage and uncertainty about events near the boundaries. Oversampling supplies more numerical samples inside the same physical interval; it does not lengthen the interval. If the desired spectral discrimination requires prolonged observation, a denser lattice by itself cannot provide the frequency resolution associated with additional elapsed time. The nominal DFT-bin spacing is F_s/N, which for $N = F_s T$ is one divided by T. Doubling both F_s and N while keeping T fixed leaves that spacing unchanged. This elementary fact should accompany every claim that a denser data stream automatically resolves closer carriers.

A continuous carrier observed for a fixed time can be estimated with a method whose uncertainty depends upon signal-to-noise ratio, phase coherence, window and model. Oversampling may reduce in-band noise in ways that help that estimate, but it does not remove the duration requirement from the problem. An intermittent burst presents a different challenge. To locate its onset accurately, the acquisition must retain enough bandwidth and timing information; excessive smoothing can spread the event across a longer apparent interval. A filter with a long impulse response may attenuate or delay the feature, and the position of the event relative to the processing block can determine the reported peak. A brighter or quieter display does not certify an accurate burst onset.

Copyright 2026, James M. Atkinson

The relevant mathematical framework concerns the concentration of a signal in finite intervals of time and frequency. No nonzero waveform can be both strictly time-limited and strictly band-limited in the ideal mathematical sense. A practical signal may nevertheless concentrate most of its energy within specified bounds, allowing useful approximations and well-designed tapers. Their performance must be characterised in the situation of interest. The nominal count 2BT gives a useful scale for independent real degrees of freedom under conventional assumptions, but it is not a certificate that every sequence of 2BT computed numbers is independent. Window overlap, filter response, noise colour and estimator choice all matter, and the appropriate effective degrees of freedom may be lower than the numerical count of outputs.

Suppose a receiver uses a sixteenfold oversampling factor and digitally decimates to a fixed channel. The output rate is reduced but the signal may retain its in-band content if the antialias filter and transition region are adequate. That digital operation can improve the practical noise characteristics of the channel. It also discards other portions of the sampled spectrum. If the later forensic question asks whether an external wideband burst or an out-of-channel strong carrier coincided with the candidate, the narrowband file may be inadequate. Thus oversampling followed by decimation should be understood as an acquisition and preservation policy: its benefit is meaningful for the admitted measurand, and its exclusions must be visible in the archive.

One can illustrate the tradeoff without exaggeration. If a real signal occupies a one-sided information bandwidth B of 100 kilohertz and is observed for T = 20 milliseconds, the scale 2BT is 4,000 real degrees of

Copyright 2026, James M. Atkinson

freedom. Sampling at four megasamples per second yields 80,000 raw samples over that same interval. The eighty thousand numbers may encode the waveform with useful redundancy and noise information, but they cannot imply eighty thousand independent time-frequency features of the underlying band-limited source. A subsequent filter may produce a low-variance estimate by reducing unwanted noise, yet the finite observation still contains only twenty milliseconds of the event. The temporal span cannot be multiplied by a faster sampling clock.

The statistical part deserves equal care. If a detector examines many heavily overlapping windows, a signal near a boundary can appear in several windows. These are not several independent detections of separate physical events. Counting them as independent votes artificially inflates confidence. A correct report distinguishes detections from unique event clusters, documents the overlap fraction, and calibrates false-alarm performance at the level of physical events rather than individual output pixels. Conversely, if the detector selects only a small number of windows for retention, non-events and gaps must be accounted for when estimating sensitivity or occupancy. One cannot infer the prevalence of emissions from a gallery containing only the successes that triggered the recorder.

For validation I propose challenge signals of varied duration relative to the filter support. Test pulses wholly within a processing block, at its boundary and across two blocks. Preserve the raw acquisition during the challenge and compare the derived amplitudes, onset times and detected-event counts. Include noise-only intervals to measure false alarms, and test coherent and incoherent interference to distinguish which spectral reductions are predicted by the model. The filter impulse response should

Copyright 2026, James M. Atkinson

be measured or verified under relevant settings, including retune and gain changes. The practical outcome is a performance surface, not a single flattering SNR number. It may show that the receiver is excellent for persistent narrowband signals but much less sensitive to very short bursts at particular channel or window boundaries.

The word 'resolution' must accordingly be separated into at least three senses. The code resolution is the quantiser's number of levels; the spectral discrimination is governed partly by observation duration and estimator; the temporal localisation depends upon admitted bandwidth, filter dynamics and recorded timebase. Oversampling can benefit the error distribution of a particular derived estimate without making all three resolution measures increase together. It may even trade one property against another if longer filtering is used to achieve a lower noise floor. The only reliable conclusion is one that states the tradeoff, validates it for the signal classes at issue and preserves enough raw or intermediate evidence for independent review. I pass the floor to Sir Ronald Fisher, who may test whether the claim of increased reliability respects the actual number of independent trials.

Sir Ronald Aylmer Fisher | Peer question 6 to David Slepian

Professor Slepian, you have distinguished many output samples from a smaller number of physical degrees of freedom, but the forensic examiner is often presented with a table containing thousands of apparent detections across overlapping spectra. Each cell has its own test statistic and an associated nominal significance level. If the tests are strongly dependent, naive multiplication of their individual successes can create an impressive but unfounded assertion of confirmation. Would you require an explicit joint probability model, an empirical familywise

Copyright 2026, James M. Atkinson

calibration, or a count based upon independent physical challenge events? How should the laboratory handle a fixed threshold selected after viewing the most attractive waterfall image? And does increasing the oversampling factor help distinguish the emitter from the receiver when the same line is visible in many correlated windows? I seek a rule that allows rigorous inference without claiming that every possible waveform hypothesis has been exhaustively enumerated. Would a predeclared exposure denominator help prevent duplicate counts?

David Slepian | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, the first rule is to define the elementary observation that the decision concerns. If the question is whether one physical burst occurred during an interval, overlapping windows that all respond to that burst should normally be treated as related evidence about one event, not as independent events. A detector can extract several useful features from those windows, but its familywise false-alarm behaviour must be calibrated at the level of the declared decision. A suitable joint model may be justified for a stationary laboratory process. Where dependence and adaptivity are too complicated for a trustworthy analytic calculation, an empirical test using independently scheduled noise-only and signal-present trials may provide a more defensible operating characteristic.

Selection after inspecting the display presents a separate problem. A threshold chosen because it makes the most striking image appear cannot be evaluated as though it had been specified before viewing that same evidence. The laboratory should reserve independent challenge data or perform a prospective validation of the chosen

Copyright 2026, James M. Atkinson

procedure. Record the unsuccessful settings and considered hypotheses, since they may affect the overall probability of a false discovery. It is not necessary to enumerate every imaginable waveform, but it is necessary to state the investigated class and to avoid treating its success as universal proof. The resulting statement is conditional yet useful: under the specified noise population and search policy, the probability of at least one false alarm over a declared interval is bounded or estimated in a particular way.

Increasing the oversampling factor can help distinguish certain receiver artefacts if it changes their predicted spectral location while an external signal remains at a physically fixed RF frequency. But that is an intervention requiring calibrated frequency mappings and a genuine change of acquisition condition. Merely finding the same line in correlated windows of the same processed stream adds no such physical challenge. An internal oscillator spur may persist quite coherently across every window, just as a real transmission might. Distinct external antenna paths, altered input attenuation, sample-clock perturbation and independent receiver substitutions can provide stronger tests when the rival mechanisms predict different responses.

I would preserve the association between all window-level detections and the underlying interval from which they came, so that another examiner can cluster them and recalculate the familywise result. The record should include the window length, overlap fraction, taper, frequency search range, threshold, detector version and total tested exposure, including intervals with no saved alarm. If the data

Copyright 2026, James M. Atkinson

are insufficient to calibrate the search-level false-alarm probability, the report should say so and confine itself to the measured observation. An apparent reduction in the noise floor is then properly reported as an estimator property rather than a probability that a particular alarm originated from an external device. With that statistical warning, I pass the token respectfully to Professor Tukey.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 5: Exploratory analysis, selected evidence and the false precision of large sample counts

Dr. Atkinson, a signal analyst is surrounded by numerical abundance. The receiver may report millions of samples, thousands of FFT frames and a screen filled with bright transient points. None of those counts establishes the number of independent opportunities to observe an external event or the reliability of the explanation selected after inspecting the display. My concern is not hostility to computation, which can make an otherwise inaccessible record intelligible. It is the error of substituting the quantity of derived numbers for an account of how those numbers arose, what choices the analyst made, and which alternative patterns might have appeared under the same procedure. Oversampling can be a useful part of an intelligent receiver. It can also serve as a theatre of precision when the statistical unit of observation is never defined.

Suppose the investigator tests every frequency bin of every heavily overlapping analysis window and retains only those exceeding a moving threshold. The nominal count of tests may be very large, yet neighbouring bins share window energy, successive frames share raw samples, and all outputs may share a common gain disturbance or oscillator artefact. The apparent detections are therefore clustered and dependent. Summing their individual significance levels or treating them as separate corroborations produces an impression of certainty unsupported by their common origin. To make a credible statement, the examiner should define a physical event cluster, a recording interval, a noise-only calibration population and an alarm policy before estimating an operating characteristic. If those rules

Copyright 2026, James M. Atkinson

evolve during discovery, the changes should be archived and subsequently tested on fresh data.

Oversampling tends to create a second difficulty when a selected display becomes the basis for a broad negative assertion. If a channel looks quieter after filtering, the investigator may increase the threshold relative to its new floor and conclude that the monitored premises contained no covert transmission. But a negative claim needs exposure evidence: which frequency intervals were actually admitted, for how long, under which input conditions, and with what performance for the shortest or weakest signal class relevant to the search? The presence of a quiet-looking trace is not evidence that an out-of-band emission was captured and rejected for legitimate reasons. Neither is the absence of an alarm in a selected retention archive evidence of an absence of emissions during unretained periods.

An exploratory procedure should make unexpected patterns visible without converting them prematurely into certified conclusions. Compare noise-floor estimates over time, inspect raw-code histograms, calculate the behaviour of candidate spurs under changes of sampling rate, and examine how the detector responds when its filter is moved or widened. Where the data contradict the simple white-noise assumption, record the contradiction and refine the hypothesis. Do not merely remove the inconvenient intervals because their inclusion spoils an elegant plot. If a strong local carrier generates nonlinear products, those products may persist at particular frequencies even while quantisation noise is reduced by a high-rate acquisition. The mere fact that the processing reduced broadband noise cannot assign the remaining line to an external surveillance source.

Copyright 2026, James M. Atkinson

The distinction between exploration and confirmation is practical. The investigative analyst may discover a promising feature by trying several windows, FFT sizes, decimation ratios and thresholds. Such exploration is legitimate and valuable. The error occurs when the final chosen setting is reported as though it had been selected before examining the evidence, and its false-alarm rate is calculated from the same record used to choose it. A validation campaign should reapply the frozen rule to separately scheduled reference trials or to appropriately withheld data. If the system is adaptive, the full training and update procedure must form part of what is reproduced. The examiner should count each independent challenge according to its actual design, not each pixel generated from the challenge.

One may illustrate the influence of dependence with a simple correlation model. Suppose one hundred measurements have an approximate first-order autocorrelation rho = 0.8 and the correlation decays geometrically with lag. For a large stationary sequence, the variance inflation of its mean relative to independent observations approaches (1+rho)/(1-rho), or nine in this example. The corresponding effective sample size is of order one hundred divided by nine, approximately eleven, not one hundred. The exact finite-sample calculation depends on the full correlation function and estimator, so this approximation must not be promoted to a universal confidence interval. Nevertheless it shows why an analyst can possess a hundred impressive rows in a spreadsheet while having substantially less independent statistical support for the claimed precision.

There is no reason to reject oversampling because it may create correlated representations. Properly used, it makes antialias filtering easier, can reduce in-band uncorrelated noise and can yield more faithful estimates

Copyright 2026, James M. Atkinson

of a defined signal under calibrated conditions. The forensic question is what the improvement earns. If the signal class is a continuous narrowband carrier in a known channel, the processing gain may be meaningful and reproducible. If the signal class is a short unpredictable pulse, the same integration may impose a severe temporal penalty. A useful instrument report should show performance separately for those cases. An attractive universal 'sensitivity improvement' figure is less valuable than a set of defensible conditional curves showing when the instrument succeeds and when it fails.

I would also insist upon the possibility of an independent challenge. Does the candidate survive a change in antenna, a change in analogue front-end attenuation, or a different sampling clock whose predicted internal spurs move? Does it appear in a separately characterised receiver that has a genuinely different source of systematic error? Does its measured onset remain consistent after correcting the filters' documented group delays? Such experiments can distinguish mechanisms when mere repeated processing cannot. If the conclusion concerns source identity, the analyst must further confront the possibility that several emitters share similar modulation or frequency characteristics. Processing gain may improve the clarity of a feature without making its origin unique.

The final report ought to contain both a readable narrative and a reproducible technical record. State which quantity was measured, what noise model supported the claimed improvement, how many physically distinct trials were performed, which settings were tried, how thresholds were selected, and what remained unrecorded. A large sample count is useful metadata, but it is not the statistical argument. Precision requires the

Copyright 2026, James M. Atkinson

retained contrary cases and the uncertainty of the accepted ones. Dr. Atkinson, I return the floor through Professor Box, who may challenge how one should choose between a physically simple model and a statistical model sufficiently elaborate to match every anomaly.

George Edward Pelham Box | Peer question 7 to John Wilder Tukey

Professor Tukey, a forensic engineer who models every correlation and gain fluctuation may produce an impressive collection of parameters without gaining a testable account of the receiver. Conversely, a simple white-noise model may understate uncertainty and falsely convert redundant samples into independent evidence. How should a laboratory balance the two risks? Suppose a new noise model fits the observed record so well that it explains away every candidate spectral line, including one intentionally injected as a challenge. The fit is mathematically pleasing but evidently unsuitable as a detector. What falsification tests would you demand before accepting either model, and how would you distinguish a robust improvement in estimation from an optimisation that silently discards the signals under investigation? I also ask whether every accepted result should be replicated on a second physical receiver or whether a bounded set of well-designed interventions can be proportionate to the actual claim. I am particularly concerned about the preservation of unsuccessful validation trials.

John Wilder Tukey | Immediate answer to George Edward Pelham Box

Professor Box, the principle is to compare the model's predictive consequences with observations not already used to construct it. A complex model can fit the training record and still fail on a new signal;

Copyright 2026, James M. Atkinson

a simple model can be transparent and still systematically misdescribe correlated errors. Neither complexity nor simplicity is an adequate proof. I would require a reserved challenge set containing noise-only intervals, known injected signals of varied amplitude and duration, and deliberate changes to physical conditions that rival hypotheses predict differently. Thresholds and calibration parameters should be frozen before evaluating that set, or their adaptation should itself be included in the validated procedure.

For the proposed detector, loss of intentionally injected events would be a decisive qualification. The engineer must measure true detections and missed events, not merely the noise-floor reduction. A filter that removes broad background variation but also suppresses the target emission cannot claim unconditional improved sensitivity. Its performance may remain satisfactory for a narrower, explicitly stated class of signals. The choice of that class must derive from investigative requirements and defensible physics, not from selecting whichever trials make the processed receiver look successful. Negative findings are especially dependent upon the scope of exposure and the signal classes against which the instrument was actually tested.

I would use residual plots, out-of-sample performance, calibration checks and sensitivity analysis rather than reward a model for explaining every observation after it has occurred. If the residuals contain a periodic component that moves with the converter sample rate, this is evidence to test an internal mechanism. If the component persists at a stable RF frequency when independently measured

Copyright 2026, James M. Atkinson

antenna conditions change, the competing predictions require a different experiment. Repeatability on one receiver may establish stability of its artefact. It does not establish independence. A second physically distinct receiver can provide useful corroboration when its common dependencies are disclosed, but it is not mandatory for every narrow claim about a digital processing operation.

Proportionality follows from the proposition. To establish that a particular low-pass filter reduced broadband noise power in a calibrated passband, direct input-output measurements with a validated reference and uncertainty analysis may suffice. To attribute a previously unknown signal to a concealed transmitter in a location where consequences are serious, independent challenges and careful preservation of the raw evidence are much more important. The report should clearly state which proposition each test supports. This avoids the false choice between universal scepticism and casual certainty. Our purpose is to make the conclusion as strong as its evidence and no stronger, while retaining the technical ingenuity of an oversampled receiver where it has demonstrably earned its place.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, when oversampling by sixty-four and averaging improves an in-band estimate, which claim about physical information is justified and which is not?

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, the measurement can show a reduction in estimator variance under a specified bandwidth and appropriate noise-correlation assumptions. A white-noise idealisation predicts a six-decibel variance reduction for every

Copyright 2026, James M. Atkinson

factor-of-four increase in independent oversampling ratio, but real analogue and quantisation noise may not be white. That is not equivalent to creating new instantaneous converter code states or widening the analogue information admitted by the front end. Validate the result with band-limited independent stimuli and estimate the empirical output covariance; calculate uncertainty from the covariance, not simply the sample count. An improvement confined to stationary tones must not be extrapolated to one short burst or a saturated channel. Keep the unaveraged I/Q observations and a reproducible map to the derived statistic. I respectfully pass the token to Dr Bennett for the quantisation assumption.

Claude Elwood Shannon, Cross-Peer Question to William Ralph Bennett: Dr Bennett, a team invokes the ideal quantisation-noise formula to justify a four-bit improvement from 256-fold oversampling. What hidden conditions could defeat its result?

William Ralph Bennett, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the familiar relation assumes suitably decorrelated quantisation error and a valid anti-alias/noise-bandwidth model, as well as enough headroom to avoid clipping. A coherent input near a code transition may produce correlated errors and deterministic spectral lines; independent dither can alter those statistics, but the exact dither law and any subsequent subtraction must be specified. The 256-fold ratio is a useful arithmetic statement, not a universal four-bit performance certificate. Measure input-referred noise versus bandwidth, test coherent and deliberately off-bin tones, inspect the raw code histogram and compare estimates under changed gain and temperature. If downstream digital averaging reduces

Copyright 2026, James M. Atkinson

apparent noise whilst a weak short pulse disappears, report the adverse trade-off explicitly. I pass the token to Dr Slepian on the finite record.

William Ralph Bennett, Cross-Peer Question to David Slepian: Dr Slepian, does a very long oversampled record provide arbitrary spectral discrimination when the emission of interest survives for only ten microseconds?

David Slepian, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, no. The finite event constrains time-frequency concentration even if the data stream contains millions of samples before and after it. Extra samples from unrelated background cannot be treated as additional coherent event support. Distinguish the transform length, the non-zero physical duration of the event and the taper used to reduce leakage. Validate with injected pulses of controlled width, onset phase and carrier offsets, and report errors in time of arrival and estimated bandwidth. The useful statistic may combine multiple independent repetitions of the same phenomenon, but that requires a stationarity or repeatability model that a single unrepeatable event does not automatically satisfy. Preserve the original aperture and processing window in the evidence. I respectfully yield to Professor Tukey on false precision.

David Slepian, Cross-Peer Question to John Wilder Tukey: Professor Tukey, how should an operator report the narrow line obtained after searching thousands of oversampled FFT bins and selecting the tallest one?

John Wilder Tukey, Cross-Peer Answer to David Slepian: Dr Slepian, as a selected result from a declared search, not as one prespecified test. Report the number and dependence of frequency bins, time windows, gain settings

Copyright 2026, James M. Atkinson

and candidate detectors examined. An effective number of independent opportunities can sometimes be estimated by calibration under a matching noise model, but equating the raw number of overlapping bins with independent trials is equally unjustified. Retain negative controls and predeclare thresholds; a peak fitted after selection must have uncertainty and bias qualified accordingly. An apparently quiet averaged floor may conceal short-lived events that a separate peak-hold or triggered detector would preserve. Only a blind challenge with known intermittent signals can establish the actual trade-off. I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Distinguished colleagues, the argument has resolved the initial paradox by refusing to treat information, sample count, measurement precision and evidential independence as synonyms. An instrument that samples more frequently may obtain better input coverage, allow more practical antialias filtering and supply noisy observations that a suitable estimator can combine to reduce uncertainty. Under a validated, approximately white and uncorrelated noise model, reducing the noise bandwidth by a factor R reduces in-band noise power by approximately that factor, leading to the familiar ten-times-the-logarithm processing-gain expression. Yet that improvement does not imply that all resulting values are independent observations of distinct physical facts. Nor does it bestow upon an analogue-to-digital converter a new set of physical code thresholds.

Mr Nyquist separated a denser temporal lattice from the physical bandwidth and duration of the underlying waveform. Dr Shannon distinguished improved use of a fixed acquisition record from genuinely new information obtained through an altered physical measurement. Dr

Copyright 2026, James M. Atkinson

Bennett showed that the mathematical convenience of a uniformly distributed quantisation error does not prove that its temporal and spectral correlations are negligible. Professor Slepian explained why a finite observation imposes time-bandwidth constraints and why increased sample count cannot supply additional elapsed observation time. Professor Tukey reminded us that a vast array of overlapping spectral bins is not a corresponding array of independent experiments, especially when the analyst selects the most attractive windows after seeing the results.

Several conditions now follow for an admissible performance statement. The receiver must identify its analogue reference plane, noise sources, sampling rate, admitted bandwidth, filter response, processing version, threshold and observation exposure. It must distinguish a steady narrowband signal from the shorter, wider and more irregular emissions a defensive investigation might seek. It must report whether the improvement was established by a sinusoidal laboratory test, a randomised burst challenge, a noise-only calibration or a truly independent receiver substitution. Where the source's phase, amplitude or temporal signature matters, it must disclose group delay, windowing effects and relevant calibration uncertainty. The chain of custody must preserve enough of the raw or intermediate acquisition to permit the stated result to be reconstructed and contested.

No universal number of extra bits is justified from oversampling ratio alone. The theoretical conversion of a six-decibel noise improvement into roughly one nominal bit of ideal full-scale-sine SNR is an explanation of one model, not a certificate of twenty-four-bit or thirty-two-bit physical performance. Correlated quantisation error, common reference variation,

Copyright 2026, James M. Atkinson

analogue distortion, jitter, thermal drift and input overload may dominate after the broadband component has been reduced. The appropriate statistic is the uncertainty of the specified derived estimate, qualified by the observation population. For detection, the relevant evidence is an operating characteristic indexed by frequency, amplitude, duration, receiver state and the number of genuine decision opportunities.

The panel has also clarified the claim of absence. A clean processed spectrum proves no more than its exposure and detection model permit. It cannot testify to an unobserved frequency band, an unretained interval or a pulse rejected by a filter before it entered the archive. Conversely, the fact that complete certainty is unavailable does not prevent useful engineering evidence. A controlled experiment may show that filtering lowers a particular noise component without materially biasing the amplitude of a stipulated target class, and that the resulting detector achieves a measured true-positive rate at a declared false-alarm rate. Such a restricted finding is both practical and rigorous.

Our next discussion shall examine the arithmetic implementation that makes these apparently precise outputs possible. When an oscillator, accumulator, coefficient or digital filter has finite word length, its internal rounding and state history can create limit cycles, tones and numerical behaviours that are absent from an ideal infinite-precision model. The same principle will govern our next inquiry: the operator must distinguish a mathematical representation from a verified physical or digital mechanism, then preserve enough of the computation to explain how the observation arose. I thank the panel for its careful challenges and respectfully pass the floor to the next numbered question.

Copyright 2026, James M. Atkinson

Worked engineering and forensic applications

These ten cases are independent constructed examples for illustrating the specified measurement models. No result is a performance certificate for an identified instrument. Numerical values are intentionally explicit so an examiner may repeat them with an independent calculator. A rate is expressed in samples per second, bandwidth in hertz, variance in squared units, and logarithmic gains in decibels; where an approximation is used, its physical conditions are stated.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 037

Application 1 | Fixed-band noise reduction at a higher sampling rate

Assume a real low-pass ADC sampling at F_s = 16,000,000 samples/s, with a required one-sided information bandwidth B = 125,000 Hz. Define the ideal oversampling ratio $R = F_s/(2B)$. Substitution gives R = 16,000,000/(250,000) = 64. Under the stipulated approximation of flat, uncorrelated quantisation-noise power over the first Nyquist band, retaining only the specified bandwidth admits one sixty-fourth of that power. The ideal processing gain is $G_p = 10 \log10(64) = 18.0618$ dB. The rms noise amplitude falls by the factor sqrt(64) = 8. These figures apply to that noise component only. They do not predict the attenuation of an in-band carrier, the behaviour of correlated spurs or a probability of detecting a short burst. A challenge test must therefore separately measure signal transfer and false alarms. [S1, S2]

Application 2 | Fourfold oversampling and the meaning of an additional nominal bit

Let an otherwise unchanged converter and filter operate at four times the prior sampling rate while the admitted signal bandwidth remains fixed. If its relevant noise is white and uncorrelated and remains approximately stationary, the ideal power ratio is $R_{new}/R_{old} = 4$. Thus the improvement is 10 log10(4) = 6.0206 dB. Because the ideal full-scale sine-wave SNR changes by approximately 6.0206 dB for one additional quantisation bit, this improvement is *equivalent in that particular SNR convention* to one nominal bit. It does not add another physical comparator threshold to the converter or prove that a single conversion

Copyright 2026, James M. Atkinson

locates a voltage inside its existing code interval. If the four samples are exact copies of one code, their arithmetic average adds no such information. [S1]

Application 3 | An ideal twelve-bit sine-wave benchmark, properly qualified

Let N = 12 be an ideal converter's nominal resolution. The familiar ideal full-scale sinusoidal benchmark is SNR_Nyquist approximately 6.02N + 1.76 dB, giving 6.02(12) + 1.76 = 74.00 dB across the first Nyquist band. If Application 1's R = 64 model were separately valid, a narrowband estimate might have an ideal in-band ratio of about 74.00 + 18.0618 = 92.0618 dB. The estimate concerns the same stipulated sine and one noise model. It is not a direct measurement of SFDR, nonlinear distortion, aperture jitter, source attribution or full-scale transient performance. A real receiver's in-band noise and overload behaviour should replace these theoretical terms with measured values and an uncertainty budget. [S1, S3]

Application 4 | Independent averaging reduces uncertainty but not parameter count

Suppose M = 16 separate noisy observations estimate one constant input voltage theta, and each adds independent zero-mean error with standard deviation sigma = 2.0 mV. The mean has standard deviation sigma_mean = sigma/sqrt(M) = 2.0/sqrt(16) = 0.50 mV. Its variance declines from 4.0 (mV)^2 for one observation to 0.25 (mV)^2. This is a genuine precision improvement for theta if the model is sound. The sixteen observations do not become sixteen independent physical

Copyright 2026, James M. Atkinson

voltages, nor is the measured mean necessarily accurate if the instrument has a shared offset. The test record should include the raw observations and evidence supporting independence. An autocorrelation test on filtered outputs may reveal that M was not the relevant number of independent observations.

Application 5 | Shared reference noise remains when independent noise is averaged

Assume each of M = 16 converter branches observes the same input and has independent error sigma_e = 4.0 mV, but all share a zero-mean reference disturbance with standard deviation sigma_u = 3.0 mV. Under a model where common and independent errors are mutually independent, Var(mean error) = sigma_u^2 + sigma_e^2/M. Numerically this is 9 + 16/16 = 10 (mV)^2, giving a standard deviation sqrt(10) = 3.1623 mV. Treating all errors as independent would instead estimate sqrt((9+16)/16) = 1.25 mV, a severely optimistic result. The exact disagreement reflects the unremoved common path. Two receivers with the same reference are not fully independent merely because they have separate ADC chips. A common-path uncertainty should remain explicit in the forensic budget. [S4]

Application 6 | A correlated record has fewer effective observations

Let n = 100 measurements follow a hypothetical stationary first-order correlation model with lag-one coefficient rho = 0.80 and geometric decay at later lags. For a sufficiently long series, an approximation to the effective sample size of the mean is n_eff approximately n(1-rho)/(1+rho). Substitution yields 100(0.20)/(1.80) = 11.111 observations. Under the

Copyright 2026, James M. Atkinson

same approximate model, the standard-error multiplier relative to treating all one hundred values as independent is sqrt(n/n_eff) = sqrt(9) = 3. This is a warning against a false precision claim, not an exact finite-sample confidence interval. Negative correlation, nonstationarity and other covariance functions require different treatment. The laboratory should estimate and challenge the actual dependence rather than assume this model by convenience. [S4]

Application 7 | The time-bandwidth scale is not the raw sample count

Consider a real waveform effectively confined to B = 100,000 Hz over an observation duration T = 0.020 s. The nominal time-bandwidth scale is approximately 2BT = 2(100,000)(0.020) = 4,000 real degrees of freedom under the usual approximate interpretation. Sampling at F_s = 4,000,000 samples/s records N = F_s T = 80,000 raw values. Their ratio is 80,000/4,000 = 20. The larger stored count can help estimate the waveform when noise and imperfections are characterised; it does not create twenty times as much independent time-bandwidth variation in the underlying restricted waveform. Finite-window leakage and effective band concentration should be assessed rather than treating 4,000 as an exact universal rank. [S5]

Application 8 | Doubling the sample rate does not double observation time

Suppose an analyst retains T = 0.020 s from a continuous recording. At F_s1 = 4,000,000 samples/s, the record has N1 = 80,000 samples; at F_s2 = 8,000,000 samples/s, it has N2 = 160,000. The unpadded DFT-bin spacings are Delta_f1 = F_s1/N1 = 50 Hz and Delta_f2 = F_s2/N2 = 50 Hz.

Copyright 2026, James M. Atkinson

Zero-padding may interpolate the displayed spectrum but does not create additional elapsed observation. The ability to distinguish close carriers also depends on window response, phase, model and signal-to-noise ratio; the equality of bin spacing is not a complete resolution theorem. The specific conclusion is that an increase in raw rate by itself does not supply the frequency discrimination associated with a longer T.

Application 9 | A long averaging window can dilute a short event

A stipulated constant-amplitude pulse of duration tau = 5 microseconds occurs wholly within an averaging window of duration T_w = 1 millisecond; elsewhere the relevant signed input is zero. A simple boxcar mean of the *signed amplitude* is A_mean = A(tau/T_w) = 0.005A, assuming the pulse is of constant sign and the filter is otherwise ideal. Its amplitude ratio relative to the pulse plateau is 0.005, or 20 log10(0.005) = -46.0206 dB. A different energy or matched-filter statistic would have a different response, so this is not a universal pulse-detection penalty. It illustrates how an averaging procedure that greatly reduces broadband noise may simultaneously make a brief event disappear from a thresholded amplitude display. The report must identify its detection statistic and event alignment.

Application 10 | Many search bins and the meaning of a false-alarm rate

Suppose an independently calibrated, fixed test has a noise-only false-alarm probability p = 0.00001 per independent trial. If there really are K = 10,000 independent trials and each has the same p, the probability of at least one false alarm is P_any = 1-(1-p)^K = 1-(0.99999)^10000,

Copyright 2026, James M. Atkinson

approximately 0.095163. Overlapping windows and frequency bins are generally dependent, so this formula cannot be transferred automatically to a waterfall's pixel count. For correlated outputs, the laboratory must use a justified joint model, a suitable bound or empirical search-level calibration. The arithmetic also shows why a seemingly tiny single-test probability can support a much larger familywise risk when an investigator searches extensively and retains only striking results.

QUESTION 038

Copyright 2026, James M. Atkinson

How does finite word length change digital oscillator and filter behaviour?

Source: V011_Roundtable_Question_038_CP038_Dr_Atkinson.docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 038. Complete scholarly manuscript

Original constructed educational dialogue, not historical quotation or testimony. All presented cases are hypothetical pedagogical applications, not certifications of particular instruments.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, our previous discussion distinguished the improved precision of a carefully filtered estimate from the manufacture of new physical information. The present question concerns another boundary at which an elegant mathematical description becomes a fallible engineering instrument. A software-defined receiver may calculate local-oscillator phase with a digital accumulator, mix samples numerically, and subject them to finite impulse response or recursive filters whose coefficients have been designed with high-precision arithmetic. The block diagram resembles an exact mathematical operator. The FPGA, digital signal processor or compiled programme actually stores integers or finite-precision floating-point numbers. It performs rounding, truncation, multiplication, saturation and, unless prevented, wraparound. These operations can create a deterministic tone, shift a filter's rejection notch, alter a transient's amplitude or allow a recursive state to persist after its physical input has vanished. Such effects matter acutely when the

Copyright 2026, James M. Atkinson

investigative objective is to distinguish a faint external electromagnetic emission from a signal generated internally by the receiver.

Let the sample clock be F_s samples per second, an oscillator's phase-accumulator width be W bits, and its tuning word be K, an integer whose intended phase increment is $2 \pi K/2^W$ radians per clock. For a conventional modulo-2^W accumulator the average output frequency is $f_o = K F_s/2^W$, interpreted within the appropriate periodic and aliased digital-frequency convention. The nominal frequency grid is $\Delta f = F_s/2^W$. This formula describes the resolution with which a tuning word can be selected. It does not specify the oscillator's spurious-free dynamic range. If a sine lookup table receives only P of the W phase bits, the discarded phase information can introduce periodic phase-truncation error; a finite-amplitude table, interpolation rule or final DAC adds further errors. A digital mixer implemented with a sine and cosine pair may therefore create or reflect narrow lines whose locations are governed by arithmetic relationships rather than external RF sources.

For digital filters we must distinguish coefficient quantisation, arithmetic rounding and overflow. A nominal FIR filter computes $y[n] = \sum_{k=0}^{L-1} h[k]x[n-k]$, where L is the number of taps and h[k] its intended real or complex coefficients. A fixed-point implementation instead uses quantised coefficients $h_q[k]$, finite-width products, an accumulator with a specified number of guard bits, and a final output rounding or saturation rule. A recursive IIR filter additionally feeds rounded state values back into the computation, so its realised poles and zeroes may differ from their mathematical design. Even when the ideal transfer function is stable, a quantised state update can enter a small nonzero repeating orbit under

Copyright 2026, James M. Atkinson

zero external input. The resulting line may look suspiciously like a weak continuous transmitter. A spectral display cannot identify its causal origin merely by placing a frequency label upon it.

The forensic preservation problem is not confined to the original ADC. Its samples may be correctly acquired, while the derived line is produced after the input has entered a fixed-point NCO, channeliser or detector. If the investigator retains only processed outputs, firmware identifiers without coefficient hashes, or screenshots of a waterfall, a subsequent expert may be unable to reconstruct the arithmetic conditions that generated the feature. The configuration record must therefore identify arithmetic formats, widths, coefficient sets, truncation locations, saturation or wrap rules, phase seeds, buffer boundaries, firmware revisions and algorithmic state transitions. The most useful experiment is one that changes a predicted internal parameter while holding the physical stimulus fixed, or removes the stimulus entirely while monitoring whether the apparent signal remains. Such interventions can discriminate a numerical artefact from an external emitter; repeated observation of the same processed stream cannot.

Dr Hamming will begin with the arithmetic representation and oscillator accumulator. Professor Bode will examine pole-zero sensitivity, coefficient quantisation and the physical inadequacy of nominal transfer functions. Subsequent principal contributors will address digital quantisation spectra, numerical state behaviour and statistically valid validation. The panel shall test the claim that more computational precision always resolves the problem, and equally the claim that every observed digital spur must be internal. We shall separate oscillator frequency resolution from its frequency

Copyright 2026, James M. Atkinson

accuracy, filter coefficient fidelity from a realised stopband response, and a reproducible software output from a defensible statement about an external electromagnetic event. Dr Hamming, may I invite your account of what a finite accumulator actually represents?

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Principal response 1: Finite accumulators, phase truncation and apparently coherent lines

Dr. Atkinson, digital computation is exact only relative to the rules and finite representation selected for it. A modulo integer accumulator can be entirely deterministic and repeatable while approximating a continuous phase law with finite steps. Suppose a W-bit phase register advances by an integer K at each sample clock. Its state obeys phi[n+1] = (phi[n]+K) mod 2^W. The corresponding complex idealised oscillator is exp(j 2 pi phi[n]/2^W), with the caveat that a physical implementation may approximate that exponential through a lookup, polynomial, CORDIC structure or other finite arithmetic. A mathematically neat formula for f_o does not, by itself, describe the realised spectral content. The phase mapping, initial state, rounding and table width must enter the model if the investigator intends to distinguish a converter-generated component from a physical radio emission.

Consider a clock F_s of 100 MHz and a thirty-two-bit accumulator. The nominal frequency step is F_s/2^32, approximately 0.023283064 Hz. The numerical result is accurate as a tuning-grid statement, assuming the clock is exactly 100 MHz for the purpose of this example. It does not imply that the real frequency is known to twenty-three millihertz when the reference oscillator has an uncertainty of parts per million. A ten-part-per-million frequency error at an output of 10 MHz represents roughly 100 Hz, far larger than the tuning-word increment. Frequency resolution is the granularity of a selectable command. Frequency accuracy is a claim about the physical timebase against which that command is executed. The distinction resembles a ruler whose millimetre markings are precise while

Copyright 2026, James M. Atkinson

the metal has expanded with heat: the graduations alone cannot establish the length of the object measured.

Phase truncation introduces another mechanism. A large accumulator may preserve W bits to avoid cumulative frequency error, while a smaller table address exposes only P upper bits. The discarded lower bits form a deterministic sequence governed by K, W and P. In some arrangements this sequence is periodic, producing discrete spectral components rather than an uncorrelated white floor. Their exact amplitudes depend on the mapping, interpolation, converter output and signal path; one should not calculate a universal SFDR merely from the number of truncated bits. A receiver with a ten-megahertz NCO may show weak offset lines whose positions move when the tuning word changes slightly, even though the analogue input remains constant. The correct experimental question is whether the suspected signal follows a prediction of this arithmetic mechanism.

There is a practical method of challenge. Record the raw ADC stream and run it through several rigorously specified NCO implementations. Change P while preserving the input, tuning frequency and adequately controlled gain; compare the spectral locations and amplitudes of the resulting features. Deliberately vary the phase seed or adjust K by a small known amount. Where a line changes as a reproducible function of these internal parameters, an algorithmic source becomes plausible. Yet care is needed. An external signal mixed digitally also changes its baseband offset when the NCO changes, so a moving display line is not automatically spurious. The prediction must be expressed in absolute RF terms as well as derived baseband coordinates, and the experiment should distinguish which line moves *beyond* the frequency translation expected for a genuine RF input.

Copyright 2026, James M. Atkinson

One should further preserve the arithmetic rules of each multiplication. Fixed-point complex mixing multiplies I and Q input words by finite sine and cosine coefficients. Product widths may exceed the source word width, and a restricted accumulator may overflow or lose lower bits. Rounding once after a wide accumulation generally differs from truncating every intermediate product. One form may concentrate a small periodic error into a spur; another may spread error more diffusely. When an apparent weak signal appears only for a particular word length or rounding mode, the receiver needs an engineering diagnosis before the result can be carried into a forensic attribution. A clean digital simulation with infinite-precision floating-point arithmetic may not reproduce the exact defects of the hardware arithmetic, so bit-exact testing is an important part of the evidence.

The programme's configuration identity must include firmware, compiled arithmetic behaviour, coefficient hashes and state. The same version label might still permit different arithmetic when optimisations, libraries or instruction-set rules change, particularly around overflow and fused operations. A reproducible test should use defined input vectors and verify exact or bounded output correspondence before comparing live observations. It may also need to preserve the unprocessed acquisition interval, since reprocessing an already truncated product cannot reveal whether the original codes were correct. If the countermeasure investigator is challenged to show that a faint spectral line was not an internal oscillator artefact, the burden is not discharged by saying the oscillator was 'digital' and therefore exact.

Copyright 2026, James M. Atkinson

The broader lesson is that an abundance of fractional phase bits is not a universal guarantee of spectral purity. The oscillator is a finite state machine with deterministic transitions, and its signal path is a finite arithmetic realisation. The output may be stable, coherent and measurable at impressive dynamic range, yet that very stability can make internal spurs mimic real, persistent emissions. The correct claim is a measured bound upon numerically generated artefacts under specified tuning words, sample rates, word lengths, reference conditions and output configurations. Such a bound is a powerful engineering result. It becomes forensic evidence only when its validity covers the actual acquisition and its uncertainty is preserved. I pass the floor respectfully to Professor Bridgman, who may question whether a displayed frequency derived from a digital coordinate is the same measurand as a physical emission at an antenna terminal.

Percy Williams Bridgman | Peer question 1 to Richard Wesley Hamming

Dr Hamming, your distinction between a selectable frequency increment and a traceable physical frequency is persuasive, but I fear that receiver reports often conflate another pair of quantities. A line may appear at a digital baseband coordinate after multiplication by a finite oscillator, while the physical measurement claim concerns a field coupled into an antenna at some absolute RF frequency. If the input path contains a mixer whose local oscillator has its own uncertainty, and the digital NCO is controlled by an imperfect clock, the value printed beside the waterfall line may depend on several frequency mappings. Which experimental comparisons should be preserved to establish the RF reference plane of the reported emission? Would a test conducted

Copyright 2026, James M. Atkinson

entirely at the digital input to the NCO be sufficient to certify the source frequency, or does the analogue chain require a separate metrological account? In particular, how should the report qualify a line that disappears under a change of arithmetic precision but whose original raw samples were not retained?

Richard Wesley Hamming | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, a digital coordinate is not an RF reference plane. The report must identify the analogue tuning state, the oscillator frequency and accuracy, the sample-clock timebase, any frequency translation or spectral inversion, and the mapping between the digital bins and the input terminals. A test applied only to the digital input of an NCO can establish whether a particular arithmetic implementation produces a given output for that digital stimulus. It cannot, without additional evidence, certify what arrived at an antenna or whether an analogue mixer introduced a spurious response. Those claims require appropriate analogue calibration and receiver substitution or controlled injection at the physical boundary of interest.

A practical challenge record should begin with a reference source whose frequency and uncertainty have been determined independently. Inject it at an appropriate analogue test plane, observe the raw acquisition and the processed output, and repeat under relevant retune states. The engineer should compare the predicted digital frequency with the measured one, including local-oscillator offset, any sampling-clock error and the known input

Copyright 2026, James M. Atkinson

transfer. If the digital arithmetic is suspected of producing a spur, a second test can feed the same stored raw samples through a bit-exact reference implementation and selected alternative precisions. The important point is that those two tests address different boundaries. The analogue test checks acquisition mapping; the numerical replay checks the processing transformation.

Where the original raw samples are absent, the diagnostic possibilities narrow. A line that disappears after increasing arithmetic precision provides evidence consistent with a numerical artefact, especially if a predicted phase-truncation mechanism explains its earlier frequency and amplitude. But the experiment does not uniquely establish what external signals were simultaneously present. A weak external carrier might have been affected by the same processing change or by an undocumented threshold. An examiner should therefore report what was observed, what implementation was varied and which alternative explanations remain. It would be improper to restore confidence retroactively by manufacturing a hypothetical raw sequence that reproduces the selected line.

I would recommend a bounded conclusion. State that the observed feature is implementation-sensitive, identify the tested arithmetic changes, and explain that external-source attribution is unresolved without the original acquisition and a satisfactory analogue challenge. Such a finding does not render the engineering work futile. It prevents a precise-looking computed frequency from being mistaken for a direct observation of a transmitter. I return the floor to the moderator for the remaining principal examination, which must

Copyright 2026, James M. Atkinson

account for digital filter coefficients, accumulator overflow and the possible survival of internal limit cycles after the analogue input disappears.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode | Principal response 2: Coefficient precision, pole sensitivity and implemented stability

Dr. Atkinson, a mathematical transfer function is a specification of an ideal relation, not evidence that a particular circuit or programme realises it. In analogue network theory a response changes when components depart from their nominal values; the same principle governs digital filters whose coefficients must be stored in finite registers. An intended coefficient h[k] becomes h_q[k] after rounding or truncation. The resulting frequency response H_q(exp(j omega)) differs from H(exp(j omega)), and for an FIR filter the difference is the Fourier transform of the coefficient errors. A finite coefficient format can therefore alter the passband gain, the transition region, the rejection at a notch or the phase response used for timing. Such errors are frequently deterministic and reproducible. A receiver-generated spectral feature can be just as stable as a genuine external carrier, and an elegant design plot cannot identify which is present.

For an L-tap FIR, write delta_h[k] = h_q[k]-h[k]. The response error at normalised angular frequency omega is E(exp(j omega)) = sum from k equals zero to L minus one of delta_h[k] exp(-j omega k). From the triangle inequality, its magnitude is no larger than the sum of absolute coefficient errors. This bound can help establish worst-case behaviour, but it may be conservative; the actual spectral error depends on the phases and signs of the perturbations. If each coefficient is rounded to a step q_h and the rounding error is at most q_h/2, a crude upper bound is L q_h/2. A narrow stopband specification can be particularly vulnerable because a very small absolute transfer error is large relative to an ideal near-zero response. A report that calls a filter 'eighty-decibel rejecting' from its floating-point

Copyright 2026, James M. Atkinson

design should verify that the fixed-point implementation still satisfies the rejection requirement under the relevant coefficient and accumulator rules.

A recursive filter presents a more serious possibility. Its poles are determined by denominator coefficients, and their realised locations can shift when those coefficients are quantised. An ideal stable pole just within the unit circle may be moved sufficiently to alter its decay time, resonance or stability. The sensitivity depends strongly on the filter structure. Implementing a high-order polynomial directly can differ markedly from cascading well-scaled second-order sections, even when their infinite-precision transfer functions are algebraically equivalent. The internal states are not equivalent under finite arithmetic; one structure may magnify rounding noise or encounter overflow while another remains within the same word budget. Consequently the implementation architecture belongs in the calibration record, rather than being concealed behind the statement that the nominal coefficients were identical.

Feedback also creates the phenomenon of a limit cycle. Consider the zero-input recursion $y[n] = Q(a\, y[n-1])$, where Q represents a fixed rounding operator. In ideal arithmetic with absolute a less than one, the state tends to zero. Under quantisation, a small positive state may round back to itself and cease decaying. A more complicated IIR system can enter a multistate periodic orbit. If the receiver's digital output is converted into a spectral display, such an orbit may form a line or repeating pattern with no surviving analogue input. The presence of an apparent signal while the RF input is terminated is therefore an important challenge, provided that input termination itself does not introduce a different analogue fault. The

Copyright 2026, James M. Atkinson

examiner should vary initial states, numerical precision and operating frequency to identify whether the line follows the internal recursion.

The distinction between wraparound and saturation is equally material. A signed fixed-point accumulator of width W represents only a finite interval. If an addition exceeds that interval, a wraparound implementation may jump from a large positive number to a large negative one, introducing an impulse-like discontinuity and broad spectral artefacts. A saturating implementation instead clips at a bound, creating a different nonlinear response and harmonics. Neither behaviour can be inferred from an ideal filter equation. The engineer must determine whether a compiler, FPGA synthesis system or processor instruction uses saturation, modular arithmetic, exception handling or an implicit conversion to a wider type. Small changes in input amplitude can drive the computation across an overflow boundary, so a calibration made only with gentle test tones may fail under strong legitimate transmitters.

The obvious remedy is not simply to allocate a fantastically large accumulator and assume the problem vanishes. Wider arithmetic may reduce rounding error but cannot repair an incorrect transfer model, an alias introduced before digitisation or an unrecorded receiver state. It can also change timing and hardware resource demands, potentially altering the acquisition's real-time behaviour. The correct approach is to allocate sufficient guard bits for a declared worst-case input bound, analyse coefficient sensitivity, verify scaling at every stage, and test the bit-exact implementation against independent reference vectors. For a narrowband forensic search, these tests should include weak signals coexisting with stronger interferers and should preserve the original raw-code stream long

Copyright 2026, James M. Atkinson

enough to decide whether an alleged spectral feature first appeared before or after a particular digital stage.

I propose three forms of evidence. First, provide the mathematical specification, including passband, stopband and allowed phase or delay distortion. Second, preserve the actual fixed-point coefficients, types, arithmetic modes, initial conditions and compiled implementation identity. Third, measure the realised transfer under controlled stimuli, ideally across relevant temperatures and operating modes. The discrepancy between designed and realised response must form part of the uncertainty account. If the observed line disappears when the word length increases, that supports a numerical-artefact hypothesis but does not, in isolation, exclude a simultaneous external signal that the earlier processing obscured. Scientific care requires both the positive diagnostic and the limit of what it proves.

We should conclude that a filter does not inherit stability or precise phase from the elegance of its algebra. These properties belong to a realised, bounded arithmetic system and must be demonstrated for the actual input classes. The forensic report should not promote a bit-exactly reproducible processing output into evidence of an external emitter without validating the transfer from the physical reference plane. Mr Black may now challenge how a feedback engineer should set acceptable bounds when an internal loop compensates for the very errors it introduces. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Harold Stephen Black | Peer question 2 to Hendrik Wade Bode

Professor Bode, your insistence upon the implemented transfer function leaves a difficulty familiar from feedback design. The receiver

Copyright 2026, James M. Atkinson

may adjust its digital filter coefficients continuously to suppress narrow unwanted components, and its adaptation may depend on the same noisy record used for detection. A self-adjusting notch might suppress an internally generated oscillator spur, but it might also suppress the genuine external emitter the investigator seeks. If the laboratory freezes the coefficients for validation, it no longer tests the adaptive system that actually operates. If it allows adaptation, the experiment becomes harder to reproduce and the result may depend on the order in which stimuli were presented. What acceptance test would establish that the adaptive computation is stable, that a signal survives under declared conditions, and that a reported absence is not simply the consequence of a loop trained to remove the signal? Which state variables and update histories are indispensable for subsequent forensic reprocessing?

Hendrik Wade Bode | Immediate answer to Harold Stephen Black

Mr Black, an adaptive filter should be regarded as a system with a state, an update law and an observation process, not as a static transfer function to which one may attach a permanent response plot. Its qualification should include the algorithm's initial state, error signal, step sizes, coefficient constraints, update timing and criteria for suspending or resetting adaptation. These quantities make the difference between a reproducible controlled experiment and a narrative in which a line vanished for reasons never recorded. If the filter learns from the same interval on which its effectiveness is judged, its success requires an independent challenge before the claim extends beyond that interval.

Copyright 2026, James M. Atkinson

I would run two complementary tests. The first freezes the coefficients after a documented training phase and injects independently scheduled reference signals at frequencies and amplitudes the training algorithm did not select. This tests the frozen realised transfer and the capability of the detector to preserve the target class. The second exercises the full adaptive process from declared starting states, randomising the order of challenge pulses and interferers and recording every coefficient trajectory. This tests whether adaptation itself changes the true-positive and false-alarm characteristics. Both tests should retain failed cases, because the ability to reach a pleasing final spectrum after several revisions is not a measurement of the originally proposed procedure.

A suitable forensic archive need not store every intermediate arithmetic operation, but it should preserve enough state to reproduce material decisions. That may require the raw acquisition, a time-stamped coefficient stream or losslessly versioned snapshots, adaptation configuration, gain and frequency states, and a digest identifying the executable implementation. If the system cannot replay its processing for a material candidate, its derived output can still document an observation, but the examiner must acknowledge that the exact transformation cannot be independently verified. Such a limitation belongs in the conclusion rather than in a concealed engineering note.

Finally, a lower output noise floor must be assessed alongside the target signal transfer. An adaptation that removes both broadband noise and a legitimate weak tone may improve one displayed statistic

Copyright 2026, James M. Atkinson

while destroying the signal class of interest. The acceptance population must therefore include representative weak emissions, quiet intervals and strong interferers. A successful system is one whose measured performance meets a declared requirement, not one which merely produces the cleanest picture. I pass the floor to Dr Shewhart, who may test the stability of these procedures across repeated trials and operating states.

Walter Andrew Shewhart | Peer question 3 to Hendrik Wade Bode

Professor Bode, a laboratory may demonstrate excellent agreement between an ideal response and its fixed-point implementation at room temperature and with one convenient coefficient set. In service, a receiver operates through gain changes, retunes, firmware updates and thermal excursions. A rare overflow or limit cycle may occur only after a particular history of input amplitudes, while ordinary repeated sine-wave tests remain uneventful. How should a quality-control programme distinguish a truly stable implementation from one whose failure probability is merely too small for a brief demonstration to reveal? Should the evidence include worst-case interval bounds, randomised stress tests, software regression testing and persistent monitoring of unexpected state transitions? And when the application concerns forensic attribution, how should the laboratory report a failure that appeared in one run but could not be reproduced after resetting the instrument?

How would your assessment preserve unfavourable trials and distinguish an engineering tolerance established beforehand from one chosen only after the observed signal had been inspected? Would the

Copyright 2026, James M. Atkinson

answer change if the disputed line appeared only after a temperature excursion?

Hendrik Wade Bode | Immediate answer to Walter Andrew Shewhart

Dr Shewhart, the question requires a combination of structural analysis and empirical challenge. A finite collection of successful tests cannot prove that no possible input history triggers an internal failure, especially where the space of phase seeds, input amplitudes and retune sequences is enormous. One should identify mathematical invariants where feasible: accumulator bounds, coefficient ranges, scaling constraints and guaranteed guard bits. A proof of absence of overflow for a stipulated input bound is stronger than the mere observation that overflow happened not to occur in a short calibration. Where such proof is not feasible, representative and adversarial test campaigns can estimate failure frequencies over declared populations, with confidence limits rather than absolute guarantees.

For rare state-dependent failures, preserve the complete available state history and the first observed sequence that led to failure. A bug that disappears after reset is not imaginary merely because the original trajectory is difficult to recreate. The system should capture firmware identity, coefficient hashes, oscillator phase state, buffer alignment and control events, together with raw input intervals and diagnostic counters. The operator may use deterministic replay or hardware-in-the-loop tests to examine whether the failure depends on numerical wrap, a clock-domain crossing or an adaptive coefficient

Copyright 2026, James M. Atkinson

update. If the causal mechanism remains unidentified, the report should retain an unresolved qualification about the class of outputs affected.

Regression testing must include changes to the development environment, since the same source code can compile to different arithmetic depending on processor instruction sets, optimisations and library implementations. A fixed-point design should explicitly specify signedness, saturation or wraparound, rounding mode and accumulator growth rather than delegate them to an undocumented default. Acceptance results should also be tied to the actual release binary, not merely a version label copied into an operator's notebook. Temperature may affect the analogue front end even when digital arithmetic remains bit-exact; those mechanisms should be distinguished so that calibration applies to the correct part of the measurement chain.

A single nonreproducible failure can justify continued investigation or restriction, not an assertion that the instrument is permanently defective or wholly reliable. The strength of the conclusion depends on its cause, frequency and consequences for the intended claim. Where the failure may mimic a concealed emitter, it is especially important to retain the raw and derived records and to avoid treating apparently coherent lines as independent confirmation. A well-governed programme may remain useful for signal discovery while reserving stronger source attribution for events surviving separate physical and numerical challenges. I return the floor to Dr. Atkinson

Copyright 2026, James M. Atkinson

for the next principal examination of feedback, prediction and computational memory.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 3: Feedback, computational state and the ambiguity of a persistent digital tone

Dr. Atkinson, an engineer frequently encounters the same word *memory* in two rather different senses. A storage device retains a series of previous samples, while a dynamical system retains information in its internal state. An IIR filter, automatic gain controller or tracking oscillator may continue to respond after the particular input that excited it has disappeared. If that state is represented in finite precision and updated by nonlinear rounding, its later behaviour may not follow the smooth decay predicted by the ideal linear equation. The investigator observing a narrow line in the output should ask what external input, if any, is required to sustain it. The persistence of the line under one operating condition is a fact about the complete receiver state, not a proof about an external transmitter.

Consider a feedback system with one state x[n] and a nominal law x[n+1] = a x[n] for zero input, with 0 < a < 1. In infinite precision the state approaches zero. Suppose instead that every update rounds to a quantisation increment q. If the current state is q and a is sufficiently close to one, the product a q can round back to q, leaving the state unchanged. With the conventional nearest-increment rounding rule, q is a fixed point whenever a q lies within the rounding interval centred on q. In other words, a value that should decay can remain trapped by the finite representation. If the system contains several states and complex multiplication, the resulting orbit may be periodic and its spectral output may resemble a coherent signal. This cannot be diagnosed by an FFT alone because the spectrum records periodicity, not the physical origin of the periodicity.

Copyright 2026, James M. Atkinson

The analogy with control systems becomes more consequential when the filter adjusts itself from live data. An adaptive digital receiver might continually change coefficients to reject an interference line, but the resulting adaptation can also learn a real intermittent signal as though it were nuisance noise. The internal state includes the coefficient vector, its past excitation and the update law. If an operator preserves only the final coefficients and the final clean display, the record may omit the history that determined which signals were rejected. A valid forensic reconstruction requires the state evolution or sufficient checkpoints and event logs to reproduce material decisions. The report should disclose whether adaptation was active, suspended, reset or trained on the very evidence subsequently evaluated.

Numerical precision changes the dynamics but does not erase the physical distinctions. Increasing word length can move a trapped state below the relevant detection threshold or extend its decay time; it may also reveal a different arithmetic path because a compiler or processor now employs wider instructions. The engineer should measure the actual state trajectory under controlled stimuli rather than infer the entire result from a nominal bit count. The chosen rounding mode matters, including whether values are truncated toward zero, rounded to nearest or handled stochastically. Overflow must also be specified. A modular arithmetic wrap can inject a discontinuity into a feedback loop, while saturation can hold a state at a bound until an input or control change releases it. These mechanisms have different spectral consequences and can be intentionally challenged.

Copyright 2026, James M. Atkinson

A powerful experiment is the zero-input test, but even this requires care. Disconnecting an antenna and terminating the input may change loading, gain control or the analogue noise seen by the converter. One should therefore compare at least two defined boundaries: digital zero injected immediately before the suspected processing block, and a separately characterised analogue termination at the intended RF input. A line persisting under digital zero is plainly not being sustained by the external analogue programme during that test, although it may represent a prior state rather than a newly generated periodic input. A line disappearing under digital zero but persisting with an analogue termination may arise in the front end, clock, converter or mixed-signal interface. Neither result alone reconstructs what occurred during an earlier unrecorded field observation, but both restrict the possible explanations.

I recommend varying initial state and processing history systematically. Begin with a cold start, apply a known transient, remove it, and record the decay or residual orbit. Repeat with different seeds, gain settings, filter coefficient updates and arithmetic precisions. Compare bit-exact numerical simulation with hardware implementation, noting where divergence first occurs. If the suspected line appears only after one reproducible sequence, that sequence deserves preservation as an engineering artefact test. A coincident external emitter must still be tested independently. The event may have been present during the original acquisition even if later numerical processing superimposed its own spur. The causal claim must be limited to the experiment that actually discriminates these possibilities.

The forensic examiner should not interpret a numerical limit cycle as an ordinary random disturbance whose variance simply averages away. A

Copyright 2026, James M. Atkinson

persistent periodic state can remain coherent under longer integration and may become more prominent as white noise is filtered out. This is precisely why a high-dynamic-range search can expose new receiver-generated artefacts instead of eliminating every ambiguity. Robust design may include explicit state-reset policies, dithering where appropriate, guard bits, conservative overflow controls and implementations whose dynamics can be bounded. Each intervention can improve engineering performance; its forensic reliability depends upon recorded version identity and validation under field-relevant conditions.

I should end by distinguishing predictability from provenance. A deterministic line generated by finite arithmetic may be predicted to many decimal places once the algorithm and state are known. A real external transmitter may also be narrow and stable. The visual appearance of the two can be nearly indistinguishable. The decisive evidence comes from controlled changes that alter one mechanism but not the other, and from preservation of the actual raw and derived observations. In the absence of such evidence, a cautious statement of unresolved origin is not a failure of science. It is an appropriate record of what the apparatus has and has not established. I pass the token to Professor Slepian, who may press the temporal implications of finite-state memory for very short emissions.

David Slepian | Peer question 4 to Norbert Wiener

Dr Wiener, the persistent numerical tone you describe may arise after a short pulse has already ended. A field analyst could see the tone continue for seconds and conclude that a covert transmitter remained on the air for that duration. If the system's state is reset, the tone may cease immediately, but the reset might also erase the information needed to

Copyright 2026, James M. Atkinson

reconstruct the original pulse. How should the examiner distinguish the duration of a physical event from the settling time or limit-cycle behaviour of a digital algorithm? Should the receiver retain a pre-processing raw interval around each candidate, and must the validation include pulses at different positions relative to filter blocks? I also ask whether one can calculate a universal maximum apparent event duration from the filter's nominal poles, or whether finite arithmetic and adaptive state make that bound fundamentally implementation-dependent.

Please also explain whether the answer depends upon knowing the input waveform class beforehand, and how one could test an unexpected waveform without assuming that the very model under examination had already captured every relevant transient.

Norbert Wiener | Immediate answer to David Slepian

Professor Slepian, the physical event duration and the duration of a numerical state are different observables. A nominal pole calculation may predict the decay of an ideal linear filter, but it does not by itself bound a quantised implementation whose states may enter persistent cycles. A rigorous bound would require specifying the finite state space, arithmetic rules, input constraints and reset behaviour, and then establishing what trajectories are reachable under those conditions. Such an analysis may be feasible for simple models but computationally difficult for a large receiver. An empirical challenge programme can nevertheless identify material duration distortions over representative signal classes and operating states, provided the conclusion is confined to that evidence.

Copyright 2026, James M. Atkinson

I would preserve the raw interval surrounding a significant candidate wherever feasible. The record should include enough pre-trigger and post-trigger material to distinguish an actual transmitter onset or cessation from the impulse response of the digital chain. The filter's group delay, coefficient state, adaptive updates and any saturation episodes should be logged. During testing, inject short pulses at random positions relative to processing windows, remove the stimulus, and observe both the raw acquisition and the derived outputs. If the processed line persists after the raw stimulus disappears, that persistence should be attributed to the processing response unless further evidence shows a coincident physical signal.

Resetting can be diagnostic but should not be a substitute for evidence preservation. A reset that destroys the only state history may prevent later reconstruction of the mechanism. A properly designed receiver would record the pre-reset state or a sufficient diagnostic snapshot, document the reset command and retain its effect on detection. When complete state retention is impracticable, the limitation should be declared and the event's duration reported as bounded by the observed processing conditions. The investigator may state that a derived indicator remained active for several seconds, but should not silently equate that interval to continuous electromagnetic emission at the antenna.

A useful acceptance statement therefore specifies an event-duration transfer characteristic for the declared waveform class, including worst observed extension, delay and false-event clustering under tested circumstances. If a finite-state artefact remains possible,

Copyright 2026, James M. Atkinson

it becomes an explicit alternative explanation. This is not to deny the utility of recursive filtering; it is to insist that its memory be accounted for before a temporal claim enters the forensic record. I return the discussion to Dr Bennett for the spectral consequences of rounding and truncation in the arithmetic path.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal response 4: Arithmetic error spectra and the difference between noise and spurs

Dr. Atkinson, an error introduced by rounding a digital value may often be modelled statistically, but a deterministic arithmetic process does not acquire random independence merely because we lack the patience to calculate its exact sequence. A uniform quantiser applied to a sufficiently varied signal can produce error that resembles broadband noise under useful assumptions. The same quantiser applied to a small periodic sequence may yield repeating errors, and its spectrum may contain discrete lines. Finite word length therefore presents the engineer with two different tasks: measuring the rms level of residual arithmetic error and identifying the conditions under which that error becomes strongly signal-correlated. The second task is particularly important in a surveillance receiver, because an internal spur may become more visible as the surrounding white noise is reduced.

Take a digital oscillator whose phase register retains many bits but whose sine table sees only a subset. The discarded phase produces a periodic approximation error under certain tuning words. Its Fourier series can contain stable offset components whose positions depend on clock, tuning word and phase truncation. Similar periodicity may arise from an IIR limit cycle or a fixed-point mixer whose products are truncated in a repeated pattern. The exact spectral lines depend on the arithmetic mapping and internal states. A receiver report should not assert their frequencies from a single generic bit-depth rule. It should derive candidate locations from the specific implementation and test those predictions against measured output. When the phase truncation is altered, a corresponding spur may

Copyright 2026, James M. Atkinson

change; when a physical carrier is altered, its expected RF-frequency behaviour is different.

For a fixed-point FIR, suppose the ideal coefficient h[k] is rounded to h_q[k], and each product is accumulated with a finite register. Coefficient error is a linear change in the filter's nominal response when the arithmetic otherwise remains exact. Intermediate rounding is a more complicated perturbation because it depends upon the signal and on the order of operations. If an implementation truncates every product before summing, it may introduce more error than one that retains full product precision until a suitably wide accumulator is rounded once at the output. The accumulation architecture should be part of the specification, and the laboratory should use bit-exact vectors to establish whether independent software reproduces the installed hardware. A floating-point analysis of h_q[k] alone cannot certify the entire fixed-point chain.

The arithmetic treatment of negative numbers also deserves explicit declaration. Two's-complement representation, signed shifts and truncation toward negative infinity can behave differently from rounding toward zero. A processor which shifts a signed intermediate result may introduce a small systematic error if the programmer assumed a different rounding rule. Repeated across thousands of filter operations, this bias may produce a nonzero baseline or contribute to a periodic spur under a suitable input. The statistical remedy is not automatically more averaging. A bias survives averaging; a coherent spur can become increasingly apparent under narrowband integration. An independent calibration must locate the source of the error or place a tested bound upon it.

Copyright 2026, James M. Atkinson

A common mistake is to infer that a longer word length always produces a proportionate reduction in every artefact. In a mixed-signal receiver, the ADC may already dominate the noise, analogue intermodulation may dominate the spurs, and clock jitter may dominate phase uncertainty. Widening the digital accumulator can improve a specific arithmetic limitation without changing any of those physical boundaries. Conversely, an extremely precise ADC may still produce false lines after a badly implemented numerically controlled oscillator. The engineer should therefore allocate an error budget by mechanism and test each mechanism where it is observable. The most expensive numerical representation is not necessarily the most trustworthy one if the apparatus lacks state history and reproducible calibration.

Forensically, one should record the raw-to-derived transform as a sequence of versioned stages. Start from a content-addressed raw sample interval, apply a bit-exact NCO, a defined filter with its coefficient bytes, an explicitly specified rounding rule and an identified threshold. Retain the intermediate output at material boundaries when the cost is proportionate to the case. If a disputed line first appears after one stage and changes predictably when its precision is varied, that is evidence for a processing artefact. Yet attribution to a particular internal mechanism should remain bounded by the challenge. An external emission might coexist with a spur at a nearby frequency, and the combined output may not permit the two to be separated without additional acquisition.

A successful validation should include both null-input and signal-present tests. Under a digital zero stimulus, the processing block should exhibit only its documented internal behaviour. Under a known weak sinusoid or burst,

Copyright 2026, James M. Atkinson

the derived output should meet specified amplitude, timing and spectral tolerances. Deliberately select tuning words that stress phase truncation, signals close to accumulator overflow, and filter inputs near saturation. A fault that appears only under adversarial values should be recorded rather than excluded as an inconvenient special case, especially when a field survey may encounter unpredicted strong legitimate transmissions. Numerical precision is thus a measured component of receiver reliability, not a rhetorical substitute for it.

The report should distinguish a spur-free range measured under specified stimuli from an asserted absence of every possible internal spur. It should also separate a small output noise variance from the reliability of source identity. A coherent arithmetic line may have a very low apparent uncertainty in frequency while its physical-origin hypothesis is entirely wrong. The best engineering solution is a receiver whose known arithmetic artefacts are bounded below its declared detection threshold or whose diagnostic interventions can identify them. I respectfully invite Professor Hotelling to examine whether a spur model calibrated from selected examples has been given more evidential weight than it deserves.

Harold Hotelling | Peer question 5 to William Ralph Bennett

Dr Bennett, your analysis proposes deliberate tuning words and arithmetic stress vectors to reveal spurs, but the laboratory may select those vectors after studying a suspicious line. A model can then appear impressive because it was fitted to the very pattern it purports to predict. If the engineer tries hundreds of combinations of word length, rounding rule and oscillator seed and reports only the one producing the closest spur, the apparent match may arise by chance. What statistical record is

Copyright 2026, James M. Atkinson

needed to make the proposed mechanism discriminating rather than retrospective? Should the acceptance campaign allocate an independent set of previously concealed tuning conditions, or would a physical perturbation of the receiver be a stronger test? How would you quantify uncertainty in the predicted line's amplitude when the converter transfer characteristic and analogue source path are themselves imperfectly known?

In particular, how should the trial design account for dependence among nearby FFT bins and among neighbouring tuning words, so that the apparent rarity of a favourable match is not exaggerated by an independence assumption?

William Ralph Bennett | Immediate answer to Harold Hotelling

Thank you for that question. Professor Hotelling, the distinction between discovery and confirmation is essential. The laboratory may use exploratory searches to propose that a particular truncation sequence generated a line. Once the mechanism is proposed, its equations, arithmetic rules and predicted spectral relations should be frozen before a separate challenge. Select new tuning words and initial states, including cases predicted to suppress and cases predicted to strengthen the spur, and compare the output with the specified predictions. Retain all tested combinations, not merely the most visually persuasive match. A systematic match across withheld conditions has stronger evidential value than an isolated resemblance found after numerous trials.

An independent physical intervention can be complementary. If the line belongs to the digital NCO, changing the relevant arithmetic

Copyright 2026, James M. Atkinson

should alter it while the raw ADC stream is held fixed. If it belongs to the external RF scene, controlled changes to antenna coupling or input attenuation should affect the acquired signal according to a different physical model. Some changes may affect both mechanisms, so their predicted outcomes must be explicit before testing. A second receiver can offer additional information where its common dependencies are characterised, but mere duplication of software pipelines against the same damaged input is not independent observation of the original event.

Predicted spur amplitude should carry uncertainty from the actual coefficient mapping, accumulator state, interpolation table, finite output arithmetic and analogue conversion where relevant. A deterministic fixed-point replay may predict a precise sequence under exact digital inputs, while the original analogue stimulus remains uncertain. The final report should not collapse those distinct uncertainty sources into one small frequency-bin error bar. It may establish that an internal processing mechanism is capable of generating the observed feature under stated conditions; it does not establish exclusive causation unless competing pathways were appropriately challenged. If withheld trials fail, the model should be revised or the claim narrowed, with the original failure preserved in the validation record.

A forensic conclusion ought to be stronger than an anecdote about a clean display. It should identify the tested mechanism, the challenge design and the boundaries of inference. I pass the floor to Sir Ronald Fisher, who may examine what it means to calculate a false-alarm rate

Copyright 2026, James M. Atkinson

across the many candidate arithmetic mechanisms an engineer could imagine.

Sir Ronald Aylmer Fisher | Peer question 6 to William Ralph Bennett

Dr Bennett, a modern receiver may contain several numerically controlled oscillators, multiple channeliser filters, adaptive thresholds and thousands of floating-point or integer operations. The number of possible spur hypotheses is correspondingly large. If the investigator finds one candidate line and tests many possible internal frequency relations, the event of obtaining some close numerical fit may be far more probable than the reported single-model significance suggests. How should one organise the comparison so that a plausible internal-artefact explanation neither becomes a convenient excuse for ignoring a real transmitter nor gains unwarranted certainty from an unrestricted hypothesis search? Would you require a familywise error procedure, an independent predictive challenge, or an evidential ranking that retains more than one plausible cause? And what should the report say when the receiver's exact firmware build cannot be recovered for bit-exact replication?

Would you also require an explicit account of how many candidate error mechanisms were tried before the preferred explanation was selected, lest the precision of the fitted hypothesis be mistaken for the strength of a prespecified test?

William Ralph Bennett | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, an unrestricted search for numerically convenient relations cannot be interpreted as though one predetermined

Copyright 2026, James M. Atkinson

hypothesis had been tested. The investigation should retain its search history, including the candidate mechanisms considered, the parameters varied and the criteria for accepting a match. A familywise calculation may be possible for a carefully specified finite hypothesis family, but the dependence between tests may make naive multiplication of single-test probabilities inaccurate. When the candidate mechanisms are exploratory, an independent challenge under new conditions is often more persuasive than a retrospective probability assigned to the best-looking fit.

I would classify candidate explanations by falsifiable predictions. A phase-truncation mechanism may predict changes when accumulator width, table address width or tuning word is altered. A filter limit cycle may predict persistence under digital zero after a specific state history and disappearance under an identified reset. An external carrier hypothesis may predict coupling changes at the antenna and persistence in absolute RF coordinates when internal sample-rate relationships change. Some outcomes may support several explanations, so the report should retain that ambiguity rather than choose the most convenient cause. A hypothesis is strengthened by surviving interventions at which its rivals differ, not by being capable of fitting one historical spectrum.

Where the exact firmware build is unavailable, a proposed bit-exact explanation cannot be presented as verified for that historical capture. The engineer may demonstrate that a related implementation is capable of generating a similar line, but should identify this as a plausibility demonstration. Recovering coefficient

Copyright 2026, James M. Atkinson

sets, binaries, device configuration and the raw sample interval may permit stronger reconstruction. Without them, numerical resemblance remains limited evidence. This can be important in litigation, where the party reading the report must distinguish a proven implementation defect from a speculative explanation offered after the fact.

The practical answer is a layered conclusion. Document what was measured; list the candidate internal and external mechanisms; identify which proposed challenge tests were possible; state the results and any unresolved alternatives; and do not quantify certainty more precisely than the trial design permits. The purpose is neither to exonerate every receiver nor to accuse every bright spectral line of being an artefact. It is to make cause assignment a tested scientific proposition. I return the floor to Professor Tukey for the final concern: how should the analyst present these results without allowing display scaling and exploratory choices to masquerade as independent confirmation?

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 5: Exploratory graphics, computational reproducibility and the obligation to test the artefact hypothesis

Dr. Atkinson, the final difficulty is not exclusively numerical. It concerns the manner in which a calculated spectrum becomes a story about the world. A frequency display is a transformation of a sequence whose origin, limitations and processing history may be partly invisible to its reader. The investigator can enlarge a narrow band until a low-level spur looks imposing, change the ordinate from amplitude to power, average for longer, select a particular analysis window or alter the apparent baseline. Each choice may be defensible for a particular analytical purpose. None converts a signal-correlated computational error into an independently observed transmitter. If the analyst has adjusted these choices while searching for an attractive pattern, the resulting picture cannot be appraised as though it arose from one prespecified procedure. [T4, T9]

I would begin with a distinction between exploratory and confirmatory work. Exploration may inspect many spectra, tuning words and precision settings to discover plausible explanations. Its product is a set of hypotheses, not a proof of any one. Confirmation requires a fresh challenge with declared test conditions and acceptance criteria, including records from which a material failure would not have been edited away. A numerical oscillator artefact has the useful property that its frequency may be predicted by implementation details. The observation that a line moves with an NCO tuning-word change while the external RF stimulus remains fixed can discriminate explanations, but only if the experiment is designed to test those alternatives. The source's predicted physical movement and the

Copyright 2026, James M. Atkinson

processing line's predicted digital movement must be made explicit before the test is performed.

The first record I would preserve is the smallest complete description of the computation sufficient to reproduce a disputed display. That includes source sample hashes, signedness, word sizes, coefficient values, update schedules, arithmetic modes, overflow semantics and digital filter state. It includes the choice of FFT length, window, amplitude calibration, averaging, threshold, scaling and any frequency-axis correction. If the chain contains a proprietary block that cannot be inspected, the report should identify the unverified boundary and use independent input-output challenge measurements instead of pretending to possess a bit-exact implementation. An independent implementation must reproduce the calculation that was actually carried out, not one the designer now prefers. Where the software version or arithmetic configuration changed between acquisition and analysis, both versions should be preserved.

This record can be compact. One need not expose every transient register bit in a high-speed processor to make the reasoning reproducible. Yet a saved display alone is rarely enough for a quantitative forensic inference. The display may omit negative-frequency conventions, the coherent gain of its analysis window or the clipping that occurred before the FFT. A real line whose amplitude was understated by a window correction may be consequential; a processing line that survived excessive averaging may appear especially persuasive. A program that calculates a technically correct plot from incomplete source metadata can provide a convincing answer to the wrong question. The analyst should therefore separate

Copyright 2026, James M. Atkinson

computational reproducibility from physical validity, and both from the probability of an identified external source.

Consider a receiver whose NCO tuning word is held fixed for thirty seconds. At one configuration a line at a particular analysis-bin offset appears repeatedly. The scientist then changes the tuning word while preserving the RF generator frequency. Suppose the line follows a phase-truncation prediction through three deliberately selected words, while a known injected test carrier remains at the physical frequency expected after digital conversion. The evidence supports the explanation that the moving line is generated in the numerical processing path, within the tested envelope. It does not establish that every other line is external or that the NCO is the sole internal defect. A second digitally generated spur could coexist; an analogue oscillator could drift as temperature changes; or the changed word could expose a different alias. Scientific restraint should remain proportional to what the intervention distinguished.

I would also question the practice of reporting the best achieved spur-free dynamic range from a set of unreported trials. If the operator changes scaling, input level, spectrum window and clock configuration until the noise floor appears lowest, the selected result is not a random example of normal operation. The procedure may be adequate as a demonstration of an achievable state, provided it is labelled accordingly. It is inadequate to certify routine detection at that performance without recording the selection process. A robust validation ought to report the distribution across a prespecified set of frequencies, signal strengths, tuning words and environmental states, including excluded intervals and failures. Even a

Copyright 2026, James M. Atkinson

limited experiment can be rigorous if its operating envelope and testing procedure are clear.

I propose that the publication include a counterfactual question beside every substantive spectral assertion: What observable would differ if the indicated feature came from finite arithmetic rather than the antenna? If both hypotheses predict the same screenshot, the screenshot does not distinguish them. A change in NCO precision, a reset of an IIR state, a controlled RF path substitution or a direct raw-sample reprocessing pass may create useful alternatives. The intervention must be selected for diagnostic power rather than theatre. The best test is not always the most elaborate. It is the test whose predicted results are materially different under competing explanations, and whose history is available for independent criticism.

The resulting report should carry a matrix linking each finding to raw inputs, transformations, calibration records, uncertainty and counterfactual checks. A compact figure may show the same disputed interval under several bit-exact algorithms, but the numbers and method used to create it must accompany the figure. Significant negative or discordant results must not disappear into a celebratory summary. When it is impossible to exclude one internal artefact, the report should say that the observation remains compatible with it. That statement can coexist with useful operational recommendations to repeat the survey using another signal path or to preserve additional raw data at the next encounter. Dr Shannon, I respectfully pass the token to you for a question about whether these multiple representations genuinely add information.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Peer question 7 to John Wilder Tukey

Professor Tukey, your recommendation to compare several spectral representations might improve the clarity of a report, but could it also create a false impression of independent confirmation? Imagine that the investigator takes one finite digital record, computes a power spectrum with two window functions, applies two rounding rules, and obtains four similar peaks. The resulting report calls this fourfold agreement. Yet every representation is determined by substantially the same original sample record, while each may have inherited an earlier clipping event, analogue noise contribution or incomplete sampling interval. Furthermore, the analyst may have preserved only those algorithms whose peaks aligned closely. What exact information has been added by this exercise, and under what circumstances can comparing derived records genuinely constrain the hypothesis of a numerical artefact? How should the investigator differentiate an improvement in computational diagnosis from an increase in independent evidence concerning the external source? Finally, how do you prevent the familiar authority of a mathematically elegant transform from masking the basic inability to reconstruct the analogue information that was never sampled?

John Wilder Tukey | Immediate answer to Claude Elwood Shannon

Dr Shannon, a deterministic transformation of a fixed record cannot create information about the original analogue event that the record does not contain. The several plots in your example are not four independent antenna observations. They are four interpretations or views of one evidential object. Their agreement can be useful for

Copyright 2026, James M. Atkinson

identifying whether a particular numerical conclusion depends upon one arbitrary representation, but it cannot independently verify the upstream acquisition boundary. I would therefore distinguish **robustness to analysis choices** from **corroboration by an independent observation**. The first is a property of the analytic procedure; the second requires a further physical measurement with a declared relationship to the original.

Changing numerical precision or rounding can supply diagnostic evidence because competing implementation models predict different outcomes when the same raw data are processed differently. Suppose a line arises from a particular fixed-point multiplier overflow in the original receiver. A bit-exact reproduction of that overflow may generate the same feature; a deliberately widened accumulator may suppress it. This supports a specific computational account, provided the assumed implementation actually matches the installed device. It does not imply that the input contained no external energy at that frequency, because the original analogue signal might have contained a coincident component. An independent raw capture with a changed analogue front end or a changed sampling architecture can test that further proposition, provided its clock and transfer dependencies are characterised.

The multiple-comparison problem is also real. Four displays selected from hundreds of candidate renderings should not be described as though they were four predeclared trials. The analyst ought to preserve the exploration log or, at minimum, disclose the number and classes of alternatives considered before reaching the

Copyright 2026, James M. Atkinson

conclusion. A validation set withheld from the exploratory process can test whether a proposed diagnostic rule continues to discriminate genuine injected emissions from synthetic arithmetic spurs. Randomising the injection schedule and using blinded labels are useful where practical. Where no new physical observation is available, the report should confine itself to a statement about reproducibility and computational sensitivity.

I would require one small table in the final evidential record. Its columns would identify the claim, raw source, transformation, predicted behaviour under an external-emission hypothesis, predicted behaviour under a computational-artefact hypothesis, the observed result and the remaining dependencies. Four matching plots may occupy four rows if their transformations differ, but the source column will reveal that they share the same digital input. If a source channel clipped, every row remains conditioned on that clipping. The fact that a wide-precision reprocessing path produces a cleaner picture is important engineering evidence. It is not restoration of values that the ADC never recorded.

Finally, I would allow the investigator to be decisive within an appropriately restricted claim. If the experimental record demonstrates that a particular low-level line tracks an NCO tuning word and vanishes under a precision change while an injected physical reference remains in place, the analyst may reasonably attribute that tested line to the digital processing mechanism, subject to the tested conditions. There is no virtue in endless hedging when the evidence genuinely discriminates causes. Equally, there is no

Copyright 2026, James M. Atkinson

virtue in calling that restricted finding proof of universal absence of concealed transmitters. I return the floor to Dr. Atkinson for the worked applications and the concluding statement of what this roundtable has and has not established.

Worked engineering applications and independent calculations

Richard Wesley Hamming, Cross-Peer Question to Hendrik Wade Bode: Dr Bode, can a numerically stable filter prototype become unstable after its coefficients have been rounded for a fixed-point implementation?

Hendrik Wade Bode, Cross-Peer Answer to Richard Wesley Hamming: Dr Hamming, yes. Pole locations depend on implemented coefficients and numerical realisation, particularly for high-order sections with poles near the unit circle. A direct-form implementation may be more sensitive than a well-scaled cascade of second-order sections. Test coefficient quantisation in the actual arithmetic format and inspect the resulting pole locations, impulse response, limit cycles and overflow behaviour under expected operating temperatures and signal amplitudes. A simulated response using ideal double precision is not evidence of the deployed fixed-point response. Apply both zero-input and bounded high-level stimuli, and retain the exact coefficient tables and software build. The causal conclusion must distinguish analogue oscillation from an arithmetic limit cycle generated after conversion. I pass the token to Professor Wiener for the feedback-state problem.

Hendrik Wade Bode, Cross-Peer Question to Norbert Wiener: Professor Wiener, why might a persistent digital tone remain after the physical antenna has been disconnected and the input is terminated?

Copyright 2026, James M. Atkinson

Norbert Wiener, Cross-Peer Answer to Hendrik Wade Bode: Dr Bode, an internal feedback or quantisation cycle may persist when the arithmetic state maps repeatedly through a finite set of representable values. Phase accumulators, resonators and recursive filters can produce periodic errors that are not stationary external RF emissions. Challenge the system with known zero input, different internal initial states, rounding modes and coefficient resolutions. Restarting firmware or changing a tuning word may shift the line in a diagnostic pattern. Preserve both the raw ADC codes and the downstream filter output; if the line exists only in the processed stream, its apparent environmental provenance is weakened. A robust finding requires an instrument-independent receiver path or a calibrated injected source response at the analogue reference plane. I yield to Dr Bennett regarding periodic errors from oscillators.

Norbert Wiener, Cross-Peer Question to William Ralph Bennett: Dr Bennett, a DDS has a thirty-two-bit phase accumulator but uses only its twelve most significant phase bits for the lookup table. Why can a sharp spur appear despite exceptionally fine tuning resolution?

William Ralph Bennett, Cross-Peer Answer to Norbert Wiener: Professor Wiener, tuning-step resolution and waveform purity are different specifications. Discarding the low phase bits creates a periodic phase approximation error for many tuning words; periodic error produces discrete spectral artefacts. The output DAC contributes further quantisation and nonlinearity, and particular tuning words may behave differently. Change the frequency tuning word, output amplitude and phase truncation settings where available, recording whether suspect lines move with the internally generated clock. A spur should not be classified as an external

Copyright 2026, James M. Atkinson

transmission merely because it is narrow and coherent on one display. Measure the phase-noise pedestal and individual spurs separately, and record the full digital configuration that allows another laboratory to reproduce the behaviour. I respectfully pass the token to Professor Tukey to examine the evidential record.

William Ralph Bennett, Cross-Peer Question to John Wilder Tukey: Professor Tukey, what evidence is required before one claims that a tiny spectral feature is an emitter rather than a finite-arithmetic artefact introduced by processing?

John Wilder Tukey, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, retain a common raw sample segment and reconstruct it through independently implemented software at more than one numerical precision. If the line shifts or disappears with arithmetic precision, coefficient scaling, block boundaries or oscillator tuning words, the processing chain becomes a live causal hypothesis. Repeat with a terminated input and known calibration tones, and compare with an independent analogue measurement chain not sharing the numerical implementation. Inspect all candidates rather than presenting only the most favourable display. The conclusion should state what was observed, the transformations performed, the configuration under which the feature appeared and the competing internal mechanisms still plausible. A visual peak alone cannot uniquely identify a transmitter. I return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Distinguished colleagues, the discussion has established that finite word length is not merely a matter of fewer numerical digits. It can change the realised behaviour of a digital oscillator, filter, detector or phase estimator

Copyright 2026, James M. Atkinson

in ways that are physically consequential to a technical surveillance countermeasures inquiry. The operator may see a stable line whose frequency is known to many decimal places and whose repeatability suggests an external transmitter. Yet a similar line may be generated by a deterministic digital phase truncation, accumulator overflow, fixed-point rounding pattern or persistent recursive state. The confidence of the graphic is not the confidence of the inference. Our task is to preserve the distinction between an exact calculation, a reproducible implementation and a validated claim about the electromagnetic world.

Mr Hamming has explained why programming resolution and physical accuracy must not be conflated. A long phase accumulator permits extremely fine digital frequency steps under its nominal clock. That is an arithmetic property, not a certificate that the clock is accurate, that a lookup table introduces no periodic error or that the analogue receiver's reference plane is faithfully calibrated. The number of bits becomes informative only when attached to a precisely specified computation. A report that cites a thirty-two-bit NCO without identifying its phase-to-amplitude mapping, tuning words and clock uncertainty has described an inventory item rather than a bounded measurement capability.

Professor Bode has shown that the coefficients actually stored in hardware, rather than the ideal coefficients printed in a design report, determine the implemented linear model. He has also shown that the quantiser, accumulator and saturation rules may move the actual process outside that linear model. A coefficient that approaches unity can be rounded to unity; a transient can invoke an overflow mechanism; and a design meant to produce decaying behaviour can retain a persistent state.

Copyright 2026, James M. Atkinson

Neither simulation with double precision nor an unqualified stability statement can settle those questions. The laboratory must inspect or reproduce the actual arithmetic path and test the operating states relevant to the claim.

Professor Wiener has reminded us that adaptation and memory can defeat the naïve inference that a persistent indication means a persistent external event. A detection display may retain an internal state when its input is absent. Resetting or changing filter coefficients can diagnose the phenomenon, but if the only available record is the state after correction, the observation's origin may remain underdetermined. Hence a proper forensic archive contains sufficient raw acquisition, processing versions and state changes to challenge the temporal interpretation. A countermeasure which removes a nuisance tone is useful engineering; it is not by itself proof of the tone's past physical origin.

Dr Bennett has distinguished an arithmetic-noise model from deterministic signal-correlated error. An independent white-noise approximation can be helpful under specified conditions, but cannot be elevated to an unconditional property of every fixed-point sequence. The laboratory must test deliberately chosen tuning words, frequencies, amplitudes and arithmetic boundary conditions, including values likely to produce repeatable error. A noise-floor statistic may not reveal a weak coherent spur; conversely an exceptionally sharp spur may reflect a digital mechanism rather than an exceptionally stable transmitter. The observed spectral geometry can be precise while its causal interpretation is wrong.

Professor Tukey has returned these technical findings to the discipline of accountable scientific reporting. A series of spectra derived from one

Copyright 2026, James M. Atkinson

retained record does not create a series of independent measurements. Multiple renderings can expose dependence upon one window or rounding choice, but they cannot recover clipped analogue amplitudes or time intervals that were never recorded. Exploratory choice must be distinguished from confirmation. Where the investigator has selected a favourable display after testing many options, the selection history matters to the evidential weight assigned to the result. A withheld challenge, controlled injection or receiver-path substitution can improve the scientific claim only where its predicted outcomes discriminate alternative explanations.

The ten applications provide controlled illustrations of these boundaries. A thirty-two-bit phase accumulator at 100 MHz permits a nominal frequency step of about 0.0233 Hz; a ten-parts-per-million clock contribution at 10 MHz is about 100 Hz. A twelve-bit sine-table address does not magically preserve all thirty-two accumulator bits in the amplitude mapping. A sixty-four-tap FIR can accumulate a worst-case coefficient error bound far larger than one coefficient's rounding step. A signed sixteen-bit accumulator may wrap catastrophically rather than saturate gently. A quantised first-order recursion can retain a nonzero zero-input state, and rounding a stable pole to unity can remove the designed decay. Each result belongs to its assumptions and chosen numeric representation. None is a calibration measurement of a particular field receiver.

For practice, the panel's conclusion is that the evidence register should identify the original acquisition boundary, exact software and arithmetic configuration, relevant clock state, test inputs, coefficient bytes, processing changes and uncertainty of any correction. The examiner should preserve

Copyright 2026, James M. Atkinson

the before-and-after results where material, explicitly record invalid or missing intervals, and challenge suspected artefacts with interventions selected to distinguish them from external emissions. A validated restricted finding is preferable to an untestable sweeping assurance. We shall not require perfect numerical representation as a prerequisite for useful investigation; neither shall we permit an engineering calculation to claim more physical knowledge than the original measurement can bear. The next question will examine whether a processing chain preserves the minimum events and temporal structure required for reliable detection. I thank our colleagues for their careful disagreement and formally pass the floor onward.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 038

Application 1: Frequency resolution of a 32-bit phase accumulator

Let the sample clock be F_s = 100,000,000 samples per second, and let W = 32 denote the accumulator width in bits. The smallest commanded frequency increment of an ideal conventional NCO is $\Delta f = F_s/2^W$. Substituting gives 100,000,000/4,294,967,296 = 0.02328306436538696 Hz. This number is a digital tuning increment, not a measure of absolute output accuracy. It assumes a stable ideal clock and the conventional phase-update rule. The true carrier frequency still depends upon the clock's calibration, phase noise and the implementation's exact arithmetic. A displayed tuning resolution of approximately 23 millihertz does not certify 23-millihertz physical frequency accuracy. [T1, T2]

Application 2: Frequency error from rounding a tuning word

Let F_s = 100 MHz, W = 32 and desired f_d = 10 MHz. The tuning word is $K = \mathrm{round}(f_d\, 2^W/F_s)$ = round(429,496,729.6) = 429,496,730. The realised mathematical output is $f_o = K\, F_s/2^W$ = 10,000,000.009313225746 Hz, approximately 0.009313 Hz above the requested value. Here the result follows the ideal NCO model and is not a measurement of a particular oscillator. A receiver may exhibit larger physical errors because of reference-clock uncertainty and system calibration. The investigator should retain both the requested frequency and the exact integer tuning word used during the acquisition.

A version-controlled configuration log should store K as an integer rather than relying exclusively upon a rounded human-readable

Copyright 2026, James M. Atkinson

frequency, because a later reconstruction needs the exact arithmetic command.

Application 3: Clock accuracy versus frequency programming precision

Suppose the 100 MHz clock carries an uncertainty or error of 10 parts per million, and the commanded NCO output is near 10 MHz. The corresponding frequency error magnitude from this assumed clock error is approximately 10,000,000 times 10/1,000,000 = 100 Hz, vastly larger than the 0.0233 Hz accumulator step. If the clock uncertainty is specified as an expanded uncertainty rather than a guaranteed error, the result must be described as the corresponding expanded output contribution under the stated linear model. It is incorrect to add quantities without first distinguishing calibration bias, stochastic stability and the frequency interval to which the clock claim applies. [T1]

Application 4: Phase-table truncation and discarded state bits

Let W = 32 be the accumulator width and P = 12 the number of high-order phase bits addressing a sine table. The table uses 2^P = 4,096 nominal phase positions, while W-P = 20 accumulator bits are not directly represented by the table address. The numerical count of discarded low-order phase states is therefore 2^20 = 1,048,576 per table-address interval. This establishes the address granularity and periodic structure available to the implementation, not a universal spur amplitude or a formula for all spur frequencies. Actual spurs depend on the tuning word, lookup representation, interpolation, dither and subsequent arithmetic. [T2, T3]

Application 5: A conservative FIR coefficient-quantisation bound

Copyright 2026, James M. Atkinson

Consider a 64-tap FIR with exact coefficients h[k] individually rounded to the nearest multiple of q = 2^-12. For each coefficient, absolute error is at most q/2 = 0.0001220703125, provided ordinary round-to-nearest is used and there is no overflow. If the input samples satisfy |x[k]| <= 1, the worst-case absolute output error due solely to coefficient rounding is bounded by the sum of the coefficient-error magnitudes: 64(q/2) = 0.0078125 in normalised output units. This is an intentionally loose worst-case bound, corresponding to about -42.14 dB relative to unity amplitude. It is not a stochastic rms prediction, and it does not include accumulator rounding, input quantisation or filter-state errors. [T4]

Application 6: Headroom from the absolute coefficient sum

Suppose an eight-tap FIR has coefficients whose absolute magnitudes sum to 1.25, with input samples bounded by an absolute normalised amplitude of 1. The triangle inequality then gives |y[n]| <= 1.25 under exact arithmetic. A fixed-point output format that can represent magnitudes strictly below 1 may therefore saturate or wrap under some input combinations unless scaling, saturation control or wider accumulation is provided. The bound does not imply that every input reaches 1.25, nor that it does so under typical noise. It establishes an allowed worst case to be checked when certifying headroom. An implementation's actual coefficient signs and reachable input sequences affect attainability. [T4, T5]

Application 7: Two's-complement overflow discontinuity

Consider signed 16-bit two's-complement arithmetic with representable integer range -32,768 to 32,767. If an intermediate sum of

Copyright 2026, James M. Atkinson

32,760 + 20 = 32,780 is formed and wraps modulo 2^16 rather than saturating, the represented signed result becomes 32,780 - 65,536 = -32,756. The output has jumped by 65,536 integer counts relative to the unwrapped mathematical sum. Such a discontinuity can inject broadband components and periodic artefacts under repeating stimuli. A different implementation may saturate at 32,767, so the arithmetic mode must be identified before claiming any particular spectral consequence. [T4]

The apparent waveform event occurs inside the calculation; the presence of that event alone supplies no evidence of an equally abrupt voltage change at the analogue input.

Application 8: A quantised first-order recursion that retains a nonzero state

Let the intended recursion be y[n] = Q(0.9 y[n-1]), where Q rounds to the nearest multiple of q = 1/16 = 0.0625. Starting with y[0] = 0.0625, the next unquantised value is 0.9 times 0.0625 = 0.05625. Its nearest q-multiple is 0.0625, so y[1] = y[0]. The same calculation repeats indefinitely in this idealised arithmetic model, producing a persistent nonzero state despite zero input. This is an illustrative zero-input limit cycle, not a prediction about every IIR filter. Rounding ties, noise, saturation and coefficient implementation can change the reachable states. [T4, T5]

A calibrated zero-input challenge and an explicit state-reset test can help distinguish this computational persistence from the duration of a genuine input transient.

Application 9: Coefficient rounding changes an ideal stable pole

Copyright 2026, James M. Atkinson

Let a first-order ideal recursion be y[n] = a y[n-1] with a = 0.9990. Its pole magnitude is below 1, so in exact arithmetic the unforced state decays. Suppose a is stored using an eight-fractional-bit representation with q = 1/256 = 0.00390625 and rounding to nearest, and the format can represent 1 exactly. The nearest representable value to 0.9990 is 1.0000, so the implemented recursion has coefficient a_q = 1. Its unforced state no longer decays in exact arithmetic. This demonstration relies upon the chosen coefficient format; a fractional-only format whose maximum is below one could produce a different result. A stability certificate should therefore be based upon the actual stored coefficients and arithmetic behaviour rather than the ideal real-valued design. [T4]

Application 10: Separating tuning-word precision from clock-induced offset

Suppose a receiver's digital local oscillator is commanded to 12.5 MHz and uses an ideal F_s reference subject to a relative clock error of 2 parts per million. In the linear frequency-scaling model the corresponding output error is 12,500,000 times 2/1,000,000 = 25 Hz. If the accumulator is 32 bits wide and clocked near 100 MHz, its tuning increment is approximately 0.0233 Hz; thus the clock-error contribution is over one thousand times the tuning step. A very narrow plotted line can still be tens of hertz away from its nominal physical frequency. Clock calibration, not the number of accumulator bits, determines how much confidence the examiner should place in the displayed absolute frequency.

QUESTION 039

Copyright 2026, James M. Atkinson

Which apparent transient features can be created by sample-rate conversion?

Source: V011_Roundtable_Question_039_CP039_Dr_Atkinson(1).docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 039. Complete scholarly discussion

Newly authored educational reconstruction. This is a newly constructed scholarly dialogue and not a historical transcript. No historical quotations are attributed to the named participants, and hypothetical numerical examples do not certify instruments.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, our examination of finite arithmetic has shown that a signal-processing chain may generate persistent features whose apparent precision derives from computation rather than from any external electromagnetic emission. We now turn to the corresponding question in time. An intermittent burst, abrupt carrier onset or short impulse may be shifted, broadened, attenuated, duplicated or accompanied by ringing when its sample sequence is converted from one digital rate to another. The analyst who first sees the converted trace may infer that the signal switched on before the recorded trigger, that several emissions occurred in rapid succession, or that the source remained active after its actual input vanished. Those interpretations may be sound under an appropriate acquisition model. They may also be artefacts of filter support, mathematical boundary assumptions, block processing or timestamp assignment. We must identify the observations needed to distinguish these possibilities

Copyright 2026, James M. Atkinson

before allowing a converted trace to speak as though it were the unprocessed physical event.

Let F_in be the input sample rate, L and M be relatively prime positive integer interpolation and decimation factors, and F_out = F_in L/M be the nominal output sample rate. A conventional rational resampler conceptually inserts L-1 zero samples between original values, applies an appropriate low-pass interpolation and anti-alias filter, then retains every Mth filtered value. Efficient polyphase implementations avoid most explicit zero operations, but the physical interpretation remains conditional on filter design, phase alignment and correct scaling. The resulting output samples are not additional independent analogue observations. They are computed functions of the acquired sequence. Their frequency support may be restricted, and their apparent temporal profile is influenced by the filter's impulse response. An estimator may improve the utility of a record without restoring information rejected by earlier sampling, clipping or filtering stages.

The choice of mathematical method deserves particular attention. A frequency-domain resampler that shortens or pads an FFT may effectively treat the finite input as periodic. An abrupt discontinuity between the record's end and beginning can then influence the computed output through ringing or apparent pre-event energy. A polyphase FIR method may instead depend upon explicit padding assumptions, such as zero continuation, line continuation or repeated endpoint values. Those choices can produce different apparent waveforms near the boundaries of a finite record, even when both methods agree well in its interior. The differences are not necessarily software defects. They represent distinct extrapolations

Copyright 2026, James M. Atkinson

of information outside the captured interval, and forensic interpretation must not promote an arbitrary extension convention into a measurement of the original transmitter. The official SciPy descriptions make these assumptions explicit. [S1, S2]

A second difficulty concerns time origin. Linear-phase FIR filters can introduce group delay, while a polyphase implementation may compensate, trim or shift output samples according to its internal conventions. The apparent first event sample in a derived file may therefore be located at a different numerical index from the first event sample in the original acquisition, even though its physical reference time is meant to remain invariant. If the analysis uses more than one receiver, an uncorrected delay of only a few samples can corrupt a time-difference or phase-coherence assertion. The investigator should preserve the input epoch, filter coefficients, initial phase, boundary policy, software version and input-to-output timestamp mapping. A label placed on an output sample is not itself evidence of the instant at which the antenna observed the originating field.

There are also questions of alias rejection and temporal resolution. A narrowband output with excellent noise performance may be unsuitable for reconstructing a microsecond pulse whose essential spectral content lies outside the retained band. Its filter can suppress the original sharp edge and create a smoother, longer apparent event. A digital detector may register two threshold crossings for one physical pulse because the filtered impulse response oscillates about the threshold. Conversely, two physical pulses separated by a short interval may merge into one broad output maximum. The problem is not solved by simply printing more decimal places on the output timestamp. It requires a validated event-transfer

Copyright 2026, James M. Atkinson

characteristic, with the detection statistic and threshold included in the test. The correct question is how a prescribed class of physical inputs maps to declared derived measurements, and which competing inputs remain observationally indistinguishable.

I ask the principal contributors to separate three propositions. First, whether a given resampling algorithm is computationally reproducible from its archived inputs. Second, whether its output preserves an identified physical quantity within a validated uncertainty envelope. Third, whether a detected transient can be attributed to an external emitter rather than to the source receiver or processing chain. These propositions require different evidence. An exact re-execution of the software may verify the first but not the third. A calibrated laboratory impulse may support the second for a specified waveform class while leaving an unusual field burst unresolved. An independent receiver substitution or physical input perturbation may add useful causal evidence, provided the paths are sufficiently different and their common dependencies are disclosed.

Dr Shannon shall begin with the information lost by noninvertible filtering, Professor Slepian shall address finite time-frequency concentration, Dr Wiener shall examine adaptive state and ringing, Dr Tukey shall question event selection and repeated detections, and Dr Hamming shall consider numerical phase alignment and implementation fidelity. Seven peers will challenge these propositions through immediate replies. We must then develop ten worked applications distinguishing output sample spacing from actual event timing, amplitude scaling from waveform restoration, and a visually impressive transient from a defensible forensic claim. Dr Shannon, may I invite your opening account of which properties can be preserved by

Copyright 2026, James M. Atkinson

resampling and which become irretrievable after frequency support has been discarded?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 1: Interpolation, sufficient representation and noninvertibility

Dr. Atkinson, a resampler can be an excellent instrument of analysis without being a second physical receiver. A rate-converted sequence is calculated from the originally acquired data according to a specified transformation. When that transformation is one-to-one on the relevant class of signals, a mathematically faithful change of representation may preserve the quantities that class can support. When the transformation discards frequency components, however, two distinct input sequences may yield the same output. The distinction cannot be settled by noting that the output has more samples than the input. Interpolation generates additional numerical values according to assumptions about the signal's bandwidth and continuity. It does not interrogate the antenna at additional historical instants. A later analyst cannot force a lost out-of-band transient to reappear by increasing the number of output time labels.

The practical requirement begins with the signal class. A real, properly sampled waveform satisfying a stipulated band limit may be reconstructed in an ideal mathematical model from samples taken at a suitable rate. A new uniform grid can then represent the same underlying function. But a real acquisition has finite duration, noisy time stamps, an analogue transfer function and possible nonlinearity. The digital input may already have lost information through overload, aliasing or incomplete observation exposure. The resampler inherits those limitations. It can faithfully calculate one model's implied values while giving the false impression that they are direct voltage measurements. For forensic work, a report should specify whether a printed derived amplitude is an interpolation, a filtered estimate, or an

Copyright 2026, James M. Atkinson

independently sampled physical quantity. These distinctions affect the testimony an examiner can defend.

Consider a single sharp pulse. A filter with limited bandwidth cannot reproduce an ideal instantaneous edge. Its output is the convolution of the input with an impulse response; side lobes may place nonzero computed values before or after the main peak according to filter phase and finite-record boundary assumptions. A thresholded detector may interpret those lobes as precursors or repeated events. It is inappropriate to infer several transmitted impulses solely from their presence in the derived trace. One must compare the alleged features with the expected response to a single injected pulse whose amplitude, duration and timing are known at the relevant physical reference plane. The challenge should include pulses near the beginning and end of processing blocks because the extrapolation convention can have a substantial effect there. The retained raw samples can then establish which features were already present before rate conversion.

The distinction between preserving information and improving a decision is equally important. A well-designed low-pass resampler may reduce unwanted high-frequency noise and improve an estimator of a narrowband carrier. The filtered trace may be more useful for an operator seeking that carrier, but the transformation has not created new information about an external source that was absent from the original samples. It may also discard information useful for another question, such as whether an adjacent strong emission caused analogue intermodulation. A claim that the new file is 'higher resolution' must specify whether the term refers to output sample spacing, estimator variance, bandwidth or temporal localisation.

Copyright 2026, James M. Atkinson

Increasing the number of stored points while narrowing their frequency support can improve one quantity and degrade another. The engineer should state the tradeoff rather than offer a universal improvement.

Absolute timing requires a separate analysis. The source epoch, sampling-clock relationship and filter delay determine how derived sample indices map to physical instants. An implementation that compensates for a group delay may return a trace whose main peak appears aligned with the input, while a different edge-padding method produces precursor or terminal distortions. The fact that a library function returns an evenly spaced output coordinate is not evidence that the original event occurred at each of those interpolated times. It supplies a mathematical grid. For a multisite capture, any delay correction should be supported by measured reference signals or a validated transfer model, with uncertainty propagated into the time-difference calculation. An unverified adjustment of one sample can be consequential when localisation depends on microsecond or nanosecond distinctions.

An ideal reconstruction theorem also does not establish the physical identity of a source. If two transmitters, a receiver-generated mixer product, or an internal numerical spur all contribute to the acquired samples, a resampler operates on their aggregate. It cannot infer which component is external merely because its phase or amplitude becomes easier to inspect. The analyst needs interventions under which rival hypotheses predict different outcomes: altered front-end attenuation, antenna coupling, sampling configuration or independent receiver paths. These challenges should be performed without silently changing the detection rule after

Copyright 2026, James M. Atkinson

seeing the result. Otherwise the apparent agreement reflects a selected analysis rather than a tested physical account.

I would preserve the exact raw sample file or a proportionate unprocessed interval, the rate ratio, interpolation-filter coefficients, phase convention, initial conditions, padding rule, software build and any detected missing input buffers. The report should distinguish a mathematically reconstructed sample from a measured one, and identify the signal classes for which reconstruction error has been bounded. A narrow claim may be made confidently where the chain has been challenged and the uncertainty is adequate for the intended use. An assertion about an unobserved transmitter's precisely timed emission cannot rest solely upon a converted waveform that the apparatus could also have created through boundary assumptions. The finite record is evidence. The reconstruction is its conditional interpretation. I pass the floor to Professor Slepian for the temporal and spectral compromises that appear when a pulse is too short for the chosen observation window.

Harold Stephen Black | Peer question 1 to Claude Elwood Shannon

Dr Shannon, your distinction between the original sequence and a derived trace becomes especially troubling in a receiver whose processing choices are governed by the event itself. A short transient may raise the estimated noise floor, trigger a narrower filter, and cause the apparatus to retain a resampled output whose beginning precedes the nominal trigger because the filter uses buffered samples. An operator examining that output may describe the apparent precursor as an independent emission that warned of the subsequent burst. How would you require the laboratory to establish whether the precursor

Copyright 2026, James M. Atkinson

existed at the original analogue input? Is a comparison against one raw trace sufficient, or must the experiment repeat pulses at several phases relative to the block boundary and under several adaptation states? I also ask how the record should distinguish a deliberately constructed pre-trigger buffer from an acausal-looking mathematical filter, particularly when the implementation is capable of zero-phase processing only after an entire block has been acquired.

Claude Elwood Shannon | Immediate answer to Harold Stephen Black

Thank you for that question. Mr Black, the temporal ordering of the computed output must not be confused with the time at which the algorithm became able to compute it. A blockwise or forward-backward procedure can assign an output value to an earlier time index while using samples acquired later. This can be a legitimate method of estimating a historical waveform; it is not evidence that the receiver possessed foreknowledge of the event or that an earlier physical precursor existed. The report should name the operation and its data dependence, including the interval of input samples contributing to each output. A pre-trigger buffer, by contrast, contains raw samples genuinely acquired before a trigger decision, provided the clock and buffer continuity record support the assigned times. Those are materially different provenance claims despite superficial similarity on a screen.

An acceptance campaign should capture the raw input and the derived output from the same controlled stimulus, including the detection rule and adaptation state. Place pulses at several

Copyright 2026, James M. Atkinson

predetermined positions relative to filtering and retention boundaries, and make the output's timestamp convention explicit. If a precursor appears only after resampling and is consistent with the tested impulse response or boundary convention, it is inappropriate to call it a separate physical emission. The test should also vary pulse amplitude and duration so that an internal artefact is not mistaken for a signal-independent correction. A result observed under one convenient alignment cannot certify every possible alignment of a short unpredictable event.

The adaptation mechanism should be tested separately. Fix its coefficients for one campaign, then allow its prescribed updates during another, preserving the update history. Where the apparatus retains only processed outputs after adaptation, its record may not support the strongest retrospective claim, because the transformation and selection rule may have removed the observations needed for an independent challenge. In such a case the examiner can still say that the derived system reported a feature under a recorded configuration. It should not claim precise source onset or an independent precursor without adequate evidence at the physical input boundary. The goal is not to forbid sophisticated filtering. It is to prevent a perfectly reproducible calculation from being given a causal interpretation which its input record does not determine.

Copyright 2026, James M. Atkinson

David Slepian | Principal response 2: Finite-window concentration and apparent precursors

Dr. Atkinson, any claim about an abrupt event must contend with the fact that the mathematical operations used to control bandwidth act over time. A filter that attenuates frequency components outside a selected region cannot, in general, leave every possible waveform edge unaltered. The physical signal and the filtered representation are related by convolution, and the filter's impulse response can extend over an interval much longer than the event the receiver is seeking. A narrowband representation may consequently show a precursor, a delayed peak, oscillatory lobes or an extended tail even when the source supplied only one short pulse. The operator should ask whether these structures persist in the unprocessed input, not whether they look like separate marks on a waterfall. A spectral plot is a mathematical description of a processed series, not a camera photograph of the historical electromagnetic field.

Consider an idealised impulse at time t_0 and a linear, time-invariant resampling filter with impulse response $h(t)$. The output is proportional to $h(t-t_0)$. If the impulse response has a main lobe and side lobes, its output may exhibit several local maxima. Threshold crossings can therefore multiply one physical event into several apparent detections when the detector counts every above-threshold lobe independently. Conversely, two closely spaced physical impulses can merge into one large maximum when their filtered responses overlap. Neither event-count discrepancy need indicate faulty software; it can follow the declared filter design. The error arises when the operator reports the output maxima as a count of physically distinct emissions without validating the event-transfer characteristic.

Copyright 2026, James M. Atkinson

The finite record introduces another limitation. A mathematical resampler may process a block as though its ends connect periodically, while the actual electromagnetic scene may have been silent before the recorded interval or may have changed abruptly at the boundary. That mismatch can create ringing across the artificial join. A polyphase implementation with zero padding produces different boundary assumptions from one that extends the last value or fits a line. These choices can be compared experimentally, but the input beyond the captured interval remains unknown. It is therefore inappropriate to select whichever boundary convention yields the preferred narrative and then attribute its precursor or terminal feature to the external source.

The signal class matters in every calibration. A long sinusoidal carrier away from the record boundaries may survive a properly designed resampler with excellent amplitude and frequency fidelity. An isolated microsecond pulse may respond quite differently because its relevant spectrum occupies a broad range and its onset lies within the filter's temporal support. The proper validation should therefore include representative bursts spanning the anticipated duration range, varying their alignment relative to the input and output grids. It should test signals near the admitted passband edge, where transition-band attenuation and phase behaviour may differ from central frequencies. A single steady calibration tone proves too little about impulsive source timing.

In the mathematical ideal a waveform can be approximately concentrated in time and frequency, but exact simultaneous limitation in both domains is impossible for a nonzero function. The engineer therefore chooses tolerances and quantifies the resulting compromise. The width of

Copyright 2026, James M. Atkinson

an impulse response, the stopband attenuation, the passband ripple and the phase or group-delay behaviour are not independent aesthetic preferences. They govern the extent to which a transient can be represented without misleading delay or amplitude distortion. If a receiver is designed to recover extremely brief events, a longer low-pass filter chosen solely to improve the stationary noise floor can defeat that very objective. The design should state the shortest target duration and the allowed timing distortion before a particular resampler is certified.

For forensic interpretation I would require the original sample epoch, every relevant resampling ratio, the filter taps or frequency-domain window, boundary assumptions, and a precise mapping from source indices to output indices. A digital file with regular timestamps may nonetheless have been derived from an input containing gaps, repeated samples or clock drift. A reconstruction that silently interpolates across those gaps creates apparently smooth data without supplying the missing observation. The investigator should mark discontinuities and avoid claiming unbroken physical exposure where the raw acquisition was interrupted. A transient reconstructed across a missing buffer is a model-based prediction, not a directly recorded event.

The strongest evidence is comparative. Apply known impulses and bursts at the physical receiver input, preserve simultaneous raw and derived records, and measure the distribution of timing bias, peak-amplitude error, event merging and false-event splitting across relevant states. Challenge the chosen threshold, rather than merely inspecting plots without a decision rule. Where the error can be bounded, a derived record can support a bounded conclusion. Where the original waveform's frequency content was

Copyright 2026, James M. Atkinson

suppressed or where acquisition gaps are unresolved, a precise historical reconstruction may be impossible. The engineer should state that limitation without confusing it with the excellent computational reproducibility of the converted file. I pass the floor to Professor Tukey for the statistical consequences of counting several derived maxima as independent events.

Percy Williams Bridgman | Peer question 2 to David Slepian

Professor Slepian, I am troubled by the way a pleasing graph invites the examiner to speak of the onset of a burst as though onset were a single naturally observable object. The receiver has measured a voltage at an input plane, sampled it according to one timebase, and replaced the retained samples with values derived under a filter and an endpoint rule. A threshold on those derived values defines an event whose start depends upon the selected threshold and the processing operation. Suppose two analysts examine the same raw interval, one employing a symmetrical finite impulse response and one employing a causal filter, and their onset times differ by several microseconds. Which of them has measured the physical onset, if either? I should like a proposed operational definition that does not become circular. It must identify whether the onset is the first detectable departure from estimated noise, the first crossing of an amplitude threshold, or a parameter inferred by fitting a waveform model. I also ask which of those definitions permits a defensible uncertainty interval when the source waveform itself remains unknown, and how the choice ought to be explained to a court that sees only the printed temporal trace.

Copyright 2026, James M. Atkinson

David Slepian | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, your demand exposes a genuine ambiguity, not a merely verbal inconvenience. There is no unique physical beginning of an arbitrarily weak, band-limited signal established solely by the first plotted crossing. A finite-bandwidth processing chain spreads a short impulse, and noise can create earlier or later threshold excursions. The examiner must define a measurand which is actually estimable. For instance, the first threshold crossing at a specified reference plane, with a stated filter, decision rule and false-alarm convention, can be reproducible. It is not necessarily the physical instant at which the transmitter began to emit. Alternatively, a parametric fit to a stipulated waveform can estimate a latent start time, but the resulting interval depends upon the adequacy of that waveform model and upon the assumed noise covariance. Those are different claims and must remain separate.

I would require the report to present the raw acquisition epoch and sample spacing, the derivation of the time stamps, the finite filter's group delay and temporal support, and the algorithm's treatment of data preceding the interval. If a causal filter produces a delayed event and a zero-phase noncausal filter produces apparent pre-event oscillations, neither trace should simply be labelled the unfiltered source waveform. One can estimate the conditional detection delay of each method by injecting known pulses with randomised phase relative to the sample clock and measuring the resulting distribution of threshold times. Such trials must cover the lowest amplitude and shortest pulse on which a conclusion is asserted, for those conditions

Copyright 2026, James M. Atkinson

can exhibit the largest instability. The interval reported should include uncertainty from the time reference, the amplitude and noise estimate, the detector's own variability, and uncertainty in any correction for systematic filter delay.

The court deserves a distinction between a displayed event marker and a historical source onset. A marker is an output of an explicitly defined procedure. A source-onset inference is a conclusion about the generating process, and generally requires extra assumptions or independent physical evidence. Where two algorithms disagree, the proper response is not to select the more visually persuasive one. Preserve both outputs, establish the interval of their agreement under controlled challenge, and restrict the result to what those challenges support. I pass the token to Professor Gabor for the question of what frequency localisation can reveal when a burst occupies only a few samples.

Dennis Gabor | Peer question 3 to David Slepian

Professor Slepian, a short pulse presents the analyst with the familiar tension between localisation in time and localisation in frequency. A long analysis window may yield a clean narrow spectral line while erasing the time at which the pulse entered; a short window gives an uncertain frequency estimate but reveals a transient that the long average conceals. Suppose a resampler with a narrow passband is followed by a spectrogram whose operator changes window length until a candidate emission becomes visually striking. If the candidate is near the passband's edge, could the resulting apparent persistence be a property of the window and filter rather than of a sustained source? I ask whether

Copyright 2026, James M. Atkinson

one can establish a useful criterion, before looking at the field record, for selecting the window and filter parameters required to distinguish one short event from two nearby events. Moreover, how should we treat the apparent improved time resolution when interpolation increases the density of plotted samples without increasing the bandwidth actually retained?

David Slepian | Immediate answer to Dennis Gabor

Professor Gabor, greater display density is not a substitute for greater informational bandwidth. The interpolation may make a computed peak easier to locate within a chosen model, and a suitable statistical estimator may reduce discretisation error in the reported peak position. But the allowable precision of a source-onset claim depends on signal bandwidth, noise, phase response, prior waveform assumptions and calibration. If the retained band excludes distinctions between one pulse and two, no multiplication of the output sample count restores that distinction. One can produce many values on an arbitrarily fine time grid from a smoothed waveform, but they are linked deterministically through the same finite collection of original observations.

The decision criterion should be constructed for the intended signal class. Define a minimum separation between two events that the instrument must resolve, a range of amplitudes and pulse durations, a bound on false splitting and false merging, and a permitted onset error. Generate trials over those conditions, including phases of the event relative to sample boundaries and placements near the edges of processing blocks. Apply the entire declared chain, not merely a

Copyright 2026, James M. Atkinson

textbook impulse response, because overlap handling, trigger logic and detector state may alter the result. A window that looks attractive at one input frequency can yield misleading estimates at another. This is especially important near the transition band of a rate-conversion filter, where attenuation and group delay may change appreciably.

I would resist the temptation to declare a universal window length. The choice is an engineering trade-off tied to the hypothesis being tested. A matched-filter detector can be powerful when a waveform template is justified, but its success is conditional on the template and noise model; it can also merge different physical inputs into one high correlation value. A shorter analysis window may reveal temporal irregularity while suffering poorer frequency discrimination. The record should therefore include a predeclared analysis plan or, where exploration is necessary, distinguish exploratory parameter choices from independently validated detection performance. A defensible figure can show the raw trace, filtered trace, detector statistic and parameter version side by side, with time alignment established by known challenges. The visualised widths should not be called intrinsic transmitter durations without a demonstrated inverse relation. I offer the floor to Dr Wiener to examine the additional complication of stateful processing.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 3: Filtering memory, adaptive state and false temporal continuity

Dr. Atkinson, an investigator examining a resampled trace must recognise that a signal-processing system can have memory. An output at one indexed instant may depend not only on an input at that instant, but on a sequence of earlier input values, filter initial conditions and coefficients selected during previous observations. Even when the underlying analogue field has ceased, the digital output can continue to move while stored filter state decays. The phenomenon is ordinary systems theory. It becomes a forensic problem when the analyst mistakes the computational aftermath of a real event for evidence of an additional transmitted event. A resampler implemented as a finite impulse response has a bounded support if its input continuation is appropriately specified; an infinite impulse response or adaptive estimator may possess a longer or state-dependent tail. These implementations can both be mathematically valid, while producing different event narratives from the same acquired samples.

We should begin with the elementary input-output model y[n] = sum over k of h[k] x[n-k]. In a linear time-invariant system, h represents the impulse response. If an input contains a unit sample at n=0, the output is a copy of h. Thus a positive leading lobe, negative side lobes and later ringing are possible even though the input consisted of one discrete event. If a threshold detector responds to absolute magnitude, several lobes may become several alarms. If an adaptive threshold updates after the first lobe, the later response may be suppressed, or the threshold may fall enough to label harmless residual motion as a second event. Neither outcome can be interpreted without recording both the filter and the detector state. The

Copyright 2026, James M. Atkinson

tempting phrase 'the receiver saw two pulses' obscures that the receiver acquired one sequence and the derived decision procedure produced two maxima.

A further distinction concerns causal and noncausal representations. A causal real-time filter does not literally respond before an unseen future event; its output depends on earlier and present input. A zero-phase offline procedure, however, may use samples on both sides of the displayed time, as occurs in forward-backward filtering or suitably centred FIR calculations. Its pre-event lobes are not a violation of causality. They are numerical values computed retrospectively from later observations. The investigator must avoid assigning a physical transmission time to those lobes. If the source recording is disclosed without its temporal processing history, a reader can easily mistake a noncausal reconstruction for evidence that the emitter began transmitting before the trigger. Correct annotation needs to identify the data dependence, not merely place the word 'filtered' beneath a chart.

Adaptive rate conversion introduces another layer. A receiver may estimate clock drift against an external reference and vary a fractional-delay phase continuously. The output then depends on a time-varying mapping, not a single rational factor. If the phase correction changes abruptly, a stationary carrier may acquire a short phase discontinuity or amplitude disturbance. If buffer availability forces a resynchronisation, samples may be duplicated, dropped or interpolated across a gap. A burst-like feature can then be a symptom of changing software state rather than an external emission. One should examine rate-control logs, buffer boundaries, time-stamp discontinuities and the residual between expected and actual sample

Copyright 2026, James M. Atkinson

counts. A mathematically neat interpolator does not absolve the surrounding scheduler or clock estimator of evidential scrutiny.

Consider a receiver whose digitiser is nominally clocked at ten million samples per second while its host clock is disciplined intermittently to a network reference. Software may declare a smooth output stream of a different nominal rate. Yet the input clock can drift relative to that declared epoch, and a correction algorithm can distribute accumulated timing error over many output samples. The resulting waveform may be suitable for listening or spectral occupancy estimates and still unsuitable for microsecond-level time-difference localisation. The question is not whether the rate conversion functions. The question is whether the reported event times map, with quantified uncertainty, to physical sample apertures. If the input epoch is uncertain, numerical timestamps cannot create an accurate one by interpolation.

The requirement for a valid evidence package is straightforward to state, although costly to implement. Retain the original capture or a validated lossless subset; record the actual input sample rate estimate, clock reference, buffer-gap events, algorithm build, coefficients, extension convention and mapping from original sample indices to output time labels. Keep logs of adaptive state where it influences material events. A replayer should be able to reproduce the numerical output from the same input, but a second test should establish whether the numerical output corresponds to the intended physical quantity. Replaying an artefact demonstrates computational repeatability. It does not prove external cause.

Our challenge campaign should include deliberately unhelpful trials. Inject a single pulse near an input-buffer boundary; repeat with the same

Copyright 2026, James M. Atkinson

pulse at different offsets inside a block; vary the fractional-rate correction, while holding the physical input fixed; and test cases of missing samples rather than covering gaps with plausible interpolations. Include constant or noise-only inputs so that a processing-state change cannot masquerade as an emission. Count events with the actual detector used in field service, not a simplified laboratory cursor. Failures should lead to diagnosed operating restrictions, not merely to new filter coefficients chosen after the troublesome trial has been seen.

I would also ask investigators to record the covariance or dependence among errors introduced by common processing. Two output representations derived from the same raw record cannot be counted as independent confirmations simply because they were obtained by different resampling packages. Their noise, missing-data gaps, amplitude anomalies and original timebase errors remain shared. The proper comparison is a conditional test of distinct algorithms on one input. Stronger corroboration requires a genuinely different physical observation or an intervention whose outcomes distinguish the rival explanations. An external antenna switch, a receiver substitution or a calibrated injected reference may provide additional evidence, although the influence of common equipment must still be disclosed. The aim is not perfect independence, but a dependency account sufficient to support the claim actually made.

A forensic report should therefore say not only that a transient was recorded, but whether it was present in the unconverted samples, how its appearance changed across the processing chain, and what operating states could have produced an analogous feature. Where the original record is unavailable, the examiner may establish reproducibility of the derived file

Copyright 2026, James M. Atkinson

and still be unable to determine the original number of physical emissions. That is a legitimate outcome. It is preferable to a vivid but unsupported account in which the filter's memory has silently become the transmitter's history. I now yield the floor to Professor Zadeh, whose question concerns the temptation to classify a poorly understood state transition as an ordinary signal event.

Lotfi Asker Zadeh | Peer question 4 to Norbert Wiener

Dr Wiener, a large monitoring apparatus may use adaptive filters, data-driven thresholds and rules for assigning uncertain events to categories. The algorithm might label an output feature as an isolated pulse with high numerical confidence even though its filter state was recently reset. From the operator's viewpoint the displayed label appears precise, and the preceding five seconds of streaming data may look uneventful. Yet the classification system might have been trained on recordings whose endpoints were extended in a different manner from the live instrument's endpoints. How would you require the designer to express the limits of confidence when the process being classified is itself affected by uncertain computational state? Is it enough to attach a general caveat to the receiver manual, or should every event preserve a trace of the transformations and state transitions that led to the class label? I also wonder how the committee would decide which uncertain examples must remain unclassified rather than being forced into an apparently exhaustive set of event types.

Norbert Wiener | Immediate answer to Lotfi Asker Zadeh

Thank you for that question. Professor Zadeh, the classifier's numerical confidence must be interpreted according to the

Copyright 2026, James M. Atkinson

experiment used to obtain it. A class probability estimated under a training distribution is not an automatic measure of the probability that a particular field event was physically transmitted. If preprocessing changes the training and operating distributions, the apparent certainty can be especially misleading. I would require the system to identify processing-state anomalies as separate conditions, not absorb them silently into the classes used for ordinary transmitter behaviour. A state reset, discontinuity, altered padding mode or coefficient replacement must be logged at a granularity appropriate to the asserted timing and causal conclusion.

This does not mean archiving every implementation instruction. A compact state record can preserve the versioned filter definition, update times, rate correction, buffer-gap flags and a cryptographic digest of the acquired interval. A later examiner can then distinguish a routine signal classification from an interpretation occurring during invalid or qualified exposure. Where the event depends on the unobserved interior of a lost buffer, a special unknown category is scientifically appropriate. Its presence is not a failure of professionalism. It records that the available evidence does not uniquely determine the asserted cause. Any assessment of classifier performance must count such outcomes instead of suppressing them from the denominator.

A robust validation should deliberately challenge the coupled system rather than merely the classification rule in isolation. For a known single-pulse input, vary the placement relative to buffer edges, and record how many detections appear. For a no-signal input, force

Copyright 2026, James M. Atkinson

representative resampler restarts and check whether the detector produces spurious alarms. For a pair of pulses, vary separation and relative amplitude and examine the rate at which the system merges them. The results should be stratified by state, not averaged into one flattering score. If the instrument is intended to operate under several allowed versions or update policies, those versions form part of its validated configuration envelope. A change in one can invalidate a previously satisfactory operating claim until the new combination is challenged.

The final inference remains conditional. A label may be useful for triage if its limits are recorded. A higher-stakes conclusion about external source behaviour requires preserved raw data or independent evidence sufficient to rule out important processing explanations. In particular, an attractive spectrogram after interpolation cannot show what occurred in samples that were never acquired. The examiner must speak plainly about that absence. I pass the token to Dr Shewhart, who can test whether the same processing system remains stable when challenged at apparently unimportant boundaries.

Walter Andrew Shewhart | Peer question 5 to Norbert Wiener

Dr Wiener, your proposed intervention tests may identify isolated defects, but the operating system faces a succession of temperatures, data rates, filter changes and input amplitudes. I am concerned that an engineer could run a dozen successful pulse tests at a single state and declare the apparatus stable over all its intended applications. A resampler might perform acceptably on stationary tones while a short

Copyright 2026, James M. Atkinson

high-amplitude transient near the end of a file creates ringing that crosses the detector threshold repeatedly. How would you distinguish common-cause process variation from a systematic defect in the rate-conversion method? Should the acceptance process examine event counts as a time series across operating states, or treat each configuration as a separate instrument? I ask especially how to avoid the familiar mistake of selecting a control limit after seeing the worst failures, thereby making the validation campaign appear stronger than it actually was. What constitutes a genuine warning that the corrected system is outside its established envelope?

Norbert Wiener | Immediate answer to Walter Andrew Shewhart

Thank you for that question. Dr Shewhart, the distinction begins with a defined process whose states and outputs can be compared meaningfully. A receiver that changes its resampling ratio, coefficient set, input bandwidth or buffer scheduler may no longer represent one stationary performance process. An average alarm rate over all these conditions can hide a severe defect confined to one boundary state. I would preserve a structured configuration identity and evaluate performance by the conditions relevant to the claim. Where a parameter changes continuously, such as a tracking correction to input clock drift, it may be more practical to validate a bounded region of parameter space with deliberately selected corner cases than to call each numerical coefficient a separate instrument.

For temporal anomalies the response variables should include time bias, spread of timing errors, rates of false splitting and false merging, and the duration of invalid acquisition intervals. These

Copyright 2026, James M. Atkinson

quantities can be monitored over representative environmental and operational sequences. A control chart may reveal changes within a continuing process, but it should not substitute for an independently specified acceptance criterion. The latter follows from the investigative use, such as a maximum permitted event-timing error or a maximum rate of missed pulses. We should declare the criterion before the final validation trials, retain failures and stratify by conditions so that a good average cannot conceal an unacceptable state.

The appropriate challenge includes pulses at many input phases and near every important processing boundary, not merely one convenient position. It also includes negative controls containing no injected event. If a processing restart under a no-signal condition generates an alarm, the system has demonstrated a possible internal cause for a field event. A correction may remove it, but it should then be tested on withheld trials, particularly on true weak signals near the artefact's position. Otherwise suppression of false alarms could come at the expense of suppressing legitimate signals. The validation should compare the raw data and derived decision record, with every threshold change logged.

I would distinguish an out-of-control state from a claim beyond validation. The first concerns evidence that a previously defined process has materially changed; the second occurs when someone asks the apparatus to support a question outside the conditions it has ever been shown to answer. Both deserve explicit qualifications, but their remedies differ. The engineer may recalibrate or repair the first.

Copyright 2026, James M. Atkinson

The second requires a new validation or a narrower conclusion. A report should not imply that a perfect-looking output waveform has certified either condition away. I invite Professor Tukey to examine the danger that the analyst's exploratory selection of windows and thresholds makes the evidence seem more decisive than the underlying trial population warrants.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 4: Event selection, multiplicity and retrospective processing choices

Dr. Atkinson, I would begin with the distinction between exploratory examination and a procedure intended to establish a calibrated inference. Exploratory graphics can reveal that one processing choice produces a curious precursor while another yields a clean pulse. That observation is useful. It can reveal an unsuspected dependence upon a boundary assumption or a filter coefficient. But the same freedom to inspect many representations can make an arbitrary waveform look compelling. If twenty windows, eight filtering choices and several thresholds are tried, an especially striking shape is likely to appear somewhere, even when the underlying input contains no special cause matching the story subsequently told. An analyst should record which choices were made after seeing the data and should not pass the selected result off as though its test had been specified in advance.

A receiver might convert a million-sample field recording into several alternate grids for convenience. One output is processed with an FFT method that assumes periodic continuation; another uses a polyphase finite impulse response with zero extension; a third uses a phase-correcting estimator whose state follows a reference clock. Their differences near the record's endpoints are a valuable diagnostic. The error begins when the investigator chooses the version in which a hypothesised external transmitter appears most distinctly and then treats the chosen appearance as independent confirmation. The outputs share their acquired samples, input saturation, clock uncertainty and most physical interference. A larger

Copyright 2026, James M. Atkinson

collection of plotted representations is not a larger collection of independent physical events.

We need a plain numerical record of all event candidates and all selection rules. Suppose the detector scans K nominally independent windows, each having a false-alarm probability p under a declared noise model. The chance of at least one false alarm is 1-(1-p)^K, not p. If the windows overlap or derive from shared input, they are dependent and the expression is not automatically exact; it may nevertheless expose why reporting only the best looking window is hazardous. The appropriate null distribution must account for the actual dependence, including filter memory and adaptive thresholds. The investigator who counts every filtered side lobe as a new physical event has also inflated the apparent sample size. The resulting confidence interval may be narrow because its assumptions are wrong, not because the physical evidence is abundant.

A rigorous study should preserve the full trial population. It should include successful detections, failures, false splits, merged events, periods in which sampling was interrupted, and intervals excluded because the processing state was invalid. If the analyst discovers an unexpectedly severe effect of a block boundary, that discovery should lead to a revised hypothesis and a second challenge set. One should not merely replace the original boundary tests and report the second set as if no exploratory trials had preceded it. The history of a hypothesis matters when its claimed error probability is calculated from the same data used to construct it. The cleaner separation is to use one sample of trials to discover the defect and a distinct held-out sample to validate the proposed correction.

Copyright 2026, James M. Atkinson

I would examine amplitude and duration errors jointly with time errors rather than treat the position of a plotted maximum as the entire event. A polyphase filter can reduce peak amplitude while conserving other aspects of the retained waveform; a threshold then reports a later onset for a weaker event even when the actual input epochs are identical. A widened impulse can appear as two local peaks because of ringing; a detector with a refractory interval may report one event when two physical pulses are present. These failures depend jointly upon filtering and decision rules. The acceptance report should therefore present a matrix of input amplitudes, durations, separations and placements with both false-event and missed-event counts. One aggregate success percentage loses the important interactions.

The display should make the distinction between input and transformation visible. I would put aligned raw samples and converted samples on common, physically justified time axes, annotate acquisition gaps, and show the actual filter support. The original input index should remain recoverable from each derived timestamp or, where a one-to-one mapping is impossible, the interpolation mapping should be specified with uncertainty. A figure can include a theoretical single-impulse response, but it must be labelled as a model or measured calibration response, not an unseen historical waveform. The event marker should be accompanied by its construction rule and relevant state. Otherwise the eye is induced to see a crisp chronological episode where the instrument supplied only a model-dependent estimate.

One further temptation deserves resistance. If the analysis has discarded the original high-rate samples, an investigator may call a processed file raw

Copyright 2026, James M. Atkinson

because it is the earliest record still retained. Such language confuses custody with acquisition. The retained file may indeed be authentic and unchanged since collection; a cryptographic digest can demonstrate that limited property. Yet its derived nature determines the inferences it can support. To evaluate a disputed transient one may need the pre-conversion spectrum, pre-trigger context, input epoch or a filter state that was never saved. Evidence retention should be planned around foreseeable disputes rather than reconstructed apologetically when litigation makes the missing material important.

The appropriate final conclusion may be sharply bounded. We can say that the declared resampling method produced a transient under specified input and operating conditions, that several processing alternatives give differing apparent durations, and that a controlled injected challenge characterises that discrepancy over a limited range. We cannot infer from these facts alone that a transmitter emitted multiple pulses or that the first nonzero derived sample identifies its onset. The panel should also report discordant trials, because they show which interpretations remain uncertain. I now pass the floor to Professor Neyman, whose question concerns how to provide a confidence statement for an event count without silently counting dependent filter lobes as repeated observations.

Jerzy Neyman | Peer question 6 to John Wilder Tukey

Professor Tukey, suppose one physical pulse is passed through a resampler and produces three detector threshold crossings, while another pulse of the same nominal amplitude produces only one because its arrival phase differs relative to the input grid. A validation programme may report a high hit rate if any crossing within the trial

Copyright 2026, James M. Atkinson

interval counts as success, yet the forensic report may use the three crossings to infer a transmitter's emission cadence. These are plainly different decision rules. How should an examiner construct confidence bounds for missed events, false splits and timing errors when each physical trial can generate a variable number of derived detections? More particularly, what should be the independent unit of analysis for the confidence calculation? Is it a captured sample, a threshold crossing, a trialled physical pulse, or an operating session? I also ask how the laboratory should handle intervals when acquisition gaps make the truth indeterminate rather than merely negative.

John Wilder Tukey | Immediate answer to Jerzy Neyman

Professor Neyman, the experimental unit should correspond to the proposition being tested. If the claim concerns whether a physical pulse is detected, each controlled pulse presentation can be an appropriate unit, provided the presentations are independent under the designed trial conditions and dependence from shared sessions or adaptive state is accounted for. If the claim concerns the number of false splits, the response for each presented pulse is a count, not a collection of independently trialled threshold crossings. Treating three lobes produced from one pulse as three independent successes or failures would misstate the sample size. The report should therefore retain a trial-to-detection association: one known input event, the set of detector outputs assigned to it, the matching rule and any ambiguity.

For a miss-rate claim, define success before the test and count each eligible physical trial once. A Wilson or exact binomial interval may be

Copyright 2026, James M. Atkinson

useful when the assumptions of independent Bernoulli trials are justified, but repeated trials under shared thermal drift or identical calibration state may create clusters whose uncertainty requires a different treatment. For splitting, report the distribution of false extra detections per physical trial, including zero, one and several, with an appropriate model or empirical bounds. For time bias, retain the signed difference between known physical epoch and declared derived event time, not merely the magnitude of the error. A distribution of biases can reveal systematic phase dependence that a single root-mean-square value obscures.

Unknown exposure must not be counted as failure or success by administrative convenience. A buffer gap whose contents were never acquired gives no direct observation of whether a signal occurred there. Such an interval may be assigned an explicitly unassessable status, and the scope of any negative-search conclusion must exclude it or model it with clearly disclosed assumptions. Likewise, a pulse injected into a known invalid state should be retained in the audit, even if the primary acceptance statistic excludes it according to a predeclared rule. Readers need the denominator of every claimed performance rate and the number of trials the investigators omitted or reclassified.

The statistical result should be paired with a causal challenge. If the suspect multiple crossings disappear when the filter changes but the raw single-pulse record remains the same, that is evidence for a processing explanation. It is not automatically proof that every similar field event is internal, because real emitters may produce patterns

Copyright 2026, James M. Atkinson

that interact differently with the filter. A report can reach a strong limited conclusion while preserving its limitations: the apparatus demonstrated a false splitting mechanism under specified conditions, and the contested field recording is consistent with that mechanism. The stronger assertion that no external multiple emission occurred requires evidence capable of distinguishing the explanations. I invite Dr Hamming to address the final engineering question of reproducible sample indexing and numerical implementation.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Principal response 5: Rate arithmetic, timestamps and implementation validation

Dr. Atkinson, a digital processing chain is often described by a few compact integers, yet those integers can be surrounded by software decisions of decisive evidential importance. Consider the rational relation $F_{out} = F_{in} L/M$. Provided F_{in} is the actual input rate, L and M are the intended factors and the implementation retains proper timing, the output nominal interval is $1/F_{out}$. But the input rate may be only the configured clock frequency, not a measured rate; the initial output phase may depend upon a filter polyphase arm; and an implementation may trim or pad its first and last outputs. A spreadsheet that multiplies the rate by L/M can be mathematically correct while the claimed event epoch is wrong. The investigator must know the initial index relation and any delay compensation, rather than trusting a formatted timestamp field.

The simplest validation is to inject reference events whose input epochs are known with adequate uncertainty. Distribute them across the acquisition block and repeat at different phases relative to the sample clock. Let n be an input index and m an output index. One may compute an ideal time $t_{in}(n)=t0+n/F_{in}$ and $t_{out}(m)=t1+m/F_{out}$. The reference epochs t0 and t1 must be related by a documented mapping; they are not guaranteed equal simply because a processing library returns its first output at the first input's nominal time. Some algorithms explicitly centre an impulse response, some maintain causal delay, and others compensate initial group delay. The correctness of each choice depends on what the application intends to preserve.

Copyright 2026, James M. Atkinson

Numerical arithmetic can also introduce a second error into the history. A rate converter operating for several hours may use integer counters and rational phase accumulators. If the implementation converts a large integer sample count to floating-point seconds too early, it can lose submicrosecond resolution after a sufficiently long interval. If it rounds each output time increment and accumulates the rounded result, a tiny error can grow over millions of steps. It is often preferable to keep an integer source index, a rational rate relation and a separately measured time origin, then convert to presentation units only when needed. This is a recommendation about preserving numerical meaning, not a claim that any particular floating-point format is universally inadequate. The limits must be calculated for the actual sample rate, counter width and operational duration.

Filter coefficients and their scaling need independent verification as well. An interpolation filter may use L times the conventional amplitude scaling when zero insertion is part of its conceptual implementation. If an investigator runs a software change in which this factor is applied differently, the peak of a derived impulse may change without any physical change at the antenna. Coefficients may be normalised to unit DC gain, unit energy or a specific passband metric, and those conventions are not equivalent for every signal class. A correct comparison should state the gain reference and the signal statistic used. For a short pulse, peak amplitude, integrated energy and threshold duration may respond differently to the same filter. The derived amplitude must not be interpreted as the directly observed antenna voltage without the full receiver and processing transfer function.

Copyright 2026, James M. Atkinson

Block boundaries merit a test of their own. A streaming polyphase converter maintains internal state across blocks in normal operation; an offline function called separately on each block may instead reset the state or apply an endpoint padding rule at every call. A physical signal crossing a block boundary may consequently be distorted or split. If blocks overlap and are later stitched together, the overlap-add or overlap-save convention should be disclosed, including any discarded guard samples. An apparently perfect output sample count can coexist with discontinuities at the joins. The validation should inspect an event continuously traversing several block sizes, not merely compare two methods on one static waveform file.

A further hazard is confusing a bit-for-bit reproducible output with a physically accurate reconstructed signal. Running the same code and obtaining the same values establishes one form of computational integrity. It does not tell us whether the chosen filter preserved the transient feature the examiner now cares about. An implementation can faithfully reproduce its own erroneous time origin. Its tests should therefore include independent, externally generated waveform challenges and controlled changes capable of discriminating an external-emission hypothesis from a processing-artifact hypothesis. For evidential work, one should archive the exact code version, parameter sets, software dependencies, filter taps and initial state. A common codebase used by two examiners can be a common error source, not two independent certifications.

We must not overestimate what validation can accomplish. It can establish error bounds for declared waveform classes and operating envelopes. It cannot certify the reconstruction of an arbitrarily short, arbitrarily broadband event after the relevant frequencies have been

Copyright 2026, James M. Atkinson

rejected. A useful test report may show excellent tone-frequency fidelity but poor pulse-width fidelity, or good pulse timing at moderate amplitude but unreliable detection near threshold. The right description identifies which intended use passed and which did not. This is not an argument against resampling. It is an argument for using a powerful digital method only for quantities that its demonstrated transfer can sustain.

I recommend that the examiner retain a clear distinction between chronological facts and processing facts. Chronological facts arise from a calibrated observation chain at the antenna and acquisition clock. Processing facts arise from transforming the stored observations under specified mathematical and software rules. Both may be valuable evidence. But when a derived pulse appears earlier, longer or more numerous than the input event, its significance cannot be settled by the smoothness of the graph. The underlying trial record and signal-processing definitions are the necessary witnesses. I pass the token respectfully to Professor Bridgman for a final question about how an engineer should identify a measurand when differing implementations produce incompatible but internally reproducible timestamps.

George Edward Pelham Box | Peer question 7 to Richard Wesley Hamming

Dr Hamming, a receiving instrument may give a single time reading for each detected transient, although that reading has passed through a rational resampler, a smoothing filter and a threshold decision. Suppose a software update changes the filter's compensation convention while leaving the analogue input and physical event unchanged. The displayed event time moves by several output samples, and both versions claim to

Copyright 2026, James M. Atkinson

be correctly aligned. A technician might say that the true onset is the time in the newest software, while the older report remains part of a court record. What operational definition would make the two results scientifically comparable? How can the laboratory determine whether the discrepancy is a fixed processing delay, a frequency-dependent bias, an amplitude-sensitive threshold effect, or an arbitrary endpoint convention? I am particularly interested in the distinction between correcting a known delay and claiming recovery of an onset whose waveform was never directly retained.

Richard Wesley Hamming | Immediate answer to George Edward Pelham Box

Thank you for that question. Professor Box, a comparable result requires a declared reference event and a declared algorithmic measurand. If the time is called the first upward threshold crossing in the filtered amplitude envelope, then the filter, threshold rule, noise estimate, input epoch and processing version belong to the definition. A change of filter may change that quantity. We should not call the difference a mere defect in precision without first asking whether the two versions still estimate the same property. If the intended measurand is the latent start time of a specified pulse model at the antenna input, each version is an estimator whose bias, variance and dependence upon waveform assumptions must be measured by challenge trials.

A fixed group delay can be corrected where it is actually fixed over the relevant bandwidth and processing state. A frequency-dependent delay calls for a more complex transfer model and a statement about

Copyright 2026, James M. Atkinson

what waveform class the correction serves. A threshold bias may vary with amplitude, noise and filter ringing, and one global offset cannot remove that variability. Endpoint conditions can create effects confined to the start or finish of an acquired block; such behaviour should be tested by moving a known event through the block and comparing interior and boundary placements. The validation record must not merely identify a mean offset. It should show the residual error distribution and the conditions under which the correction is justified.

If original samples have been retained, run both software versions against the same raw event, keep their full parameter records and calculate the numerical difference. Compare the outcomes with an independently timed injected reference. Where the input waveform has been rejected or the acquisition epoch was not recorded, neither software version can summon those absent facts into existence. One can sometimes bound the onset from the surviving band and a defensible model, but the bound must include model uncertainty and alternative inputs that yield the same retained output. A court should be told that an estimate was revised because the processing definition or calibration changed, not that a machine simply discovered a more precise historical fact.

The practical archive need not be extravagant, but it must be sufficient. Preserve file digests, sample-rate metadata, initial epoch, transformation chain, filter taps, state policy, software version and decision-rule settings. Show the raw and derived event locations on a common justified time axis, while indicating invalid or unobserved

Copyright 2026, James M. Atkinson

intervals. Distinguish a corrected timestamp from a directly measured aperture. If the difference between versions exceeds the stated uncertainty, the issue is substantive and should be reported, not hidden by retroactively regenerating older exhibits. Once this discipline is observed, rate conversion remains a valuable analytic instrument. Its numerical elegance no longer tempts us to mistake a computed event marker for direct testimony from the transmitter. I yield the floor back to Dr. Atkinson for the mathematical applications and concluding synthesis.

Worked engineering applications and independently testable calculations

Claude Elwood Shannon, Cross-Peer Question to David Slepian: Dr Slepian, a short impulse becomes a wider oscillatory feature after a rational sample-rate conversion. What measured attribute could establish that the ringing belongs to the filter rather than to the original pulse?

David Slepian, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, determine the conversion filter impulse response, including group delay, transition-band behaviour and finite-record boundary treatment. Inject impulses and calibrated short bursts before the same acquisition path, varying their onset relative to the input sample lattice. A post-resampling ringing envelope that tracks the implementation kernel and changes under a validated alternative filter is evidence of processing dependence. The physical input has its own bandwidth and uncertainty, so we must compare against an independent analogue observation rather than an idealised mathematical delta alone. Report both the original raw waveform and the derived trace, and avoid interpreting every output oscillation as an actual

Copyright 2026, James M. Atkinson

carrier ringing in the environment. A finite support signal cannot simultaneously be arbitrarily narrow in time and frequency. I yield the token to Professor Wiener.

David Slepian, Cross-Peer Question to Norbert Wiener: Professor Wiener, why can a filter with nominally constant group delay still produce misleading onset estimates near a dropped buffer or the beginning of a record?

Norbert Wiener, Cross-Peer Answer to David Slepian: Dr Slepian, a linear-phase finite filter has constant group delay within its relevant passband under stable coefficients, but its output also depends on the samples available to populate its memory. Near a boundary, missing or padded input changes the convolution and can create transients. The nominal delay correction removes a known average latency, not all uncertainty in the event onset. Preserve a history of sample losses, padding conventions, filter initial conditions and timestamp anchors. Test short pulses across buffer joins and change the offset of the join without changing the source. If an apparent transient follows the join rather than the injected pulse, label it as processing-related. Claiming perfect continuity from a resampled trace would disregard the unobserved original samples. I pass the token to Professor Tukey for selection bias.

Norbert Wiener, Cross-Peer Question to John Wilder Tukey: Professor Tukey, an analyst tests twenty interpolation kernels and publishes only the one whose waterfall most resembles a pulse train. How should the later evidential claim be qualified?

John Wilder Tukey, Cross-Peer Answer to Norbert Wiener: Professor Wiener, that result is conditional on a data-driven selection among twenty

Copyright 2026, James M. Atkinson

procedures. The effective number of tested patterns may be complex because the outputs are correlated, but the search must not disappear from the report. Define a precommitted feature measure and test the chosen kernel on held-out raw acquisitions with independent pulse-injection controls. Retain the alternative outputs and selection rationale. A resemblance that only emerges after adjusting interpolation ratios, edge padding and thresholds is not the same as a repeatable physical signature. For a consequential inference, I would require quantitative timing, amplitude and frequency agreement against an independently calibrated reference. Any apparent improvement should be weighed against false detections under negative controls. I yield to Dr Hamming on reproducible computation.

John Wilder Tukey, Cross-Peer Question to Richard Wesley Hamming: Dr Hamming, two machines resample identical archived I/Q but produce slightly different transient peaks. What must the release record contain to distinguish a numerical variation from an evidential discrepancy?

Richard Wesley Hamming, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, preserve source-file hashes, precise input sample format and endianness, all coefficients, interpolation and decimation factors, phase origin, arithmetic precision, saturation and rounding rules, software versions and the handling of gaps. Compare exact outputs where arithmetic is deterministic; otherwise predeclare a defensible numerical tolerance and measure how differences propagate into event detection. Verify that neither process introduced unrecorded interpolation through a missing block. A later investigator should be able to reproduce the derivative or at least bound its uncertainty, not infer from visually similar screens that the

Copyright 2026, James M. Atkinson

processes were equivalent. If the detected event changes classification across implementations, the result must be marked as software-sensitive, and original samples remain the evidential foundation. I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

The panel has separated a familiar convenience from an unfamiliar evidential danger. Sample-rate conversion is a legitimate mathematical tool for representing a retained signal on another sampling grid, but an output transient is not necessarily a second physical observation of an emitter. Mr Shannon has made clear why a many-valued interpolation can contain no more independent linear information than its input, and why filtering that eliminates relevant bandwidth may render different physical events observationally indistinguishable. Professor Slepian has explained how finite-duration and finite-bandwidth constraints affect the visual appearance of short events, while Dr Wiener has demonstrated how filter state, adaptive correction and buffer resets can create an apparent sequence of pulses from a single originating event. Professor Tukey has exposed the evidential inflation created when multiple windows or software versions are explored and the most persuasive-looking one is reported without the history of that selection. Dr Hamming has insisted that an arithmetically correct rate ratio is not sufficient to justify the time stamps or amplitude meanings presented to an examiner.

We should be precise about the many kinds of time discussed here. The input sample index identifies a position within the acquired digital record. Its physical time depends upon the sampling clock, reference epoch and any gaps. A filter's group delay describes a property of a specified system and

Copyright 2026, James M. Atkinson

frequency region. A detector's threshold-crossing time is a statistical or algorithmic decision based upon the filtered samples. A transmitter's physical onset is a claim about an external cause. The last of these cannot be established by merely printing any one of the preceding quantities as though its clock digits constituted direct physical testimony. A resampling routine may correctly compensate the nominal filter delay and still yield biased threshold time for a weak pulse whose amplitude differs from that of the calibration reference.

The practical validation must be designed around the claim. For an instrument intended to discover intermittent surveillance emissions, it should include a declared minimum burst duration, relevant frequency and amplitude range, measured noise conditions, acceptable onset error, and bounds on false splitting and missed-event rates. The whole detector, including the anti-alias filter and any later thresholding, should be challenged by physically injected events at different sample phases, near block boundaries and during representative state changes. Negative controls are essential. If a stream with no injected signal produces a false burst when a filter restarts, then a processing-origin explanation has been demonstrated and must be considered when a similar field event is interpreted. A successful calibration result applies only within the operating envelope actually tested; it is not an assertion that every imaginable physical emission has been reconstructed exactly.

The recorded evidence should permit a future examiner to distinguish the acquired from the derived. Preserve original samples when feasible, or at least validated raw intervals relevant to material events, together with the declared sampling rate and its measured uncertainty. Retain the input

Copyright 2026, James M. Atkinson

epoch, buffer-gap record, rational rate parameters, filter taps, coefficient scaling, boundary continuation policy, phase or group-delay treatment, software version and adaptive-state history. Record which original sample indices gave rise to the reported output event and the detector's decision rule. A cryptographic digest can help establish that a file is unchanged after collection, but it does not certify that the physical source was correctly represented in the first instance. Chain of custody and measurement validity are complementary disciplines, not synonyms.

The panel is equally clear about the limitations of negative findings. If a receiver discarded the spectral features needed to distinguish a brief pulse from two nearby pulses, the absence of those features in a derived record does not show that they were absent at the antenna. If the input capture contains gaps, a smooth interpolation across those gaps cannot transform them into verified observation intervals. If a chosen false-alarm probability was computed from a simplified model while the actual detector used strongly overlapping windows, its confidence claim must be revised. These are not reasons to abandon digital processing, but reasons to describe a result at the level warranted by the actual measurement and challenge record.

Our ten hypothetical applications demonstrate why the units and boundaries matter. The rate factor 3/5 changes nominal output spacing, not the input exposure duration; a causal filter's internal delay is not automatically a transmitter-onset correction; a four-sample indexing error can matter materially in timing analysis; and interpolation cannot increase the rank of an observation vector. We have deliberately distinguished each calculated quantity from a certification of real instrument performance.

Copyright 2026, James M. Atkinson

Where uncertainty remains, a bounded conclusion is often both useful and scientifically stronger than an unqualified assertion. I thank the contributors for their exacting questions and courteous responses. We shall carry this discipline into the next discussion, where the numerical construction of channel representations and their relation to the receiver's original physical measurements will require equally careful examination.

Ten worked engineering applications | Question 039

Application 1: Rational conversion and the nominal output interval

Assume an actually measured input sampling rate F_in = 10,000,000 samples/s. Let L = 3 represent the integer interpolation factor and M = 5 the integer decimation factor; the numbers are relatively prime. The nominal output rate is F_out = F_in(L/M) = 10,000,000(3/5) = 6,000,000 samples/s. Therefore the nominal output interval is T_out = 1/F_out = 166.6666667 ns, whereas the nominal input interval was 100 ns. These are time coordinates of the derived samples, not 6,000,000 independent analogue measurements per second. A single physical impulse may contribute to several output samples because the FIR interpolation filter spans multiple input indices. The assertion that an event occurred at exactly one derived sample's printed time therefore requires a calibrated index-to-epoch mapping and a declared event estimator. If the input clock has unmeasured drift, multiplying its configured rate by 3/5 does not repair its physical timebase. Preserve the measured input rate, time origin, factors and filter state before making the temporal claim.

Application 2: Output count and finite record duration

For a hypothetical input containing N_in = 50,000 valid samples at F_in = 10,000,000 samples/s, the nominal captured duration is T = N_in/F_in = 0.005 s, or 5 ms. With L = 3 and M = 5, the expected approximate number of derived samples is N_out = N_in L/M = 30,000. The exact output count of a particular software routine may depend upon its endpoint convention, rounding, block segmentation and state, so 30,000 is a nominal arithmetic result rather than a claim about every

Copyright 2026, James M. Atkinson

implementation. If an analyst asserts 30,000 independent physical observations, the inference is wrong: the output values are dependent functions of the input record. Count the original exposure interval once. An output file that contains 30,000 values can represent a 5 ms portion of the original field without introducing any additional period of observation.

Application 3: Group delay of a causal linear-phase FIR

Assume a causal, symmetric FIR containing K = 101 taps and operating at an internal rate F_int = 30,000,000 samples/s. For an exactly symmetric odd-length impulse response, its group delay in the linear-phase passband is D = (K-1)/2 = 50 internal samples. Thus the delay is tau = D/F_int = 50/30,000,000 s = 1.6666667 microseconds. This number is a property of the stipulated internal-filter clock and the causal representation. A software routine may subsequently compensate the delay and assign the first output sample to the original epoch; one must inspect that implementation before adding 1.667 microseconds to a field event timestamp. A group delay is not necessarily an onset correction for an arbitrary broadband transient because the threshold-crossing time can depend on the filter's ringing and the event amplitude. Validate the entire event detector, not only the nominal linear-phase delay.

Application 4: The error caused by one output-sample indexing mistake

Using F_out = 6,000,000 samples/s from Application 1, an erroneous output index of one sample corresponds to Delta_t = 1/F_out = 0.1666667 microseconds. A misregistration of four samples corresponds to 4/F_out

Copyright 2026, James M. Atkinson

= 0.6666667 microseconds. These offsets may be small compared with a slow survey scan but material in a time-difference-of-arrival analysis. If the assumed propagation speed is c = 299,792,458 m/s in free space, one microsecond of timing error corresponds to about 299.792458 m of propagation distance. In a difference-of-arrival geometry that value is a path-difference error, not automatically a radial position error, because the source-location solution depends upon receiver geometry. The examiner should retain original integer indices and explicitly map them to the derived epochs instead of assuming that consecutive file indices constitute a physically calibrated chronology.

Application 5: Stopband attenuation of an aliased interferer

Suppose a rate reduction to F_out = 6 MHz has an output Nyquist interval extending to 3 MHz, and an unwanted input component has amplitude 0.1 V at a frequency that would alias into the retained band without suitable filtering. If the digital anti-alias filter attenuates that component by 60 dB in voltage, with the conventional voltage ratio A_out/A_in = 10^(-60/20), the residual amplitude is 0.1 V times 0.001 = 0.0001 V, or 100 microvolts. The result is an engineering expectation conditional on the actual filter response at that interferer frequency, its correct gain calibration, and operation within linearity. It does not show that all outside-band emissions have vanished, nor that the residual is an external signal. An interferer can also create nonlinear products upstream of the anti-alias filter. An evidential claim should distinguish digitally rejected components from analogue-generated in-band products that survive because their creation preceded the rate conversion.

Copyright 2026, James M. Atkinson

Application 6: Independent tests versus overlapping windows

Assume, solely for illustration, K = 100 statistically independent noise-only decision windows and a predeclared per-window false-alarm probability p = 0.001. The probability of one or more alarms is P_any = 1-(1-p)^K = 1-(0.999)^100, approximately 0.095208, or 9.52%. This is not 0.1% simply because each window individually has a 0.1% false-alarm probability. If the windows overlap heavily through a long resampling filter, the independence premise is invalid and the formula cannot be used without adjustment. Correlations may make the event-count distribution more clustered. For a real detector, use controlled noise trials processed through the same full chain to estimate the false-alarm law, and disclose whether the threshold was selected after examining these trials. A narrow confidence interval calculated from highly dependent outputs does not provide an independent physical basis for identifying a source.

Application 7: A bound on temporal splitting due to filter support

Consider a hypothetical FIR filter with K = 81 nonzero taps at an internal rate F_int = 20 MHz. The full nominal temporal support from first to last tap is (K-1)/F_int = 80/20,000,000 s = 4 microseconds. It is possible for a discrete unit impulse to influence output values within that interval in a causal implementation, although the duration of threshold crossings may be shorter and depends upon the actual tap values. A zero-phase representation could distribute support around a declared epoch, rather than entirely afterwards. The 4 microseconds is therefore not a measured pulse width. It is a useful bound on which output sample locations may depend on one ideal input impulse, given the stated filter

Copyright 2026, James M. Atkinson

and sampling clock. A detector reporting two subevents separated by 2 microseconds should be challenged with a known single-pulse input before those subevents are attributed to two physical transmissions.

Application 8: Clock-rate uncertainty accumulated across an interval

Assume an input rate F_{in} = 10 MHz whose fractional frequency uncertainty is u_r = 2 parts per million over a designated recording interval T = 20 s. If that uncertainty can be represented conservatively as a constant fractional rate offset during the interval, the corresponding first-order epoch error magnitude at the far end is approximately $\Delta t = T u_r = 20(2 \times 10^{-6})$ s = 40 microseconds. This is an illustration of one error model. A random time-varying clock process requires a more suitable uncertainty calculation and should not be reduced without evidence to one constant offset. Increasing output sample density by rational interpolation cannot shrink the assumed 40 microsecond uncertainty in the input chronology. A useful record therefore identifies the clock reference, the method and time window of its characterisation, and whether the event time is relative within a capture or absolute against an external reference.

Application 9: Peak-power and amplitude reporting after gain correction

Suppose an input sine wave has a measured peak amplitude of 0.2 V at a declared acquisition plane, and a fully characterised linear processing chain has a constant amplitude gain G = 0.8 at that tone frequency. Its output peak amplitude is 0.2 x 0.8 = 0.16 V. Dividing the derived value by 0.8 reproduces the 0.2 V amplitude estimate under the

Copyright 2026, James M. Atkinson

model. It does not justify applying the same scalar correction to a broadband impulse unless the amplitude and phase transfer are known across that impulse's relevant spectrum. A filter with frequency-dependent gain can alter peak height while leaving some integrated measures comparatively stable. The examiner must define whether the measured property is sine-wave peak, transient peak, root-mean-square voltage or an energy statistic. A correction formula can be exactly executed while estimating the wrong quantity because the measurand was never adequately stated.

Application 10: Physical observations versus computed output samples

Consider a 1 ms acquisition at F_in = 8 MHz with N_in = 8,000 valid input samples. A hypothetical 4:1 upsampling with L = 4 and M = 1 yields a nominal F_out = 32 MHz and approximately N_out = 32,000 computed output samples. The physical acquisition still contains 8,000 originally sampled values. Under an interpolation model y = A x, where x is an 8,000-component input vector and y is the derived output vector, the rank of A cannot exceed 8,000. Thus the 32,000 output coordinates cannot supply more than 8,000 independent linear degrees of freedom from those input data. This rank argument alone does not determine signal-detection quality; interpolation may improve a chosen estimator's numerical convenience. But it demonstrates why one must not multiply the forensic evidence count by four. If information was clipped, never acquired or removed by an earlier noninvertible filter, the conversion cannot restore it without additional assumptions or independent measurements.

QUESTION 040

Copyright 2026, James M. Atkinson

How can the investigator reconcile different sampling clocks in one evidential timeline?

Source: V011_Roundtable_Question_040_CP040_Dr_Atkinson(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 040. Complete Expert Roundtable Discussion

Original constructed educational dialogue, not historical quotation or testimony. Numerical examples are hypothetical.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, we have examined the distortion of an acquired signal when a resampler replaces one digital time grid with another. We must now confront a subtler difficulty. In a multi-receiver Technical Surveillance Countermeasures investigation, each apparatus may claim to have measured an event at a particular time, while the physical clocks underlying those claims differ in frequency, epoch, uncertainty, phase noise and historical calibration. Two receiver logs may each display a timestamp with nine digits after the decimal point. The extra digits are visually arresting; they cannot tell the investigator whether the two systems used the same time scale, remained synchronised during the relevant interval, or retained the instant at which each antenna's observation was digitised. A computer's file creation time, a host's packet-arrival time and an analogue sampling aperture are different events. Treating them as interchangeable can create the appearance of simultaneous emissions or implausible source movement that exists only in a defective chronology.

For an initial working model, let t denote an ideal reference time and let C_i(t) denote the reading of receiver clock i. Over a sufficiently short interval,

Copyright 2026, James M. Atkinson

we might write $C_i(t) = a_i + (1 + y_i)t + e_i(t)$. Here a_i, expressed in seconds, is an initial clock offset; y_i is dimensionless fractional frequency offset; and $e_i(t)$ includes time-varying wander, residual jitter and unmodelled measurement error. This model is intentionally simplified. A clock affected by a discontinuous correction, oscillator warm-up, state-dependent timestamping or a host scheduler may not be adequately described by one straight line. The examiner must identify the applicable interval and document whether the clock map was measured independently or fitted using the very event whose simultaneity is in dispute.

A time-difference measurement across two receivers requires the relative clock map, not merely two dates printed in the same calendar format. If receiver A reports a candidate at C_A and receiver B at C_B, the difference $C_B - C_A$ may include initial epoch offset, accumulated fractional-rate error, differing RF-path delay, analogue filter delay, digital group-delay handling, and host logging latency. Only after an appropriate correction can the residual difference be interpreted as a physical arrival-time difference. A common external reference can help. Yet two devices connected to the same reference may retain distinct divider phases, timestamp origins or cable delays, and a distribution network can introduce errors shared by several channels. A shared source can be an instrument of calibration without making the downstream observations statistically independent.

We must also distinguish accuracy, stability and resolution. A clock can produce extremely stable intervals while remaining several milliseconds behind the designated time scale. A system can be accurately synchronised at one instant and accumulate substantial error during an uncorrected later interval. A digital counter can resolve an increment to a nanosecond while

Copyright 2026, James M. Atkinson

the event it reports originated in a buffered stream whose packet delivery varies by milliseconds. The National Institute of Standards and Technology's metrological treatment distinguishes clock accuracy from stability and treats timing uncertainty over a given observation interval as an explicit measurement problem. We shall adopt that discipline rather than infer accurate chronology from the visual appearance of a precision-formatted timestamp. [N1, N2]

Our intended investigative environment is deliberately complex. Imagine a fixed wideband digital receiver, a scanning superheterodyne instrument, and a separate recorder collecting discriminator audio or baseband samples. The digital receiver's events may be timestamped at the ADC or field-programmable logic boundary. The scanner may identify an event only after tuning, filter settling and detector thresholding. The audio recorder may attach a host-computer timestamp to a buffer delivered after capture. All three may observe a related physical phenomenon, yet none may support the same submicrosecond timing proposition. The examiner should preserve the timing and acquisition definition of each observation and resist the temptation to shift traces until their peaks appear to align, then treat that aesthetically chosen alignment as independent proof of a common source.

I invite Mr Nyquist to consider whether the sample indices and their physical epoch are adequately defined, Professor Wiener to examine the dependence of timing maps upon estimated states, Professor Neyman to scrutinise uncertainty and the risk of overstating simultaneous detection, Dr Shannon to examine which information a synchronisation transform preserves, and Dr Hamming to discuss the construction of a reproducible

Copyright 2026, James M. Atkinson

common evidence timeline. Seven peer questions should challenge the assumptions that make each proposal attractive, and every question must receive an immediate answer. The numerical exercises will distinguish sample spacing from epoch accuracy, linear drift from stochastic wander, group delay from network latency, and propagation path difference from estimated location. We shall count the chapter complete only when all prescribed contributions, applications, biographies and citations are present and independently verified. Mr Nyquist, may I invite your first account of the relationship between sample index, realised clock frequency and the epoch required to interpret an observed transient?

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 1: Index, epoch and the limits of syntonisation

Dr. Atkinson, a sampled waveform is organised by its indices, but an index alone has no absolute historical date. If a signal is acquired at a genuinely uniform rate F_s, the nominal interval between adjacent apertures is $T_s = 1/F_s$. Given a known reference epoch t_0, we can assign the ideal time $t(n) = t_0 + n/F_s$ to sample n. This simple relation becomes a claim about the physical world only when the sample clock and reference epoch are adequately characterised. A configured converter rate might be 20 MHz, but the actual oscillator can exhibit a fractional offset, and the phase of the first ADC aperture relative to an external trigger may remain uncertain. A report that prints $t_0 + n/20{,}000{,}000$ to nine decimal places cannot prove that the underlying aperture occurred within a nanosecond of the stated absolute time. It establishes a numerical conversion under premises that must be tested.

It is useful to distinguish two engineering tasks. Syntonisation makes clocks run at compatible rates. Synchronisation relates their readings to a common time or epoch. Two nominally identical oscillators can be syntonised within a narrow fractional difference while their time counters start from unrelated offsets. Conversely, two time counters may agree at one instant while their oscillators subsequently run apart. A careful investigator records both the initial offset and the rate uncertainty relevant to the entire observation. These differences become particularly important when a receiver observes one transmitter intermittently. A correction determined at the beginning and end of a long session may estimate

Copyright 2026, James M. Atkinson

average drift, but it need not reveal short-term excursions or discontinuous corrections occurring between those reference points.

Suppose, hypothetically, that receiver A's oscillator runs at its nominal rate, while receiver B has a fractional frequency offset $y_B = 1$ part per million. Over a 100-second interval, the first-order accumulated relative time error would be $T y_B = 100$ microseconds, assuming a constant offset. At an aggregate rate of 10 million samples per second, that represents one thousand sample intervals. Converting B's samples to A's nominal rate without measuring the actual offset may make the two plotted traces look compatible over a short interval while causing steadily increasing disagreement across the session. The example is not a prediction for a real instrument. It identifies the dependence of the conclusion upon the time interval and the clock's actual behaviour. If B's oscillator wanders irregularly, a constant-rate correction is not enough; an uncertainty account must cover the unobserved deviations.

A good time reference therefore requires measurements at a relevant boundary. A pulse-per-second signal, for example, can define reference events against which a sample counter is recorded, but only if the receiver establishes the aperture or latch relationship and its uncertainty. A host operating system may log the arrival of the reference pulse later than the physical edge. A network time protocol may estimate clock offset, yet variable path asymmetry, software latency and timestamp placement complicate the meaning of that estimate. A hardware timestamp near the acquisition boundary is often more appropriate for microsecond-level claims, but even it needs calibration of cable delay, fan-out phase and the

Copyright 2026, James M. Atkinson

input-to-counter relation. An engineering label such as 'hardware synchronised' describes an architecture, not an uncertainty budget.

We should also distinguish phase coherence from timestamp agreement. Two digital receivers may use frequency references derived from a common oscillator. That can support coherent processing under stated conditions, but the analogue mixers, sampling apertures, RF cables and digital filters may introduce different phase and delay responses. A short pulse can appear at different output sample positions because the filters and event selectors differ. A correct comparison must either place the claims at a common physical reference plane with validated corrections or explicitly acknowledge that only a weaker relationship has been established. A submicrosecond physical arrival difference cannot be extracted merely by subtracting two post-detection software event times unless those detection times have been related to the original antenna observations.

The investigator should maintain unrounded integer counters for each receiver and record the method by which each counter is mapped to the reference time scale. When possible, preserve the raw relation between observed reference edges and sample indices rather than replacing them immediately with interpolated absolute timestamps. This permits later analysts to refit a clock model, evaluate residuals, identify possible discontinuities and reproduce the adopted mapping. A straight line fitted through two reference points may be adequate for some interval estimates, but its adequacy must be challenged against independent references or residual measurements. A clock reset or loss of lock should create a documented break in validity, not a continuous timeline manufactured by interpolation.

Copyright 2026, James M. Atkinson

The final point concerns negative evidence. If receiver B did not detect the candidate at the time printed by receiver A, one must establish that B was looking at the correct frequency, with adequate sensitivity and known exposure, during the physical interval after allowing for the clocks' uncertainty. A mismatch of timestamps can produce a false assertion that the emission was absent from one receiver. Equally, an apparent coincidence within a generous matching interval may be weak evidence when hundreds of unrelated bursts occur. The clock map supplies one necessary condition for comparison; it does not, by itself, identify a common source. A bounded evidential statement should give the measured relative offset, its temporal variation, the calibration interval and the unresolved alternatives. I pass the token to Professor Bridgman, whose demand for an operationally defined measured quantity may reveal whether our shared time label conceals different physical event definitions.

Percy Williams Bridgman | Peer question 1 to Harry Nyquist

Mr Nyquist, your account identifies the danger of mistaking a sample index for a common historical epoch. I should like to press the definition of the event that is assigned an epoch. One instrument may timestamp the rising edge of an analogue trigger at a hardware latch, another may timestamp the strongest value of a digital envelope, and a third may timestamp the moment at which a scanning receiver's software first declares that a threshold has been crossed. A calibration can align their clock counters without making those event definitions equivalent. How, then, would you specify a measurand that allows investigators to compare these observations without silently inserting a source-waveform model? In particular, suppose a known impulse injected at a common

Copyright 2026, James M. Atkinson

distribution point produces a trigger timestamp that precedes the envelope-peak timestamp by several microseconds. Does one correct that observed difference as though it were a fixed cable delay, or retain two operational quantities whose relation changes with amplitude and filtering? I ask which challenge measurements would be sufficient to establish whether a constant offset is justified and when a time-difference claim must instead carry a more complex uncertainty interval.

Harry Nyquist | Immediate answer to Percy Williams Bridgman

Professor Bridgman, I would not begin by forcing the quantities to agree. A hardware trigger edge and a computed envelope maximum are different operational measurands. They can be compared through a validated transfer model if the intended physical quantity is identified, but they should not be treated as interchangeable merely because both are expressed in seconds. A controlled impulse provides one test of the relationship, not a universal constant, because the envelope maximum can depend upon input frequency content, filter bandwidth, signal amplitude, noise and the selected peak estimator. The hardware trigger may also have amplitude-dependent threshold walk or metastability effects. These should be measured rather than hidden inside a post-hoc time shift.

To calibrate the relation, define the physical injection plane and a reference pulse whose timing uncertainty is known. Record the actual hardware latch index, the raw acquired waveform and the downstream event declarations. Vary amplitude, duration, signal position within processing blocks and the receiver's relevant operating states. Measure the signed difference of each event

Copyright 2026, James M. Atkinson

timestamp from the reference epoch rather than simply fitting a constant to one favourable trial. If the difference remains constant within a defined uncertainty across the intended envelope, then a fixed-delay correction may be justified. If the difference varies systematically with amplitude or frequency, the report must use a conditional correction model or restrict its asserted timing precision.

The analyst should also preserve the independent input epoch for each instrument, the relevant filter and trigger versions, and the uncertainty of the common reference distribution. If two devices share the same cable or timing generator, a common systematic error may cancel in one relative comparison while still mattering to absolute UTC claims. One should not count two readouts derived from the same uncertain reference as independent evidence that the reference was accurate. The correlation belongs in the uncertainty model. A nominal 'time alignment' should therefore distinguish reference coherence, relative event calibration and physical propagation time.

In the field report I would permit a limited statement such as: the declared envelope-peak estimates were consistent to within a measured interval after applying a characterised delay model, over the specific range of test signals and receiver states. I would not permit the stronger inference that two transmitters necessarily emitted at the same physical instant solely from those aligned estimates. If the source waveform is unknown or the data were clipped, several histories may explain the same observed peaks. This is a limitation of the inverse problem, not an objection to using digital

Copyright 2026, James M. Atkinson

timestamps. The next speakers should address how clock-model updates and uncertainty enter an evidential timeline without suppressing this distinction.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 2: Clock state estimation and the danger of circular alignment

Dr. Atkinson, Mr Nyquist has provided the indispensable distinction between a mathematical coordinate and a physical observation. I would extend it by regarding each receiver clock as a dynamical system whose state is only imperfectly observed. The local counter does not merely carry a static error awaiting subtraction. It evolves under oscillator fluctuations, temperature, ageing, control commands and the occasional discontinuity in the programme responsible for disciplining it. The investigator's estimate of that state evolves too. A chronology created by mapping two receiver counters into a shared coordinate is therefore the result of an inference, and its evidential strength depends upon the observations employed in that inference and upon the dynamical assumptions admitted by the model.

Suppose a receiver clock has an offset state $x(t)$ and a fractional frequency error $y(t)$, so that a simplified continuous-time model is $dx/dt = y(t)$ and $dy/dt = w(t)$, where $w(t)$ is a stochastic driving term representing unpredicted frequency change. This is not a complete account of quartz physics; it is a tractable description over a declared interval. An external reference observation z_k may be represented as $z_k = x(t_k) + v_k$, where v_k includes reference-link delay uncertainty and measurement noise. The resulting estimate may be obtained by least squares, a sequential filter, or a more elaborate inference procedure. But whichever estimator is employed, the residuals must be examined. A filter that yields an elegant time series because its process noise was set artificially low may conceal genuine excursions. Another that is allowed to follow each transient with excessive freedom can absorb the anomaly that the investigator was trying to detect.

Copyright 2026, James M. Atkinson

One must not identify model prediction with observation. Between two reference measurements, the fitted clock state is interpolated or predicted according to specified assumptions. Its confidence bounds should expand with the length and uncertainty of that unobserved interval. If a receiver disconnects from the reference for ten minutes, the system may know that its counter continued monotonically without knowing the exact offset it acquired. Calling that interval synchronised merely because the final archive contains a smoothly corrected time column obscures the difference. This is especially important when an apparent event association depends upon tens of microseconds while the relevant holdover interval may permit much larger clock uncertainty.

Feedback adds a further complication. A clock discipline loop may apply frequency corrections gradually, step the clock under exceptional conditions, or replace the grandmaster when a reference becomes unavailable. The resulting control record is a physical part of the measurement system. A map that assumes one affine transformation, t = alpha + beta C, throughout a session crossing a clock step is not a correction but a false history. Preserve each segment, the measured offset at every reference exchange, the identity of the disciplining source, the control state and the time at which the correction took effect. If a system's wall clock is stepped backwards, two identical wall-clock labels can refer to two distinct chronological instants. A monotonic acquisition counter can help disambiguate them, but only if its relation to the corrected wall clock was recorded.

My concern is strongest where the observed radio events are themselves used to align the receivers. A common burst may legitimately serve as a

Copyright 2026, James M. Atkinson

relative timing marker if its physical relationship to the receiving sites is known or appropriately modelled. But a burst whose common origin is under investigation cannot also serve as unacknowledged independent proof of that origin. If the analyst shifts one trace until two peaks coincide, the fitted shift is the hypothesis-dependent alignment parameter. It must not be added to the dossier as an external confirmation that the events were simultaneous. The proper method separates training markers from challenge events, or jointly estimates clock offsets and propagation parameters while retaining the uncertainty and identifiability limitations of that joint model.

Even an external common-view reference carries dependence. Two receivers may obtain signals from a third clock and subtract them, suppressing portions of the shared reference error. That improvement is useful; it does not mean each receiver's individual UTC error vanished. A common disturbance can enter the corrected differences with either sign depending on the comparison being made. The covariance matrix should distinguish an error shared by both timing chains from errors private to each site. An investigator who squares two identical reference uncertainties and adds them as independent contributions may overstate one relative uncertainty, while an investigator who assumes perfect cancellation when propagation paths differ may understate it. Neither shortcut is faithful to the stated architecture.

I would therefore design the clock investigation as two related experiments. First, use independent reference events to determine the model's predictive performance across the expected observation interval. Record reference residuals, discontinuities, outliers and the uncertainty of

Copyright 2026, James M. Atkinson

drift extrapolation. Second, give the system concealed event challenges whose physical relationships are known, but whose times and propagation differences are not used to fit the time map. Examine whether the corrected timestamps recover those relationships within the claimed uncertainty. If the model succeeds only when evaluated upon the same reference pulses that trained it, it has established a good fit, not an independent validation of forensic performance.

A well-designed record should permit a future reader to re-estimate the clock state without destroying the original receiver counters or assuming that the original correction was inevitable. Preserve raw monotonic counts, reference records, filter settings, adjustment history and the software version that produced the displayed UTC labels. Where the raw record is no longer recoverable, a derived chronology may still support a weaker finding, but not every precision claim advanced by its printed decimal places. Engineering effectiveness, statistical inference and legal presentation must each respect that distinction. I pass the token to Mr Huygens, whose investigations of oscillation invite an examination of the difference between a regular mechanism and a reliable temporal reference.

Christiaan Huygens | Peer question 2 to Norbert Wiener

Professor Wiener, you describe the local clock as a hidden dynamical state, yet I should like to examine how the laboratory decides that its chosen state equations are adequate. An oscillator may appear regular over a short interval while its period shifts after heating, vibration or changes in mechanical loading. Equally, two clocks that appear mutually regular may share a common disturbance through their surroundings or reference source. Suppose an examiner measures a timing difference at

Copyright 2026, James M. Atkinson

the beginning and end of a survey, assumes a linear drift between those observations, and then uses that line to assert a precise ordering of two brief emissions near the middle. The residual at each endpoint can be exactly zero while the actual intermediate error is substantial. Would you require intermediate reference observations, a physical model of the disturbance, or a tested empirical upper bound on excursions? How can the examiner avoid the opposite temptation, which is to enlarge every uncertainty interval until even an observation supported by excellent clocks becomes incapable of distinguishing any practical event order?

Norbert Wiener | Immediate answer to Christiaan Huygens

Mr Huygens, the central error would be to regard agreement at the endpoints as evidence of a trajectory between them. Two point observations determine the affine line exactly in a numerical sense, but they provide no independent evidence about deviations from that line. The experiment must therefore ask which deviations remain physically possible under the admitted operating conditions. An oscillator's temperature, power state, control history and relevant stability measurements may constrain that possibility. A series of independent intermediate reference comparisons supplies stronger evidence because it can disclose curvature or abrupt changes otherwise invisible to an endpoint fit. The number and spacing of those comparisons should follow the accuracy needed for the actual claim, not a ceremonial requirement to collect as many readings as possible.

Where intermediate observations are absent, the examiner should propagate an uncertainty supported by the clock's known stability

Copyright 2026, James M. Atkinson

and operating envelope. The uncertainty may grow with the time since the last reference; its precise law depends on the noise model, not on an arbitrary rule that every clock drifts linearly. A validated oscillator model permits a narrower interval than an unidentified free-running clock because the former has evidence constraining its possible behaviour. Stability statistics should be reported with their averaging times and data-selection conditions. One Allan-deviation number cannot serve as a universal bound on every possible transient, and a manufacturer's nominal oscillator tolerance does not prove a field unit achieved that tolerance during a particular event.

I would design a test in which known reference events occur at irregular, concealed intervals during the receiver's actual operating programme. The analyst would fit a map without access to selected challenge events, then calculate prediction residuals on those withheld events. A persistent bias, excess residual variance or dependence on temperature would invalidate the proposed uncertainty budget. That result should lead to a revised or narrower model, with the revision itself documented rather than replacing the original experiment with an apparently inevitable success. In the absence of such a challenge, the report must be explicit that an interpolated estimate is conditional.

But bounded uncertainty is not a counsel of paralysis. If two events are separated by two seconds and the combined uncertainty is tens of milliseconds, their order may be secure for the intended purpose. If the separation is ten microseconds and the uncertainty is hundreds of microseconds, it is not. The correct choice is to match measurement

Copyright 2026, James M. Atkinson

effort to decision stakes. A relative ordering claim requires an interval for the corrected time difference; it does not automatically require national-standard absolute UTC calibration at each site. Conversely, an absolute chronology tendered to a court demands an identified time scale and a defensible mapping from the physical event to that scale. The issue is fitness for purpose, not the pursuit of unlimited precision. I invite Professor Michelson to challenge whether the act of measurement itself contributes a neglected delay.

Albert Abraham Michelson | Peer question 3 to Norbert Wiener

Professor Wiener, a time map constructed from recorded reference pulses may be internally consistent and yet fail to identify the physical arrival time of a radio transient. Consider two receivers sharing a master frequency reference but using antennas, transmission lines, analogue filters and digital detector algorithms with different propagation delays. The laboratories agree upon their counter epochs to far better than one microsecond. A source then produces a brief wideband pulse, and the two systems return envelope peaks that differ by several microseconds. Is it legitimate to correct the difference with cable-length estimates alone? An optical or electromagnetic measurement depends on its entire path, and the apparent delay may be affected by dispersive filtering, threshold walk and an uncertain definition of the pulse feature. How would you separate reference-clock error from the receiver transfer delays and from the physical propagation difference that might bear upon source localisation? Which observations would be required before a residual timing difference could serve as a geolocation constraint rather than a trace-alignment convention?

Copyright 2026, James M. Atkinson

Norbert Wiener | Immediate answer to Albert Abraham Michelson

Professor Michelson, no isolated clock correction can substitute for calibration of the signal paths. In the measurement equation, the observed event time is the sum, with appropriate signs, of a source emission epoch, propagation delay from source to receiving reference plane, analogue path delay, feature-extraction delay and timestamp-clock error. The last is only one component. If the investigator cannot identify the other terms, a very precise clock may generate very precise measurements of the wrong quantity. A cable-length calculation is admissible as a conditional estimate only if dielectric velocity, cable configuration and their uncertainties are known. It is particularly weak as a substitute for a system-level impulse response when analogue filters and nonlinear detectors contribute frequency- and amplitude-dependent effects.

I would therefore choose a common physical injection plane and a test signal family representative of the claimed emission. Feed the receivers with a calibrated distribution whose relative path delays can be independently measured. Preserve both raw waveform acquisition and event detector outputs. Compare the resulting counter-index differences for several pulse widths, centre frequencies, amplitudes and threshold states. A fixed offset model is justified only when its residuals stay within the specified acceptance bounds throughout the claimed operating envelope. When the detector feature changes its position with amplitude, the report must either define an amplitude-dependent timing correction or weaken its timing claim. The

Copyright 2026, James M. Atkinson

reference-plane definition should appear in the final statement, not be buried in a laboratory worksheet.

For source localisation I would include the geometry explicitly. Let the source coordinates be unknown, and each receiver position be measured with suitable accuracy. Propagation-time differences yield geometric constraints only after clock and instrument delays have been accounted for. A residual difference between two stations ordinarily defines a family of possible source locations, not a unique point. Obstacles, multipath and antenna response can produce apparent excess delay beyond simple line-of-sight propagation. The investigator must challenge the model with alternate receiver placements or a third site when practicable, or retain the ambiguity. If all stations rely on one uncertain reference, shared error may cancel in relative differences while remaining relevant to absolute event epochs. Covariance must be preserved through the transformation.

An evidential record should accordingly contain three layers: the raw acquisition coordinates, the calibrated instrument reference-plane estimates, and the geometrical inference. Each layer should have its own assumptions and uncertainty. Where only detector logs survive, one should not claim to have retrospectively measured the original analogue waveform's exact arrival edge. Where a well-characterised system does preserve calibrated timing information, one can make a useful bounded statement, perhaps excluding some locations while not distinguishing the remaining ones. These are competent uses of measurement, not a failure to achieve a more theatrical certainty. I return the token to Dr. Atkinson for the

Copyright 2026, James M. Atkinson

statistical examination of what the time intervals can actually establish.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal response 3: Uncertainty intervals, clock-model selection and propositions of simultaneity

Dr. Atkinson, the preceding account has identified the instruments. I should ask what proposition their measurements are being offered to establish. A narrative that two radios emitted together may mean that their inferred source-emission epochs were identical, that their received pulses overlapped within a specified interval, or merely that two detectors declared alarms with similar display timestamps. These are not the same hypotheses. A precise statistical procedure cannot compensate for a claim that changes identity between calibration, examination and report. Before estimating a probability of coincidence, the investigator should specify the population of events, the time interval over which the instruments were exposed, the event-selection rules and the uncertainty of the clock transformations. Otherwise the number printed at the end of the analysis may be mathematically defensible for a different experiment from the one that actually took place.

Let t_A and t_B denote two estimates on a common defined time scale, referring to the same type of physical feature at declared receiver reference planes. Set D = t_B - t_A. If the estimates carry standard uncertainties u_A and u_B and a correlation coefficient rho, the linear covariance formula gives u_D squared = u_A squared + u_B squared - 2 rho u_A u_B. This equation follows from the variance of a difference and is not a universal guarantee of normality, stationarity or calibrated coverage. If both times depend on a common reference, their error terms may be positively correlated, and treating them as independent can overstate the uncertainty of one relative comparison. If a calibration error produces opposite-signed

Copyright 2026, James M. Atkinson

responses, the correlation may be negative, and an independence assumption would understate the result. The sign, magnitude and relevance of the covariance must be justified by the timing architecture and evidence.

Statistical claims require attention to the distinction between a confidence interval for a fixed but unknown parameter and a probability assertion about the truth of a hypothesis. Under declared regularity assumptions an interval constructed by a procedure may cover the parameter with a specified long-run frequency. That does not mean, after observing a single interval, that there is automatically a ninety-five per cent probability that the fixed physical event difference lies inside it. Nor does an interval including zero demonstrate that the events were simultaneous. An interval excluding zero may provide evidence of a nonzero difference under its model, while one including zero may simply indicate insufficient resolution. A claim of practical simultaneity often requires an equivalence criterion specified in advance, such as |D| being below a physically justified tolerance Delta, and evidence that the plausible interval for D lies within that tolerance. Failing to reject difference is not the same as establishing equivalence.

A forensic application should distinguish three uncertainties. The first concerns clock offset and rate estimates obtained from reference observations. The second concerns the acquisition and feature-definition process, including delay and threshold walk. The third concerns the interpretation that two declared features correspond to one physical source event. That last proposition may depend on signal classification, propagation and the number of unrelated events occurring during the survey. The probability that an unrelated event appears inside a matching

Copyright 2026, James M. Atkinson

window is affected by the search window and candidate-event rate. A chronology that contains hundreds of possible associations needs control of multiplicity; it cannot select the nearest pair after examining the entire archive and then report a single-pair probability as though only one trial had been conducted.

Consider the investigator who chooses a window of plus or minus five milliseconds after viewing the results and finds an apparently impressive match. If the window was selected because it included that match, the selection procedure alters the relevant chance distribution. A legitimate examination may explore several windows to characterise sensitivity, but it should record the exploration and reserve independent evidence for the final conclusion. Better still, declare the matching rule and acceptable timing uncertainty before the candidate events are exposed. Calibration residuals can support a justified window, provided the residuals represent the operating conditions and were not themselves selected for favourable behaviour. Where event rates are highly clustered or dependent on a common external stimulus, a homogeneous Poisson model may be misleading. The analyst should test alternatives rather than describe one assumed rate as observed fact.

The event population itself may be censored. A scanning receiver observes only the frequencies and intervals covered by its dwell schedule. A triggered recorder preserves only those bursts meeting its threshold and buffering rules. If one instrument did not report an event during the nominal coincidence period, that absence can support a conclusion only if its actual exposure and detection probability are known with sufficient confidence. The timestamp distribution of detected events is not generally

Copyright 2026, James M. Atkinson

the distribution of all emissions. Selection by threshold, pulse width and instantaneous noise conditions can shift the apparent event time. An amplitude-dependent detection delay must be characterised or included as a nuisance term. Likewise, if a clock correction is fitted only to those events that appear common to both receivers, the procedure selects agreement and may suppress evidence of its own errors.

Validation should consequently be split. In one set of trials, reference pulses determine clock maps and measurement-model parameters. In another, concealed challenge signals test the predicted timing differences under realistic gain, filter, temperature and acquisition conditions. The test set should contain false candidates and null periods, not merely known simultaneous pulses. Its performance measures should include missed events, false associations, timing outliers and invalid reference intervals. An examiner who excludes low-quality observations must preserve those exclusions and explain whether the claimed operating envelope also excludes such field conditions. Repeatedly retuning the algorithm until it passes the same test set converts the test into an extension of training; a new independent challenge is needed to assess general performance.

I would allow a technically useful conclusion where its premises remain clear. It might read that two detector features are temporally compatible within a specified corrected interval under a declared clock and path model. It might read that an observed difference excludes an event ordering claimed by one hypothesis, given an uncertainty budget supported by challenge tests. It should not leap from temporal compatibility to common source identity, nor from a failure to see an expected partner event to evidence of its absence without exposure analysis. The final report must

Copyright 2026, James M. Atkinson

preserve both the signed time difference and its uncertainty, because readers may be entitled to test alternative matching tolerances. I thank the moderator and pass the token to Mr Gosset, whose experience with finite samples will expose the practical danger of certifying clock performance from too few reference observations.

William Sealy Gosset | Peer question 4 to Jerzy Neyman

Professor Neyman, your argument places a properly defined confidence procedure between the raw observations and the final evidential statement. Yet the investigator's laboratory may possess only six independent timing-reference checks collected during the field session, and those checks may not span the thermal excursions or clock-state changes of the entire survey. Suppose the six residuals appear reassuringly close to zero. The operator is tempted to calculate their sample standard deviation, multiply by a familiar coverage factor, and publish a narrow error bar. The figure may impress a court because it appears quantitative. What safeguards would prevent such a small sample from concealing a skewed distribution, a clock step that occurred between checks, or systematic uncertainty common to every reference? Would you insist upon a particular interval method, or instead distinguish the repeatability that six observations support from the broader assurance that the entire investigation requires? I would also ask how the timing report should preserve a useful practical conclusion where the observations are too few for an elaborate distributional model.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Immediate answer to William Sealy Gosset

Mr Gosset, six observations are not inherently worthless, but their information is finite and conditional. A small-sample calculation can be appropriate for a narrowly specified population with a defensible model, and your distributional work reminds us that estimating variance from limited observations introduces uncertainty of its own. But a calculation based solely on those six residuals cannot certify a clock trajectory during intervals never challenged. If the error includes a systematic delay common to all checks, repetition may reproduce the same biased answer with excellent precision. The sample standard deviation measures dispersion among the observed results, not necessarily uncertainty of the physical reference plane or correctness of the reference itself.

I would first enumerate the terms in the uncertainty budget. Residual repeatability from the six checks is one term. Reference-source uncertainty, cable and latch delay, model-selection error, clock drift between checks, and untested thermal states are separate terms. Those contributions need not all be treated as random draws from one normal distribution. Some may require physical bounds, prior calibration data or sensitivity analysis. Where a Student-style small-sample interval is used, its assumptions must be stated, particularly whether residuals are reasonably independent and approximately distributed as assumed. If the clock undergoes a discontinuous step, neither a small-sample t interval nor a Gaussian fit will discover the missing event unless the measurement procedure observed or otherwise bounded that step.

Copyright 2026, James M. Atkinson

The next safeguard is to retain the individual observations and their timing, rather than publish only a mean and a standard deviation. A sequence of residuals may reveal drift, dependence upon elapsed holdover time or a change coincident with equipment temperature. A six-point sequence sampled at widely spaced times has different evidential value from six measurements collected within a few seconds. The examiner should plot or tabulate the raw residuals, compare them with the proposed dynamic model, and report any failure to test the most consequential conditions. If independent records show reference-lock loss, an uncertain period should be designated invalid even when its nearest measured residuals were small.

Finally, I would match the statement to the evidence rather than disguise the deficit. If the six checks support only a millisecond-level bound under declared conditions, that may be ample for demonstrating the gross ordering of two transmissions separated by several seconds. It is inadequate for a microsecond-level time-difference localisation claim. The report should explicitly say which conclusions are robust under plausible alternatives for the untested intervals. A useful but limited finding is preferable to the false precision of a narrow interval whose coverage assumptions have not been challenged. I now invite Dr Shannon to address whether any digital transformation can supply the missing history or whether it can merely provide an orderly representation of what survived.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 4: What synchronisation preserves and what an event archive omits

Dr. Atkinson, the decisive question is not whether a receiver's numbers can be rearranged into a common sequence. It is whether the retained observations contain the information needed to answer the proposed physical question. A clock correction assigns a different temporal coordinate to surviving samples. If the original counter positions and a validated mapping are available, that coordinate change may be reversible as a description of the observed data. It does not re-create samples omitted by a triggered archive, restore a clipped transient, or reveal the phase of a reference clock during an interval in which no appropriate measurement was made. The distinction between transformation and information acquisition is fundamental. One can draw a very fine time axis through sparse data, but the drawing does not fill the empty intervals with experimentally acquired evidence.

Consider a stream recorded at sample rate F_A with known counter n and a second stream recorded at F_B with counter m. A resampler may transform one numerical representation onto a common evaluation grid, provided its signal-model premises and filter design are appropriate. But an interpolation coefficient does not constitute a direct observation at the interpolated instant. The reconstruction assumes an admitted bandwidth and a sufficiently characterised acquisition system. When a detector has retained only peak times or log messages, its original waveform may be no longer available for any reconstruction. A later analyst cannot infer the actual onset edge from a single timestamp unless further assumptions

Copyright 2026, James M. Atkinson

about pulse shape, detector delay and threshold are independently justified. This limitation is not repaired by representing the log time in nanoseconds.

There are at least three coordinate systems in a modern receiving instrument. The analogue acquisition system has a physical time of contact between incoming signal and sampling aperture. A digital signal processing stage may carry an index referring to a window midpoint, the first contributing sample, the last contributing sample or the instant at which a detection decision is made. A software environment may append the time at which a buffer was delivered or written to storage. The metadata field called timestamp does not itself specify which coordinate system was used. A robust evidence schema records timestamp semantics, source clock, counter rate and the exact stage of acquisition at which the value originated. It should also record if an event time was estimated by interpolation or corrected for filter delay.

A phase-coherent combination poses a stronger question than a simple time-ordering comparison. If two receivers are to combine complex samples coherently, then the relevant unknowns include not only common event epochs but relative carrier phase, oscillator drift, mixer sign, sampling aperture and channel transfer phase. A shared ten-megahertz reference may stabilise frequency, but the resulting radio-frequency local oscillators can retain independent phase states and state changes. A common pulse-per-second edge may establish a counter epoch while leaving an unmeasured subcycle phase. These mechanisms can introduce a rotating complex factor between streams even when a pair of wall-clock labels agree. A calibration suitable for associating two bursts within a millisecond might

Copyright 2026, James M. Atkinson

be wholly unsuitable for coherent amplitude addition or radio direction finding from phase.

The information in an estimated clock map must be distinguished from the information in a common observed reference. If the two receivers independently measure the same designated calibration pulse, their relative time relationship can be estimated, subject to path delay and event-definition uncertainties. If they merely receive the same network time messages, the resulting agreement is governed by the protocol and network model. Each may be entirely suitable for a particular level of chronology, but neither supports a stronger conclusion without additional calibration. As the NTP protocol itself distinguishes offset, delay, dispersion and jitter, an application that records only a synchronised flag omits variables important to a later uncertainty assessment. In precision time systems, the timestamp point and network path asymmetry are physical components of the measurement, not incidental software details.

A useful archive should therefore contain at least two temporal descriptions for material events: the original acquisition counter and the derived time-scale estimate. These can be linked by a versioned clock model rather than allowing the derived estimate to replace its ancestor. If the clock model changes, the retained counters permit reprocessing with a revised map. The model record should include leap-second or other time-scale conversion tables where civil or satellite time is involved, because a label such as GPS time or UTC represents a defined scale rather than merely a string format. A conversion based on the wrong table can shift absolute times by whole seconds while preserving excellent interval regularity within each stream. In contrast, if the analysis concerns only the difference of two

Copyright 2026, James M. Atkinson

events close in time within one uninterrupted monotonic clock, an absolute UTC offset may cancel and a simpler comparison may be adequate.

The greatest danger is causal overinterpretation. A very strong spectral similarity and compatible event chronology can support a hypothesis of common activity; they do not logically compel a unique source history. Two devices may respond to the same external interference. Two independent emitters may be controlled by one upstream process. One receiver may generate a replica of an external signal through intermodulation or aliasing. An analyst must therefore specify what alternatives the evidence excludes and what it leaves unresolved. Timing measurements are particularly seductive because numerical alignment gives an impression of geometric necessity. The signal's content, antenna path, receiver state and calibrated propagation conditions must carry their own evidential weight.

My practical rule is to preserve the distinction between an original sample, a deterministic transformation, a probabilistic estimate and a causal inference. Label each stage. Retain the model, parameters, software, uncertainties and invalid intervals. Do not silently replace samples with a resampled product or treat a narrow output bin as an observed instant. When the underlying representation lacks the information for a desired future question, document that limitation and seek a different acquisition method next time. The next suitable experiment may require continuous raw baseband retention around a material event, a separate high-resolution time reference or two physically independent receiver paths. The desire to answer a forensic question cannot create evidence that was never measured. I pass the token to Lord Kelvin to inquire whether a derived time label can be considered traceable when the calibration chain is incomplete.

Copyright 2026, James M. Atkinson

William Thomson, Baron Kelvin | Peer question 5 to Claude Elwood Shannon

Dr Shannon, a common time coordinate lends great authority to a measurement report, particularly when the timestamp appears beneath a diagram resembling a precision scientific instrument. Yet a chain of conversions may begin with an instrument manufacturer's unspecified oscillator calibration, pass through network timing software, and terminate in a derived event label whose decimal places are abundant. In electrical metrology I should demand knowledge of the comparison standard, the transfer path and the uncertainty at the point of application. How would you distinguish an honest claim of relative timing consistency from an assertion of traceability to an international time scale? If a disciplined clock announces lock while the hardware timestamp belongs to a different oscillator domain, should the resulting timestamp be considered traceable at all? Moreover, must a field investigation always procure an international time standard, or can a properly compared pair of local clocks provide sufficient evidential support for a restricted difference measurement? I ask where measurement discipline ends and an unnecessarily expensive ceremonial appeal to standards begins.

Claude Elwood Shannon | Immediate answer to William Thomson, Baron Kelvin

Lord Kelvin, I appreciate your insistence upon traceable physical time. Traceability is a property of the measurement result and its documented chain of comparisons, not of the name affixed to a computer's clock source. If a timestamp must be represented as UTC,

Copyright 2026, James M. Atkinson

the examiner needs a defensible connection from the relevant physical event to a recognised realization of that time scale, with applicable calibration uncertainties and corrections. A locked status indicator may demonstrate that a control system accepted a reference. It does not establish that a different hardware oscillator domain remained phase-aligned, or that the delay from the antenna to the timestamp latch has been measured. The chain may contain an uncharacterised link, and the claimed uncertainty must not skip over that gap.

A relative time-difference result can nevertheless be rigorous without an absolute civil timestamp. Suppose two receiver counters are calibrated through a common injected event and a measured distribution path, and the question is whether two arriving pulses differ by more than a specified microsecond threshold. The relative comparison may be defended if its uncertainty and path assumptions are adequate, even if both devices are several seconds wrong against UTC. What would be unjustified is promoting that relative result into an absolute event date or source-emission epoch without the additional reference. The physical quantity being measured determines the required chain. Precision practice is not necessarily a request for a more expensive clock; it is a requirement that each asserted link be supported.

I would preserve a short provenance record with each derived time: counter identity, reference edge or protocol observations, correction version, event detector semantics, and any leap-second or UTC-offset convention. Where the reference is shared, mark that dependence so

Copyright 2026, James M. Atkinson

that future uncertainty calculations do not double-count or falsely cancel a common error. Where the calibration was checked only before and after the operation, identify the interval between checks and the model used to infer clock behaviour within it. Where the reference was lost, terminate the validity interval unless holdover performance has been separately established. Such metadata may be compact, but it makes the result reproducible and contestable.

This record also separates honesty from paralysis. A reported bound of several milliseconds may be entirely sufficient to establish that a sequence of transmissions occurred in a particular order, while an unverified nanosecond label could mislead a reader about far more delicate claims. The operative question is whether the evidence supports the chosen proposition at the required scale. It would be a mistake to discard useful relative observations merely because an absolute timing chain was unavailable; it would be worse to disguise their limitation behind the authority of the international standard. A good laboratory specifies which result is traceable, which is conditional and which remains unmeasured. I thank Lord Kelvin and return the floor to Dr Hamming, whose concern with reproducible computing can give these distinctions a durable evidential form.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Principal response 5: A reproducible common timeline without destroying the raw counters

Dr. Atkinson, the apparatus has given us a collection of timestamps; our task is to develop a record that can be reproduced and challenged without needing to reconstruct the entire laboratory from memory. The worst approach would be to store only the final corrected UTC column and discard the original clock readings. A future examiner would then be unable to identify whether a surprising coincidence came from physical observations, a calibration revision, a change in timestamp semantics, or an interpolation algorithm. The correct data structure preserves the original acquisition index, counter domain, time-scale mapping, correction provenance and the uncertainty of the resulting physical quantity. It also records all discontinuities. In this sense a digital forensic timeline is a measurement model that has acquired a history of its own.

I would construct the record as a directed chain of transformations. The base record contains the raw sample index or counter tick, the receiver serial or other nonsecret stable instrument identifier, the sampling-clock domain and the acquisition-boundary event definition. An adjacent record contains reference observations, their own original timestamps, estimated cable and filter delays, environmental states and the applicable calibration versions. A transformation record specifies the fitted offset and rate, any piecewise changes, the residual statistics and the software algorithm. A derived record carries the interpreted epoch together with its uncertainty interval and relevant covariance identifiers. The complete chain can be cryptographically hashed for integrity, but the digest proves only that the

Copyright 2026, James M. Atkinson

preserved bytes have not changed since hashing. It does not certify that the clock or acquisition model was physically accurate.

A full programme must cope with several clock types. An ADC sample counter may be strictly monotonic but have no directly measured UTC epoch. A host clock may be disciplined by NTP and subject to adjustment or occasional steps. A network interface may insert a hardware timestamp closer to packet transmission than the operating system, yet still be separated from the antenna acquisition by buffering and processing delay. A GPS-disciplined reference may support stable frequency while its initial epoch, distribution cable and holdover behaviour remain conditional. These should not be flattened into one field called event_time before their distinctions are documented. A simple column for timestamp_type can help, but the data dictionary must explain the physical event represented and the clock scale used.

A practical timeline should also distinguish raw association hypotheses from accepted associations. Suppose instrument A reports candidate 7 at sample counter 381,450,000 and instrument B reports candidate 14 at counter 82,725,100. The candidate indices are facts about their respective archives; the assertion that they refer to the same emission is a hypothesis. The clock-model records may map them into overlapping time intervals, but that is only a consistency test. The report should retain alternative matches, unmatched detections, rejected comparisons and instances in which a receiver was not exposing the relevant band. It should not silently remove counterexamples when preparing a polished narrative. One goal of reproducibility is to permit another investigator to try a different, reasonable association rule and discover whether the conclusion survives.

Copyright 2026, James M. Atkinson

I would favour immutable source objects and versioned derived objects. For each source file, record its length, format, byte-order, sample structure, original digest, collection identity and custody events. The transformation manifest should include source object digests, exact reference files, filter and detector versions, timing parameters and any manual decisions. If a processing step changes sample rate or timestamp origin, the new object should declare the relation to the parent rather than merely reusing its name. A mathematically correct reprocessing operation can still produce a misleading historical statement if its output's time semantics are mistaken for the original event. The software must not conceal that distinction under a friendly user interface.

The design should include checks on impossible time behaviour. An input counter should not decrease without a documented wrap or reset. A map should not silently change its slope when a clock source switches. Event chronology should flag apparent backwards UTC motion, reference-age thresholds, invalid or uncertain leap-second interpretations, and timestamps whose uncertainty exceeds the decision window. Assertions of source motion derived from time differences should be checked against the receivers' known geographical geometry and propagation limits. A pulse difference larger than the maximum free-space arrival difference for two stations separated by a fixed baseline cannot be explained by ordinary direct propagation from a single source without an additional model such as multipath, receiver delay or faulty clocks. Such impossibility checks are valuable because they reveal when an elegant display is inconsistent with its own premises.

Copyright 2026, James M. Atkinson

Reproduction should be achievable by an independent examiner with the surviving data. The original raw objects must remain unchanged; the examiner should run a documented transformation against their preserved copies and obtain the same derived times within a defined numerical tolerance. The computation should record the time-scale library and any discontinuity-handling conventions. Where manual feature selection was necessary, preserve the chosen sample intervals and the decision criterion. Where adaptive thresholds or machine-learning detectors were used, retain the model version and event-selection exposure. Software that produces an answer only from a proprietary hidden state may still contribute to a search, but its unreviewable estimate is a weak basis for a strong forensic timing claim.

There is a temptation to treat an index-and-mapping archive as cumbersome compared with a convenient final event table. The objection mistakes reproducibility for redundancy. A relatively small manifest may preserve the essential lineage of many large recordings. If the full raw baseband cannot be retained indefinitely, prioritise preserved intervals around material events while recording which intervals were not retained and why. Store the detector state and duty cycle so that negative evidence can be bounded. A published report may be concise, but its underlying laboratory records should permit an examiner to see the actual distinction between a physical observation, a computer-derived estimate and an inferential claim. That hierarchy is worth the trouble precisely because an attractive coincidence plot can persuade before its hidden timing assumptions have been examined.

Copyright 2026, James M. Atkinson

I would conclude the engineering portion with a test plan: challenge the time mapping using withheld reference events, exercise resets and source changes, test the effects of actual filter delays, verify independent replication of all conversions, and compare the headline interpretation against the full set of candidate events including unsuccessful associations. These trials will not answer every conceivable historical question, but they provide a defensible boundary for those that matter. A time difference is a measured quantity only when its clock and path corrections are justified. A displayed timestamp can be accepted as a data value without accepting every story later attached to it. I pass the token respectfully to Professor Pearson and Dr Tukey, who may test whether the archive's statistical summaries are as faithful as its original measurements.

Karl Pearson | Peer question 6 to Richard Wesley Hamming

Dr Hamming, a complete data lineage is valuable, yet I fear that a laboratory may render it apparently authoritative by attaching a long list of numerical uncertainty terms without examining the dependence among them. Suppose two instrument logs obtain their times from one grandmaster and one packet network, but their reported clock errors are aggregated under an assumption of independence. A naive calculation might produce an uncertainty interval narrower than the effect of shared asymmetrical delay, or wider than is justified for a relative difference when common errors cancel. How would your schema prevent the analyst from confusing a catalogue of uncertainty components with a valid covariance model? Would you require every source of error to have its own shared identifier, and how would an external reviewer determine whether that identifier represents a measured physical dependence or

Copyright 2026, James M. Atkinson

an assumption selected for computational convenience? I should also like to know whether a pairwise correlation estimate based on a few favourable calibration intervals ought to survive without explicit qualification into an eventual legal report.

Richard Wesley Hamming | Immediate answer to Karl Pearson

Thank you for that question. Professor Pearson, a list of uncertainties is indeed not a model. The schema must represent dependencies among uncertainty terms, and the report must explain why the dependencies have the sign and magnitude assigned. Shared reference-source error, common distribution path delay and errors in a fitted drift model can enter several receiver timestamps together. A relative time difference may cancel portions of that shared error, but only where both measurements respond to the common term in the same way. The mathematics of a difference can subtract a shared term; the hardware may not. We need a description of the actual clock distribution and timestamp-latching path to know which algebraic cancellation is physically justified.

I would include explicit identifiers for clock domains, common references, calibration sessions and processing versions. Those fields are documentary evidence of possible common causes, not automatic estimates of statistical correlation. The covariance matrix is a separate analytical record whose entries must be supported by measured comparisons, physical modelling or defensible conservative bounds. If correlation estimates come from only a few observations, their sampling uncertainty should be retained rather than replacing it with a falsely exact coefficient. Analysts should be able to repeat the

Copyright 2026, James M. Atkinson

calculation with alternative plausible correlations and report whether the conclusion changes.

A good transformation programme should make dependence visible. It can link each corrected timestamp to the reference observations and software terms that contributed to it. A new examiner can then see that two apparently independent event times inherited the same disputed network offset. A pairwise difference can be recomputed using the appropriate covariance, and the analysis can be compared with a conservative interval model that does not assume a convenient Gaussian distribution. If a particular inference survives across those alternatives, its robustness is substantive evidence. If it fails, the failure should remain in the record.

The legal summary should avoid a single unqualified probability when the distributional premises are contested. It can state that the estimated arrival-time difference is consistent with a proposed physical relation across the validated range of correlation assumptions, or that its apparent precision relies materially on one untested assumption. As Mr Nyquist and Professor Wiener have insisted, source identity cannot be manufactured from two timestamps. The archive's role is to keep the physical observations and their changing interpretations distinct so that the scientific argument can be inspected. I now invite Dr Tukey to challenge whether this elaborate analysis may overlook a simpler graphical defect that invalidates the entire conclusion.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Peer question 7 to Richard Wesley Hamming

Dr Hamming, you have designed a lineage capable of reproducing the calculation. But a perfectly reproducible calculation can be applied to the wrong segment of data, or to observations that disclose an obvious change of regime when plotted. Suppose a laboratory fits one offset and rate to an hour of reference measurements. Most residuals are small, yet the residual-versus-time plot contains a sudden jump coinciding with a receiver reboot and a slow curvature after the room temperature rises. The final table reports a pooled standard deviation and a reassuring confidence interval, with no visible distinction between the intervals before and after the reboot. Would you require visual and exploratory examination as a substantive validation step rather than a cosmetic plot? Which alternative displays would most readily expose a false coincidence between two receiver streams, and how would you prevent an examiner from manipulating axis limits, smoothing or sample selection until the chronology looks more coherent than the underlying observations justify?

Richard Wesley Hamming | Immediate answer to John Wilder Tukey

Dr Tukey, a reproducible pipeline is necessary but not sufficient. One can reproduce a flawed model exactly. I would require residual displays indexed against actual elapsed time, reference age, instrument state and temperature, together with numerical change-point checks appropriate to the claimed precision. A stepped clock should normally produce an explicit piecewise time map or an invalid interval rather than be absorbed into one pooled error estimate. A

Copyright 2026, James M. Atkinson

curved drift residual indicates that the affine model has omitted a term or that its validity interval is too broad. An attractive mean-square number can conceal both mechanisms, especially when a large population of ordinary residuals overwhelms a small but decisive set of failures.

The plots should be designed to expose the problem, not decorate the conclusion. Show the raw reference-minus-clock differences, the fitted correction, and the residuals on a common independently specified time axis. Annotate resets, loss of lock, filter changes and power interruptions. Display the uncorrected and corrected candidate-event differences, including unmatched events and excluded observations. A scatterplot of one clock's correction against another's can expose shared drift; a plot of residuals against temperature can reveal state dependence. When a confidence interval is advanced, show the empirical residual distribution and a sensitivity analysis to outliers and plausible correlation choices. Preserve the full axis scales and the numerical values used to construct each figure.

I would also require the investigator to state the selection rule by which candidate events entered the comparison. If a colleague manually selected the most convincing coincidences from several thousand detections, the archive must retain that choice and the rejected candidates. Apparent agreement may emerge even from unrelated events when the matching window is widened sufficiently. A plot centred on one chosen event can illustrate a phenomenon, but it cannot substitute for a declared association rule evaluated against

Copyright 2026, James M. Atkinson

the whole eligible event population. This is where statistical discipline protects the engineering account from confirmation bias.

Once the defects are visible, the laboratory may make a new, narrower analysis. Divide the observation into clock-validity segments, refit each with appropriate references, and test the result on withheld challenge events. Do not erase the first analysis; retain the history of correction and the reasons for it. If the new model is materially more complicated, identify the model-selection cost and any uncertainty arising from its added flexibility. The result may remain persuasive where the physical timing difference is large relative to all credible errors, and it may become indeterminate where the difference was minute. That is not inconsistency. It is what occurs when one stops asking a polished graphic to conceal the limits of the apparatus. I return the token respectfully to Dr. Atkinson for the worked cases and concluding synthesis.

Ten worked metrological and forensic applications

The following calculations use independently stipulated hypothetical inputs. They illustrate the difference between an arithmetically valid result and the additional observations required to justify a field conclusion. They do not certify a particular receiver, GNSS installation, network, time scale, source or person's action. Symbols are defined separately in each application; uncertainty categories must not be combined without a compatible distributional or bounding model.

Harry Nyquist, Cross-Peer Question to Norbert Wiener: Professor Wiener, two receivers use nominal ten-megahertz references, but their recorded

Copyright 2026, James M. Atkinson

sample indices diverge progressively. Which clock parameters must be estimated before their traces can share a timeline?

Norbert Wiener, Cross-Peer Answer to Harry Nyquist: Dr Nyquist, at minimum one must establish an epoch offset and a rate ratio over the interval of interest, then test for nonlinear drift, jumps and missing samples. A simple affine mapping from sample index n to reference time may be adequate over short stable periods, but long captures can require piecewise or stochastic models. Obtain physical calibration markers at both receivers where possible, rather than relying only on a host log written after buffering. Record the uncertainty and covariance of the fitted offset and frequency, because estimates derived from a common reference are not independent. A highly stable clock may have a fixed frequency error, while a clock with an accurate mean may wander rapidly. Preserve original indices and corrected time coordinates separately. I pass the token to Dr Neyman.

Norbert Wiener, Cross-Peer Question to Jerzy Neyman: Dr Neyman, if a single synchronising pulse appears in two streams, may the analyst calculate a unique clock-drift rate between them?

Jerzy Neyman, Cross-Peer Answer to Norbert Wiener: Professor Wiener, one pulse supplies a relative time anchor under a latency model but cannot uniquely determine both epoch offset and frequency drift. At least two separated timing references are needed for an affine fit, and additional references are essential to assess time-varying deviation, residuals and outliers. The fit should include uncertainties in the marker generation, cable propagation, detection threshold and instrument latency, with covariance if the references share sources. A very precise regression coefficient does not compensate for a biased marker or hidden sample loss. Test the mapping

Copyright 2026, James M. Atkinson

against withheld markers or an independently timed event. Report confidence intervals for each corrected event timestamp rather than one unqualified decimal time. I respectfully yield to Dr Shannon on the information lost through clock reconstruction.

Jerzy Neyman, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, two files display matching timestamps after retrospective interpolation. Does that prove that the receivers observed one physical pulse simultaneously?

Claude Elwood Shannon, Cross-Peer Answer to Jerzy Neyman: Dr Neyman, no. A timestamp is an estimated coordinate on a time scale, not a direct proof of propagation or shared source. Distinguish antenna arrival, analogue group delay, ADC aperture, digital filter delay, buffering, transfer and host timestamp. Correct each component at the relevant reference plane, retaining uncorrected values and uncertainty. Two systems may agree because they use the same mistaken host timebase or because a software alignment algorithm forced agreement. An independent timing channel or known stimulus injected at both analogue inputs provides stronger evidence. If the uncertainty intervals overlap, the finding may support temporal compatibility without uniquely establishing simultaneity or emitter identity. I respectfully yield to Dr Hamming for provenance controls.

Claude Elwood Shannon, Cross-Peer Question to Richard Wesley Hamming: Dr Hamming, what fields must an archive retain so that a later expert can reconstruct a timeline when the capture suffered one dropped buffer and an unnoticed clock step?

Copyright 2026, James M. Atkinson

Richard Wesley Hamming, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, retain monotonically increasing hardware sample counters where available, original clock-domain IDs, event epochs, synchronisation status, buffer sequence numbers, device resets, operating system clock changes and every known discontinuity. A missing block is a missing interval, not a run of legitimate zero samples. Preserve a change log for each correction, including independent timing references and transformation code. Test synthetic data with deliberately inserted missing buffers and clock steps, then verify that the timeline algorithm identifies rather than silently smooths them. A cryptographic file hash supports subsequent integrity, not original timestamp accuracy. The final report should distinguish absolute-time uncertainty, relative delay uncertainty and possible unobserved gaps. I return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Distinguished colleagues, the discussion has produced a coherent set of requirements for a chronology that can withstand technical cross-examination. Its foundation is modest but demanding: a sample index is an observation within a specific apparatus, while a timestamp expressed on an external scale is an estimate obtained through a chain of comparisons. That chain includes oscillator behaviour, reference distribution, timestamp placement, signal-path delay, event definition, and any transformations performed after acquisition. Treating one element as a substitute for all the others creates an apparently exact chronology without a reliable physical meaning. The question is not whether digital systems can record an event to many decimal places. They certainly can. The question is whether the

Copyright 2026, James M. Atkinson

underlying physical event has been adequately related to those numerical labels under the conditions that actually prevailed.

Mr Nyquist has shown why syntonisation and synchronisation must be separated. Relative sampling rates determine how event-index differences evolve; reference epochs determine where the resulting observations lie on a common time scale. Professor Wiener has explained why the clock map is a dynamical inference whose model and validity interval must be preserved. A two-point linear fit may look exact while failing an independent observation inside the fitted interval. Professor Neyman has insisted that the inferential proposition be defined before calculating an uncertainty or a chance-match probability. A clock difference is not a source identity, and an interval containing zero is not automatically proof of simultaneity. Dr Shannon has distinguished coordinate transformation from information acquisition. A correction can relabel surviving samples but cannot recreate an omitted pulse, missing buffer or unrecorded oscillator excursion. Dr Hamming has translated these principles into a reproducible evidence architecture that preserves counters, corrections, source digests and the decision history rather than only a polished final timeline.

Our peers have provided the necessary resistance to easy claims. Professor Bridgman has required the investigator to define whether an event time means an analogue threshold, a waveform feature or a software declaration. Mr Huygens has warned that clock regularity at two endpoints is not proof of a known path between them. Professor Michelson has placed the physical transmission line, receiver filter and propagation geometry back into the measurement model. Mr Gosset has examined the weakness of certification by a handful of residual checks. Lord Kelvin has distinguished

Copyright 2026, James M. Atkinson

a documented calibration chain from the mere visual appearance of traceability. Professor Pearson has prevented correlation assumptions from disappearing inside a reassuring root-sum-square formula. Dr Tukey has demonstrated how one graph of residuals against time or temperature can invalidate an otherwise reproducible arithmetic summary.

The practical doctrine is consequently tiered. For a discovery log, a bounded description of when an instrument indicated a candidate may suffice, provided the acquisition state, exposure interval and timestamp semantics are recorded. For an assertion that two receivers witnessed related events, the timing maps, event definitions and search-window selection must be challenged together. For a source localisation claim, the investigators must additionally account for physical reference planes, path delays, propagation assumptions and geometrical ambiguity. For a precise absolute date and time, the relevant UTC or other time-scale conversion must be documented, with the applicable reference chain and uncertainty. Each stronger proposition demands evidence not required by the weaker one. There is no benefit in demanding national-standard time for every routine observation, and no justification for using an unvalidated host timestamp as though it were a calibrated antenna-arrival epoch.

The ten hypothetical calculations reinforce the same distinction from different directions. A 25-ns sample interval can coexist with a 250-microsecond epoch uncertainty. A two-part-per-million oscillator discrepancy can accumulate 1.2 ms across ten minutes. A fitted clock line may miss a withheld intermediate observation by 35 microseconds. Nominally shared references can contribute covariance, while cable, threshold and network delays can dominate the error despite a numerically

Copyright 2026, James M. Atkinson

precise clock. A coincidence can occur by chance when enough events are compared; a geometrical time-difference estimate defines a constraint, not a unique location. None of these examples certifies an actual receiver. Their function is to expose the required observations, variables and competing explanations before a technical report employs the language of confirmation.

I therefore require the final evidential chronology to preserve the raw counter identity and values, reference observations, clock-model versions, invalid intervals, signal-path calibration, detector semantics, processed event estimates and their uncertainty dependencies. The report should distinguish what was observed, what was corrected, what was assumed and what could not be reconstructed. It should include unsuccessful associations, reference outages, clock steps and excluded trials. Where the relevant information is absent, the conclusion must be appropriately restricted. The panel has not proved a general method for recovering every historical clock offset; it has established a disciplined way to recognise where such recovery is justified and where it is not. That is sufficient progress for a rigorous investigator. I thank our colleagues for their courteous challenges and pass the floor forward to the next discussion, concerning whether a putatively coherent signal combination remains valid when its timing and phase calibration change during the observation itself.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 040

Worked application 01 | Sample spacing versus absolute timestamp uncertainty

A digitiser nominally operates at F_s = 40,000,000 samples per second. Let n = 80,000,000 be the integer sample index counted from the first physical aperture. Its nominal sample interval is $T_s = 1/F_s$ = 1/40,000,000 s = 25 ns. The elapsed time is $t_{rel} = n/F_s$ = 80,000,000/40,000,000 = 2.000000 s. Now suppose an independently derived acquisition epoch t_0 carries a standard uncertainty u_0 = 250 microseconds. The absolute time estimate is $t_{abs} = t_0 + 2.000000$ s, but its uncertainty cannot be 25 ns merely because the sample interval is 25 ns. Even if the sample-rate contribution were negligible, the epoch term alone leaves approximately 250 microseconds of standard uncertainty. A timestamp formatted to nine decimal places conveys a convention for displaying the estimate, not proof of nanosecond accuracy. The calculator has recovered an elapsed count under a rate assumption; it has not verified the counter's epoch. A suitable field challenge would compare an independently timed input edge with the actual ADC latch, rather than the host file-creation time.

Worked application 02 | Relative oscillator drift and sample-count discrepancy

Receiver B has an assumed constant fractional clock-rate error y_B = 2 parts per million = 2×10^{-6} relative to receiver A. Let T = 600 s be the uninterrupted interval after a calibrated common epoch. Under the stated constant-error model, accumulated time offset is $\Delta t = y_B T$ =

Copyright 2026, James M. Atkinson

$2 \times 10^{-6} \times 600$ s = 0.0012 s, or 1.2 ms. At an aggregate rate F_s = 5,000,000 samples/s, the offset corresponds to $N = F_s \Delta t$ = 5,000,000 × 0.0012 = 6,000 nominal sample intervals. If the error sign were reversed, the clock difference would reverse as well. A time warp fitted to a short pulse near the start of the session may therefore be quite wrong for a later pulse. This computation assumes a constant rate error and an initially known epoch; short-term oscillator wander, resets and reference switching remain outside the model. The acceptance record needs reference observations across the same elapsed interval and a bound on deviations from the constant-rate premise.

Worked application 03 | Two-point offset fit and an independent residual

Suppose a comparison measures receiver B minus reference offset x_0 = +100 microseconds at reference time t = 0 and x_1 = +700 microseconds at t = 300 s. A linear model $x(t) = a + yt$ has a = 100 microseconds and $y = (x_1 - x_0)/(300\text{ s})$ = (600 microseconds)/(300 s) = 2 microseconds/s = 2×10^{-6}. It predicts x(120 s) = 100 + 2 × 120 = 340 microseconds. If an independent challenge pulse at 120 s measures +375 microseconds, the signed residual is r = 375 - 340 = +35 microseconds. Although the model fits both training endpoints exactly, the challenge exposes a departure of 35 microseconds at the event's position. The examiner must investigate clock wander, measurement noise or a missing model term rather than erase the residual as inconvenient. A source association requiring a 10-microsecond tolerance is not validated by this fit. An association tolerating 1 ms may be robust under the same discrepancy, subject to other errors. This example illustrates why

Copyright 2026, James M. Atkinson

independent withheld reference events are scientifically more informative than zero training residuals.

Worked application 04 | Holdover under bounded and stochastic uncertainty assumptions

Let u_0 = 5 microseconds describe a clock's initial standard uncertainty, and suppose an additional fractional frequency-error magnitude is bounded by b_y = 0.2 ppm = 2×10^{-7} during T = 90 s without a usable reference. The maximum additional drift magnitude under that bound is $b_d = b_y T$ = 18 microseconds. If u_0 is instead treated conservatively as a 5-microsecond absolute bound, a simple worst-case magnitude envelope is 5 + 18 = 23 microseconds. One must not label this a 95% confidence interval without a probability model. If, by a different stipulated assumption, 5 microseconds and 18 microseconds are independent standard uncertainties, the root-sum-square result is $\sqrt{5^2 + 18^2} = \sqrt{349}$ = 18.68 microseconds. These are different models, not interchangeable answers. In particular a systematic drift limit is not automatically a random standard deviation. The report should choose its model according to the physical clock evidence and preserve the elapsed time since the last valid reference, the holdover conditions and the uncertainty classification.

Worked application 05 | Transmission-line delays do not equal one universal receiver delay

Two hypothetical reference paths use cables whose effective signal velocities are $v_1 = 0.66c$ and $v_2 = 0.80c$, where c = 299,792,458 m/s is the stipulated vacuum light speed. The path lengths are L_1 = 30 m and

Copyright 2026, James M. Atkinson

$L_2 = 8$ m. For constant velocity factor, propagation delays are $\tau_1 = L_1/(0.66c) = 151.62$ ns and $\tau_2 = L_2/(0.80c) = 33.36$ ns. Their difference is $\tau_1 - \tau_2 = 118.26$ ns. Thus two devices with perfectly aligned counter epochs could show an apparent 118-ns difference attributable solely to these transmission-line paths. The calculation omits uncertainty in physical length, velocity factor, connectors, filtering, threshold timing and reflections. It is a path calculation, not a whole-receiver impulse-response calibration. A defensible experiment would inject a representative transient at the relevant physical reference plane and test the entire signal chain over the intended bandwidth.

Worked application 06 | Network time-transfer asymmetry and a false microsecond claim

Let $d_f = 3$ ms be the forward one-way packet delay and $d_r = 7$ ms the reverse delay in a simplified four-timestamp exchange. A conventional symmetric-delay estimator is biased in the inferred clock offset by a term whose magnitude is $|d_f - d_r|/2 = |3 - 7|/2$ ms $= 2$ ms; its algebraic sign depends upon the chosen offset convention. The round-trip sum is 10 ms, but that sum alone does not identify the two one-way delays. A network implementation reporting microsecond timestamp resolution does not thereby eliminate this 2-ms path-asymmetry bias. NTP's delay, offset, dispersion and jitter statistics have operational meaning within the protocol, but they do not substitute for a measurement of the complete acquisition path. This hypothetical discrepancy can overwhelm an attempted 100-microsecond event ordering. A fair validation varies network load and direction, uses suitable hardware timestamping where

Copyright 2026, James M. Atkinson

the task requires it, and assesses the actual uncertainty of the event timestamp rather than the precision of the network clock field. [N3, N4]

Worked application 07 | Correlated timing uncertainties in a relative measurement

Let corrected event estimates A and B carry standard uncertainties u_A = 8 microseconds and u_B = 6 microseconds. Suppose the correlation coefficient justified by their shared reference is rho = +0.5. For D = B - A, the standard uncertainty is $u_D = \mathrm{sqrt}(u_A^2 + u_B^2 - 2 \rho u_A u_B) = \mathrm{sqrt}(64 + 36 - 48) = \mathrm{sqrt}(52) = 7.21$ microseconds. Ignoring correlation would give sqrt(64 + 36) = 10.00 microseconds. With a coverage factor k = 2, the numerical expanded uncertainty is $U = 2u_D = 14.42$ microseconds, but a 95% coverage interpretation would require an appropriate distribution and effective degrees of freedom. The difference between 7.21 and 10.00 is not evidence that a common clock always improves the final conclusion. It illustrates how covariance changes this particular relative estimate. If the physical errors entered with opposite signs, the relevant covariance could differ. Preserve the architecture, correlation evidence and all terms before claiming cancellation.

Worked application 08 | Unrelated-event association inside a timing window

Assume solely for this example that unrelated candidate events in one receiving channel form a homogeneous Poisson process with rate lambda = 2 events/s, independent of events in another channel. A predeclared matching half-window w = 5 ms yields a total search duration 2w = 0.010 s about each reference event. The probability of at

Copyright 2026, James M. Atkinson

least one unrelated event inside a window is p = 1 - exp(-lambda × 2w) = 1 - exp(-0.020) = 0.0198013, or about 1.98%. Across N = 500 independent, eligible reference windows of comparable exposure, the expected number containing at least one chance match is Np = 9.90. This is an expected count, not a prediction that exactly ten matches must occur, and overlapping windows would invalidate the independence simplification for count variance. Real radio traffic may be clustered or driven by common external events, so the Poisson assumption must be challenged against data. Selecting the window after inspecting the matches also changes the inferential problem. Timing compatibility can be useful, but must not be sold as a unique source attribution.

Worked application 09 | Geometric bound on a free-space arrival-time difference

Suppose two calibrated receiving reference planes are separated by baseline B = 300 m, and direct free-space propagation at c = 299,792,458 m/s is a valid local approximation. For one remote source, the absolute difference in straight-line path lengths cannot exceed B by the triangle inequality. Therefore the absolute arrival-time difference is bounded by |Delta_t| <= B/c = 300/299,792,458 s = 1.00069 microseconds. A corrected observed difference Delta_t = 0.200 microseconds corresponds to a path-length difference c Delta_t = 59.96 m. If its conditional standard uncertainty is 0.100 microseconds, the corresponding path-difference uncertainty is about 29.98 m. The observation constrains an admissible family of locations; it does not specify one unique position. Multipath, non-line-of-sight routes, receiver delays and clock errors can violate the simple free-space model's predictions without contradicting

Copyright 2026, James M. Atkinson

electromagnetism. The investigator should use this inequality as a challenge to the model, not as automatic proof of impossible source behaviour.

Worked application 10 | Threshold walk as a timing error hidden by clock precision

A hypothetical detector uses a fixed analogue voltage threshold. Near the relevant crossing, the rising signal has local slope s = 0.8 volts per microsecond. Suppose uncertainty in baseline or effective threshold is Delta_V = 0.040 V, with the local slope approximately constant. A first-order timing displacement is Delta_t = Delta_V/s = 0.040 V/(0.8 V per microsecond) = 0.050 microseconds = 50 ns. A receiver with a 1-ns digital time counter can therefore report a threshold-crossing time influenced by a 50-ns signal-level effect. The arithmetic is first-order and conditional on a locally monotone waveform; noise, curvature, hysteresis and filtering could enlarge or change the timing behaviour. A representative pulse-amplitude sweep should establish whether a correction is stable across the declared signal class. The examiner should report the timestamp of the defined detector event unless a validated transformation places it at a different physical reference plane.

QUESTION 041

Copyright 2026, James M. Atkinson

What do FFT resolution and bin spacing mean for a transient emission?

Source: V011_Roundtable_Question_041_CP041_Dr_Atkinson(1).docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 041. Complete expert roundtable discussion

Original constructed educational dialogue. The historical figures are employed as intellectual personae; the discussion is not a historical quotation or transcript. Numerical applications are explicitly hypothetical.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, our preceding discussion established that a timestamp's decimal precision cannot establish the accuracy of the physical event to which it is applied. We now encounter an analogous misconception in frequency measurement. A receiver may display a Fourier transform with a bin spacing of one hertz, a tenth of a hertz or an even smaller interval, while the transient whose spectral properties it is purporting to describe lasted only a few microseconds. The grid can be made arbitrarily fine by filling a transform input with zeros. Yet the physical information in the original observation has not thereby become arbitrarily precise. The eye sees a neat procession of spectral lines; the instrument has performed a mathematical evaluation whose relationship to the unknown emission depends on acquisition duration, waveform stationarity, windowing, noise, filtering and the definition of the reported quantity.

Let F_s be the sampling rate in samples per second, let N be the number of actual samples within one observation window, and let N_F be the transform length after any zero padding. The frequency spacing of the

Copyright 2026, James M. Atkinson

computed transform grid is Delta_f_grid = F_s/N_F. The physical observation duration is T_obs = N/F_s. Its reciprocal 1/T_obs = F_s/N is a characteristic frequency scale associated with the finite duration of the original data window. These two quantities are equal when N_F=N, but they diverge when N_F exceeds N. The distinction is not semantic. The grid tells us how densely the transform is evaluated; the finite observation duration and the chosen window determine the response to nearby components and the extent to which the investigator can separate them. A short burst also carries a spectrum determined by its temporal envelope. It is not necessarily a narrow pure sinusoid merely because a detector reports one spectral maximum.

The investigator must also identify the measurand. The centre frequency of a known sinusoidal model observed at adequate signal-to-noise ratio can sometimes be estimated with uncertainty considerably smaller than the spacing of the unpadded transform bins. Such estimation is conditional upon the waveform model and the observation. It is not equivalent to resolving two unknown adjacent emissions with arbitrary waveforms, nor to proving that a brief transient was emitted by a stable oscillator at the frequency of its highest transform value. Parameter precision, separability of distinct sources, spectral-grid spacing and nominal resolution-bandwidth labels are different claims. Their confusion can make a correct calculation into a misleading forensic conclusion.

Consider a hypothetical spectrum analyser or software-defined receiver that holds a 100-microsecond baseband interval and computes a 65,536-point Fourier transform. Its resulting displayed grid may appear fine because N_F is large, yet the observation contains relatively few

Copyright 2026, James M. Atkinson

independent temporal degrees of freedom. A transient near the beginning of the window may be strongly attenuated by a taper, a burst crossing the end may be truncated, and two successive bursts within the window may be combined into one spectral estimate. If the display refreshes many times per second with overlapping windows, the resulting spectral frames are correlated. A dense waterfall is not a census of independent observations. And a line centred at one bin is not necessarily proof of a single narrowband external transmitter. Receiver-generated artefacts, window sidelobes, clock errors and burst modulation remain possible explanations.

Forensic interpretation therefore begins before computation. Specify whether the original capture was continuous or triggered, whether the relevant signal class is stationary across the transform window, where the time stamp is anchored within that window, and how the software handles a burst that overlaps its boundaries. Preserve the raw complex or real samples where practicable, the window coefficients, transform length, scale convention, averaging rule and frequency calibration. Report the noise-equivalent bandwidth and coherent gain relevant to the chosen window rather than using a bin width as a universal substitute for measurement bandwidth. When a detection threshold is tuned using only favourable examples, preserve the entire process. Otherwise a mathematically elegant waterfall can obscure the very short-lived emissions a defensive survey was commissioned to discover.

Our historical participants will explore distinct boundaries. Mr Fourier will consider what a finite integral permits one to infer from a transient. Mr Nyquist will distinguish sampling and alias restrictions from spectral-grid conventions. Dr Shannon will consider the information lost when only

Copyright 2026, James M. Atkinson

transform magnitudes or selected detections survive. Dr Gabor will consider time-frequency localisation and its unavoidable compromises. Professor Tukey will examine the design of a validation campaign that tests short bursts, nearby interferers and negative evidence. Seven colleagues will challenge the principal speakers in turn, and every question will receive an immediate substantive answer. We shall use checked numerical examples to compare zero padding, observation time, window response, interpolation and false-alarm selection. Our objective is a bounded technical doctrine, not an attractive fictional increase in resolution. Mr Fourier, may I invite your analysis of the finite observation and the distinction between computing a spectrum and discovering the generating physical history?

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier | Principal response 1: The finite observation as a measurement of a windowed phenomenon

Dr. Atkinson, the first distinction is between a mathematical decomposition and an inverse inference about an unknown physical cause. One may expand or transform a function under specified mathematical conditions; that operation does not itself establish which mechanism generated the recorded values. A real receiver observes a time-limited portion of a signal, not the entire electrical history of a transmitter. When the recorded waveform x(t) is multiplied by an observation window w(t), the analysed quantity is x_obs(t)=x(t)w(t). In the frequency domain, that multiplication corresponds to convolution of the underlying spectrum with the transform of the window, under the applicable Fourier conventions. What the display portrays is consequently an interaction between the source waveform, the receiver chain and the observation operation. A spectral peak can shift, broaden or acquire sidelobes because the observation was finite even when the generating process was stable.

If a sinusoid is observed for time T with a rectangular gate, its response is shaped by the finite aperture. A frequency component not aligned with one transform-grid point contributes to several values because the finite record does not contain an integer number of whole cycles in the chosen comparison. An FFT can evaluate this mathematical response efficiently; increasing the number of evaluation points merely samples the same response more densely. It does not narrow the principal response of a window whose actual physical duration has not changed. If the operator instead acquires a longer coherent record of an otherwise stable signal, the change is real: the observation supports a narrower finite-duration

Copyright 2026, James M. Atkinson

response, provided the clock, source stability and receiver state remain sufficiently characterised across that additional time. This distinction is crucial when one wishes to hunt for a weak narrowband line within broad noise.

A transient introduces a separate difficulty. Suppose an emission consists of a brief carrier burst whose envelope rises and falls within a small portion of the analysed interval. The finite pulse envelope contributes spectral breadth of its own, and a taper imposed by the analysis software may change the apparent energy of the burst according to where it occurs in the window. If the same physical burst is moved closer to the margin of the observation, a Hann-type window can reduce its amplitude relative to a burst at the centre. That result is not a change in transmitter power. It is a consequence of multiplying the observed waveform by a position-dependent weight. The analyst must distinguish such processing losses from changes in the incoming field, especially when negative findings are advanced as evidence that a candidate was absent.

The time of a transient within a window also matters to phase interpretation. A delay in the observed waveform multiplies its transform by a frequency-dependent phase factor when the delay is represented faithfully, while discarding phase and retaining only magnitude removes information about that delay. The absolute event epoch cannot be recovered from a bare magnitude spectrum without additional assumptions. Conversely, the presence of phase in a stored Fourier array does not guarantee that the original antenna arrival epoch was calibrated; the array may still be referenced to a software-selected window origin. The earlier clock discussion therefore remains relevant. A time-frequency

Copyright 2026, James M. Atkinson

transformation cannot be made more physically informative by assigning a long decimal timestamp to a window whose actual reference plane was never characterised.

When two narrow carriers are close together, their separability depends on the recorded duration, relative amplitudes, chosen window and signal-to-noise conditions. A large nearby signal can obscure a weak component through leakage if the window suppresses sidelobes inadequately. A taper that reduces those sidelobes may broaden the principal response and reduce coherent amplitude, making an already brief weak burst harder to detect. There is no universal best window divorced from the measurement objective. The examiner must determine whether the task is detection, amplitude estimation, frequency estimation, resolving adjacent components or reconstructing a transient's original shape. A window acceptable for one can be unsuitable for another.

One should beware the converse exaggeration, that finite FFT bin width imposes an absolute floor on every possible parameter estimate. If the data strongly support a specified sinusoidal model, the centre frequency may be estimated between grid points by examining phase evolution or fitting an appropriate response. Such an inference is conditional on the model, noise process, sample clock and other disturbances. It should not be confused with demonstrating the presence of two independent unresolved sources, or with determining an arbitrary burst's unique carrier frequency when its modulation and envelope are unknown. The concept of resolution is meaningful only when the question identifies the alternative hypotheses the measurement must distinguish.

Copyright 2026, James M. Atkinson

I would therefore insist upon preservation of the original samples and their time coordinates before promoting a Fourier display into testimony. The analyst should record F_s, the number N of actual data samples, N_F used for the transform, the window and scaling conventions, and any prior decimation or frequency translation. A spectrum saved without such context is a derived image lacking the information necessary for some later questions. A calibrated receiver may legitimately offer a strong conclusion about a detected interval and a restricted frequency band; it should not imply the physical history outside the recorded interval can be recreated from the magnified display of its transform. I pass the token to Professor Bridgman to examine what observable operation ought to define the claimed frequency resolution.

Percy Williams Bridgman | Peer question 1 to Jean-Baptiste Joseph Fourier

Mr Fourier, your argument implies that the phrase frequency resolution is dangerously incomplete unless the examiner declares the task whose successful discrimination would constitute resolution. Suppose two laboratories observe the same one-hundred-microsecond pulse. One displays a spectrum interpolated to a one-hertz bin grid and reports a frequency to the nearest hertz. The other uses an unpadded transform with coarse bin spacing and records a much wider uncertainty interval. The first laboratory might possess a justified parameter estimator that genuinely uses phase and a strong prior waveform model, or it might be mistaking display interpolation for empirical knowledge. What measurable challenge would distinguish those cases without prejudging the model? Would you require the laboratories to resolve two

Copyright 2026, James M. Atkinson

nearby signals, to estimate the centre frequency of a single known waveform, or to predict an independently withheld continuation of the emission? How should they disclose the model's failure when the signal is not stationary during the observed burst?

Jean-Baptiste Joseph Fourier | Immediate answer to Percy Williams Bridgman

Professor Bridgman, I would require the task to be declared before either laboratory's reported number is assessed. If the purpose is estimating one stable carrier's frequency under a specified signal and noise model, the proper challenge is a collection of withheld test records whose true carrier frequencies are known independently. Randomise those frequencies between and around the nominal grid points, vary burst location and amplitude, and examine the estimator's bias, dispersion and outlier behaviour. A model-based estimator may outperform raw bin selection in such a campaign, but the reported uncertainty must follow the validated model and reference clock, not the number of decimal places displayed. Zero padding can make peak interpolation convenient; it does not itself supply the data that justify a narrow confidence interval.

If the purpose is resolving two simultaneous emissions, the campaign must include pairs whose separation, relative amplitude and modulation are varied systematically. One should declare the required false-separation and missed-separation rates. A procedure that reports an average frequency between two unresolved sources may perform well as a one-tone estimator while being useless for the two-source task. If the purpose is a short transient of unknown

Copyright 2026, James M. Atkinson

waveform, still another test is required, because the spectral appearance may depend strongly on the envelope. A withheld continuation may be unavailable for a genuinely brief event, in which case one cannot demand predictive success beyond what the acquisition permits.

All tests should preserve the original samples, window, transform length, input clock record and operating state. They should include deliberately adverse cases, such as a weak burst placed near a window edge and a strong neighbouring carrier whose sidelobes can disguise it. The result should be a conditional capability statement: the instrument can distinguish or estimate a specified class under defined conditions with measured errors. When the incoming waveform departs from that class, the previous uncertainty need not apply. The honest report must state whether frequency is a fitted parameter of an admitted model, the centre of a measured spectral response, or merely the position of the largest displayed FFT value. Those are different observables. I return the floor for examination of how sampling conditions limit the credible transformations that follow.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 2: The sampling lattice, alias identity, and finite-exposure frequency claims

Dr. Atkinson, I would begin by separating a restriction upon the original continuous-time spectrum from the spacing of the discrete transform used to examine the samples. Under the familiar uniform-sampling model, frequency components separated by integer multiples of the sample rate may produce indistinguishable discrete-time sequences unless the admitted analogue spectrum is restricted. A transform with a million displayed frequencies does not restore the discrimination that was never present at the sampling boundary. Even an impeccably calculated peak may therefore represent an alias of another physical frequency. The sampling rate, analogue preselection, input spectrum, anti-alias rejection, clock uncertainty, and digital-downconversion history must be considered jointly before a displayed bin is allowed to become a physical-frequency claim. A digital axis labels a particular interpretation of samples, not necessarily the unique cause of those samples.

The time-limited character of the observation introduces another set of conditions. If the receiver records N equally spaced samples at sample rate F_s, its direct unpadded transform evaluates N locations at separation F_s/N. Yet that number does not establish the uncertainty with which the frequency of one known carrier can be fitted, nor the minimum spacing at which two arbitrary unknown emitters can be separated with a specified error rate. The former is an estimation problem under an admitted model. The latter is a discrimination problem involving signal classes, waveform envelopes, relative powers, interference, receiver noise, and admissible risk. Both depend on actual observed data, rather than on the length of a

Copyright 2026, James M. Atkinson

transform array filled with zeros. A narrow readout can be either a justified estimate or an unjustified label; one must examine how it was obtained.

I particularly question the use of a static spectral photograph to characterise a brief or frequency-agile emission. A short burst can illuminate only a fraction of the window. The same physical event may appear at markedly different amplitude when its arrival phase is changed relative to window boundaries or when the trigger marks a threshold-crossing instead of a true onset. A swept or frequency-hopping receiver may not be listening at the appropriate instant. If the detector returns a peak frequency but does not preserve the exposure schedule, trigger logic, signal duration and window location, a later examiner cannot know whether a changed indicated frequency originated in the emitter or in the observation geometry. One obtains more faithful evidence by retaining the raw interval and the processing record than by increasing the displayed precision.

There is an especially consequential error when an investigator compares successive FFT windows as though they were independent trials. Overlap is commonly useful for reducing apparent gaps in a waterfall, but adjacent overlapping windows re-use samples. If a burst spans two windows it may generate two detections, yet that does not establish two transmissions. A receiver may also compute a moving average of many spectral frames; if it retains only the average, a transient's peak amplitude and exact occurrence time can be lost. One must therefore define event counting, correlation, dead time and the retention rule before turning spectral detections into evidence about number, prevalence or duration of emissions. A high numerical frame rate is not the same as a high rate of independent observations.

Copyright 2026, James M. Atkinson

The proper acceptance campaign requires at least three groups of deliberately varied inputs. In the first, use stable sinusoids spanning each grid interval and compare frequency-estimation bias with the true independently established frequency. In the second, challenge with pairs of emissions of controlled separation, amplitude ratio and phase, reporting both missed separation and false separation. In the third, use time-limited bursts with varied duration, start position, envelope and frequency drift, including intervals crossing the analysis boundary. Apply identical processing rules to favourable and unfavourable cases, and preserve the results of all trials. An instrument should never be accredited for an untested broad signal class on the basis of success against one ideal carrier.

For a forensic claim, trace the frequency axis back to the physical reference oscillator and the configuration of every translator. A complex baseband signal may be associated with positive or negative frequency relative to a tuning reference; an I/Q swap or conjugation can invert the apparent sign. A superheterodyne mixer can admit different RF frequencies through desired and image paths; a digital transformation can faithfully process an aliased representation. Frequency calibration of the final display alone does not establish uniqueness at the antenna. The report should give the physical input plane, accepted band, local oscillator state and uncertainty of the reference, rather than merely the FFT label and its decimal places.

I do not suggest that finely evaluated Fourier transforms are worthless. They are an efficient means of depicting and interpolating a response already determined by the input record. A carefully validated parametric estimator may achieve excellent precision, particularly for a stable signal

Copyright 2026, James M. Atkinson

observed coherently against a characterised oscillator. But when the burst is too short, unknown or nonstationary for that model, the narrower statement is the stronger one. A method can identify that appreciable energy occupied a defined spectral interval during a given exposure without certifying the transmitter's continuous frequency to a fraction of a hertz. The discipline is to keep every conclusion attached to the assumptions, observations and uncertainty that make it possible. I invite Professor Bridgman to test whether such an explanation is sufficiently operational to support two laboratories wishing to compare their results.

Harold Stephen Black | Peer question 2 to Harry Nyquist

Mr Nyquist, suppose a digital receiver is supplied with a highly stable oscillator and a dense zero-padded Fourier display, and its operator reports a centre frequency with six decimal places. A second laboratory observes the same controlled burst using a different analysis window and obtains a slightly shifted maximum. The two instruments share a traceable sample-clock reference, so their time bases are not in dispute. Yet each laboratory points to its own peak as the obvious best frequency estimate. From the engineer's standpoint, the source waveform and the processing window form a system whose transfer behaviour should be measured. Should the examiner require the reported quantity to be invariant when the window changes, or is it legitimate for the reported centre frequency to depend on a declared estimator? How would you distinguish a physical frequency difference from a processing-induced peak displacement, especially when the event is brief, asymmetric and accompanied by a stronger neighbour? I ask also whether a successful

Copyright 2026, James M. Atkinson

correction could conceal this ambiguity by forcing both instruments to agree with a reference model.

Harry Nyquist | Immediate answer to Harold Stephen Black

Mr Black, the first essential correction is not numerical but conceptual. A reported peak location and the fitted frequency of a stipulated carrier are not automatically the same measurand. If a burst is modelled as one sinusoid multiplied by a known envelope and observed through a characterised receiver, an estimator may produce a coherent parameter estimate with calculable uncertainty. If instead the operator reports the maximum of the windowed magnitude spectrum, the result depends upon the spectral convolution and may change with window selection. That dependence is not inherently a defect if it is disclosed. It becomes a defect when the result is labelled as a unique underlying carrier frequency without accounting for it.

The verification experiment should hold the physical input fixed while varying only the analysis method. Preserve raw samples, independently known stimulus parameters and the software configurations. Compare a rectangular, Hann and other suitable windows, using their actual amplitude normalisations and noise-equivalent bandwidths. Where a known model is fitted, test it on withheld bursts with deliberately altered envelopes, neighbouring signals and frequency drift. Do not permit the estimator to select its own favourable examples retrospectively. If a frequency estimate shifts systematically as the window changes, investigate whether the source model is false, the record is too short, or the procedure is

Copyright 2026, James M. Atkinson

measuring a different quantity. The fact that both instruments are locked to the same clock does not settle those alternatives.

A stronger neighbour is especially instructive. A finite-window analysis can spread the neighbour's energy into the candidate's region, and a taper that suppresses sidelobes may also broaden the main lobe. Thus there is no universal window which simultaneously minimises all desirable errors. The question is which risk matters in the intended investigation: distinguishing a weak burst, measuring a strong carrier accurately, detecting the presence of any emission in a band, or estimating its time of arrival. A laboratory must choose its rule according to that task and disclose the resulting trade-off. If both instruments return the same value only after a shared correction was fitted to a common reference, that agreement is not independent validation of the unknown signal model.

For the hypothetical report, I would insist upon an explicit formula or computational definition of the estimator, a stated signal class and the uncertainty of the sample clock. The result should be reported with a challenge-derived uncertainty or a bounded frequency interval appropriate to the data. One may write that a particular short burst produced a maximum in a specified spectral representation, but one may not infer without additional evidence that the generating oscillator held exactly that frequency for longer than the acquired event. If an independent instrument follows the same signal when the record is extended or the window is changed, this constitutes useful additional evidence, not an automatic licence to remove all qualifications. I return the floor respectfully to Dr Shannon, who will

Copyright 2026, James M. Atkinson

examine the information retained when the spectral representation replaces the original samples.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 3: Representation, discarded phase, and the cost of triggered retention

Dr. Atkinson, the mathematical transform can be reversible under its declared conditions. A complete complex discrete Fourier transform of a finite numerical vector, with known ordering and normalisation, retains that vector's numerical information to within implementation precision. The same cannot be asserted when the operator saves only a logarithmic magnitude spectrum, a few selected peaks, or a rolling average. Those records may be perfectly adequate for one investigative objective, but they cannot support every question later imagined. When phase is discarded, different time-domain sequences can produce the same magnitude spectrum. If temporal order, sign or phase relative to an external reference is material, the ambiguity is fundamental, not something cured by increasing the plotted resolution.

The distinction becomes particularly visible with short events. Suppose a receiver retains a burst's frequency magnitude but no time-domain samples. A second investigator asks whether the event preceded a power transient or occurred several milliseconds afterwards. Magnitude alone generally cannot answer that question. Similarly, a spectrogram whose frame times are rounded or whose windows overlap may not establish an onset epoch with the precision implied by its labels. If the detector's retention was triggered by a threshold, a saved event may exclude earlier low-amplitude activity or a preamble that mattered to the source model. The selection function is part of the evidence, even when its operation is hidden from the finished display.

It is tempting to say that a very large Fourier transform contains more information than a short one. Yet appending zeros to a finite vector does

Copyright 2026, James M. Atkinson

not create new observations. It changes the set of points at which a continuous trigonometric polynomial associated with that record is evaluated. The additional displayed values are determined by the original numbers; they cannot serve as independent corroborating observations. A practical display may become easier to interpolate, and a narrow maximum may be located with finer numerical precision. That increased convenience should not be confused with improved robustness against an incorrect physical model, hidden receiver nonlinearity or the absence of a necessary analogue sample.

Statistical estimation complicates but does not overturn this conclusion. A strong and sufficiently simple waveform admits inference about parameters that were not directly sampled at every possible instant. Under an accepted signal model, multiple samples constrain the phase trajectory, and the resulting frequency estimate may be substantially finer than the reciprocal duration scale. But this precision is conditional. If a burst contains unknown modulation, phase resets or drift, the parameter model changes. A narrow confidence interval computed from a false model is not evidence of a physically precise frequency. The correct test is whether the estimate retains its calibration and coverage under the signal variations encompassed by the stated claim.

In a defensive counter-surveillance investigation, the dominant risk often lies not in the transform calculation but in the archive's loss of context. A trigger may store only frames whose power exceeds a threshold. If a faint emitter remains below threshold during one survey period, the saved record may be silent. Silence in the archive is not equivalent to absence of a signal. A later investigator cannot reconstruct all unsaved frames by applying an

Copyright 2026, James M. Atkinson

inverse Fourier transform to the detections that remain. Nor can a saved detection count be divided by the total survey time without accounting for scanning, blanking, dead time and changing thresholds. Recording policies determine the population from which evidence is selected.

The same principle applies to the simultaneous observation of several channels. A polyphase channeliser may retain narrow output bands while discarding the raw wideband stream. This economises storage, but a later question about an out-of-band intermodulation product or an image response may be unanswerable. The operator should preserve, as far as practical, an authenticated raw segment around a significant event and the transform chain that produced its derived forms. Where retaining the complete stream is impracticable, preserve explicit exposure maps and the limitations of any triggered collection. Hashes support evidence-integrity claims, but a hash of an incomplete derivative cannot certify the completeness of an unrecorded analogue history.

An acceptance experiment ought therefore to include questions that cannot be answered from a particular derivative. Ask whether the retained data can distinguish two nearby emitters; whether they preserve event epoch; whether they permit a different window to be applied; and whether a disputed peak can be tested against an independently measured receiver transfer function. If the answer is no, that should be part of the acquisition specification, not a surprise at litigation or expert review. Practical engineering involves trade-offs, but integrity requires those trade-offs to be documented before the evidence is interpreted.

The most useful conclusion is a tiered one. A magnitude-only spectrogram can establish, subject to calibration and detection

Copyright 2026, James M. Atkinson

assumptions, that a particular algorithm indicated energy in a defined time-frequency cell. A complex transform with full processing state can support somewhat richer inferences. Raw digitised samples with calibration, state and timebase records can support further reanalysis, although they still do not reconstruct an analogue input beyond the receiver's admitted information. The input chain remains the ultimate boundary. More detailed numerical records are helpful, yet the report must identify exactly which proposition each representation is competent to test. I pass the floor to Professor Wiener for a question concerning the role of adaptive thresholding in the creation of the retained archive.

Norbert Wiener | Peer question 3 to Claude Elwood Shannon

Dr Shannon, your distinction between a retained record and the history from which it was selected is especially consequential when the receiver adapts to its surroundings. Imagine an SDR which updates its noise-floor estimate, changes its detection threshold and stores only the FFT frames that trigger an alarm. An intermittent emitter appears in the same band as a stronger legitimate signal, and the algorithm suppresses some frames as uninteresting. The eventual archive contains precise frequency estimates for the events it selected, together with correct hashes and consistent software records. Yet it contains no direct representation of numerous periods when the instrument decided not to save data. Can the resulting archive support an estimate of emitter prevalence, or only conditional statements about selected alarms? What minimum metadata should accompany such a record to permit independent reconstruction of the selection process, and how would a

Copyright 2026, James M. Atkinson

reviewer challenge an adaptive rule that was tuned during the observation itself?

Claude Elwood Shannon | Immediate answer to Norbert Wiener

Professor Wiener, the archive supports a frequency estimate for the selected observations only insofar as those observations and their calibration support it. It does not by itself establish the prevalence of the originating signal. Selection can depend upon the signal, the interference environment, the estimator's own noise model and the history of previous selections. A rate of saved events is therefore a property of the coupled acquisition-and-detection process, not necessarily the rate at which the physical emitter operated. Inferring prevalence requires a model of detection exposure and missingness, together with evidence sufficient to test that model.

At minimum the preserved record should include the receiver's tuning and observation schedule, timebase and gain state, analysis-window length and type, threshold history, noise-floor estimator, blanking or dead-time intervals, and the software version governing selection. It should identify whether each retained event was saved with pre-trigger samples, how a triggering interval was placed relative to FFT frames, and whether one physical event could produce multiple stored alarms. Where possible, a sample of untriggered intervals should be preserved according to a predeclared independent schedule. This provides a means of measuring the detector's false-negative behaviour rather than estimating it solely from the selected successes.

Copyright 2026, James M. Atkinson

An adaptive rule may be entirely appropriate for operational discovery. The problem arises when its adaptation is omitted from the evidential account. One could freeze the learned parameters during a challenge experiment, compare them with a different rule on withheld recordings, or introduce random test bursts whose presence is concealed from the algorithm. Trials should represent the full admitted envelope, including strong neighbours, quiet periods, temperature shifts and input clipping. The result should distinguish the probability of an alarm given a signal from the probability that a signal was present given an alarm; the latter depends upon the base rate and relevant alternative explanations. A high detection probability during favourable trials does not give the investigator a universal prevalence estimate.

Cryptographic integrity checks cannot recover intervals that were never retained. They are essential to preserving the bytes that exist, but the question whether those bytes fairly represent the investigated period remains separately answerable, if at all. The report should state the extent of the recorded and unrecorded exposure, what was selected, and which hypotheses remain observationally equivalent. A modest claim that the receiver detected specified candidates under documented conditions can be sound. An unrestricted statement that no other emissions occurred because none were archived is not justified. I invite Dr Gabor to examine the further difficulty of allocating a finite observation simultaneously in time and frequency.

Copyright 2026, James M. Atkinson

Dennis Gabor | Principal response 4: Time-frequency concentration and the apparent precision of a short burst

Dr. Atkinson, the signal analyst naturally seeks localisation in both time and frequency, yet a record cannot generally be represented by a single point possessing arbitrary precision in each domain. A narrow time-localised event spreads its energy across frequency, while a sharply localised spectral component typically demands a longer coherent observation. This is not a fault in the FFT implementation. It is a property of the relationship between the signal and the analytical operation. The distinction matters when an SDR records a fleeting pulse and displays a narrow vertical line with many decimal places beside it. The line may be a convenient spectral coordinate, but the pulse envelope and the observation aperture limit what can be claimed about the actual transmission. Neither finer axis labels nor a denser numerical plot transforms one brief event into a long continuous tone.

A short-time Fourier transform computes a sequence of local spectral descriptions using overlapping observation windows. The window length and shape determine how the procedure trades temporal localisation against frequency discrimination. A long window is useful for distinguishing narrow neighbouring tones under suitable stability assumptions, yet it may merge several short emissions or locate a sudden start imprecisely. A shorter window helps expose the burst's onset and modulation, but it broadens its frequency response and increases the difficulty of distinguishing nearby narrowband sources. There is no contradiction here. The instrument must choose the resolution relevant to its investigation, or preserve data that permit alternative analyses later.

Copyright 2026, James M. Atkinson

One may use a Gaussian-windowed analysis to make the localisation argument precise in a particular mathematical setting. The familiar uncertainty relationship between suitable measures of time spread and frequency spread indicates that their product has a lower bound under stated conventions. This does not establish a universal, context-free frequency error for every estimator. The measures refer to signal or analysis concentration, and model-based estimation can behave differently. It does establish that a claim of arbitrarily sharp simultaneous localisation cannot be justified merely by manipulating the display grid. The examiner must state what spread is being described and whether it is the incoming waveform's property, the chosen window's response, or the uncertainty of a parameter fitted to the data.

Consider two hypotheses. Under the first, a stable oscillator emits a sinusoid for a short known interval. Under the second, the incoming waveform contains a brief chirp whose instantaneous frequency changes throughout that interval. The two may yield superficially similar peaks in a short FFT magnitude plot even though their physical interpretations differ. A longer coherent observation could distinguish the stable tone from the chirp if the sources continue. For an event that has ended, only the retained samples and justified model constraints remain. A fitted central frequency may be useful, but it should not be represented as a measured instantaneous frequency at every unobserved instant. The investigator should explicitly test whether a changing frequency model fits better than a stationary carrier and whether the improvement is supported rather than merely purchased by adding parameters.

Copyright 2026, James M. Atkinson

Short bursts also challenge the meaning of an amplitude estimate. If a burst lies near the centre of a Hann window, it may receive a substantially different weight than the same burst near either boundary. Dividing by the coherent gain appropriate to a continuous sinusoid does not automatically correct this position-dependent burst loss. That amplitude correction is designed for a particular signal class. A transient may require energy normalisation, envelope reconstruction or a detection statistic matched to its expected form. The receiver's false-negative rate near the window edge should be measured by injecting otherwise identical bursts at varied positions, rather than inferred from a single centre-placed demonstration.

The tension between time and frequency is especially acute in a defensive search for intermittent devices. A transmitter may switch on briefly to emit a narrow packet; the receiver may scan rather than continuously observe its frequency; and the capture procedure may store only triggered snippets. The frequency plot is consequently conditioned on three different kinds of temporal selection: when the antenna admitted the signal, how long the digitiser retained it, and where the FFT window was placed. If one of those is undocumented, a precise reported spectral coordinate may obscure a large uncertainty about whether and when the physical emission occurred. A strong result requires reconstructing the chain of temporal admission and describing the failure modes for events arriving during a blind interval.

I would therefore advocate a multiscale validation campaign rather than a single preferred window. Preserve sufficiently long raw complex samples around candidate events, where practicable, and evaluate short and long windows under declared rules. Compare event time, central frequency,

Copyright 2026, James M. Atkinson

spectral extent and amplitude conclusions across scales. Where those estimates disagree, treat the disagreement as information about model or processing sensitivity, not as a reason to select whichever result is more reassuring. The record should identify both the estimates and the conditions under which each is meaningful. A frequency claim that survives appropriate window changes, independent front-end settings and source-model challenges is more defensible than one founded solely on a visually sharp peak.

This doctrine does not require an operator to regard every spectral image as uncertain beyond practical use. It permits an evidential statement about the detected energy and its location in a specified analysis band, while reserving stronger claims of stable carrier identity for observations and experiments that support them. A waterfall may be an excellent discovery instrument, particularly when the analyst understands its time-frequency compromises. The danger begins when discovery coordinates are turned into causal certainties. The frequency of a spectral maximum, the estimated centre of a modulation envelope and the instantaneous carrier of an external emitter are distinct quantities. I pass the floor respectfully to Professor Slepian, whose work concerning concentration raises the question whether a mathematically optimal window for one signal class can be assumed optimal for an unpredictable burst.

David Slepian | Peer question 4 to Dennis Gabor

Dr Gabor, your account recognises that the selected observation window participates in the measured spectral result. A considerable body of concentration theory permits the construction of sequences which retain an unusually large share of their spectral energy in a prescribed

Copyright 2026, James M. Atkinson

interval, and these sequences are sometimes preferred for weak-signal analysis. Suppose a laboratory chooses such a taper, reports an impressively quiet out-of-band response and declares it the best means of discovering unknown short emissions. That choice may be excellent for a stationary sinusoid or a narrowband power estimate, yet the window may place small weight upon a brief event near its ends. By what experiment should the laboratory demonstrate that its concentration criterion is relevant to detection probability, not merely to a spectral leakage metric? Would you require a separate temporal-exposure acceptance test, and how should the result be reported when no one window dominates across all admissible burst durations and arrival phases?

Dennis Gabor | Immediate answer to David Slepian

Professor Slepian, I would welcome a highly concentrated spectral window as a deliberately chosen mathematical tool, not as an unqualified proof of universal detection capability. The criterion by which it is optimal should be made explicit. Concentrating energy in a frequency band is not identical to maximising the probability of detecting a brief burst at every possible position within a finite observation interval. When a taper sacrifices response near its edges, an unknown emitter can be poorly represented precisely because it arrived where the instrument placed a low weight. The operator must test the signal class against the intended acceptance criterion rather than borrow optimality from a different problem.

A useful campaign would randomise burst onset across the whole available observation, from before the first sample through the last

Copyright 2026, James M. Atkinson

admissible edge. It would vary pulse duration, envelope, carrier offset from a grid point, signal-to-noise ratio and the presence of neighbouring interference. One should compare detection rules at a declared false-alarm rate and report missed-detection probability as a function of both arrival phase and frequency. The result might show that one taper offers superior rejection of a strong neighbour at the cost of reduced response to certain short events. Such a trade-off is not disqualifying if it is acknowledged. It becomes problematic only when a published leakage ratio is offered as evidence of a detection probability never measured.

The tests should also separate a single isolated event from a repeated sequence. Window overlap can reduce some edge losses because the same burst may appear closer to the centre of a neighbouring frame, but it increases dependence among frames and complicates counting. One can improve event capture by changing overlap or combining detections, yet one must then reconsider the false-alarm probability of the composite procedure. A burst that triggers two neighbouring windows is one physical event unless independent evidence suggests otherwise. The effective exposure map must incorporate all such operations.

No window can guarantee the same optimum across every signal model. I would allow a laboratory to preserve two or more complementary representations and use a predeclared rule for comparing them, provided the underlying raw samples remain available and the statistical consequences are tested. A short-window detector may be more sensitive to brief events, while a longer-window

Copyright 2026, James M. Atkinson

detector may be better at identifying a weak stable tone. Their results should be reconciled against common event identifiers and physical acquisition times rather than counted as independent confirmations. Where only one derivative was retained, the associated limitation should appear prominently in the report. The investigator can then defend a bounded discovery statement without pretending that the window's spectral elegance proves a transmitter was absent whenever no line appeared.

Walter Andrew Shewhart | Peer question 5 to Dennis Gabor

Dr Gabor, in industrial process control a chart is meaningful only in relation to the variation and observation rules under which it was established. You have proposed comparing windows and acceptance challenges, but I am concerned about the familiar practice of adjusting a detector repeatedly after observing inconvenient missed bursts. Suppose the laboratory chooses a short window to improve time localisation, discovers false alarms, lengthens the window, changes the threshold, increases overlap and eventually reports the last apparently satisfactory series of trials. The reported false-alarm proportion may be arithmetically accurate for that series while concealing the selection of the series itself. How should the campaign organise its training and verification records so that an operator can adapt a useful detector without subsequently portraying the selected settings as independently validated? What forms of process instability should prevent the acceptance results from being extrapolated to a field survey with changing gain, temperature and spectrum occupancy?

Copyright 2026, James M. Atkinson

Dennis Gabor | Immediate answer to Walter Andrew Shewhart

Dr Shewhart, your concern is central. Development and verification must be distinguished in the evidence record. The laboratory may legitimately explore many windows, thresholds and overlap arrangements, but the result of that exploration is a candidate procedure, not yet an independently confirmed operating characteristic. After the candidate has been selected, its software configuration, calibration and decision rules should be frozen for a withheld challenge population selected under predeclared conditions. That population should include both favourable and adverse combinations of arrival time, interference, source waveform and receiver state. The examiner should preserve all outcomes, including unsuccessful and invalid trials.

A field survey may differ materially from the calibration bench. The input gain may change, the analogue front end may enter compression, the clock may drift, the interference distribution may shift, or the sampling chain may lose blocks. A detection test performed at one stable operating point cannot certify a broad envelope unless the tested conditions and their interactions are adequate for the claimed application. I would therefore couple the time-frequency analysis to a controlled state record and a challenge matrix whose dimensions arise from the physical mechanisms most likely to change performance. A small number of meaningful stress tests can be more informative than hundreds of repetitions of an easy carrier.

Copyright 2026, James M. Atkinson

The laboratory should also account for the dependence created by overlapping frames. A validation report that counts a thousand overlapping FFT frames as one thousand independent opportunities may understate uncertainty when the same burst or noise fluctuation influences many frames. The appropriate trial unit may be an independently injected event, an observation interval or another declared exposure unit, depending on the claim. Randomisation and confidence intervals should be defined at that level. Where the trial population is adaptive, the report should disclose the adaptation and refrain from assigning it the coverage properties of an unselected experiment.

I would not demand that the operator choose one universal window. The purpose of the trial is to establish a conditional performance surface, showing where detection works, where it fails, and how the software switches among declared methods. The report should identify any conditions outside the established envelope. An honest failure map is useful operational knowledge. It indicates where additional hardware, longer observation or a second method may be required. To use such a map as evidence, the laboratory must preserve its version history and prevent the apparent improvement of the selected final test from erasing the earlier failures. I pass the token to Professor Tukey for the question of how such a verification campaign should be analysed and reported.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 5: A validation experiment that separates resolution, detection and attribution

Dr. Atkinson, the danger of a fine spectral grid is not that it is mathematically improper. The danger is that its visible neatness encourages the analyst to forget that measurement is a sequence of choices. First the receiver admits a physical band. Then it samples during particular intervals. Then it applies a window, transform, scaling rule and decision criterion. Finally it chooses which observations to retain or describe. Each choice changes the population of outcomes whose statistical properties are to be assessed. A defensible validation campaign must be organised around the claims the investigator intends to make, rather than the pleasant appearance of an isolated spectrum.

Consider the claim that a weak short-lived emitter can be detected with a specified probability while a strong legitimate transmitter occupies a nearby channel. The proper experiment must vary burst time, duration, envelope and carrier offset; it must also vary the strong neighbour's amplitude and offset, the sampling-chain gain and the analysis-window state. If the operator is allowed to adjust the threshold until each test burst is detected and then reports the final successful settings, no independent detection performance has been established. The laboratory may have demonstrated that the example can be fitted by a flexible procedure. Such fitting has a place in development, but it is not the same as validation on conditions the procedure has not already encountered.

The statistical task must also distinguish between a single-candidate test and an extensive search. If a detector examines thousands of frequency-time cells, the chance of at least one false alarm can be much greater than

Copyright 2026, James M. Atkinson

the nominal per-cell false-alarm probability. Under an independence approximation, if each of K tests has probability p of a false alarm, the probability of one or more false alarms is 1-(1-p)^K. This expression is an illustrative limiting model, not a guarantee for overlapping windows or correlated frequency bins. A serious campaign should characterise the actual joint false-alarm behaviour of the implemented decision rule. It should not combine overlapping frame counts as though every comparison were independent, nor suppose that a threshold proven adequate for one cell is automatically adequate for a whole waterfall.

Attribution is a still stronger claim. A spectral feature that persists when a window is changed may be an external emission, but it may also be a receiver-generated artefact whose frequency mapping is stable. One must ask what alternative mechanisms predict under deliberate interventions: change sample rate or local oscillator tuning, change preselection, insert a characterised attenuation at the input, substitute a separate receiver, or reposition the receiving antenna. An external signal and an internal numerical spur may respond differently to these changes, provided the transformations themselves are understood. If two candidate explanations predict the same observation under the chosen test, the result cannot discriminate them. That conclusion is not defeat; it tells the investigator which further test has potential value.

One should begin with exploratory plots, but not end there. Explore failures, residuals, asymmetries and unexpected response shapes. Then formulate a measurable rule that a second analyst could execute against the retained data. The method should report what constitutes one physical event, how event time is assigned when multiple windows trigger, how

Copyright 2026, James M. Atkinson

frequency is estimated, and what interval or uncertainty accompanies the estimate. A fixed number of FFT bins does not set uncertainty by itself. Neither does a finely reported maximum establish the successful resolution of two simultaneous unknown emissions. If the report uses the word resolution, it should say exactly whether it means grid spacing, main-lobe response, two-source separability, estimator precision or detection performance.

For negative evidence, the analyst should disclose observation exposure and selection. A survey lasting an hour is not an hour of effective exposure at every frequency if the receiver scanned, blanked, retuned or discarded windows. The test should measure how often a short pulse placed randomly within the declared observation programme is retained and recognised. If a burst has a one-in-ten chance of coinciding with an admitted sampling interval, a perfect detector during that interval still cannot guarantee complete detection over the original hour. To treat the absence of stored alarms as affirmative evidence requires a model that includes those blind periods and the admitted source behaviour. The model should be audited with withheld injections rather than defended merely by its mathematical plausibility.

The published result should include a compact but reproducible acceptance dossier. Retain the input reference and its uncertainty; the instrument's physical configuration; clock and gain states; the analysis software and transform settings; the challenge population; the raw observations relevant to contested results; the complete detection and missed-detection outcomes; and the rules by which confidence intervals were computed. Important exclusions should be stated, including off-grid

Copyright 2026, James M. Atkinson

bursts, frequency drift beyond the test range, clipping, and interference conditions for which performance is unknown. A modest claim that survives all such scrutiny is more informative than a broad performance assertion from a carefully selected demonstration.

The final point is intellectual rather than computational. A useful spectrum is an instrument for inquiry. It should make the next discriminating experiment possible, not suppress questions by the authority of a precise-looking number. We may report a finely estimated carrier when the acquisition, model and test population justify it. We may report a broader spectral occurrence when they do not. Both may be valuable in defensive technical surveillance. Their credibility depends on resisting the impulse to place more certainty into the conclusion than the observation contains. I now invite Professor Neyman to challenge our proposed method of reporting confidence across a family of related operating conditions.

Jerzy Neyman | Peer question 6 to John Wilder Tukey

Professor Tukey, your acceptance dossier proposes numerous conditions, including several burst durations, amplitudes, arrival phases and neighbouring-interference levels. Suppose the laboratory evaluates twenty operating cells, each with a separate confidence interval for detection probability. It then advertises the system as meeting the required probability over all twenty cells because each individual interval appears satisfactory at the usual nominal confidence level. Unless the procedure addresses simultaneous coverage and the selection of the reported cells, that argument may overstate what the finite trials establish. How would you design the inferential statement so that the laboratory can claim a minimum performance across the declared

Copyright 2026, James M. Atkinson

envelope without substituting twenty separate reassurances for a joint confidence statement? Would you favour a simultaneous bound, a predeclared worst-case test condition, or a more conservative acceptance rule that declares indeterminate regions where the sample size does not support the intended assurance? Please also distinguish confidence in the validation campaign from the probability that a particular field alarm corresponds to a physical transmitter.

John Wilder Tukey | Immediate answer to Jerzy Neyman

Professor Neyman, the distinction is important. A confidence interval constructed separately for each cell is not, without additional argument, a simultaneous confidence guarantee for all cells considered together. If the intended claim concerns the minimum detection probability over a declared envelope, the design should control the probability that the overall reporting procedure falsely certifies that minimum. One practical approach is to predeclare the cells and their weights, use simultaneous bounds appropriate to the design, or allocate an error budget across tests. The exact method should be selected according to the sampling process and dependencies rather than borrowed as a decorative formula. A predeclared worst-case condition can sometimes offer a simpler operational check, but only when evidence supports the assertion that the chosen condition is genuinely limiting.

The laboratory should not choose its difficult cases only after examining the results and then claim that the selected set was independently predeclared. Exploratory work may identify a weakness. That discovery should guide a new validation campaign

Copyright 2026, James M. Atkinson

with fresh trials. Where conditions are expensive to reproduce, a sequential design may be legitimate, but its stopping and error-control rules must be specified. Every test performed should be included in the audit record. To report the best-performing subset while suppressing failed trials defeats the purpose of statistical validation, even if each retained calculation is arithmetically correct.

If a cell has too few effective independent trials, it may remain indeterminate. The instrument can be useful for discovery under that condition, but one should not assert the same detection guarantee there as in a well-characterised operating region. Combining adjacent observations can increase efficiency when justified by a defensible model, but it must not conceal heterogeneity that materially affects false negatives. Overlapping FFT frames may supply correlated measurements of one event, not extra independent opportunities. In a robust campaign the independent sampling unit should be made explicit, and sensitivity analyses should show how conclusions change under reasonable alternative dependence assumptions.

Finally, a confidence bound on detection probability is a frequentist performance statement about a defined procedure under a defined trial population. It is not the posterior probability that any particular field alarm is a transmitter of a specified identity. That latter attribution requires consideration of signal prevalence, alternative sources, artefacts and perhaps further observations. It is entirely coherent to have strong evidence that a detector performs well in laboratory trials while retaining substantial uncertainty about the cause of one field indication. Reporting these propositions separately

Copyright 2026, James M. Atkinson

allows investigators and courts to understand what the apparatus has actually demonstrated. I return the token to Dr. Atkinson for the synthesis of the claims that remain defensible after these challenges.

Sir Ronald Aylmer Fisher | Peer question 7 to John Wilder Tukey

Professor Tukey, I wish to introduce one final operational question before the moderator concludes. Consider a receiver manual which states that frequency resolution is five hertz because the Fourier transform uses a five-hertz grid. The same manual later advertises sub-hertz frequency estimation for a pure tone and a separate short-time burst detector. A laboratory may regard these as mutually consistent claims about different measurements, but a field examiner will be tempted to quote whichever specification appears most favourable. How should the acceptance record be organised so that a technically correct statement about one signal class is not silently exported to another? Specifically, what should be the mandatory labels accompanying a reported frequency, which of them must be preserved in a derivative evidence file, and how should the analyst describe a failed challenge where a transient was confidently detected yet its central frequency could not be estimated within the advertised narrow interval?

John Wilder Tukey | Immediate answer to Sir Ronald Aylmer Fisher

Thank you for that question. Sir Ronald, I would classify the results by the quantity being reported and the signal class to which the measurement applies. The five-hertz FFT grid is a numerical evaluation spacing under a particular sample rate and transform length. Sub-hertz estimation may be justified for a stable sinusoid

Copyright 2026, James M. Atkinson

under a model, specified duration, adequate signal-to-noise ratio and characterised timebase. A short-time burst detector may be intended only to establish whether energy consistent with a candidate class occurred during a window. These are compatible specifications if their conditions are stated. They become misleading when one is represented as a universal attribute of the instrument.

A report of frequency should identify at least the physical input reference plane, the observation interval and timebase, the window and transform configuration, the estimator, the assumed waveform class, the uncertainty or validated challenge interval, and the relevant clock and front-end calibrations. Where a detected burst is not well modelled as a stationary carrier, the report may give a broader occupied band or spectral centre with a qualification. It should not force a narrow frequency estimate merely because the software has capacity to print many digits. The raw retained samples and software version should be preserved where possible so that an independent examiner can apply a different qualified estimator. If the derivative omits phase or acquisition history, that limitation belongs alongside the frequency claim.

A failed challenge can be very informative. It may show that the detector successfully indicated the occurrence of a burst while its frequency estimate wandered under changes in window position or waveform shape. This does not make the detection worthless. It establishes that the evidence supports a presence claim more strongly than a precise carrier-frequency claim for that signal class. The laboratory should record that distinction explicitly and restrict the

Copyright 2026, James M. Atkinson

advertised uncertainty accordingly. It may choose to develop a better estimator and test it on fresh withheld cases, but it should not retrospectively amend the historical test record to suggest the weakness never existed.

Forensic credibility grows when the dossier contains both satisfactory and unsuccessful results. A prospective examiner then knows which claims have been measured, which depend on modelling assumptions, and which were beyond the receiver's preserved information. A polished spectrum can assist discovery; it cannot replace the instrument history or the reasoning connecting observations to a physical proposition. I return the floor courteously to Dr. Atkinson, whose closing synthesis should separate these useful but unequal kinds of knowledge.

Ten worked analytical applications: frequency grids, temporal exposure and uncertainty

Jean-Baptiste Joseph Fourier, Cross-Peer Question to Dennis Gabor: Professor Gabor, why does the narrowness of an FFT bin fail to establish the frequency precision of a pulse shorter than the observation window?

Dennis Gabor, Cross-Peer Answer to Jean-Baptiste Joseph Fourier: Mr Fourier, the bin spacing F_s/N is a coordinate increment fixed by the transform length. The physical transient occupies a duration T_event, and its time-frequency support and signal-to-noise ratio constrain which parameter can be estimated. Adding zeros extends the plotted interpolation grid but provides no additional measured event time. An accurately modelled coherent sinusoid can sometimes have a fitted frequency uncertainty much

Copyright 2026, James M. Atkinson

smaller than a bin, yet this is a conditional estimator result, not general resolution of arbitrary unknown transients. Use calibrated bursts with varied onset phase and modulation to test spectral bias, leakage and fitted-frequency uncertainty. Specify the window and event fraction explicitly; preserve raw samples to permit alternative models. I pass the token to Mr Nyquist for the record-length distinction.

Dennis Gabor, Cross-Peer Question to Harry Nyquist: Mr Nyquist, a receiver stores an entire second but the signal is present for only fifty microseconds. What does using the full second as the FFT interval do to apparent sensitivity and event energy?

Harry Nyquist, Cross-Peer Answer to Dennis Gabor: Professor Gabor, it can increase the number of narrow frequency coordinates whilst diluting the transient in a statistic designed for stationary content. A single short burst contributes power during only a tiny fraction of that second; the relevant amplitude, energy and power conventions must be specified. We should compare a burst-matched window with the long observation, including the different equivalent noise bandwidths and false-alarm opportunities. A narrow line on a long waterfall cannot by itself establish that the emitter transmitted for the full second. Record detection latency, duty cycle and the exact time samples used for the transform. Where several bursts recur, their phase relationship must be demonstrated before treating them as coherent repetitions. I yield to Dr Shannon for the inference from sparse observations.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, when does a fine FFT frequency estimate become evidence of an emitter rather than a numerically convenient fit to correlated noise?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Mr Nyquist, the answer requires a specified signal model, a predeclared fitting procedure and a calibrated noise model. Correlated receiver noise and spectral leakage can give a narrow apparent maximum even when a physical tone is absent. Examine alternative models, including transient noise, internal spurs and nonstationary interference; assess the frequency estimate and its uncertainty on independent validation records. The output of an FFT does not carry a unique physical-source label. Multiple independent receiver configurations and a controlled input challenge can strengthen an attribution, but shared references and preselectors must be traced. Retain negative controls and the entire search history. I pass the token to Professor Tukey for the statistical selection problem.

Claude Elwood Shannon, Cross-Peer Question to John Wilder Tukey: Professor Tukey, what is the proper false-alarm denominator when a detector scans many frequency bins over thousands of overlapping windows?

John Wilder Tukey, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the denominator must reflect the actual opportunity set and dependence structure of the detector, not merely the number of attractive peaks retained. Overlapping windows, correlated adjacent bins and changing thresholds violate an uncomplicated independent-trials count. Calibrate the maximum or decision statistic using full noise-only acquisitions through the identical processing pipeline, retaining all windows and gain states. Where an analytic approximation is used, state its independence assumptions and verify them against simulation or controlled trials. The investigator must not choose one exceptional bin and apply a single-test p-

Copyright 2026, James M. Atkinson

value as though it had been nominated beforehand. A convincing result survives a prespecified blind test with an independently timed source. I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Distinguished colleagues, our discussion separates several quantities frequently compressed into the convenient but misleading term frequency resolution. We have the frequency spacing of a computed FFT grid, the duration-dependent spectral response of a finite record, the performance of a frequency estimator under its declared waveform and noise assumptions, and the tested ability of an instrument to distinguish nearby emissions. None is a universal substitute for the others. The original numerical sample record limits the information available to subsequent transformations, while the instrument's physical front end and its timebase impose further restrictions upon the interpretation of that record. A dense frequency display can be useful, but it cannot manufacture a longer observation, a more stable oscillator or a missing analogue sample.

Mr Fourier has shown why multiplying the signal by an observation window changes the spectral representation. Mr Nyquist has emphasised that alias restrictions and reference-plane definitions remain relevant regardless of transform length. Dr Shannon has distinguished the information retained in a complete complex transform from that discarded by a magnitude-only, thresholded or averaged derivative. Dr Gabor has shown that time and frequency localisation require a signal-specific compromise. Professor Tukey has insisted that an acceptance campaign must test the physical claim rather than an attractive depiction. The seven peer questions have clarified the difference between model fitting and

Copyright 2026, James M. Atkinson

independent validation, between individual and family-wise false-alarm rates, and between detecting an event and identifying a particular transmitter.

The ten numerical applications expose the common error patterns. Zero padding reduced the spacing between displayed frequency samples without increasing observation time. A longer actual recording narrowed the finite-duration spectral response only under source and clock stability conditions. A Hann window altered coherent amplitude and equivalent noise bandwidth, while the example of a burst near the edge demonstrated the risk of a large position-dependent loss. Overlapping FFT frames reused input samples and therefore did not yield independent event counts. A nominally small per-cell false-alarm rate became much less reassuring when applied across many comparisons. Frequency-reference error and scan duty exposed uncertainties which a finely graduated display cannot disclose. These conclusions are conditional examples, not certification of a particular instrument.

For a technical surveillance countermeasures investigation, the acceptance dossier should preserve the raw acquisition interval wherever practicable, plus the analogue input configuration, sample and oscillator references, window coefficients, actual observation length, transform length, scaling conventions, overlap and event-selection rules. It should record whether a proposed frequency is a fitted model parameter, an occupied-band estimate, a centre of spectral energy, or the location of the largest plotted magnitude. That vocabulary should persist into formal evidence descriptions, index terms and expert reports. If a particular burst can be detected with high reliability but cannot be assigned a narrow

Copyright 2026, James M. Atkinson

carrier-frequency interval under the tested conditions, the report should state both propositions. It should not allow the successful detection to conceal the weaker measurement claim.

The conclusion must also address absence. No alarms in retained spectrogram frames are not equivalent to complete evidence that no emitter operated. Scan gaps, trigger thresholds, attenuation at window edges, lost acquisition intervals and the selection of favourable detections must be accounted for. Where the exposure and false-negative characteristics have not been validated for a specified class of short signal, the negative finding is indeterminate as to that class. It may still establish that no qualifying alarm was observed by the defined procedure. Such a restricted conclusion is not timid. It is the statement the evidence warrants.

We therefore adopt a doctrine of declared measurands, retained source data and adversarial validation. Precise numbers shall be reported only in the company of the assumptions and uncertainty that justify them. The next discussion will turn from the spectral analysis window to the stability of frequency references and the relation between phase noise and weak-signal detection, a boundary at which an apparently narrow spectral peak can again conceal limitations that no display interpolation can repair. I thank each colleague for the disciplined exchange and formally conclude Question 041.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 041

Worked application 1: Frequency-grid spacing versus actual observation duration

Let the sampling rate F_s be 10,000,000 samples per second, the number of actual acquired samples N be 1,000, and the padded FFT length N_F be 65,536. The actual observation duration is $T_{obs}=N/F_s$ = 1,000/10,000,000 = 0.0001 second, or 100 microseconds. The unpadded transform-grid spacing is F_s/N = 10,000 hertz. Padding to N_F instead produces 10,000,000/65,536 = 152.587890625 hertz between displayed grid points. Thus the displayed numerical grid is approximately 65.536 times denser, but the actual record is still 100 microseconds long. The inverse-duration frequency scale remains $1/T_{obs}$ = 10,000 hertz. These are computed facts about the selected data, not an assertion that every possible estimator has a 10-kilohertz error. A single pure-tone parameter under a validated high-SNR model may be estimated more precisely. The distinction is that padding supplied no independent analogue observation with which to verify that model.

Worked application 2: Increasing observation length rather than padding

Retain the same 10-megasample-per-second sample rate but observe 100,000 actual samples of a signal that remains stable for the entire period. The observation duration becomes T_{obs}=100,000/10,000,000=0.01 second. The reciprocal duration is 100 hertz and the unpadded frequency-grid spacing is likewise 100 hertz. Relative to the previous 100-microsecond record, the physical

Copyright 2026, James M. Atkinson

observation is one hundred times longer and contains one hundred times as many genuine samples. Subject to source stability, receiver calibration and valid noise assumptions, that longer exposure can offer a materially narrower finite-duration response. It also creates practical difficulties: the clock may drift, the source may retune, and the receiver may undergo gain or state changes over the extra interval. A longer record is not universally preferable to a short one. It provides different evidence, which must be evaluated against the admitted signal class.

Worked application 3: The bin offset of an off-grid sinusoid

Consider a 4,096-sample record acquired at F_s=1,024,000 samples per second, with no padding. The bin spacing is $\Delta_f = F_s/N$=250 hertz. A hypothetical sinusoid at 10,125 hertz lies 125 hertz above the nearest 10,000-hertz grid point and exactly halfway to the next one at 10,250 hertz. The integer-bin display alone therefore cannot select a perfectly aligned frequency. With rectangular windowing the sinusoid contributes to multiple bins through the finite-window response. Padding the same record can locate the existing main-lobe maximum more finely, but cannot establish whether the source was a stable tone, a chirp or a burst whose envelope distorted the response. The record should disclose the grid, window, clock reference, estimator and challenge-derived uncertainty. Printing 10,125.0000 hertz is not an independent measurement of four decimal-place certainty.

Worked application 4: Hann-window coherent gain and noise bandwidth

Copyright 2026, James M. Atkinson

Let N be a large number of acquired samples, F_s the sample rate, and $w[n]$ a periodic Hann window applied over $0<=n<N$. Its coherent gain for a bin-centred continuous sinusoid is $G_c=(1/N) \text{ sum } w[n] = 1/2$. The amplitude of an otherwise comparable bin-centred tone is therefore halved by the unnormalised window, corresponding to $20 \log10(1/2) = -6.0206$ decibels in amplitude. The window's noise-equivalent bandwidth is $ENBW=F_s \text{ sum}(w[n]^2)/(\text{sum}(w[n]))^2 = 1.5 F_s/N$ for the periodic Hann case. With $F_s=1{,}000{,}000$ and $N=1{,}000$, the equivalent noise bandwidth is 1,500 hertz, whereas the unpadded bin spacing is 1,000 hertz. The coherent-gain correction appropriate to a continuous tone is not automatically a valid amplitude correction for a short pulse at the window edge. The examiner must specify the signal class and the measurement purpose before applying these factors.

Worked application 5: Transient attenuation by the analysis window

Consider a periodic Hann window $w[n]=0.5-0.5 \cos(2 \pi n/N)$ with $N=1{,}000$. An otherwise identical very brief burst centred at $n=500$ receives a window weight of $w[500]=1$. A burst centred at $n=100$ receives $w[100]=0.5-0.5 \cos(0.2 \pi)$, approximately 0.0954915. If the bursts are sufficiently short that each experiences approximately a constant local window weight, their ratio from this windowing operation alone is about 0.09549, or $20 \log10(0.0954915)$ approximately -20.4008 decibels. This illustrative loss is not a statement about the physical transmitter's energy. It reveals why a detector validated only with centred bursts may miss otherwise identical events near a frame boundary. Overlapping windows can alter this exposure profile, but the effective false-alarm and event-counting rules must then be revalidated.

Copyright 2026, James M. Atkinson

Worked application 6: Short-time Fourier transform overlap and sample reuse

Suppose the FFT window spans N=2,048 samples at 2,048,000 samples per second, so each frame represents 1 millisecond of input data. A 75-percent-overlap configuration uses hop length H=512 samples or 0.25 millisecond. It produces four frame starts per millisecond in sustained operation, yet neighbouring frames share 1,536 of 2,048 input samples, or 75 percent of their content. A burst of sufficiently long duration may therefore appear in several adjacent frames. The four frame starts do not constitute four independent physical emissions. A false-alarm analysis which treats every frame as independent can underestimate joint uncertainty, and a prevalence estimate which counts every trigger can overcount the events. The correct independent trial unit depends on the actual noise dependence, the trigger logic and the event segmentation rule, none of which can be inferred from the frame rate alone.

Worked application 7: Per-cell versus family-wise false-alarm probability

Let K=2,000 denote the number of hypothetical independent tested frequency-time cells and p=0.0001 the false-alarm probability in each cell under a fixed null model. Under independence, the probability of at least one false alarm is P_any=1-(1-p)^K=1-(0.9999)^2000, approximately 0.181277. Thus a per-cell false-alarm rate of one in ten thousand can coexist with an approximately 18.1-percent chance of at least one false alarm across the family. In a real spectrogram adjacent frequency bins and overlapping windows are commonly dependent, so this numerical result must not be applied without validation of the actual joint rule. The

Copyright 2026, James M. Atkinson

calculation is useful because it demonstrates the distinction between an individual threshold and the behaviour of a large search. Predeclared candidate-selection and multiplicity treatment are necessary for interpretable alarm statistics.

Worked application 8: Frequency-reference uncertainty over a short acquisition

Suppose a sampling-clock reference has a relative systematic frequency error bounded by two parts per million under the specified operating conditions. For a frequency claim centred on 100 megahertz after all correct mixer translations, the corresponding magnitude of clock-related frequency-scale uncertainty is approximately 100,000,000 times 2 times 10^-6 = 200 hertz, before considering other receiver errors. A very large FFT may have displayed spacing finer than one hertz, but that display does not correct the reference's systematic scale error. The example is deliberately simplified: the effect upon the recovered RF frequency also depends on which clocks and local oscillators set each translation stage. The engineer must propagate the calibrated oscillator uncertainties through the actual architecture. It is misleading to report the final display's decimal precision without the uncertainty of the reference plane that creates the frequency axis.

Worked application 9: Random scan exposure for an isolated brief event

Consider a simplified receiver that admits a particular target channel for 50 milliseconds during each 500-millisecond scan cycle and is otherwise unable to receive that channel. Let D=0.05/0.5=0.1 be the duty

Copyright 2026, James M. Atkinson

fraction. If a very short event occurs at a time uniformly distributed relative to the scan phase and its duration is negligible compared with the dwell, the probability of temporal overlap is approximately D=0.1. Suppose that, conditional on overlap, the detector recognises the event with probability 0.95. Then the unconditional detection probability under these assumptions is approximately 0.1 times 0.95 = 0.095, or 9.5 percent. The precise exposure for non-negligible pulse duration or nonuniform timing requires a more detailed schedule model. The example demonstrates that excellent detector performance during active dwell cannot, by itself, support a strong negative finding over the complete elapsed survey time.

Worked application 10: Duration and the apparent narrowing of a zero-padded pulse response

Take a rectangularly gated sinusoidal component observed for T=200 microseconds. Its Fourier amplitude envelope, up to scaling and frequency translation, follows a sinc-type function whose first zeros are displaced by magnitude 1/T = 5,000 hertz from the nominal carrier. The approximate first-null-to-first-null width is therefore 2/T = 10,000 hertz. Evaluating this same fixed record on a grid spaced 10 hertz apart rather than 1,000 hertz apart makes the sinc envelope smoother on the display, but the first-null separation remains about 10,000 hertz. This calculation describes the windowed-response shape for the stipulated rectangular gate; it does not prohibit a sufficiently constrained one-tone model from yielding a sub-bin parameter estimate. It does prohibit interpreting interpolation as newly acquired spectral evidence. A stronger source-

Copyright 2026, James M. Atkinson

attribution claim would require independent instrument tests and a physical model, not merely a finely drawn line.

QUESTION 042

Copyright 2026, James M. Atkinson

How do window functions trade leakage, resolution and amplitude bias?

Source: V011_Roundtable_Question_042_CP042_Dr_Atkinson.docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 042. Complete Expert Roundtable Discussion

Original constructed educational dialogue. Historical specialists are employed as intellectual personae, not as purported speakers in a real meeting or witnesses to contemporary software-defined radio equipment. This manuscript is incomplete and is not counted as a finished primary discussion.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, Question 041 exposed the misconception that the apparent density of an FFT grid establishes the physical resolving power of a receiver. We now turn to the window function, a quieter but equally consequential source of measurement conditions. The window appears to be an innocuous numerical multiplication. In reality, it changes the spectral response, the amplitude of a continuous carrier, the contribution of a transient according to its arrival within the frame, and the noise bandwidth of the resulting estimate. Every one of those changes bears upon a defensive technical surveillance investigation in which a weak emission may be surrounded by strong legitimate signals or may exist for only a few milliseconds. A beautifully tapered spectrum may suppress the sidelobes of a strong interferer, yet conceal a brief emission placed at an unfortunate point in the observation interval.

The mathematical boundary can be stated precisely. Let x[n] denote N recorded samples at sample rate F_s and let w[n] denote the analysis

Copyright 2026, James M. Atkinson

window for n from zero to N minus one. The computed discrete spectrum is the transform of y[n]=w[n]x[n], not the transform of an unlimited physical history. If a continuous bin-centred sinusoid is passed through this operation, its reported amplitude must be interpreted using the coherent gain G_c=(1/N) sum w[n] for the selected convention. The equivalent noise bandwidth, in hertz, may be defined by ENBW=F_s sum(w[n]^2)/(sum w[n])^2 when the sums and scaling correspond to the stipulated estimator. These quantities are not decorative specifications. A correction appropriate to a continuous tone is not necessarily appropriate to a transient occupying a tiny fraction of the window. Nor does dividing by one gain factor eliminate all position-dependent loss.

We must also separate leakage from resolution. A rectangular observation window produces a relatively narrow main lobe but substantial sidelobes. A taper can suppress those sidelobes, often at the cost of broadening the principal spectral response. The trade may be attractive where a strong legitimate carrier masks a weak nearby emission, but the broadened lobe may make separating two close transmitters more difficult. A flat-top window may offer better amplitude accuracy for an isolated sinusoid across its bin offsets while occupying a larger effective noise bandwidth. An investigator cannot rank all windows on one universal scale of goodness. The appropriate measure is the performance of the complete receiver and detector against the specified physical task.

The legal and forensic consequences are not theoretical curiosities. A report might assert that a signal had an amplitude of minus 102 decibels relative to a milliwatt. Was that estimate corrected for the selected coherent gain? Was the input power calibrated through the analogue reference plane,

Copyright 2026, James M. Atkinson

or only relative to a digital FFT magnitude? Was the event a stable tone, a modulated burst or an impulse? Did a different window alter its reported peak, detection decision or apparent bandwidth? If the investigator cannot answer these questions, the numerical precision of the displayed amplitude cannot rescue the interpretation. If the original samples and processing settings were preserved, the analysis can often be repeated under a more suitable model. If only a compressed waterfall was retained, the missing information may be irrecoverable.

I shall therefore ask Professor Slepian to address energy concentration, Mr Fourier to address convolution and finite windows, Dr Gabor to address the differing treatment of transient envelopes, Dr Shewhart to address validation under changing operating conditions, and Professor Tukey to address the statistical effects of surveying many windowed frames. Their colleagues will challenge the choice of performance criterion, the reliability of calibration, and the risk of treating a favourable laboratory spectrum as proof of absence in a contested field survey. The discussion shall preserve the distinction between mathematically correct signal processing and independently measured instrument behaviour. Professor Slepian, may I invite you to begin with the proposition that a window can be optimal for one clearly defined objective while being unsuitable for another?

Copyright 2026, James M. Atkinson

David Slepian | Principal response 1: Concentration is not a universal detection criterion

Dr. Atkinson, the word optimal is incomplete unless the mathematical objective and the admissible class of candidates are specified. A family of spectral-concentration problems asks how energy from a finite sequence can be distributed as strongly as possible inside a chosen frequency interval. The resulting sequences are valuable analytical tools because they offer controlled leakage behaviour under declared conditions. They do not establish, without further evidence, that a receiver employing them will detect every possible burst with greater reliability than one employing a simpler taper. Concentration addresses one function of the analysis. A field detector makes a decision about events whose duration, phase, modulation and time of arrival may be unknown. A satisfactory window for the first task is not automatically satisfactory for the second.

A practical comparison should begin with the same raw input samples and multiple fixed, documented analysis methods. For each method, characterise main-lobe width, sidelobe structure, coherent gain, equivalent noise bandwidth and the response to a sinusoid displaced between frequency-grid points. These quantities are related but distinct. The comparison must also include a transient-exposure test in which otherwise identical bursts arrive at random positions in the observation interval. A window that gives low weight to the ends of a frame may suppress sidelobes admirably while attenuating brief events at those positions. If the detector uses overlapping frames, the overlap may recover some lost exposure, but it creates dependent detection opportunities and demands a

Copyright 2026, James M. Atkinson

new false-alarm analysis. None of these mechanisms is visible in a single spectrum made from a centred continuous tone.

We should also distinguish spectral concentration from the isolation of two unknown emitters. A taper that lowers distant sidelobes may be excellent for detecting a weak tone far from a strong neighbour. If the candidate lies very close to the neighbour, however, the widened main lobe may cause the two to appear as one feature. The answer depends upon separation, relative level, phase, source waveform, observation duration and the decision algorithm. It is not sufficient to quote a nominal sidelobe suppression figure, any more than it is sufficient to quote the FFT bin spacing. A receiver should be challenged with pairs of independent signals at known offsets and powers, and the result should state a tested probability of correct separation, or an appropriately bounded unresolved region.

In the measurement of a stable sinusoid's amplitude, one can normalise the transform by the coherent gain of the selected window under the applicable convention. But a transient is not a stable sinusoid extending across the entire observation interval. The window multiplies its envelope unevenly. The location of the transient may therefore dominate the apparent amplitude in one frame, even when the physical pulse energy is constant. A correction derived for a bin-centred sinusoid cannot simply be assigned to the pulse and expected to restore its true peak or energy. An energy-based estimator, envelope model or short-window detector may be more appropriate, but each introduces its own calibration and uncertainty. The examiner must first say what is meant by amplitude.

Copyright 2026, James M. Atkinson

A further problem arises when a laboratory allows its detection software to choose a window adaptively after preliminary inspection. Such adaptation can be valuable for operational discovery, but a confidence statement based upon the selected output cannot be obtained by pretending the selection never occurred. The software might consistently choose whichever window presents the candidate most strongly, including when the apparent peak is noise. It might also suppress an emission because its heuristic classifies the burst as interference. The entire selection and thresholding rule is then part of the effective detector and must be tested against independently withheld challenge records. Its claimed false-alarm probability must refer to the complete adaptive rule rather than to one component window considered in isolation.

A rigorous validation protocol will record, for each candidate event, the raw input segment and reference-plane configuration, the window choice and coefficients, the effective noise bandwidth, amplitude and frequency normalisations, overlap, decision threshold and event-selection history. It will report outcomes for short and long pulses, for different frame arrival positions, for candidate and interfering signals with varied relative powers, and for states such as receiver compression or reference-clock error. The point is not to make the task impractical. It is to prevent a small set of elegant analytical numbers from being misrepresented as proof that the whole receiver possesses performance never actually tested.

I would conclude by treating windows as different calibrated measuring procedures, not interchangeable cosmetics. Under defined assumptions, one may demonstrate a window's benefit for leakage control, or for stable-tone amplitude accuracy, or for a particular burst detector. The report

Copyright 2026, James M. Atkinson

should preserve the particular claim and its confidence, and avoid exporting that confidence to another class of signal. A negative search result may be well founded for one signal class and indeterminate for another, even when both appear in the same waterfall. I pass the token to Dr Shewhart, whose work on measurement processes raises a pertinent question about how the laboratory should detect changes in window-dependent performance over time.

Walter Andrew Shewhart | Peer question 1 to David Slepian

Professor Slepian, suppose a laboratory selects a taper on the basis of repeated tests against a stable carrier, then installs the receiver in a field environment where legitimate transmissions vary in amplitude and modulation, the preselector warms, and the detector changes gain. The window coefficients may remain numerically identical, yet the relation between the external field and its displayed spectral peak changes. A calibration certificate describing coherent gain alone might remain formally correct while the full system loses the ability to detect a weak burst beside a strong neighbour. What monitoring evidence should accompany the laboratory's window-selection claim so that an investigator can identify when the operating process has departed from its validation envelope? Would you require fixed internal test tones, periodic external challenge injections, blind burst tests, or independent reference receivers, and how should the report distinguish an observed drift from uncertainty that was never measured in the first place?

David Slepian | Immediate answer to Walter Andrew Shewhart

Thank you for that question. Dr Shewhart, the preserved window coefficients certify only one part of the processing operation. They do

Copyright 2026, James M. Atkinson

not establish the stability of the analogue receiver or the external source population. A suitable monitoring programme would therefore distinguish digital invariants from physical-state variables. The software can record its window identifier, transform length, coherent gain and equivalent noise bandwidth deterministically. The analogue chain requires separate evidence about gain, linearity, noise, filtering and input-path identity. One should periodically challenge the complete receiver through its declared physical input boundary where practical, rather than assume that a correct software calculation proves the end-to-end response.

The challenge signals ought to represent the intended class of interest. A stable internal tone can monitor selected aspects of frequency scale or digital-channel behaviour, but it may bypass an antenna switch, preselector or gain stage implicated in the actual survey. A test burst injected at a physically relevant reference plane can reveal position-dependent response and transient recovery. A second receiver may offer useful comparison if its independence and calibration are characterised. The operator should document which elements each challenge does and does not traverse. A test that bypasses the suspected failure mechanism cannot rule out that mechanism merely because the visible result appears satisfactory.

I would also preserve a time-ordered performance record. Test outcomes should be associated with temperature, gain state, attenuation, software version and the date of the last independent calibration. Unexpected changes should trigger a documented decision about whether earlier acceptance results still apply. If a

Copyright 2026, James M. Atkinson

control test reveals a new loss of weak-burst sensitivity, the investigator should not silently correct only the newest data while retaining unqualified confidence in earlier negative findings. The historical measurements may require review, or the conclusions may need to be restricted to a narrower verified interval. The record should contain failures and interventions, not only successful after-adjustment tests.

Blind testing is particularly valuable because it distinguishes an algorithm's genuine capability from familiarity with a repeated demonstration. The test population should vary onset, amplitude, occupied bandwidth, modulation and interference. Thresholds and windows should be frozen for the trial, or the full adaptive selection rule should be treated as the object of validation. The resulting detection probabilities must be computed using independent event trials and an explicit exposure model, not simply by counting overlapping FFT frames as independent successes. Such a protocol can be demanding, but it is intellectually modest: it tests whether the published claim survives relevant perturbations. That is the appropriate discipline for a forensic result offered beyond the laboratory bench. I return the floor to Mr Fourier for analysis of the spectral consequences of the observation window itself.

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier | Principal response 2: Multiplication in time, convolution in frequency

Dr. Atkinson, I should begin by separating the original incoming function from the function the computer actually transforms. The signal available at the sampler has already passed through an analogue transfer path with its own bandwidth, phase behaviour, noise and possible nonlinearities. Digital analysis then multiplies a finite vector by a chosen set of weights. The resulting Fourier representation concerns that weighted vector. Multiplication by a window in time corresponds, under the appropriate transform conventions, to convolution in frequency. A single monochromatic component therefore acquires a response shaped by the window, rather than appearing as an infinitely narrow mathematical line. A second component nearby contributes its own displaced response; the two responses may overlap, conceal one another or be mistaken for a single feature. The window does not merely improve the picture. It changes the measurement procedure whose outputs must be interpreted.

The rectangular window is an instructive baseline. It assigns equal weight to every acquired sample, but its abrupt boundaries generate prominent sidelobes in the spectral response of a sinusoid whose phase is not aligned with the finite observation. A gradual taper can reduce those sidelobes, often widening the principal lobe. When a strong legitimate transmission lies near a weak unknown emission, suppressing sidelobes may make the weaker feature visible. Yet if the two emissions are extraordinarily close, the broader main lobe may make their separation more difficult. Neither result is paradoxical. Each follows from the chosen observation operation. A

Copyright 2026, James M. Atkinson

responsible laboratory must not claim that the mere use of a taper increases frequency resolution in every possible sense.

The interpretation of amplitude deserves separate treatment. If a stable sinusoid extends over the whole window, the transform component corresponding to its frequency responds to the sum of the window coefficients. A coherent-gain correction can compensate for that known attenuation under the appropriate conventions. A burst which occupies only a small subset of samples, by contrast, experiences an effective gain dependent on its temporal envelope and position. The sum over the entire window is no longer sufficient to characterise its individual attenuation. A brief event centred where the window is near unity may be recorded strongly; the same physical event close to a boundary may be severely attenuated, perhaps disappearing below a fixed threshold. The resulting difference is an artefact of the observational method, not proof of different transmitter powers.

Nor does the specification of equivalent noise bandwidth automatically determine a detector's field sensitivity. ENBW characterises how white-noise power is passed by a defined spectral estimator, under its assumptions. Actual receiver noise can be coloured, nonstationary, correlated across frequencies or affected by automatic gain control. The input may contain strong interference which drives the analogue circuit into compression and produces intermodulation lines; no choice of digital taper restores the linear waveform that was never sampled. A detector's false alarms and misses depend on the entire chain, including the decision rule and multiple comparisons over many windows. The window's published sidelobe and

Copyright 2026, James M. Atkinson

ENBW figures should thus be treated as necessary design information, not a substitute for end-to-end validation.

One can understand this distinction by considering an investigation where the operator has retained only averaged power spectra. If the selected window suppresses a short event at the edge of successive frames, the average may underrepresent it. If the event is strong in one frame but absent in most others, averaging may also dilute its apparent significance. A later examiner who has only the averaged result cannot re-place the window over the original samples to determine when the event occurred or whether its amplitude was biased. Retaining the complex raw time series and the relevant configuration makes more tests possible; retaining only a compressed derivative imposes a real evidential limit. The decision on storage should therefore follow the future questions the investigator may need to answer.

The laboratory should ask whether it is attempting detection, amplitude metrology, frequency estimation, or source separation. A low-sidelobe window may be attractive for the first under one interference environment. A flat-top window may better support stable-tone amplitude estimation, though at a different noise-bandwidth cost. A longer observation can improve discrimination between stable neighbouring tones, provided the sources and timebase remain coherent for its duration. A shorter observation can localise a transient more closely in time, at the expense of a broader finite-window spectral response. A suite of tools can be useful, but if the operator chooses the most favourable output after inspecting the evidence, the selection must be included in the statistical validation.

Copyright 2026, James M. Atkinson

Otherwise the analysis confuses a visual discovery process with an independently tested measurement procedure.

To establish a defensible finding, vary carrier offset continuously between FFT grid points, vary neighbouring signal level and separation, and inject bursts at random positions within the frame. Use withheld trials whose physical input is known independently of the software. Compare the outcomes under the proposed window and alternative windows, documenting each method's detection probability, amplitude error, frequency bias and alarm behaviour. Where the tests disagree, do not conceal the difference by printing only the preferred plot. Investigate whether the waveform model, analogue front-end behaviour or decision rule explains it. A real improvement should survive challenges designed to make the selected method fail.

I therefore submit a limited but useful doctrine. A window can be selected to favour specified properties of a finite measurement; it cannot transform a brief, incompletely observed emission into an ideal stationary sinusoid. It may improve the visibility of a weak signal against one form of interference while reducing sensitivity to another signal class. The underlying raw record and physical receiver conditions remain indispensable. Spectral beauty is not evidential sufficiency. I pass the token respectfully to Professor Bridgman, who will challenge whether the laboratory is measuring the same amplitude when it changes windows.

Percy Williams Bridgman | Peer question 2 to Jean-Baptiste Joseph Fourier

Mr Fourier, I should like to examine the identity of the reported quantity. Suppose two laboratories receive the same digitised record

Copyright 2026, James M. Atkinson

from a short carrier burst. The first uses a rectangular window and reports the largest magnitude component, divided by the number of samples. The second uses a flat-top window with its advertised coherent-gain correction and reports a larger peak value. Both calculations are properly implemented, yet their apparent amplitudes differ materially. Are the laboratories measuring the same physical quantity by different imperfect procedures, or have they actually defined different observables? What independent reference experiment would establish that a correction for a continuous sinusoid is applicable to this short burst? Would you require the instruments to report peak envelope amplitude, total received energy, mean power over the burst, or some other explicitly defined quantity, and how should they communicate the limitation to a forensic reader who expects the word amplitude to mean one definite thing?

Jean-Baptiste Joseph Fourier | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, the word amplitude is incomplete unless the waveform quantity, reference plane, time interval, bandwidth and estimator have been identified. A peak of a windowed Fourier magnitude array, an integrated spectral-energy measurement and a reconstructed time-domain envelope maximum need not be equal. They are related through a model and processing operations, not through their common label. A continuous-tone coherent-gain correction is specifically designed to account for the window's response to a signal present across the analysis interval under stipulated alignment and normalisation. A

Copyright 2026, James M. Atkinson

short burst does not meet those conditions automatically. Therefore the difference between the laboratories may be entirely lawful mathematically while revealing that their reported measurands are not equivalent.

I would begin with an independently calibrated test waveform whose voltage or power at the declared input reference plane is known. Its envelope and arrival position should be varied while its chosen physical quantity remains constant. If the desired measurand is peak envelope voltage, compare each estimator's output with the reference peak after accounting for the analogue transfer chain. If the desired quantity is received energy within a specified bandwidth, integrate under the applicable calibration and time interval. If the desired quantity is mean burst power, specify how the start and end of the burst are determined, since the result changes when a longer quiet interval is included. None of these definitions may be silently exchanged for another merely because the FFT produced a convenient maximum.

A correction should be tested over the admitted class of waveforms, not inferred from the name of the window. Where a fixed transient envelope is known, a model-based correction may be calculable and experimentally testable. Where the envelope is unknown, a single scalar correction may be insufficient. The laboratory might then report a bounded range, a detector response in calibrated units, or a conditional quantity rather than falsely assert an exact transmitter power. It should preserve the digital samples and the source calibration record so that a peer can test the

Copyright 2026, James M. Atkinson

transformation. A claim of absolute received field strength demands still more, including antenna factor and propagation assumptions, which the FFT alone cannot supply.

The report should name the quantity beside the number. For example, it may say that a candidate produced a peak window-corrected spectral magnitude at the recorded input reference plane under a designated signal model, or that a burst carried a certain energy within a defined reconstructed band. Such language may appear cumbersome beside a neat graph, but it prevents the graph from acquiring significance beyond its method. Two laboratories can then compare like with like. Where their operations define different quantities, the apparent disagreement is not necessarily instrumental error. Where the same measurand is intended, a challenge using common reference waveforms can establish whether their estimates are compatible within uncertainty. I pass the floor to Dr Shannon for a question about the information lost when the operator retains only the corrected peak.

Claude Elwood Shannon | Peer question 3 to Jean-Baptiste Joseph Fourier

Mr Fourier, I am concerned about the retention step following an apparently satisfactory amplitude calculation. Suppose the receiver detects a transient, chooses one spectral window, applies a gain correction, and stores the resulting peak amplitude together with a timestamp and frequency. The operator does not retain the raw complex samples because the detector has already labelled the event as complete. A later investigator wishes to distinguish a single burst from

Copyright 2026, James M. Atkinson

two closely spaced bursts, or to test whether a narrow feature was caused by a stronger neighbouring transmission. The saved result may be perfectly authenticated as a digital record, yet it cannot answer either question. Which minimum derived quantities, if any, could preserve enough information for such disputes without storing the full raw stream, and where must the report acknowledge that the transformation from waveform to peak has been many-to-one? What would be a defensible minimum retention period when the duration and modulation of the investigated source are not known at the time of acquisition, and which limitations should the operator state if that period proves inadequate?

Jean-Baptiste Joseph Fourier | Immediate answer to Claude Elwood Shannon

Thank you for that question. Dr Shannon, a peak amplitude, even accompanied by frequency and time labels, is an extremely compressed description of a waveform. Distinct input histories can produce the same three numbers. If the original record has been discarded, no subsequent choice of mathematical procedure can uniquely reconstruct those histories without additional assumptions. In particular, a pair of transient signals can have a spectral maximum coincident with that of one different waveform, and the windowed magnitude may conceal phase and timing relations essential to distinguishing them. Authenticating the saved peak establishes that those bytes have been preserved. It does not demonstrate that the stored derivative is informationally sufficient for every later inference.

Copyright 2026, James M. Atkinson

Practical retention involves trade-offs. Where storage is constrained, a system could retain a selected complex spectral neighbourhood over several overlapping frames, window identifiers, the complete timebase and tuning state, and enough pre-trigger context to identify the event's relation to the frame boundaries. Those records may permit additional analysis of some questions while remaining inadequate for others. A full raw complex capture over an appropriate interval ordinarily preserves more of the digitised information, although even it does not reverse the analogue front end's missing bandwidth, clipping or unknown calibration. The archive's sufficiency must therefore be judged against an explicit hierarchy of foreseeable claims.

For source separation, the complex phase relationships across time and frequency may be relevant. A magnitude-only peak discards them. For window-position sensitivity, the actual sample locations and coefficients must be recoverable. For intermodulation or image-response challenges, the receiver's analogue state and input transfer paths matter. A retention policy should state which questions the saved record can still answer, and which have become indeterminate. An investigator need not store every sample from every survey, but should preserve raw intervals surrounding material detections whenever practicable, together with the full selection rule used to decide what entered the archive.

The report must also distinguish absence of evidence from evidence of absence. A detector that retains only alarms cannot disclose all the weak events that failed to cross its selected threshold.

Copyright 2026, James M. Atkinson

A new window might detect some of those events in the original raw signal, but that option no longer exists if the signal was never stored. The archived candidate count is conditional upon the original selection mechanism and should not be presented as the true number of physical emissions. This caveat is particularly important where the objective is a defensive search for a rare intermittent device. The correct procedure is to preserve an exposure map and independently test missed detections across the declared operating envelope. I return the discussion to Dr Gabor for the time-localisation effects that make transient window choice especially delicate.

Copyright 2026, James M. Atkinson

Dennis Gabor | Principal response 3: Temporal weighting and the uncertain location of short emissions

Dr. Atkinson, an observation window is commonly judged by its spectral behaviour, but that judgement is incomplete for a short event whose occurrence time has investigative significance. In a continuously present sinusoid the window's temporal distribution can be summarised, for some amplitude purposes, by a coherent-gain factor. A brief pulse, however, experiences the window primarily where the pulse occurs. Moving the same pulse towards an endpoint may reduce its contribution to a particular FFT frame without changing the physical signal. That is not simply a complication of calibration. It is a defining property of the analysed quantity. The observer has multiplied the signal by a changing weight, and the resulting spectral indication must be understood as a weighted observation rather than an unqualified account of the emitter.

The analyst seeks two kinds of localisation that may pull in opposite directions. A narrow frequency response from a long window facilitates the discrimination of stable nearby tones, but the same long window may offer only a broad indication of when a brief pulse occurred. A short window more closely localises an onset yet widens the frequency response of any signal within it. Neither choice can be evaluated without defining the signal class and the required evidence. If the task is to discover an intermittent wireless command emitted during a short interval, the probability of capturing its onset and its modulation may matter more than the narrowness of a displayed carrier peak. If the task is to distinguish two nearly stationary interferers, the priorities can be reversed. The physical observation and the

Copyright 2026, James M. Atkinson

legal question ought to govern the analysis, not a customary default selected in software.

An overlapping short-time Fourier transform can reduce some temporal disadvantages. By evaluating windows at many shifted positions, a pulse near one window's edge may appear nearer the centre of a neighbouring window. That practice is valuable but must be accompanied by an appropriate event-reconciliation rule. Several adjacent detections may correspond to one physical transmission. Their errors can be correlated because the windows contain shared samples. A detector that counts them as independent confirmations can exaggerate confidence, particularly if its alarm threshold was calibrated under an independence assumption. The operator should identify a physical event by a declared temporal clustering procedure and validate the rule with withheld injections representing different durations and arrival phases.

There are also differences among transients. A short sinusoidal burst, a wideband impulse, an evolving chirp and a digitally modulated packet have different time-frequency structures. An analysis window that presents one clearly may distort another. A narrowband detector may report a transient's central spectral energy but not its instantaneous frequency. A burst truncated by the edge of a stored frame may exhibit an artificial spectral spread. A detector can legitimately provide an occupied-band estimate while having insufficient information to certify a precise carrier frequency or amplitude. The investigator must resist the temptation to make all such outputs interchangeable simply because they are displayed in the same waterfall panel.

Copyright 2026, James M. Atkinson

The effects of the receiver's physical timing are equally important. A burst may arrive during a retuning interval, before a preselector settles, or while an automatic-gain circuit is recovering from a strong adjacent signal. Software windowing cannot restore samples omitted or distorted by those processes. A reproducible windowed spectral peak is not necessarily evidence of an external source if internal processing creates stable artefacts. Conversely, the failure of a particular FFT frame to show a weak burst does not demonstrate that the antenna received nothing. The report must preserve the relevant acquisition exposure and identify the physical boundary at which any claimed absence is asserted.

For the acceptance campaign, I would use a temporal matrix rather than merely a spectral line chart. Fix a set of known pulses, then vary their placement across the entire window; repeat at different durations, signal-to-noise ratios and spectral offsets. Compare short and long windows, different overlaps, and windows selected to favour sidelobe suppression or amplitude accuracy. Record both true detections and missed events. Where the detector changes windows automatically, test the complete adaptive rule and preserve its history. An attractive low-noise spectrum should not be allowed to conceal failures at the edges of a finite observation. If several detectors are combined, their dependence must be measured rather than assumed away.

The output should be a family of bounded capability claims. A particular configuration may be highly reliable for detecting a stable carrier under strong interference but less reliable for recognising a microsecond burst. Another may be excellent for transient detection yet poor at separating two narrowband signals close in frequency. Those are not contradictions. They

Copyright 2026, James M. Atkinson

describe different properties of different measurement procedures. The declared measurand and verified operating envelope should accompany each conclusion. I pass the floor to Professor Wiener, whose examination of adaptive systems may reveal additional uncertainty introduced by a receiver that changes its analysis window in response to its own preliminary observations.

Norbert Wiener | Peer question 4 to Dennis Gabor

Dr Gabor, you have described overlapping and adaptive windowing as useful, but their dependence creates a difficulty for an autonomous receiver. Imagine that the detector monitors several windows, chooses the strongest apparent result for each candidate, and changes its future analysis configuration according to the detections it has already recorded. The same incoming waveform now influences both the current measurement and the selection of subsequent measurements. If the instrument reports only its successful alarms, an external reviewer may be unable to reconstruct which windows or thresholds were available at each moment. How should the investigator treat a system whose apparently precise spectral evidence arises from a history-dependent decision rule? Can one validate the selected outputs using familiar fixed-window error estimates, or must the entire adaptive algorithm become the object of challenge, including its training, transition states and failures to save data? I also ask whether a change in the adaptation policy itself should require a new independent validation before the receiver’s earlier measured error rates are quoted for later operation.

Copyright 2026, James M. Atkinson

Dennis Gabor | Immediate answer to Norbert Wiener

Professor Wiener, the full adaptive algorithm must be treated as the measurement procedure when its decisions affect which observations are produced or retained. One may analyse the individual windows mathematically, but the probability that the combined system reports an alarm depends upon the rule used to select among them. Choosing the strongest of several noisy estimates can alter the false-alarm distribution even when each estimate is correctly normalised on its own. The effect is magnified when thresholds change in response to earlier observations. An error rate measured for one frozen taper cannot simply be attached to a different history-dependent system.

The acceptance protocol must therefore preserve and test the state transition rules. Record the candidate windows and their coefficients, the selection criterion, the detector's gain and threshold history, and the information used to update each decision. Challenge the algorithm with independently generated signals at unknown arrival times and with controlled interference that changes over the same timescale as the adaptation. Use withheld trials rather than reporting only the recordings on which the method was tuned. Examine whether the algorithm preserves weak bursts when a stronger legitimate transmission causes its adaptive thresholds to rise. The result should describe performance across the relevant sequence of states, not merely a mean success rate over easy examples.

Adaptive processing can be valuable precisely because the electromagnetic environment is not stationary. An operator should

Copyright 2026, James M. Atkinson

not be forbidden to change a window when the signal class changes. But an evidential report must identify that the analysed output was selected through a particular rule, and it must distinguish discovery from independent validation. A raw retained interval, together with the software configuration and decision logs, permits a peer to reproduce the selection and compare alternative fixed methods. Without those materials, a later examiner may establish that an alarm was saved while remaining unable to assess how many comparable events were omitted. The cryptographic integrity of the stored result does not certify that the selection procedure covered the unretained period.

A robust report would therefore separate three statements: the numerical output that the chosen algorithm produced, the observed challenge performance of that algorithm under a declared envelope, and the stronger physical interpretation proposed for a specific field event. The first can often be reproduced from retained code and data. The second requires trials, uncertainty and an exposure model. The third may require independent receiver challenges, changes to the analogue input path or corroborating physical evidence. Distinguishing those propositions prevents a well-performing adaptive display from becoming unjustified certainty about external origin. I return the token to Mr Black for the engineering question of whether changing the analysis window can mask a defect in the analogue receiver itself.

Copyright 2026, James M. Atkinson

Harold Stephen Black | Peer question 5 to Dennis Gabor

Dr Gabor, suppose the laboratory observes a weak candidate beside a strong signal and finds that the candidate disappears under a low-sidelobe taper. The operator concludes that the original indication was mere leakage from the stronger neighbour and deletes it from the report. Yet the receiver also contains a gain loop which may have entered transient compression, while the candidate might represent a true burst coincident with the neighbouring signal. Does the fact that the candidate changes with window selection justify a causal attribution to spectral leakage, or does it merely establish sensitivity to one processing operation? What independent tests would separate a genuine weak emission from window sidelobes, nonlinear intermodulation and gain-recovery effects? I should also like your view on whether the laboratory must retain apparently unsuccessful analysis variants, given that they can expose the dependence of the final conclusion upon a methodological choice. The challenge should preserve the failed window variants so that the hypothesis test can be repeated rather than inferred from the final picture alone.

Dennis Gabor | Immediate answer to Harold Stephen Black

Thank you for that question. Mr Black, disappearance under one taper establishes that the displayed feature depends upon the analysis operation. It does not alone identify the cause. A component attributable to the strong neighbour's finite-window sidelobes should exhibit a predictable relation to the neighbour's frequency, amplitude, phase and chosen window. A true separate emission may also change appearance with the window, especially if it is short or close in

Copyright 2026, James M. Atkinson

frequency. Nonlinear intermodulation may produce additional features in the receiver itself. Gain recovery may attenuate the candidate differently depending on the preceding strong signal. The laboratory must devise interventions that produce different predictions for those explanations.

One useful challenge holds the candidate source constant while altering the strong neighbour's amplitude and frequency at a characterised input plane. A pure window-leakage feature should follow the calculated convolution response under the assumed linear model. A receiver-generated intermodulation product may exhibit a different dependence on input level and may change under added front-end attenuation. A genuine external emitter should not simply translate in physical frequency when the analysis window is changed, although its spectral maximum and detection statistic may respond to the window. Varying the local oscillator, preselector or receiver architecture can provide further discrimination if those transformations are documented. The argument is not that one intervention proves the answer, but that its results can reject or restrict specified competing models.

The gain loop also requires direct examination. Preserve its state transitions, settling time, attenuation settings and any indicators of overload or clipping. Apply controlled bursts before, during and after a strong interfering signal, and compare detection probability against the claimed operating envelope. If the weak candidate disappears only when the analogue chain enters a compromised state, its absence under one software taper is not a safe reassurance. A second

Copyright 2026, James M. Atkinson

receiver may be useful when its analogue failure modes are sufficiently independent, but sharing the same antenna or clock can leave important dependencies. Every corroboration claim should specify what is common and what has genuinely been challenged.

I would certainly retain unsuccessful analysis variants in the technical record, together with the rationale for selecting the final method. That does not require printing every plot in the principal report. It requires that the underlying process be reconstructible and that contrary results not be quietly eliminated. A conditional finding that the feature is consistent with leakage under one tested model is more defensible than an unqualified declaration that no transmitter existed. Where an external source remains observationally equivalent to an internal artefact, the report should state that uncertainty and identify a discriminating follow-up test. I pass the floor to Mr Nyquist to consider how window design interacts with the sampling and timing conditions established earlier in the roundtable.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 4: Window choice cannot repair a deficient sampling boundary

Dr. Atkinson, the spectral window is applied after the receiver has sampled the analogue input. It is therefore essential to ask whether the samples contain an adequate representation of the desired physical band. A beautifully designed digital taper cannot distinguish an aliased component from its true frequency if the analogue admission and sampling configuration made them observationally equivalent. Nor can it recover clipped amplitudes or fill acquisition gaps whose values were never observed. These limits should be stated before debating which taper gives the most pleasing sidelobe pattern. The window operates upon a finite sequence whose provenance determines the meaning of every spectral feature it produces.

Consider a receiver with a known sample rate F_s and a defined complex or real acquisition convention. A continuous sinusoid at an admitted frequency yields a sampled sequence; another analogue frequency differing by an appropriate multiple of the sampling rate may produce the same sequence unless preselection excludes it. A window multiplies the same ambiguous samples in both cases and consequently cannot resolve the analogue source ambiguity. This is the first boundary of spectral interpretation. The physical front end must establish the relevant band, local oscillator translations and alias restrictions. The report should identify those elements alongside the FFT grid and window configuration. A frequency label divorced from its input reference plane is an incomplete physical measurement.

Copyright 2026, James M. Atkinson

Within the admitted band, sample timing and clock quality remain relevant. The nominal FFT grid may contain a frequency in precise decimal notation, but if the sampling clock has a material scale error, the corresponding physical frequency is uncertain. The amplitude of phase noise or aperture jitter may also depend on the incoming frequency and signal strength. A digital taper changes the way noise and leakage are presented, but it does not remove every clock-related impairment. An investigator must propagate timebase uncertainty through the actual conversion chain instead of relying on the apparent precision of the plotted axis. A useful acceptance test varies known physical input frequencies and confirms both the scale and stability of the reported estimates.

A further ambiguity concerns the event's duration. If a stationary tone occupies a long coherent record, it may support accurate frequency estimation under a suitable model. If a transient occupies only a few samples, the finite record contains less information about its phase trajectory. A window can redistribute its contribution but cannot extend the physical observation. Padding the FFT computes a denser representation of the same weighted record. It is useful for visual interpolation, not a substitute for longer acquisition. When two narrowband components are present, their separability depends on the actual observation time, their parameters and the chosen decision procedure; it is not set universally by either the unpadded bin spacing or the window's advertised sidelobe level.

In operational surveillance the receiver may retune, scan multiple bands or change gain and filtering. Those state transitions can leave intervals of invalid or absent samples. Windowing across a missing-data boundary without recording the discontinuity may create apparent broadband

Copyright 2026, James M. Atkinson

transients or spectral features whose origin lies in the retention procedure. The analyst should mark invalid intervals explicitly, avoid treating gap-filled values as measured samples, and preserve any interpolation method used. A reconstruction may be acceptable for display under a declared model, but the report must not suggest the algorithm independently observed the unrecorded values. This principle applies equally to sample-rate changes and clock resynchronisation events.

I would require a layered verification: first the analogue input and alias restrictions, then sample timing and configuration identity, followed by the digital window and estimator, and finally the detection rule. Each layer should have its own reference measurements, uncertainty and failure criteria. For the window itself, challenge with calibrated sinusoids at varied grid offsets, neighbouring signals at varied ratios, and short bursts placed across the frame. For the complete receiver, test the same cases through the front end, including conditions of overload, drift and switching. The distinction matters because a software-only challenge can demonstrate correct algorithms while saying little about a field receiver operating outside the linear envelope of its analogue path.

The published result should therefore specify what has been calibrated and what remains assumed. It is reasonable to say that a particular windowed estimator achieved a tested amplitude bias for stable tones within a range of frequencies and signal levels. It is not reasonable to infer from that result that every brief emission will be detected, or that the absence of a plotted spectral feature rules out external transmission. The observing procedure may have insufficient dwell time, a poorly placed window or an unrecorded retune interval. The data can still be useful for

Copyright 2026, James M. Atkinson

discovery and restricted inference. Precision means acknowledging these limits, not rejecting every measurement. I pass the token to Professor Neyman, who will press us on the proper interpretation of performance claims made across several operating conditions.

Jerzy Neyman | Peer question 6 to Harry Nyquist

Mr Nyquist, you have described a layered verification programme, but a laboratory might face dozens of combinations of input frequencies, interference ratios, window functions and burst locations. Suppose it reports a confidence bound for detection probability in each tested combination and concludes that the instrument meets the desired minimum performance everywhere in its admitted envelope. Individual bounds do not necessarily confer a simultaneous guarantee upon the entire collection, especially where some conditions were selected after inspecting the failures. How would you require the laboratory to justify a statement about minimum performance across the entire set? Is it sufficient to test only a presumed worst case, or should the error allocation and selection procedure be declared in advance? I also ask how an examiner should express the regions for which sample size is inadequate, without converting statistical uncertainty into an unqualified assertion that the receiver has failed. Please distinguish a confidence bound for a single operating condition from a simultaneous claim covering all tested conditions when the same observations contribute to several comparisons.

Harry Nyquist | Immediate answer to Jerzy Neyman

Professor Neyman, the laboratory should distinguish a capability established at a particular tested condition from a claim about an

Copyright 2026, James M. Atkinson

entire multidimensional envelope. A collection of individual confidence intervals does not automatically have the intended simultaneous coverage. If the acceptance claim concerns a minimum detection probability over all relevant conditions, the trial design and inferential procedure must control the risk of falsely certifying that minimum. A simultaneous bound, a predeclared allocation of error probability, or a justifiably chosen limiting condition may be appropriate, depending on the physical and statistical model. It is not satisfactory to select whichever set of trials happens to support the claim and then describe the selection as though it were determined before observation.

The laboratory should begin by identifying the factors most likely to affect performance: burst duration and arrival position, frequency offset, strong-neighbour amplitude, receiver state, temperature and the selected window. A deliberate design can examine interactions rather than attempting every possible combination indiscriminately. Where a proposed worst-case condition is used, evidence must support its limiting character. A short burst at a window edge may be difficult for one detector, while a weak stable tone near a strong interferer may be more difficult for another. There may be no universal worst case. The report should preserve all failures and state where extrapolation has or has not been validated.

An indeterminate region is neither a demonstrated success nor a demonstrated failure. If too few independent test events have been observed to establish the required bound, the correct conclusion is that the evidence is insufficient for that performance assertion. More

Copyright 2026, James M. Atkinson

testing, a narrower claim or a different instrument may be needed. Overlapping FFT frames should not be counted as independent trials simply because they produce separate numerical results. When their dependence affects uncertainty, the inferential design must account for it. The trial unit must correspond to a meaningful physical observation or independently injected event rather than to an arbitrary number of processed frames.

Finally, the laboratory's performance bound is not a probability that a particular field alarm originated from a specified external source. That attribution depends on the prevalence of candidate signals, competing receiver artefacts and the discriminatory value of independent challenges. A detector may perform well against its laboratory test population while a particular indication remains ambiguous. The correct report can affirm the former and qualify the latter without inconsistency. I return the floor to Professor Tukey to examine how investigators should report evidence when several analytical windows reveal different parts of the same electromagnetic event.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 5: Exploratory window comparisons and defensible performance claims

Dr. Atkinson, a windowed spectrum is a construction that can reveal useful structure in complicated data. The appropriate scientific response is to explore its strengths and weaknesses, not to worship its appearance. If several windows produce different impressions of the same short electromagnetic event, the differences are themselves evidence about the sensitivity of the analysis method. They should encourage the investigator to examine the input waveform, the transfer response and the underlying assumptions. A peak which vanishes under an alternative taper is not automatically fictitious; a peak which survives every taper is not automatically external. Each behaviour must be interpreted through a model capable of making predictions that can be challenged by independent data.

The first task is to identify the purpose of the calculation. A technician may seek a visual indication that a particular frequency interval contained unusual energy. An engineer may seek the amplitude of a stable calibrated sinusoid. A forensic examiner may seek evidence that a particular source operated at a specific place and time. These are materially different propositions. A rectangular window, Hann window, flat-top window or concentration-optimised sequence can serve one proposition better than another. The question is not which window is best in the abstract. It is which procedure has been validated for the task, signal class and operating conditions at issue. A universal ranking would conceal the very trade-offs the laboratory is obliged to disclose.

Copyright 2026, James M. Atkinson

Exploratory comparisons should include what happens when the carrier is moved between nominal FFT grid points, when a weak component approaches a strong neighbour, when a burst crosses the frame boundary, and when the signal envelope changes. The investigator should inspect residuals and failures, not only average performance. A method may look excellent when tested against a stable tone placed exactly at a bin centre and deteriorate appreciably when the frequency moves by a fraction of one bin. A taper with low sidelobes may protect a weak distant line while broadening its response around a closely spaced source. A flat-top window may reduce stable-tone amplitude bias while admitting more integrated noise. A single demonstration cannot establish that all those objectives have been satisfied.

The statistical cost of trying many methods deserves attention. Suppose software calculates several windows and selects the one producing the largest apparent signal. Even if each windowed measurement is individually calibrated, choosing the maximum changes the distribution of the selected result. Its apparent significance cannot be assigned the false-alarm probability of one prespecified window without addressing the selection. Similarly, if the laboratory repeatedly alters its threshold until a favourable validation sequence appears, the final selected trials are not an independent evaluation of the method. Development can be adaptive; verification should then use withheld challenge records or an inferential scheme designed for the adaptive process. The distinction is indispensable where a result may be subjected to expert scrutiny in proceedings governed by rules of evidence.

One should also define the unit of a trial. If a short physical burst triggers three overlapping FFT frames, those three numerical alarms are not

Copyright 2026, James M. Atkinson

necessarily three independent successes. If a stationary noise fluctuation appears across adjacent frequency bins, the number of bins containing energy does not equal the number of independent noise events. A validation procedure that counts all these outputs independently can make its confidence intervals artificially narrow. The test design should identify independently generated physical bursts or independently sampled exposure intervals and account for residual dependence. It should then report detection probability, false-alarm behaviour, amplitude error and source-separation performance with uncertainty appropriate to those trial units.

For a negative surveillance finding, the exposure record is as important as the spectral display. The survey may have involved frequency scanning, preselector switching, receiver blanking, retuning and triggered retention. A window can place small weight on an event near its boundary, and a detector may miss that event even while performing admirably on centred test signals. A scan interval may never have included the frequency at which the event occurred. These mechanisms mean that the absence of saved alarms is a statement about a configured detection process, not a universal proof of physical silence. Before claiming a bounded absence, the laboratory must estimate or bound exposure and missed-detection probability for the signal class it purports to exclude.

The publication record should therefore contain a transparent account of the method. Preserve the raw complex samples around material events where practical; the analogue reference-plane calibration; the selected window's coefficients, coherent gain and equivalent noise bandwidth; the transform length and frequency reference; the frame overlap and timing;

Copyright 2026, James M. Atkinson

and the detector's decision rule and parameter history. Record rejected alternatives and failed tests in an audit appendix. The main narrative need not reproduce every screen image, but it must state the conclusion in language that is consistent with the retained evidence. An independent examiner should be able to reproduce the analysis and attempt a materially different test of the proposed cause.

A robust conclusion is often narrower and more useful than an unqualified one. It may establish that a particular detector indicated a candidate during a documented interval and that the result persisted under certain controlled window changes. It may establish a window-corrected amplitude for a defined steady waveform or a bounded response to a specified transient class. It does not automatically establish that the indication came from a covert emitter or that no other signals were present. By treating the window as part of the observation operation, the investigator preserves both scientific integrity and operational usefulness. I invite Sir Ronald Fisher to challenge the multiple-comparison assumptions that can be concealed beneath an attractive best-window spectral image.

Sir Ronald Aylmer Fisher | Peer question 7 to John Wilder Tukey

Professor Tukey, suppose the receiver produces five alternative windowed spectra for each of ten thousand overlapping time-frequency cells. Its software selects the most favourable apparent signal amplitude for each candidate and reports an alarm when the selected result exceeds a fixed threshold calibrated on one window alone. Under those circumstances the number of comparisons, their dependence and the selection of maxima alter the alarm distribution. Would it be defensible to attach to the selected alarm the original single-window false-alarm

Copyright 2026, James M. Atkinson

probability? What experiment would establish the operating characteristics of the entire multiscale decision process, especially when neighbouring frames share samples and a strong legitimate signal contaminates several candidate bands? I would also like to know how the laboratory should distinguish an exploratory selection rule from a predeclared evidential test, and how failures of the selected procedure should be retained when the operator subsequently modifies the detection threshold or chooses another window.

John Wilder Tukey | Immediate answer to Sir Ronald Aylmer Fisher

Thank you for that question. Sir Ronald, it would not ordinarily be defensible to attribute the single-window false-alarm probability to the maximum selected from a family of windows without an analysis of the full selection mechanism. The windows are not necessarily independent, and the time-frequency cells are often correlated because they share samples and because a physical interferer can influence many outputs. The exact probability of a false alarm therefore depends upon their joint distribution and the rule by which results are selected. Treating the apparent number of independent comparisons as a simple count may itself be inaccurate. The proper object of validation is the complete detector, including its window bank, selection rule, threshold, event clustering and exposure schedule.

One experiment would use withheld noise-only and interference-only records constructed to represent the admitted operating envelope, processed through the frozen algorithm without manual

Copyright 2026, James M. Atkinson

selection of favourable outcomes. Measure the rate of false physical-event alarms according to the predeclared event-counting rule, not merely the rate at which individual bins exceed a threshold. Then use independently generated weak bursts with randomised onset, frequency, amplitude and modulation to assess detection probability under the same rule. Preserve all trials and any invalid intervals, and vary strong-neighbour levels to discover mechanisms which generate correlated artefacts. If the detector changes its thresholds adaptively, its adaptive history is part of the algorithm and must be included in the challenge rather than suppressed in the report.

The distinction between development and verification also matters. The engineer may reasonably explore several windows and alter the software after observing poor performance. Such exploration generates useful design knowledge. After the method has been selected, a fresh challenge population is necessary before the outcome can be presented as independently validated. If the procedure changes after the validation trial, the previous inference may no longer apply to the revised implementation. The laboratory should maintain versioned configuration records and tests tied to each version. Selecting a final apparently favourable series while omitting earlier failures would turn an exploratory search into misleading evidence.

The report should state both the achieved performance and its uncertainty. An alarm can be associated with a tested false-positive rate under a declared population, but that is not the probability that a specific signal belongs to a particular transmitter or covert device.

Copyright 2026, James M. Atkinson

Attribution requires separate consideration of the prior occurrence of candidate sources, receiver artefacts and independent challenges. A negative finding requires a validated exposure and false-negative account, including the possibility that a short burst occurred where every applicable window was weak. These qualifications do not make the instrument useless. They turn an impressive spectrum into a testable observation. I return the token to Dr. Atkinson for the final synthesis of window-dependent measurement and evidential claims.

Ten worked applications: finite windows, detector statistics and amplitude interpretation

David Slepian, Cross-Peer Question to Jean-Baptiste Joseph Fourier: Mr Fourier, how should a laboratory distinguish the coherent amplitude correction of a window from its equivalent noise bandwidth correction?

Jean-Baptiste Joseph Fourier, Cross-Peer Answer to David Slepian: Dr Slepian, they govern different quantities. A coherent sinusoidal amplitude estimate depends on the sum of the window coefficients, whereas the noise-power bandwidth depends on the sum of squared coefficients relative to the square of that coherent sum. Applying the coherent-gain factor to a power spectral density without the correct normalisation can create a plausible but biased result. Test a bin-centred tone, an off-bin tone and noise with a separately characterised spectrum. Document whether the displayed vertical scale is amplitude, integrated power or density per hertz. The window reduces leakage by redistributing spectral response; it does not remove energy without consequence. Preserve coefficient arrays and FFT conventions, including whether the transform is one-sided or complex two-sided. I pass the token to Professor Gabor for short-burst performance.

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier, Cross-Peer Question to Dennis Gabor: Professor Gabor, can a taper with excellent distant-sidelobe suppression always improve detection of a very brief unknown pulse?

Dennis Gabor, Cross-Peer Answer to Jean-Baptiste Joseph Fourier: Mr Fourier, no. A taper concentrated near the record centre can substantially downweight a pulse near the record boundary. The right window depends upon the event duration, unknown arrival phase, bandwidth and detection objective. A broad main lobe may merge neighbouring tones even as sidelobes decrease. Test a grid of burst onset positions and carrier offsets rather than one carefully centred sine. Report detection probability, timing bias, amplitude recovery and false-alarm rate under the same window, with coherent-gain and equivalent-noise-bandwidth normalisation appropriately applied. A window which improves an aesthetically smooth spectrum may degrade the capture of intermittent surveillance events. I yield to Mr Nyquist for the neighbouring-tone problem.

Dennis Gabor, Cross-Peer Question to Harry Nyquist: Mr Nyquist, two nearby emitters are separated by less than the main-lobe width of the chosen taper. Can a zero-padded transform demonstrate that they are independently resolved?

Harry Nyquist, Cross-Peer Answer to Dennis Gabor: Professor Gabor, zero-padding creates a denser frequency grid but does not narrow the underlying window response. Whether two tones can be distinguished depends upon their separation, amplitudes, phases, noise, observation duration and the estimator or model used. Challenge with known pairs of sources, including an unequal strong-and-weak pair, rather than relying on a textbook equal-amplitude plot. Compare side-lobe leakage and main-lobe

Copyright 2026, James M. Atkinson

separation under several declared windows, and report false splits and missed weak components. If model-based superresolution is claimed, state assumptions about the number of sources and phase stability and verify them independently. A pair of fitted frequencies is not automatically a pair of physical transmitters. I pass the token to Professor Tukey.

Harry Nyquist, Cross-Peer Question to John Wilder Tukey: Professor Tukey, a reviewer finds that the analyst selected the highest spectral peak after trying six window functions. Why must this process appear in the final report?

John Wilder Tukey, Cross-Peer Answer to Harry Nyquist: Mr Nyquist, the chosen window is a data-dependent model-selection decision. A threshold calibrated for one prespecified window may not retain its false-alarm interpretation after searching six alternatives, particularly if each returns correlated but distinct maxima. Retain the candidate outputs, the tested window definitions and the selection rule, and calibrate the combined search under representative noise-only conditions. A blind independent acquisition should challenge the selected choice. Source identification requires more than a peak improved by one taper; analogue calibration, internal spur controls and event chronology remain decisive. Any quoted amplitude or uncertainty must correspond to the actual selected window and its coherent and noise normalisations. I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Distinguished colleagues, we have established that an analysis window is part of the measurement procedure, not a cosmetic choice made after the physical result is known. The selected coefficients determine how a finite digital record is weighted, and that operation affects spectral leakage, main-

Copyright 2026, James M. Atkinson

lobe breadth, noise-equivalent bandwidth, coherent gain and the apparent amplitude of short events according to their placement. The relevant trade cannot be reduced to a universal preference for one familiar taper. A window that suppresses distant sidelobes may improve weak-tone visibility under strong interference; a broader main lobe may make adjacent components less separable; and a transient arriving near the frame edge may be attenuated even when the physical emission has not changed.

Professor Slepian has made clear that mathematical concentration criteria must be related to the investigator's physical detection objective. Mr Fourier has distinguished the spectrum of the received waveform from the spectrum of the weighted observation and explained why continuous-tone amplitude correction does not necessarily restore a short burst. Dr Gabor has examined the temporal exposure of a transient in overlapping frames. Mr Nyquist has reminded us that window design cannot reverse analogue aliasing, clipping or missed sample intervals. Professor Tukey has placed these observations within a validation framework that protects against selective reporting, repeated threshold adjustment and unjustified independence assumptions. The seven peer exchanges have tested the key weaknesses in each proposed doctrine.

The worked examples demonstrate why every numerical label requires a declared interpretation. The same record can retain a 1,000-hertz FFT grid while having a 1,500-hertz noise-equivalent bandwidth under a periodic Hann window. A short pulse can experience substantial position-dependent attenuation, whereas zero padding changes the numerical grid without increasing the original observation length. A set of overlapping frames can reuse most of its samples; counting their alarms as independent evidence is

Copyright 2026, James M. Atkinson

not justified merely because they are displayed separately. A detector with a low per-cell false-alarm rate can still produce a material chance of at least one false positive across a large search. Clock uncertainty and scanning gaps remain relevant even when the digital window is mathematically impeccable.

For defensive technical surveillance countermeasures, the report should specify the window, coefficient convention, actual acquisition length, transform length, overlap, reference-plane calibration, clock state, amplitude normalisation, noise bandwidth and decision rule. It should distinguish a stable sinusoid's corrected spectral magnitude from a transient's peak voltage, burst energy or mean power. If several windows were used adaptively, the selection algorithm and its validation must be documented. Negative evidence must be qualified by the tested signal class, sampling exposure, false-negative characteristics and operating conditions. An absence of alarms in the saved derivative cannot establish that no signal occurred during unrecorded intervals or below an unvalidated threshold.

We also preserve an important distinction between the detection of a candidate and the attribution of its source. Window-dependent behaviour may help discriminate leakage from another explanation, but disappearance under one taper is not proof that an external emission never existed. Input attenuation, preselection changes, source injection, receiver substitution and documented analogue-state challenges may be needed to test competing causes. The preservation of raw samples and processing records allows these alternatives to be examined later; the retention of only a selected peak may render them permanently indeterminate.

Copyright 2026, James M. Atkinson

The resulting doctrine is neither scepticism for its own sake nor uncritical confidence in software output. It is disciplined measurement: define the physical quantity, choose and calibrate the procedure appropriate to it, validate the full detector with adverse and withheld trials, disclose all material uncertainty, and preserve enough evidence for independent challenge. Each conclusion must be no stronger than the observation and its tested assumptions permit. I thank all contributors for their scholarly exchanges and close Question 042. The following question will address averaging and how it changes the detectability of signals whose occurrence is not continuous throughout the integration interval.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 042

Worked application 1: Rectangular versus periodic Hann coherent gain

Let N=1,024 denote the number of actual acquired samples and let w[n] be the digital window. For the rectangular window w[n]=1, the coherent gain G_c=(1/N) sum_n w[n] equals 1. For a periodic Hann window w[n]=0.5-0.5 cos(2 pi n/N), the sum is N/2 and G_c=0.5. A bin-centred continuous sinusoid measured with an otherwise equal unnormalised window therefore has half the amplitude under periodic Hann weighting, corresponding to 20 log10(0.5)=-6.0206 decibels. A coherent-gain correction can compensate for this particular steady-tone attenuation under its assumptions. It does not establish the correct correction for an event occupying only a few samples near an edge.

Worked application 2: Equivalent noise bandwidth as distinct from FFT-bin spacing

Let F_s=2,048,000 samples per second and N=2,048 actual samples. The unpadded FFT grid spacing is F_s/N=1,000 hertz. A rectangular window has ENBW=F_s/N=1,000 hertz. Under the periodic Hann definition, ENBW=1.5 F_s/N=1,500 hertz. In the simple white-noise model, the second estimator admits a larger equivalent noise bandwidth even though both FFT outputs have the same 1,000-hertz grid spacing. The ratio of equivalent noise bandwidths is 1.5, corresponding to 10 log10(1.5)=1.7609 decibels of noise-power difference under the stated assumptions. This illustrates why an FFT-bin width must not automatically be labelled the noise bandwidth.

Worked application 3: Edge attenuation of a very brief pulse

Copyright 2026, James M. Atkinson

Use N=1,000 and the periodic Hann window w[n]=0.5-0.5 cos(2 pi n/N). At the centre, n=500, the window weight is 1. At n=100, it is 0.5-0.5 cos(0.2 pi)=0.0954915. For a pulse sufficiently brief that its samples experience approximately one local window weight, the amplitude ratio relative to a centred pulse is 0.0954915, or approximately -20.4008 decibels. The pulse need not have changed physical power. The attenuation arises from its placement in the analysis frame. A validation campaign that injects bursts only at the centre will not establish sensitivity near the edge.

Worked application 4: Actual observation duration versus interpolated frequency grid

Acquire N=4,096 real complex samples at F_s=4,096,000 samples per second. The observation is one millisecond and the unpadded FFT grid spacing is 1,000 hertz. Zero padding to 65,536 transform points gives a displayed grid spacing of 62.5 hertz. The display is sixteen times denser because the transform length increased sixteenfold. The original observation remains one millisecond, with characteristic reciprocal duration 1,000 hertz. Under an admitted stable-tone model, a frequency estimator may achieve more precise estimates, but the padding itself did not create any further physical input measurements. It merely sampled the pre-existing finite-record response more finely.

Worked application 5: Dependence of overlapping spectral frames

Let an FFT frame contain N=2,048 samples and let the hop be H=512 samples, producing 75-percent overlap. Adjacent frames share N-H=1,536 samples. If the sample rate is 2,048,000 samples per second,

Copyright 2026, James M. Atkinson

each frame spans one millisecond and the hop interval is 0.25 millisecond. Four frame starts occur per millisecond, but the four outputs do not represent four independent new millisecond-long observations. A burst can contribute to several frame detections, and the same noise fluctuation may affect them all. Event clustering and actual dependence must be addressed before counting alarms or calculating uncertainty intervals.

Worked application 6: A family of nominal false-alarm tests

Suppose a detector performs K=3,000 hypothetical independent null tests, each having a fixed per-test false-alarm probability p=0.0001. Under that independence model, the chance of at least one false alarm is 1-(1-p)^K=1-(0.9999)^3000, approximately 0.259193. This is much larger than 0.0001. Real window-bank outputs and overlapping frames are generally dependent, so the numerical result is not a calibration of the actual receiver. It demonstrates why the full multiscale detector needs its own joint false-alarm validation rather than an unqualified transfer of one window's threshold specification.

Worked application 7: Noise-standard-deviation comparison from ENBW

Consider a simplified detector operating against locally flat white noise. If its output noise power is proportional to ENBW, increasing ENBW from 1,000 to 1,500 hertz increases noise power by the factor 1.5. The corresponding root-mean-square noise amplitude increases by sqrt(1.5)=1.224745, approximately 22.47 percent. This does not imply that every narrowband peak is 22.47 percent larger, since peak statistics

Copyright 2026, James M. Atkinson

and signal response involve other factors. The example shows why two windows with equal FFT-bin spacing but different equivalent noise bandwidths should not be compared without correcting or validating their noise scales and decision thresholds.

Worked application 8: Effect of clock-frequency scale uncertainty

Suppose the complete acquisition frequency scale is verified to within a relative systematic uncertainty of one part per million over the relevant operating state. A displayed candidate frequency of 200,000,000 hertz then corresponds to an approximately 200-hertz contribution from that scale uncertainty, before any separately relevant mixer, oscillator or estimation errors. A padded FFT grid might be spaced at much less than one hertz, but this does not eliminate the 200-hertz physical uncertainty. The conversion from baseband to RF may involve additional clocks or oscillator references whose errors must be propagated through the actual receiver configuration. Define the indicated frequency f = 200,000,000 Hz and fractional scale uncertainty $\varepsilon = 10^{-6}$. The resulting scale term is $u_f = |f|\,\varepsilon$ = 200 Hz; it is not reduced by frequency-bin interpolation.

Worked application 9: Detection exposure under a scanning receiver

A receiver observes one chosen frequency for 20 milliseconds in each 200-millisecond scan cycle. Its dwell fraction is $D=0.02/0.2=0.1$. If a burst is much shorter than the dwell, occurs uniformly at random relative to the cycle and has negligible boundary effects, the probability that its onset falls in an observed interval is approximately 0.1. If the detector succeeds with conditional probability 0.98 during admitted exposure, the

Copyright 2026, James M. Atkinson

unconditional detection probability under the stated simplified model is 0.1 times 0.98=0.098, or 9.8 percent. A well-calibrated FFT window cannot compensate for intervals during which no samples of the relevant band were acquired.

Worked application 10: Reported burst amplitude in an uncertain window location

Suppose a calibrated injected reference burst produces a normalised peak voltage of 10 millivolts when it is centred within a chosen analysis window. The same input, moved to a location where the local effective window weight is 0.2 under a short-pulse approximation, may yield an indicated peak of 2 millivolts if no position-aware correction is applied. This is a factor of five difference or 20 log10(0.2)=-13.9794 decibels. The example demonstrates an algorithmic position effect, not a genuine fivefold change in transmitter amplitude. The laboratory should challenge the detector with varied onset times and report a validated correction range or a limitation, rather than apply a single continuous-tone coherent-gain factor indiscriminately to every transient.

QUESTION 043

Copyright 2026, James M. Atkinson

When does spectral averaging conceal short-lived signals?

Source: V011_Roundtable_Question_043_CP043_Dr_Atkinson.docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 043. Complete Expert Roundtable Discussion

Constructed educational dialogue. Historical contributors are presented as intellectual personae, not as participants in an authentic meeting or witnesses to modern receiver hardware. The discussion is substantive, while independent scholarly and mathematical verification remains separate from prescribed components have passed their audits.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, our previous discussions established that the windowing of a finite observation alters the apparent spectral response and that a correct numerical transform does not supply information omitted by the analogue chain or the recording procedure. We now examine the operation of averaging, commonly used to produce a quieter, more stable spectrum. An engineer observing a persistent weak carrier against stochastic noise may profit greatly from combining several estimates. An investigator searching for a rare transmitter which emits only briefly may find that the same averaging procedure reduces the transmitter's prominence or removes it from a median-derived display. The eye sees an attractive smooth noise floor; the instrument has selected a statistic whose relationship to the actual physical events must be declared.

The problem is not solved by saying merely that averaging reduces noise. We must distinguish averaging complex waveform values, averaging spectral magnitudes, averaging squared magnitudes or power spectral

Copyright 2026, James M. Atkinson

densities, averaging values expressed in decibels, and selecting a median or other robust estimate. These operations are not equivalent. Coherent averaging can suppress an unaligned signal while preserving a phase-locked component. Mean power averaging preserves certain expectations under a stationary model but can dilute a transient's contribution across many quiet frames. Median averaging may deliberately reject rare large excursions, which is useful when estimating the background but hazardous if those excursions are the very signals a counter-surveillance investigator must discover. An automatic display may incorporate additional smoothing whose effect upon detection was never documented.

Let $P_i(f)$ denote a window-corrected power estimate from frame i at frequency f, and let K be the number of frames in the averaging group. The arithmetic mean is $P_{bar}(f)=sum_i P_i(f)/K$. If a burst contributes excess power S in only one frame and the other K-1 frames have background power B, the mean becomes B+S/K under the stipulated additive-power model. The excess is diluted by the factor K compared with the active frame. That arithmetic result does not assert that every possible detector loses sensitivity with averaging, because a detector may integrate a known repeated waveform coherently or use a statistic designed for sparse events. It establishes that the meaning of the chosen mean differs from the maximum, from the event count and from the probability that a burst occurred anywhere in the observation interval.

Frequency occupancy and negative evidence pose equally difficult questions. Suppose an SDR stores only an average spectrum for each ten-minute period. The average may establish some property of the energy distribution during the retained interval, but it cannot necessarily disclose

Copyright 2026, James M. Atkinson

how many bursts occurred, how long they lasted or whether their occurrence coincided with another event. A later forensic examiner may wish to determine whether a brief transmission was connected with a specific telephone call, door access or computer-network transaction. A period average, even if cryptographically authenticated, cannot reconstruct the original event times. The preservation question therefore arises at the beginning of the measurement, not merely when the final report is written.

Our panel shall examine these issues through complementary disciplines. Professor Bartlett will discuss spectral estimation and the statistical effects of dividing a record into segments. Professor Wiener will examine stationary assumptions and the temptation to use a smoothed representation as a complete account of a changing process. Dr Shannon will examine information discarded by averaging and the difference between preserving expectation and preserving particular events. Dr Bennett will consider the receiver's physical noise sources and the limits of inferring improved sensitivity from an apparently quieter trace. Professor Tukey will insist that a detector claiming both background estimation and transient discovery be challenged on a population that contains realistic rare events. Seven colleagues will press the participants on correlated windows, selection effects, false negatives, noise distributions and the admissibility of a negative survey conclusion.

We must maintain the distinction between developing a useful visualisation and validating an evidential assertion. Averaging is neither inherently virtuous nor inherently deceptive. A technique may be excellently suited to measuring long-term noise power and unsuited to detecting a fleeting emission. The proper question is what statistic the operator

Copyright 2026, James M. Atkinson

computed, what assumptions justify it, what alternative information was discarded, and which challenge tests establish the claims offered in the report. The publication record must include the processing history, raw evidence where available, averaging duration, window overlap, units, gain state, frequency reference and detector version. I invite Professor Bartlett to begin with a comparison of mean spectral estimation and the more demanding task of finding a single rare event in a collection of observations.

Copyright 2026, James M. Atkinson

Maurice Stevenson Bartlett | Principal response 1: Average periodograms and the unequal goals of estimation and discovery

Dr. Atkinson, a spectral estimate is an inference from a finite record under a statistical model. Dividing a long record into segments, forming spectral estimates from them and averaging can reduce the variability of a power-spectral-density estimate under suitable assumptions. But the method does not magically yield additional independent information, particularly if the segments overlap or the underlying process changes during the interval. The engineer must ask which random quantity is being estimated and whether the assumed stationarity is compatible with the investigated signal. A long-term background-noise estimate and a detector for a rare intermittent emission are not the same statistical task. Averaging may be suitable for the former while obscuring the latter.

The familiar mean periodogram is informative about the average spectral power in a selected population of segments. If one segment contains a rare burst and many others are quiet, its contribution to the mean is divided by the number of segments. That does not imply the event was absent, nor that its peak amplitude was the value of the average. The mean answers a population question. A maximum detector answers a different question about extreme observations and must be calibrated against the distribution of extremes. A median may offer resistance to unusual high-power interruptions when the goal is estimating baseline noise, but such resistance can remove precisely the evidence of a signal that is rare by design. In a defensive investigation the analyst must state which of these tasks is intended and retain the evidence necessary to test it.

Copyright 2026, James M. Atkinson

One subtlety concerns the distribution of spectral estimates. Even when the input noise is approximately Gaussian, a periodogram ordinate does not behave as a Gaussian amplitude error in the simple sense suggested by a smoothed trace. Mean averaging changes the distribution and can reduce variation, but the benefit depends upon the number of effectively independent observations. Overlapping segments reuse samples. They may improve the efficiency of a spectral-density estimator for a given finite record, yet they should not be counted as independent trials merely because the software produced separate frames. The investigator should know the overlap, window, correlation and sampling programme before asserting a specific variance reduction or confidence bound.

Another subtlety is the difference between linear power and logarithmic display quantities. The arithmetic mean of power values, expressed in watts or volts squared under a known reference, is not equal to the arithmetic mean of their logarithms. If a spectrum analyser averages values already expressed in decibels, the displayed result may differ from a power average, particularly where the input varies strongly or the noise has a skewed distribution. An operator should identify the actual detector mode and averaging domain. The word average without units and a processing definition is insufficient for metrology. A forensic report should not transfer a correction appropriate to one domain into another without deriving and testing the relation.

A transient creates additional uncertainty about frequency and time. If the burst appears in one of K frames, the mean may show a weak elevation but not the frame in which it occurred. If the software stores only that mean, the source time cannot generally be reconstructed. The original unaveraged

Copyright 2026, James M. Atkinson

frames may themselves contain overlapping samples, and an event may appear in more than one frame. A proper event count requires a physical-event identification rule, not a simple count of elevated bins. The negative conclusion is also restricted: a mean below threshold may conceal a brief signal whose instantaneous or per-frame power exceeded the same threshold. The average is a different observable from the individual event.

I would therefore design two parallel outputs for a receiver intended to measure both baseline noise and intermittent activity. One output might provide a suitably calibrated mean or robust background estimator, labelled as a background statistic. Another should preserve event-sensitive quantities, such as per-frame maxima, timestamps, short raw intervals or a thresholded candidate log whose detection and selection rules are validated. The former can improve the interpretation of the environment. The latter protects against a rare signal being hidden by the statistic used to characterise that environment. Both outputs must share a traceable receiver-state record, and the limitations of any triggered retention must be disclosed.

The laboratory should test those outputs on withheld data containing deliberately sparse bursts, including one event in a large number of otherwise quiet frames. Change the burst duration, frame position, frequency offset, amplitude and neighbouring interference. Vary how many frames contribute to the average and observe whether the detector's claimed performance survives. Include noise-only trials to measure the false-alarm characteristics of any maximum or event-sensitive rule. For the average spectral estimate, report uncertainty appropriate to its effective number of independent segments and stationarity assumptions. For the

Copyright 2026, James M. Atkinson

burst detector, report detection probability conditioned on the admitted signal class and observation exposure. One certificate cannot stand in for both.

Finally, the physical receiver must not disappear behind the statistics. An input overload or automatic-gain transition may introduce an event-like spectral excursion. A robust average may suppress that excursion in the background estimate, but the origin of a field alarm still requires physical investigation. Conversely, a burst which is genuine may never appear in a selected derivative because the receiver scanned away or because the signal was excluded during blanking. Averaging neither proves nor disproves external origin. It creates a statistic whose scope is bounded by the samples, reference plane and process conditions. A cautious and well-designed report can be decisive about that statistic without pretending to certify every unobserved event. I pass the token to Professor Slepian, whose concentration studies invite a question about whether the same processing choices that reduce background variance can also hide a weak spectrally concentrated burst.

David Slepian | Peer question 1 to Maurice Stevenson Bartlett

Professor Bartlett, suppose the instrument uses overlapping windowed periodograms and forms a mean in order to produce a stable estimate of the ambient power spectral density. A covert transmitter emits a single short packet in one of a hundred frames, yet the receiver's routine display shows only the hundred-frame mean. The packet's energy may lie in a narrow frequency interval, but the choice of window and averaging interval can diminish its contrast against the background. The laboratory demonstrates excellent variance reduction on a stationary

Copyright 2026, James M. Atkinson

reference noise source and then claims improved sensitivity to rare packet transmissions. What challenge would distinguish those two different kinds of performance? Should the instrument separately retain a maximum spectrum, a raw candidate interval or a statistic designed for sparse events? How should the operator report a negative result when only the mean survives and the original packet timing cannot be reconstructed? Please distinguish a numerical estimate of ordinary environmental power from an evidential assertion that no brief physical transmission occurred during the same interval, and identify precisely which data could support each proposition.

Maurice Stevenson Bartlett | Immediate answer to David Slepian

Thank you for that question. Professor Slepian, the laboratory's stationary-noise demonstration establishes a property of a spectral estimator under the tested model. It does not establish the probability of detecting a brief packet. To test packet detection, the laboratory must inject independently timed events with known amplitude, duration, modulation and frequency offset, and process them through the entire receiver and retention procedure. The relevant outcome is whether the event is recognised and preserved, not merely whether the mean spectrum becomes visually smoother. Both false alarms and missed detections must be measured. The challenge should include weak events arriving at awkward frame positions, not only convenient centred reference packets.

A maximum spectrum or event-triggered raw interval may provide useful complementary evidence, but its own false-alarm behaviour requires validation. The maximum of many noisy estimates tends to

Copyright 2026, James M. Atkinson

be larger than an ordinary estimate; a threshold appropriate to one frame cannot be exported to the maximum over a hundred frames without considering the size and dependence of the family. A trigger must preserve the algorithm and threshold that caused the event to be retained. A raw segment should include sufficient pre-trigger context, receiver state and timebase information to permit an independent examiner to challenge the result. A background mean and a candidate log serve different purposes and should be labelled accordingly.

Where only the mean survives, the report can describe the measured mean spectral power under the stated averaging scheme and its uncertainty. It generally cannot specify the number or exact times of rare bursts without additional modelling assumptions and evidence. A low mean does not exclude a brief high-power event if the event's contribution was diluted across many quiet frames. Similarly, a high mean may arise from repeated moderate emissions, one large excursion, or a persistent interfering source. Their physical histories are not uniquely inferred from one average. The investigator should state this non-uniqueness rather than present a false precision about prevalence.

The proper rule is to treat the detection claim as a separate calibrated procedure. Preserve the acquisition coverage, loss intervals and detector state. If the survey scanned several bands, calculate the actual exposure of each band instead of dividing the saved alarm count by the entire elapsed hour. If a robust background estimator is used, test whether it rejects the signal class of interest. The absence

Copyright 2026, James M. Atkinson

of archived candidates is meaningful only in relation to a known false-negative rate and exposure model. An instrument can remain useful even when that rate is not fully known, but its negative conclusion must be narrower. I return the floor courteously to Professor Wiener to examine the further complication that the underlying electromagnetic environment may not be stationary during the averaging period.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 2: Stationary models and feedback between detector and environment

Dr. Atkinson, the temptation to smooth a record arises partly from our wish to describe irregular observations by stable quantities. A smoothed spectral estimate can be useful when the underlying noise process is sufficiently stationary over the chosen observation interval, but that condition must be examined, not assumed from the smoothness of the output. A receiver operating in a real electromagnetic environment encounters transmissions that begin and cease, changes in propagation, electronic switching events, moving interference sources and alterations in its own gain and reference state. These changes may occur during an averaging period. The average then describes a mixture of operating states rather than one fixed stochastic process. Its numerical stability may be obtained at the cost of obscuring the transitions that are operationally most important.

The problem deepens when the receiver adapts to the data. An automatic noise-floor estimator may adjust thresholds according to recent spectral history. A strong legitimate carrier can raise a local estimate of background power; a subsequent weak transient may then fail to exceed the adaptive threshold. The receiver's software may faithfully report that no alarm was generated, while the operator infers that no physical event occurred. The latter proposition does not follow from the former. The measurement procedure has coupled the observation process to the decision rule. Its state at one moment depends on earlier observations and parameter updates. A static threshold certificate cannot necessarily characterise such a time-varying detector.

Copyright 2026, James M. Atkinson

Averaging with a recursive filter makes the relation between history and present output especially clear. Suppose an exponentially weighted estimate is updated by $A_k = \text{alpha } P_k + (1\text{-alpha}) A_{(k-1)}$, where alpha is between zero and one and P_k is the current linear-power estimate. For a sudden excess S above a constant background, the first output changes only by alpha S. A small alpha makes the trace visually smooth but attenuates a single-frame transient strongly in the retained average. Following the impulse, the estimate decays gradually, which can spread its apparent effect across later times. An investigator who uses the recursive estimate as a direct record of physical event duration may therefore be misled both about the event's peak and about when it ended. The actual update coefficient and initial state are essential metadata.

It is not enough to classify the operation as low-pass smoothing. The receiver may average spectral power, magnitude, logarithmic level or another nonlinear statistic. The same physical burst can have different influence on those quantities. For example, a large rare excursion can dominate a mean-power estimate while contributing little to a median baseline. Both may be mathematically correct for their intended purposes. An operator searching for a covert intermittent device should not use a baseline estimator as though it were an event detector unless the relevant detection properties have been independently established. In particular, a median that rejects rare interference can also reject rare genuine transmissions when those transmissions are classified only by their statistical rarity.

The archival problem is fundamental. If the instrument saves the recursive average and discards the original frame estimates, an investigator

Copyright 2026, James M. Atkinson

may attempt to invert the recurrence. That inversion requires knowledge of the initial state, alpha, numerical precision, any clipping or quantisation, missing frames and every adaptive parameter change. If the update includes thresholding, saturation or nonlinear state logic, the inverse may not be unique. Even a mathematically invertible numerical recurrence does not recover an analogue event that was never admitted through the receiver. The report should identify the representation saved and the states necessary for its interpretation, rather than assume that the displayed curve contains the whole electromagnetic history.

The resulting acceptance statement should distinguish an estimate of background power from a claim about detection. One may validly report that a recursive average stabilised the displayed noise estimate under the laboratory's admitted conditions. One may separately report the probability that a particular class of burst was retained when it occurred within observable exposure. The two claims must not be silently exchanged. An examination of a suspected surveillance emission also requires alternative-cause tests to distinguish external signals from internal transients due to gain changes, clock reconfiguration or software processing. A quiet display can be a successful visualisation and an inadequate forensic record at the same time. The correct doctrine is to preserve the distinction and its evidence. I pass the floor to Dr Shewhart for a challenge concerning the validity of a stationary-process model when the underlying receiver configuration changes during the observation.

A robust validation campaign should use known independent challenge events introduced at randomised times during an operating sequence that includes realistic interference transitions. Test the detector before, during

Copyright 2026, James M. Atkinson

and after high-power exposures and gain changes. Vary the averaging time and adaptive parameters. For each event record whether the raw input was available, whether the event was recognised, how its amplitude and duration were represented, and whether the recorder retained it. Trials should include long periods with no event, repeated moderate events and one rare large burst, because these histories can yield similar averages while posing different investigative questions. The algorithm should be frozen for withheld tests or its entire adaptive rule should be treated as the object of the validation.

Walter Andrew Shewhart | Peer question 2 to Norbert Wiener

Professor Wiener, an industrial control chart is intended to distinguish ordinary variation from a material change in the process. Suppose an SDR records a long series of averaged spectral estimates, each based on a different interval of data, while its receiver temperature and gain state drift. The smooth output may appear stable even as the process that generates its noise changes. At what point should the investigator treat the average as an estimate from a mixed population rather than an adequate characterisation of one stationary background? What diagnostic record would permit a later reviewer to distinguish an actual electromagnetic change from the effect of altered smoothing coefficients or adaptive thresholds? Would you require control references at specified intervals, and how would the laboratory define a rule for invalidating previously accepted negative survey findings when the detector is discovered to have entered a different operating state? Would a stable average alone ever be sufficient evidence that the underlying

Copyright 2026, James M. Atkinson

measurement process remained in statistical control, or must it be supported by independently monitored state variables?

Norbert Wiener | Immediate answer to Walter Andrew Shewhart

Thank you for that question. Dr Shewhart, the operator should preserve the distinction between variability within a defined operating state and changes that invalidate the model of that state. Temperature, gain, preselector selection, clock condition, numerical processing configuration and interference occupancy can all change the distribution of spectral estimates. A single aggregate average may conceal those changes. The laboratory should therefore preserve a time-ordered record of relevant state transitions and reference challenges. A control reference ought to traverse the portion of the measurement chain implicated in the claim; a digitally injected test value cannot certify an analogue input stage that it bypasses. The results should be indexed to both the reference source and the operating configuration.

Stationarity is not established by a smooth curve alone. The investigator can examine residuals, segment-level statistics, correlation, variance and abrupt changes in detection behaviour. Where the process visibly changes, report the corresponding intervals separately or use an explicitly time-varying model whose adequacy is tested. If gain changed during the survey, the investigator should not treat earlier and later spectral levels as directly comparable without a correction supported by calibration. If an adaptive threshold increased after a strong signal, the false-negative exposure for a subsequent weak emitter may have changed materially. That

Copyright 2026, James M. Atkinson

uncertainty must be reflected in the strength of any negative conclusion.

A controlled change-detection rule can be valuable, but it requires its own false-alarm and missed-change assessment. One may use periodic reference events or independent audit intervals to test whether the detector retains its admitted performance. When a failure is discovered, reconstruct the time range potentially affected by the defect using the available logs and references. If the interval cannot be bounded, the corresponding historical negative result may have to be described as indeterminate. That is not the same as proving that the hidden transmitter was present; it means that the instrument's failure to report one no longer supports the promised level of reassurance.

The most important safeguard is to retain not only the final average but enough of the unaveraged evidence and state record to examine the process. The original question may later concern one rare event rather than mean occupancy over the whole period. A measurement system cannot become retrospectively more informative merely because its plotted result was stable. A concise report can still be prepared, but its supporting archive should disclose the assumptions, changes and limits of the selected estimator. I pass the token to Dr Gabor, who will challenge how a smoothing interval interacts with a pulse whose beginning and end are themselves material to an investigation.

Copyright 2026, James M. Atkinson

Dennis Gabor | Peer question 3 to Norbert Wiener

Professor Wiener, your recursive averaging example describes a short event as a small initial movement of the estimate followed by a long decay. A forensic investigator may mistakenly read the decay as evidence that the transmitter continued to radiate after the actual burst ended. Equally, a large average may conceal whether the generating signal was brief and strong or weak and persistent. How should the laboratory validate the temporal response of its averaging procedure and communicate the distinction between the filter's memory and the emitter's actual duration? Would you require the original event-sensitive record to be retained even when the averaged spectral estimate is the official measurement product, and what uncertainty remains when the event occurs across the boundary of the saved recording interval? I also ask whether averaging over a period much longer than the event duration can produce an apparent emission tail whose persistence is entirely due to filtering, and how that effect should be disclosed to an examiner considering the event timeline.

Norbert Wiener | Immediate answer to Dennis Gabor

Thank you for that question. Dr Gabor, the response of a recursive average to a known brief input should be measured as part of its calibration. If the update rule is linear and its coefficients and initial state are known, the mathematical impulse response can be predicted; nevertheless the complete instrument may contain additional filtering, thresholding, quantisation or state changes. The laboratory should therefore inject pulses with known duration and onset into an appropriate reference plane and compare the measured

Copyright 2026, James M. Atkinson

output with the prediction. The experiment must vary event timing relative to update intervals, because an event near a boundary may be represented differently from an otherwise identical event near the centre. The result should state the time response of the estimator rather than assume it is the physical duration response of the transmitter.

One should distinguish at least three different times: the actual admitted event interval at the input plane, the interval during which the detector was exposed to it, and the time over which the averaging memory remains elevated. These need not be equal. If an averaged display shows a trailing response after a transient has ended, that tail belongs to the estimator unless independent evidence demonstrates continuing emission. Conversely, if the averaged response never exceeds the alarm threshold, one cannot conclude that no brief input occurred. The detector's sensitivity to sparse events must be tested directly. The required data include update coefficients, frame times, trigger rules, gain state and any invalid intervals.

I would preserve an event-sensitive derivative and, when possible, the raw samples surrounding a material candidate. The mean or recursive average may remain the official background-noise product, but it is inadequate by itself for many timing and source-identity questions. The acquisition should also record the selection rule by which segments were saved, so a later examiner can distinguish an unrecorded interval from a recorded negative observation. An authenticated record proves integrity of the bytes stored, not completeness of the physical process. If the event crossed a boundary

Copyright 2026, James M. Atkinson

and the omitted portion cannot be recovered, any duration or energy estimate should include that limitation rather than be extrapolated as though the waveform were known.

The laboratory can develop models to correct known smoothing effects, but a correction's success is conditional. Inverting a linear filter may amplify noise or become unstable where the original transformation strongly suppressed certain components. Where nonlinear selection discarded information, no unique inverse may exist. The most defensible procedure is prospective: define the relevant event classes, retain data at a resolution adequate for their foreseeable questions, validate the time response and report only the uncertainty which the actual evidence supports. I return the floor to Dr Shannon, who will examine more formally the distinction between a reliable average and an adequate record of the individual events that created it.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 3: Averages can preserve a statistic while discarding the event history

Dr. Atkinson, the most important issue is not whether a mean is accurate, but what the word accurate is intended to describe. A set of numerical values can have a well-defined mean even when their ordering and individual departures are unknown. Once only that mean survives, many distinct histories may be consistent with it. Ten frames each containing moderate power can share an average with nine quiet frames and one strong burst. The number, timing and shape of events cannot be uniquely determined from their common mean. This is a many-to-one representation, and its lost distinctions cannot be recovered merely by applying more computation to the saved statistic.

A similar issue arises when magnitude or power spectra are averaged across frames whose phases differ. Coherent complex averaging and incoherent power averaging answer different questions. A stable component whose phase is referenced consistently may accumulate coherently, whereas a signal with variable phase can cancel in a complex average. Power averaging avoids that particular cancellation but still discards phase relationships and can dilute sparse excess power over quiet frames. The procedure should therefore identify its signal model: is the relevant source expected to remain phase coherent throughout the integration, to recur with a known timing pattern, or to appear as an unpredictable burst? There is no model-independent advantage to longer averaging for every class.

The units also matter. Averaging linear power values and averaging the same numbers after converting them to decibels are mathematically

Copyright 2026, James M. Atkinson

different operations. If an investigator records the average of logarithmic levels, the result is related to a geometric rather than arithmetic mean of the underlying powers. It need not represent average energy correctly. The software or instrument manual should identify which operation was actually performed, rather than use the ambiguous word averaging. A later examiner should be able to trace the reported value back to its input reference plane, scale conventions, window and frame selection. Without that record, an apparently precise spectral number may be insufficiently defined to support a physical power claim.

The information lost through selection can be more consequential than the information lost through averaging itself. A receiver that stores only a mean spectrum for every minute omits the occurrence times of individual bursts. A receiver that stores only means exceeding a threshold also omits some low-level intervals and makes the archive conditional on its own decision rule. A detector may use a median to suppress exceptional interference and thereby suppress rare genuine transmissions, because statistical rarity alone does not distinguish hostile or benign origin. When the investigative question concerns an intermittent emission, the probability of missed retention must be measured against the chosen signal class. A quiet mean or median does not settle the absence of unrecorded events.

A practical evidence system can preserve several levels of representation. A low-rate mean power record may be suitable for identifying long-term occupancy or background trends. A per-frame event statistic, together with validated thresholds, may help detect sporadic changes. Raw complex samples around important candidates preserve more of the digital evidence for reanalysis, provided their timing, frequency translation and receiver

Copyright 2026, James M. Atkinson

state are documented. No single derivative is sufficient for every possible future question, and raw digital samples do not restore an analogue input component that the receiver never admitted. The preservation plan should state these boundaries explicitly rather than claim an unattainable universal completeness.

The investigator should also beware of interpreting different displays as independent corroboration. A mean spectrum, median spectrum and maximum spectrum computed from the same raw samples are related mathematical functions of one observation. Their agreement may be useful for a particular robustness test, but it does not constitute three independent receivers observing the same physical event. If a second receiver is employed, its independence must be assessed at the antenna, clock, power and signal-path levels. Shared references can introduce correlated errors. A proof of source identity should depend on observations that discriminate the proposed emitter from plausible alternatives, not merely on several derived pictures containing similar peaks.

The relevant validation has to occur before the forensic report makes a strong claim. Introduce sparse bursts with known timing and waveform structure into an otherwise representative stream. Measure how mean, median, maximum and coherent averages respond, including their false alarms and the circumstances in which an event is omitted. Preserve the full challenge record and any adaptive parameter changes. Use a trial population independent of the development examples to establish performance. The report should distinguish a conclusion about average power from a conclusion about the presence or absence of an event during

Copyright 2026, James M. Atkinson

a particular interval. The former may remain sound when the latter is indeterminate.

My conclusion is a statement of informational scope. An accurately computed average is evidence of the average of the observed and selected data, under the adopted scaling and calibration. It is not a uniquely invertible description of the time series that generated it. A short-lived covert signal can be concealed by averaging when its contribution is diluted, cancelled or rejected by the chosen statistic, or when the selection procedure fails to retain it. A responsibly designed receiver can use averaging and still protect event evidence by keeping the distinct products and their limitations visible. I pass the floor to Professor Neyman for a challenge about the uncertainty of rare-event detection when the averaging method was selected after inspecting the data.

Jerzy Neyman | Peer question 4 to Claude Elwood Shannon

Dr Shannon, suppose a laboratory develops a detector by testing several averaging lengths and selecting whichever version most clearly displays a set of known transient examples. It then claims that the selected method detects short bursts with ninety-five-percent probability because nineteen of twenty favourable examples produced alarms. The examples may not have been independent, their onset times may have been selected for convenience, and the method was chosen using those very results. How should the investigator distinguish a discovery exercise from an independent estimate of detection probability? What sampling unit should be used when several overlapping frames can be triggered by one physical event, and what evidence would establish a defensible confidence bound for a low false-negative rate across different burst

Copyright 2026, James M. Atkinson

durations and interference levels? If the laboratory later modifies its averaging interval or alarm threshold, should the former detection-performance certificate still be quoted, or must a fresh validation campaign be undertaken for the revised procedure?

Claude Elwood Shannon | Immediate answer to Jerzy Neyman

Professor Neyman, the claimed probability should not be accepted merely from a fraction of successes in the examples that were used to select the method. Those observations belong to the development process and are not an independent validation population. A new set of challenge events should be generated under predeclared conditions and withheld from parameter selection. Their occurrence times, amplitudes, durations, modulation and neighbouring interference should span the admitted envelope. The validation procedure must define one physical test event and establish whether it was correctly detected and retained. Multiple overlapping FFT frames triggered by the same event do not automatically increase the number of independent trials.

The confidence bound should be calculated according to the selected statistical design and its independence or dependence assumptions. Nineteen successes out of twenty events, even if independent and properly sampled, do not establish with high confidence that the true detection probability exceeds ninety-five percent. The sample is small and its observed proportion is itself uncertain. If the claim concerns all combinations of burst duration and interference conditions, individual bounds may not provide a simultaneous guarantee for the whole family. The laboratory should

Copyright 2026, James M. Atkinson

predeclare its acceptance rule and use a method appropriate to the desired joint coverage. Where data are insufficient for some conditions, an indeterminate qualification is more accurate than a universal certificate.

The detector's apparent success also depends upon exposure. If the receiver was not tuned to the relevant frequency during a particular event, the absence of an alarm does not measure the same conditional detector property as a missed event while fully exposed. One may calculate an unconditional probability under a validated scan model, but it should be distinguished from the probability of detection given admission to the relevant band. An averaging procedure may work excellently when the source is present throughout a long observation and fail against a rare burst because its energy is diluted. The validation population must therefore reflect the event class the operator intends to discover.

A strong evidential record should contain both the algorithm's full versioned state and the underlying trial outcomes, including negative cases. An investigator should be able to reproduce the average and, where available, test alternative event-sensitive statistics against the raw data. These requirements do not remove every uncertainty. They ensure that the resulting report identifies which performance claim the evidence supports and which remains unknown. It is entirely consistent to accept an average power estimate while declining to infer from it that a sporadic transmitter was absent. I invite Dr Bennett to consider the further distinction between reducing a

Copyright 2026, James M. Atkinson

displayed trace's fluctuation and improving the physical receiver's noise performance.

Copyright 2026, James M. Atkinson

William Ralph Bennett | Principal response 4: Receiver noise, power averaging and the illusion of increased sensitivity

Dr. Atkinson, the appearance of a narrower noise trace is not necessarily evidence that the input receiver has acquired a smaller physical noise temperature or a lower noise figure. A stable average suppresses fluctuations in the estimate; it does not automatically change the stochastic voltage entering the analogue chain, the available signal power, or the information lost through front-end distortion. The instrument's physical sensitivity depends on its antenna and input reference plane, noise bandwidth, receiver gain and nonlinearity, and the performance of a detector defined against a particular signal class and false-alarm criterion. An operator who treats the smoothness of the plotted spectrum as a direct measurement of sensitivity may therefore confuse two different properties: the variance of a displayed estimator and the receiver's ability to discover an unknown weak event.

An instructive example is the average of K independent power-spectrum estimates under a stationary-noise model. The variance of their arithmetic mean decreases as K grows, and the typical visible fluctuation becomes smaller. But a burst that appears in only one of those estimates contributes its excess power divided by K to the mean. If the averaging interval grows from ten to one hundred quiet-dominated frames while the burst duration stays fixed, its contribution to the displayed average is further reduced. A detector that integrates a known persistent tone over a longer interval may improve its ability to measure that tone. The same procedure can impair a detector whose task is to find one short event at an unknown time. The

Copyright 2026, James M. Atkinson

difference is a consequence of the measurement objective and signal occupancy, not an inconsistency in mathematics.

The physical noise model must also be made explicit. Thermal noise generated in a resistor or electronic input has a spectral density related to temperature and resistance under stated assumptions, and its contribution to the measured power depends on the admitted bandwidth. Receiver noise can also include shot noise, flicker noise, oscillator phase-noise effects, interference and gain-dependent distortions. Some components may be correlated in time or across channels. Averaging repeated numerical values does not necessarily confer the usual independent-sample variance reduction upon correlated noise. Nor can it undo an analogue overload that created spurious products in every frame. The laboratory should challenge the entire input chain, not just the arithmetic averaging routine, before advertising an improved measurement limit.

Consider a spectrum analyser with video filtering after detection. A smaller video bandwidth can produce a smoother displayed trace, improving the repeatability with which a persistent feature is visually read. This does not mean that the receiver's instantaneous physical noise voltage has become smaller. The detector and display may respond more slowly, and a brief event can be attenuated or broadened in time. The distinction between measurement resolution bandwidth and video bandwidth must be retained, together with the averaging domain. Mean power, mean logarithmic level and peak-hold are not equivalent. An instrument can offer several of these modes legitimately, but each requires the appropriate calibration and interpretation.

Copyright 2026, James M. Atkinson

The distinction becomes more consequential when an SDR survey is conducted in the vicinity of strong legitimate transmissions. A strong neighbouring signal can cause front-end compression or intermodulation, raising or altering the apparent noise floor. An averaging method may reduce the visual irregularity of the output without revealing that the amplifier has entered an invalid state. A weak external burst may be missed because the receiver no longer operates in its calibrated linear region. The output may still display a handsome steady baseline, precisely because smoothing conceals the transient response. Therefore the acquisition record should preserve input gain, attenuation, overload indicators and relevant calibration tests through the operating interval.

One should test the detector with both persistent and intermittent reference signals. For the persistent tone, compare measured amplitude and frequency uncertainty as the averaging length increases, while independently monitoring the input power and receiver state. For the intermittent emitter, randomise burst onset and duration, vary the number of quiet frames in the average, and measure event retention at a fixed false-alarm criterion. Repeat near strong interferers, under representative receiver gain states and at several temperatures. The results may demonstrate a legitimate advantage for long-term spectral-density estimation and a material disadvantage for rare-event discovery. A scientifically honest specification can report both without contradiction.

The retention strategy is as important as the estimator. If the receiver keeps only the averaged trace, later investigators may be unable to discover whether one large burst or many smaller events produced it. A companion event-sensitive channel can preserve peaks, individual segment decisions

Copyright 2026, James M. Atkinson

and short raw intervals around material candidates, while a separately labelled mean spectrum provides background context. But peak-hold and event-triggered storage must themselves be tested against noise extremes and selection bias. The archive should include the algorithm version, averaging interval, detector mode and physical measurement plane. A count of saved candidate alarms must be related to effective observation exposure, not to an assumed continuously observed hour.

I would therefore avoid the phrase improved sensitivity without specifying the measure of improvement. A lower variance of a background-power estimate is one legitimate outcome. A lower threshold for detecting a persistent calibrated sinusoid at fixed false-alarm rate may be another. Reliable discovery of sporadic weak emissions requires its own test population and timing model. The result of one cannot be used as a certificate for the others. A system's technical merits can be stated precisely and modestly, without denying the utility of averaging. I invite Dr Hamming to challenge the assumption that collecting many spectral frames necessarily supplies enough independent evidence to justify the advertised noise reduction.

Richard Wesley Hamming | Peer question 5 to William Ralph Bennett

Dr Bennett, you have explained that averaging can reduce the variability of a spectral estimate without changing the input noise itself. Suppose a receiver forms one hundred periodograms from a continuously sampled stream, but consecutive frames overlap by seventy-five percent and share a common oscillator whose phase noise changes slowly. Its software reports a reduction in noise-estimate uncertainty by a factor of ten, as though the one hundred estimates were

Copyright 2026, James M. Atkinson

independent. That calculation might be correct for one hundred independent samples of an ideal process, yet materially optimistic for correlated spectral frames. What measurement would establish the effective number of independent observations, and how should the laboratory distinguish noise correlation created by shared samples from correlation caused by common oscillator or interference mechanisms? Could a system still improve its estimate by averaging in spite of this dependence, and how should the benefit be stated without overclaiming a nominal square-root law?

William Ralph Bennett | Immediate answer to Richard Wesley Hamming

Thank you for that question. Dr Hamming, averaging can indeed improve an estimate in the presence of some dependence, but the improvement cannot be inferred from the raw frame count alone. The relevant quantity is the variance or uncertainty of the actual estimator under the process being measured. With correlated frames, the variance of their mean depends upon covariance terms as well as individual variances. Under a stationary sequence model, one may express the variance of the mean through a sum of lag-dependent covariances. That expression reduces to the familiar inverse-K form only when the pertinent covariances vanish. A laboratory should therefore characterise the correlation of its frame estimates under representative conditions, rather than report the square-root of the displayed number of FFT computations as a universal gain.

Shared samples create one source of correlation that follows from the overlap and window schedule. Common oscillator noise or

Copyright 2026, James M. Atkinson

environmental interference introduces others, potentially on timescales longer than one frame. The experimental design should vary overlap while holding the underlying acquisition duration fixed, and separately challenge oscillator reference conditions or interference levels where feasible. If the apparent uncertainty reduction changes materially with those conditions, the simplified independence model is not adequate. The report should state the empirical variance of the chosen estimator and the conditions under which it was measured. It may still be useful to calculate an effective sample size, provided the method and its assumptions are disclosed.

The detector's operating characteristics should also be measured directly. Inject independently timed weak bursts and determine whether the averaging scheme retains them under the stated false-alarm criterion. A common oscillator can influence frequency estimation and coherent integration in ways not represented by a simple power average. A persistent signal and an intermittent signal can therefore respond differently to the same noise process. A single statistical gain figure cannot establish both detection capabilities. The confidence intervals for the challenge campaign must reflect independently generated physical events or appropriate clustering, not the number of correlated spectral cells.

The positive claim may be narrower and still valuable: the implemented average produced a measured reduction in the variance of a particular background-power estimate over a specified duration and receiver state. If the laboratory also demonstrates an improved detection probability for a defined persistent tone, it may state that

Copyright 2026, James M. Atkinson

separately. Where burst performance deteriorates, it must report the deterioration rather than conceal it behind a smooth trace. This distinction allows an instrument to be judged fairly on its genuine merits. I pass the token to Professor Bridgman for the further problem of whether averages expressed in different measurement domains refer to the same physical quantity.

Percy Williams Bridgman | Peer question 6 to William Ralph Bennett

Dr Bennett, the word average seems to carry several meanings in the receiver's interface. One mode averages linear electrical power, another averages decibel values, a third averages complex voltages, and a fourth retains the greatest peak from each interval. The display may label every one of these choices simply as trace averaging, even though their mathematical and physical properties differ. Suppose a forensic examiner compares results from two instruments without preserving their actual detector modes. Both show the same nominal amplitude in decibels, but one has been computed by taking the logarithm after power averaging while the other has averaged the logarithms. What should be demanded to establish that the two reported values address the same measurand? Would a common reference signal suffice, or must the calibration campaign vary the signal's distribution, duty cycle and noise statistics to expose the difference between the operations? In particular, could a stable calibration tone conceal the disagreement while a varying-power test reveals it, and should the forensic report include the exact mathematical averaging definition?

Copyright 2026, James M. Atkinson

William Ralph Bennett | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, the named quantity and the operation used to derive it must be specified before results can be meaningfully compared. Averaging watts and then converting to decibels produces, in general, a different result from averaging logarithmic levels first. Coherent complex averaging can cancel contributions whose phases differ, whereas power averaging does not cancel them for the same reason. Peak-hold is an extreme-value statistic rather than a mean. These operations are not errors merely because their results differ, but their differences are material when the report asserts that they estimate the same physical quantity. A single steady calibration tone may fail to reveal some of the discrepancy, because the relevant values remain nearly constant across the averaging interval.

I would test a set of independent references with varied temporal structure. Include a stable sinusoid, noise with a characterised distribution, an intermittent burst of known duty cycle, and a mixture with a strong neighbour. The purpose is to determine how each algorithm responds to the data population for which the claimed measurand is intended. Calibration must also follow the physical input path and identify the reference plane, impedance, bandwidth and gain state. A digital software comparison can establish that the arithmetic is implemented correctly; it cannot certify analogue response where the test signal bypasses the front end. The

Copyright 2026, James M. Atkinson

measurement result should be reported with its detector domain, averaging rule, time interval and uncertainty.

The distinction is particularly important for a rare event. A logarithmic average can be dominated differently by low-level intervals than a power average, while a maximum trace can be driven by a single noisy fluctuation. The latter requires an independently validated false-alarm rule before an isolated maximum is interpreted as an emission. A power average can faithfully describe mean energy while failing to retain event time. A coherent average can be powerful for a phase-locked signal but can attenuate a transmitter whose phase changes unpredictably. The investigator must choose the method for the scientific question and avoid retrospective selection of the most persuasive output.

If the two instruments cannot be related through a demonstrated model and a representative challenge set, their numerical agreement should be regarded as limited. The report may preserve each instrument's result as an observation from its own defined procedure, without combining them into a false common measurement. Conversely, a demonstrated relation between methods can support a correction with a stated uncertainty. The strength of the conclusion depends on the evidence for that relation, not on the similarity of the units printed on the screens. I return the floor respectfully to Professor Tukey for the problem of validating a receiver that offers both baseline smoothing and event-sensitive detection.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 5: Rare-event validation and the danger of selecting favourable averages

Dr. Atkinson, a collection of averaged spectral displays is a useful starting point for inquiry, not its conclusion. We ought to examine which questions those displays answer well, which questions they answer badly and which questions they cannot answer because the underlying data were discarded. The choice between mean, median, maximum and coherent averaging should follow the intended measurand and the admitted signal class. It is misleading to call one method universally best when it improves background-power precision but suppresses the very rare events the investigator is commissioned to discover. The legitimate use of several methods requires a declared selection policy and a validation experiment that tests the full procedure, not merely each method in isolation.

The first part of the campaign should be exploratory and unashamedly so. Use simulations and independent reference injections to discover how the detector behaves under persistent tones, single short bursts, repeated packets, changing interference and receiver gain transitions. Compare the raw records with the average and event-sensitive outputs. Explore where a median suppresses an unusual high-power excursion, where a mean dilutes a one-frame burst and where a maximum triggers on pure noise. Such exploration helps identify possible failure modes and choose a candidate procedure. It should be documented, but its selected favourable outcomes are not an unbiased estimate of the final procedure's field performance. A fresh validation population is needed once the method is chosen.

The second part should employ withheld challenge trials representing the claimed operating envelope. Randomise event onset relative to the FFT

Copyright 2026, James M. Atkinson

windows, vary signal duration, duty cycle, amplitude and modulation, and place strong neighbouring emissions at selected offsets. Use independently known sources to distinguish true events from receiver-generated artefacts. Preserve all valid and invalid outcomes, together with the software configuration, reference plane, clock condition and detector state. If the method is adaptive, the adaptation and its training history are part of the implemented detector. A confidence statement about a frozen mean estimator should not be transferred to a more complicated algorithm that chooses between mean and maximum according to its own recent history.

One must define what constitutes an independent trial. A single physical burst may influence several overlapping FFT frames, and the same interference event may contaminate many bins. Counting those correlated numerical results as separate confirmations leads to overconfident uncertainty estimates. A trial should correspond to an independently generated physical event or another justified sampling unit. Event clustering should be predeclared and evaluated under different burst durations, since an overly generous clustering window may merge separate transmissions while a narrow one may split one event into several apparent alarms. The selected unit determines the meaning of a detection rate, and the report should not alter it silently after observing the outcomes.

A further question concerns multiple comparisons. A detector may examine a large number of frequency-time cells and choose the most conspicuous excursions. Even if a per-cell threshold has a small false-alarm rate, an entire survey can produce some false alarms merely through the number of tests. Dependence among cells makes a simple independence calculation only an illustration, so the full implemented decision rule should

Copyright 2026, James M. Atkinson

be challenged using noise-only and interference-only populations. The laboratory should distinguish the probability of an alarm given no qualifying signal from the probability that a particular alarm is caused by a covert emitter. The latter requires source prevalence and alternative explanations which are not supplied by the detector's false-alarm specification alone.

For negative evidence, the challenge must include exposure. A scan lasting an hour may observe a given channel for only a fraction of that time. An alarm-free average may cover only the intervals that were actually sampled, and a rare burst may have occurred elsewhere. A claim that no hidden transmitter operated requires evidence about the transmitter class's possible timing, the receiver's dwell pattern and the probability of detection during admitted exposure. If those conditions are unknown, an appropriate conclusion may be only that no qualifying alarm was retained. Such a statement can be operationally useful but must not be inflated into a universal absence finding.

The retained evidence should also support review of competing causes. An anomalous spectral excursion may be genuine transmission, a power-line event, automatic-gain recovery, local oscillator behaviour or numerical processing. A mean may hide the transient; a maximum may reveal it without identifying the cause. Independent receiver substitution, controlled input attenuation, retuning and source injection can provide information when they produce different predictions for the alternatives. The report should preserve the outcomes of both confirming and disconfirming trials. A smooth display and a persuasive narrative do not eliminate the need for a reproducible test of causation.

Copyright 2026, James M. Atkinson

The final product should identify the measurement purpose and the statistical operations in a compact, inspectable form. Report background estimates separately from event detections. Specify average type and duration, window overlap, detector thresholds, event-clustering policy, reference calibration, data retention and uncertainty. Include a map of periods in which observation was invalid or impossible. Preserve raw sample intervals around material candidates wherever feasible. This is not a demand for universal storage of every bit. It is the requirement that evidential claims remain bounded by the information the instrument actually retained. I invite Sir Ronald Fisher to challenge how an investigator can estimate a low false-negative probability when the signal of interest is rare and the receiver may select the most favourable averaging rule after inspecting the data.

Sir Ronald Aylmer Fisher | Peer question 7 to John Wilder Tukey

Professor Tukey, suppose a laboratory evaluates ten averaging rules using a small collection of twenty independently injected bursts, selects the rule which detected the most bursts, and then reports that the selected detector has near-perfect sensitivity. That procedure uses the same data for selection and assessment, so its reported performance may be optimistic even when the individual calculations are correct. Would you require another blind test population, and how should the confidence statement account for the repeated search among methods? I am also concerned that each injected burst may appear in several overlapping FFT frames, creating an illusion of a much larger sample size. What would constitute a legitimate independent observation, how should false positives be counted in a wideband receiver examining thousands

Copyright 2026, James M. Atkinson

of spectral cells, and how ought the laboratory communicate the uncertainty remaining when only a few rare events have been deliberately tested? Would the numerical confidence interval have the same meaning if the selected algorithm had instead been fixed before the twenty trials began, and what limitation follows from that distinction?

John Wilder Tukey | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, the selected method should ordinarily be tested against a fresh withheld population if the earlier bursts were used to choose among the candidate rules. The development outcomes remain valuable as evidence of why the method was chosen, but they do not provide an independent estimate of its performance after selection. If a design intends to use all observations in one integrated inferential procedure, its error control must explicitly account for the selection. Without such an adjustment, the smallest apparent error rate among many tested choices is an optimistic description of the final detector. A competent report should distinguish the exploratory selection process from validation and preserve all unsuccessful trials rather than presenting only the best result.

The independent trial unit should be a defined physical event or justified observation interval, not each numerical frame generated from shared samples. If one injected packet triggers five overlapping FFT frames, it generally contributes one trial to the packet-detection estimate, while the detector's event-clustering rule determines whether the output is recorded as one alarm or several. That clustering rule itself should be tested because it can merge

Copyright 2026, James M. Atkinson

neighbouring events or split a long one. For false-alarm evaluation, the relevant rate may be alarms per independently exposed interval or per unit effective observation time, depending on the task. The result should preserve the actual scan schedule and invalid intervals so that an apparent decrease in alarms cannot be caused simply by reduced exposure.

A confidence bound derived from only a few independent events will be broad. The laboratory should not represent a small favourable sample as proof of near-certain detection across all frequencies, amplitudes and burst types. A predeclared acceptance rule should specify the minimum performance, the confidence required and the relevant operating envelope. If the programme covers several distinct conditions, its claim about minimum performance must account for joint coverage or specify a defensible limiting condition. Where the data cannot establish the proposed bound, the outcome is indeterminate, not proof of failure and not certification of success. Additional challenge trials or a narrower claim may be warranted.

Finally, the probability that a particular field alarm represents a covert transmitter is not equal to the detector's sensitivity or its false-positive rate. Attribution depends on the prevalence of physical sources, competing artefacts and the discriminatory value of independent interventions. A receiver can be well validated for detecting a class of injected signals while one field indication remains ambiguous. Conversely, a low average spectral level does not establish the absence of short transmissions when the retention rule can hide them. The honest report should preserve these distinct

Copyright 2026, James M. Atkinson

propositions and the evidence supporting each. I return the token to Dr. Atkinson for the final synthesis of what spectral averaging can and cannot establish about intermittent electromagnetic events.

Ten worked applications: spectral averages, event retention and statistical uncertainty

Maurice Stevenson Bartlett, Cross-Peer Question to Norbert Wiener: Professor Wiener, does averaging a hundred successive spectra imply that a single short emission will remain visible after the noise floor settles?

Norbert Wiener, Cross-Peer Answer to Maurice Stevenson Bartlett: Professor Bartlett, only under conditions favourable to that statistic. Arithmetic averaging of power spectra can dilute a one-frame burst by approximately the number of contributing frames when it does not recur, while a peak-hold detector may preserve visibility at the expense of a different false-alarm structure. The outcome depends on whether spectra, complex amplitudes or logarithmic display values are averaged and on their window overlap and normalisation. Challenge the processor with pulses of known duration and phase relative to frame boundaries, and compare the raw sequence with averaged products. A smoother display is not evidence that the environment was uniformly quiet. Store event-preserving excerpts or validated trigger records alongside the averaged survey trend. I pass the token to Dr Shannon for what the mean discards.

Norbert Wiener, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, if only the average spectrum was retained, what physical claim about intermittency can no longer be verified?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Answer to Norbert Wiener: Professor Wiener, many distinct temporal histories can have the same average power spectrum. A continuous low-level source and rare stronger bursts may contribute similar averages after appropriate scaling, yet imply very different surveillance risks. Once only the mean remains, individual arrival times, durations and sequencing may be irretrievable. A later investigator can analyse the average as a specified statistical product, but cannot treat it as a record of every event. If the application requires proof of absence during short intervals, retain time-resolved spectra or raw I/Q at adequate cadence, and document scanner dwell and processing dead time. Describe unobserved intervals explicitly instead of extrapolating the averaged trace to them. I yield to Dr Bennett on noise-model dependence.

Claude Elwood Shannon, Cross-Peer Question to William Ralph Bennett: Dr Bennett, a spectral average reduces random-looking fluctuations. Why might that improvement exaggerate confidence when quantisation or receiver-generated interference is correlated?

William Ralph Bennett, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the familiar reduction in standard error with the square root of the number of averages assumes effective independence and an appropriate distribution. Reused input samples, overlapping windows, common clock spurs and gain-state correlations reduce the effective independent information. A deterministic artefact may remain as a stable line regardless of the number of averages. Measure covariance between frames and repeat the acquisition with a terminated input, independent clock and alternative gain setting. Report the processing bandwidth and both spectral-density and integrated-power measures; do not conflate them.

Copyright 2026, James M. Atkinson

If a short burst was missed by the averaging scheme, that is a detection-system limitation, not improved converter noise performance. I pass the token to Professor Tukey for the selection and reporting rule.

William Ralph Bennett, Cross-Peer Question to John Wilder Tukey: Professor Tukey, how should the analyst compare average, median and maximum spectra without retrospectively selecting whichever makes one suspicious line strongest?

John Wilder Tukey, Cross-Peer Answer to William Ralph Bennett: Dr Bennett, specify in advance the operational objective: background power estimation, robust rejection of outliers or interception of rare events. Those estimators answer different questions. Compare them in a blinded set containing both noise-only intervals and known injected short signals; measure error, detection probability and false alarms per time and frequency exposure. A median can suppress intermittent events, while a maximum tends to rise with the number of opportunities searched. The mean may provide a reliable stationary-background estimate without capturing every transient. Preserve or at least account for the original frame-level records and disclose all tested statistics. Reporting only the winning estimator would invalidate a single-test significance claim. I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator concluding synthesis

Distinguished colleagues, we have distinguished the stability of a spectral estimate from the detection of a short-lived electromagnetic event. Averaging is a legitimate and often powerful operation when its purpose is stated. Mean power estimates can characterise an admitted background process; robust statistics can reduce the effect of unusual observations upon a baseline; coherent integration can improve estimation of a suitable

Copyright 2026, James M. Atkinson

phase-locked waveform; and display smoothing can make persistent features easier to inspect. None of those achievements, without further evidence, establishes the receiver's probability of detecting an unpredictable brief transmission. A smooth waterfall may be a good background display and an insufficient record of the events that occurred within its averaging interval.

Professor Bartlett has emphasised that the mean periodogram and a rare-event detector answer different questions. Professor Wiener has shown how recursive averages and adaptive thresholds can make the displayed result depend on preceding observations, sometimes extending an event's apparent duration or concealing an event's peak. Dr Shannon has explained why an accurate average is not an invertible account of the individual frames which created it. Dr Bennett has separated reduced estimator variance from changes in the receiver's physical input noise and sensitivity. Professor Tukey has required independent tests, predeclared event units and transparent reporting of false alarms, missed detections and selective retention. The seven peer exchanges have challenged the stationarity, independence and inferential assumptions beneath an apparently simple average.

The ten worked applications provide quantitative discipline. One large burst among ninety-nine quiet frames produced a modest power mean, and the corresponding median omitted the exceptional level entirely. A recursive average attenuated the burst's first contribution and retained a decaying memory after the event ended. Averaging power in linear units produced a different result from averaging decibels. The familiar variance reduction from independent measurements was much weaker under a stipulated

Copyright 2026, James M. Atkinson

positive-correlation model. A small nominal per-cell false-alarm probability became less reassuring across many comparisons, and intermittent scan exposure limited unconditional detection despite strong conditional performance. Coherent voltage averaging cancelled opposed phases even though the mean power remained nonzero. Thirty successful independent tests did not support an implausibly narrow high-confidence performance guarantee. Every calculation is a stipulated example, not an instrument certificate.

A defensive technical surveillance countermeasures report should identify the averaging domain, window, interval, overlap, input reference plane, sample and frequency calibration, threshold history and event-retention rule. It should preserve per-event evidence and raw intervals where practical, separately from any long-term background estimate. A detector claiming to discover sporadic transmissions should be validated with randomly timed sparse bursts and appropriate interference, rather than only with continuous carriers or conveniently centred reference signals. Its false-positive and false-negative characteristics must be calculated using meaningful independent trial units and exposure conditions. The same observations processed under several methods do not become independent corroboration merely because the software produces several plots.

The central evidential qualification concerns negative findings. An alarm-free average cannot establish universal absence if short emissions could have been diluted, cancelled, rejected by a robust estimator, omitted by triggered retention or missed during a scan gap. The investigator may still state that the particular validated procedure detected no qualifying event

Copyright 2026, James M. Atkinson

during its admitted observation intervals. A stronger assurance claim requires evidence about detection probability and source behaviour within the stated envelope. Where such evidence is insufficient, the result must remain bounded rather than amplified by rhetoric.

We therefore accept spectral averaging as an important instrument of measurement, not as a universal method of surveillance discovery. The correct procedure is to define the measurand, choose the statistic whose properties address it, preserve the evidence that alternative questions may require, and test the full process under conditions designed to reveal material failure. The following discussion will examine how overlapping analysis windows alter the count of genuinely independent detection opportunities, a question which has already appeared repeatedly in the present exchanges. I thank the contributors and formally conclude Question 043.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 043

Worked application 1: Dilution of one burst in a hundred-frame power mean

Let K=100 denote the number of equally weighted spectral-power frames, B=1 milliwatt the background level in each frame, and S=99 milliwatts the additional power of a burst present in only one frame. The active frame contains B+S=100 milliwatts, while the remaining ninety-nine contain B. Their arithmetic mean is [100+99(1)]/100=1.99 milliwatts. The excess above the background in the averaged result is 0.99 milliwatt, whereas the active frame's excess was 99 milliwatts. The excess has therefore been diluted by the factor 100. A low final mean does not establish that no high-power event occurred in the contributing interval; it describes a different measured quantity.

Worked application 2: Mean versus median of sparse spectral power

Take an ordered population of 100 spectral-power readings, ninety-nine equal to 1 arbitrary power unit and one equal to 100 units. The arithmetic mean is (99+100)/100=1.99 units. The median is 1 unit because both central order statistics come from the ninety-nine low readings. The median may therefore be useful for estimating the ordinary background while completely omitting the exceptional event from the displayed statistic. The result is not a defect in the median. It demonstrates that robustness against rare excursions and sensitivity to rare emissions are different objectives. The event-sensitive record must be preserved separately if that rare excursion is investigatively material.

Copyright 2026, James M. Atkinson

Worked application 3: Initial response of an exponential power average

Let the recursive update be $A_k=\alpha P_k+(1-\alpha)A_{(k-1)}$, with $\alpha=0.05$. Suppose the initial average equals a background B and the current frame contains additional power S=50 units. The immediate excess in the updated average is $\alpha S=2.5$ units, only five percent of the burst excess. If the following frames return to background, the excess after ten further updates is $2.5(0.95)^{10}$, approximately 1.4968 units. The apparent persistence of the raised average reflects the filter's memory rather than a verified continuation of transmission. Reconstructing the original burst from the average requires knowledge of the update rule, starting state and missing-data history.

Worked application 4: Power averaging versus decibel averaging

Consider two linear power measurements, $P_1=1$ milliwatt and $P_2=100$ milliwatts. Their arithmetic power mean is 50.5 milliwatts, or $10 \log10(50.5)=17.0329$ dBm. The individual readings are 0 dBm and 20 dBm; their arithmetic average in decibels is 10 dBm, corresponding to 10 milliwatts. Thus averaging the power values and then converting to decibels gives a markedly different result from averaging logarithmic values first. Neither operation is inherently improper, but the word average does not identify which quantity was measured. The detector mode and averaging domain must accompany any physical power claim.

Worked application 5: Variance reduction under independent frames

Suppose K=20 independent, identically distributed spectral estimates have common variance σ^2 under a valid stationary model. The

Copyright 2026, James M. Atkinson

variance of their arithmetic mean is sigma^2/K and its standard deviation is sigma/sqrt(K)=0.223607 sigma, about 22.36 percent of the standard deviation of one estimate. This is the familiar variance-reduction benefit of averaging independent observations. It does not apply without qualification to overlapping FFT frames with shared samples or to a time-varying noise environment. The actual covariance structure determines whether the reduction is smaller or larger than the simple independence model predicts.

Worked application 6: Effective sample size under positive correlation

Assume one hundred spectral estimates have equal variance sigma^2 and the same pairwise correlation rho=0.2, a deliberately simplified equicorrelation model. The variance of their mean is sigma^2[1+(K-1)rho]/K, giving sigma^2(1+99(0.2))/100=0.208 sigma^2. An equivalent independent-sample count defined by K_eff=sigma^2/Var(mean) is approximately 4.8077, not 100. Such broad positive correlation can arise in a different form from common noise or slowly varying state, although real FFT-frame covariance need not be equicorrelated. This example shows why the actual dependence must be characterised before claiming a nominal tenfold reduction in the standard deviation of a spectral estimate.

Worked application 7: A family-wise false-alarm illustration

Let K=2,000 be the number of hypothetical independent noise-only tests and let p=0.0001 be the fixed false-alarm probability of each test. Under the independence model, the probability of at least one false alarm is 1-(1-p)^K=1-(0.9999)^2000, approximately 0.181277, or 18.13

Copyright 2026, James M. Atkinson

percent. Overlapping spectrogram cells and several alternative averages are not normally independent, so this calculation is not a measured alarm probability for a real SDR. It demonstrates that an apparently reassuring single-cell threshold must not be substituted for validation of the complete multi-cell decision rule.

Worked application 8: Observation duty factor and unconditional detection

Suppose the receiver admits a particular band for fifty milliseconds in each five-hundred-millisecond scanning cycle. The dwell fraction is D=0.05/0.5=0.1. Assume an isolated event is so short that boundary effects are negligible and its onset is uniformly distributed relative to scan phase. If a fully exposed burst is recognised with probability 0.9, the unconditional probability under the simplified model is approximately 0.1 times 0.9=0.09, or nine percent. Averaging cannot recover an event that occurred entirely outside the admitted dwell. A negative finding requires consideration of the physical exposure schedule as well as the conditional detector behaviour.

Worked application 9: The distinction between coherent and incoherent averaging

Let two calibrated complex voltage samples have equal unit magnitude but opposing phase, represented by 1 and -1. Their coherent complex mean is (1+(-1))/2=0, whereas their mean squared magnitudes equal (|1|^2+|-1|^2)/2=1. Thus the complex mean can cancel even when each contributing frame contains unit power. A phase-locked signal may benefit from coherent integration, but a signal whose phase reverses or

Copyright 2026, James M. Atkinson

changes unpredictably may not. The chosen averaging domain must match the admitted waveform model. A zero complex average is not proof that every underlying frame contained zero energy.

Worked application 10: Zero-miss sample size and a one-sided lower performance bound

Suppose a detector is challenged by n=30 independent physical events drawn from one specified signal class and detects all thirty. Under a simple binomial model with unknown true detection probability p, a one-sided 95-percent exact lower confidence limit after thirty successes is p_lower=(0.05)^(1/30), approximately 0.904966. Thus even a perfect observed record of thirty successes does not justify a 95-percent confidence claim that the detection probability exceeds 99 percent. This calculation concerns one predeclared homogeneous test population. It does not provide simultaneous assurance for many frequencies, burst durations or interference environments, and overlapping frames do not create extra independent successes.

QUESTION 044

Copyright 2026, James M. Atkinson

How should overlapping windows affect counts of independent detection opportunities?

Source: V011_Roundtable_Question_044_CP044_Dr_Atkinson(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 044. Complete Expert Roundtable Discussion

Original constructed educational dialogue. Historical participants are used as intellectual personae, not as literal speakers in any historical meeting. This discussion consists of original educational dialogue, not historical quotation.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, the preceding discussion demonstrated that spectral averaging can provide a reliable estimate of a selected background property while concealing the duration, timing or even existence of a rare event. It also demonstrated that overlapping FFT frames often reuse the same samples. Our present inquiry asks the further question which follows naturally: when a digital receiver reports several alarms in overlapping windows, how many independent detection opportunities have actually occurred? An instrument may calculate thousands of spectral frames per second, yet those frames do not automatically represent thousands of independent observations of the physical environment. A burst crossing several analysis windows may be one transmission, while one slowly varying interference process may produce a family of correlated spectral excursions. The meaning of an alarm count depends on the acquisition design and event definition rather than the number of numerical arrays produced by the processor.

Copyright 2026, James M. Atkinson

We can state the counting problem mathematically. Let N denote the number of samples in one FFT frame, let H be the hop length between successive frame starts, and let F_s be the sampling rate in samples per second. The nominal frame duration is $T=N/F_s$ and the hop duration is $h=H/F_s$. The overlap fraction is $(N-H)/N$ when H is no greater than N. If N=4,096 samples and H=1,024, consecutive frames overlap by 75 percent. Their starts are separated by one-quarter of a frame duration. The software therefore generates four frame starts in a period the length of one frame, but the resulting estimates share substantial underlying evidence. Whether their detection decisions are correlated also depends upon window coefficients, the signal, the noise process and the decision statistic. None of these dependencies can be inferred from the frame count alone.

One must distinguish at least four objects: an FFT calculation, a detector threshold crossing, a retained alarm record, and a physical emission. The number of calculations can exceed the number of threshold crossings; one crossing may be suppressed by a retention rule; and several retained alarms may be generated by one physical event. Conversely, one frame may contain several independent emissions whose spectral overlap makes them appear as a single peak. The conversion from numerical observations to physical-event counts is therefore an inference requiring definitions, algorithms, uncertainty and empirical challenge tests. A database which stores only an alarm count but not the event-segmentation policy can become dangerously misleading when a later examiner attempts to reconstruct transmitter activity.

Statistical confidence requires equal care. The common square-root reduction in error from independent averaging does not automatically apply

Copyright 2026, James M. Atkinson

to overlapping frames. The variance of a mean from dependent observations includes covariances among those observations. Likewise, the probability of at least one false alarm in a collection of threshold tests cannot be computed by a simple independence formula without examining whether the tests are dependent and how the software combines them. A very large number of densely overlapping windows can give the appearance of abundant corroboration while reusing only a limited interval of measured radio-frequency input. We require methods that make this dependence explicit and testable.

The panel will examine these boundaries from several perspectives. Professor Bartlett will consider the covariance of spectral estimates. Dr Shewhart will ask how the detector distinguishes natural process fluctuations from new physical events. Professor Neyman will examine uncertainty and simultaneous claims across many correlated tests. Professor Wiener will assess history-dependent clustering and feedback. Professor Tukey will develop a practical validation campaign for a wideband defensive survey. Seven colleagues will challenge those responses with questions about sample reuse, false alarms, event identity, timing uncertainty and evidence preservation. We shall distinguish overlapping mathematical observations from truly independent acquisition paths and from the far stronger claim that a particular external source has been independently corroborated.

We will not reject overlap as an engineering method. It can improve time coverage, mitigate window-edge losses and supply useful estimates for an evolving signal. The task is to describe what it achieves and what it does not. A receiver should be judged on demonstrated detection and attribution

Copyright 2026, James M. Atkinson

performance, not on the visual abundance of its waterfall frames. I invite Professor Bartlett to address the covariance structure of overlapping spectral estimates, and to explain why the number of frame starts is an inadequate measure of the independent information available to an investigator.

Copyright 2026, James M. Atkinson

Maurice Stevenson Bartlett | Principal response 1: Covariance and the effective number of observations

Dr. Atkinson, the central distinction is between producing numerous statistics and acquiring numerous independent observations. A sequence of windowed Fourier estimates can be generated from a finite record with almost arbitrarily dense overlap. If the hop is one sample, consecutive windows of thousands of samples differ only by a small portion of their inputs. Their outputs can be highly dependent under many signal and noise models. Even when the sample-level noise is independent, the overlap and subsequent nonlinear power calculation can introduce dependence among spectral estimates. One must therefore examine the covariance of the actual estimator rather than divide uncertainty by the square root of the number of numerical frames on the screen.

For a sequence of K estimators with common variance sigma squared and lag-dependent correlations rho_h under a stationary approximation, the variance of their arithmetic mean is sigma squared divided by K multiplied by a factor which incorporates the weighted sum of the lag correlations. In one conventional form the factor is 1+2 sum over h from one to K minus one of (1-h/K)rho_h. If all relevant lag correlations vanish, the independent-sample result emerges. If positive correlation persists across many lags, the effective information in the K results can be much smaller than their nominal count. This formula is a model-dependent calculation and should be verified against actual receiver and noise conditions. It is not evidence that every overlapping spectrogram has one universal effective sample size.

The window coefficients matter. A rectangular window, a Hann taper and a concentration-optimised sequence assign different weights to shared

Copyright 2026, James M. Atkinson

samples. Their output statistics can consequently exhibit different covariance for the same hop length. A frequency bin occupied by a persistent strong carrier may exhibit a different dependence structure from a noise-only bin. When the receiver's analogue gain or noise floor changes with time, the stationary approximation may fail, and a single effective sample-size calculation for the entire session may be misleading. The laboratory must first identify a reasonably homogeneous operating interval or adopt and test a model which describes the changes. A numerical average can be stable even though the process generating the data has changed.

One should be cautious when translating this problem into the count of physical events. A single transmission may occupy several consecutive windows. If the software records an alarm each time a frame crosses threshold, a long packet can be overcounted. If it clusters alarms using a fixed time gap, two separate packets close together may be merged. The appropriate cluster duration depends upon the admitted source waveform, receiver timing accuracy and detector response. A clustering rule therefore requires validation against known bursts whose separation and modulation have been varied independently. It cannot be treated as merely an administrative database setting.

In an unattended defensive surveillance system, several numerical stages may affect the count: digital channelisation, FFT-window overlap, spectral smoothing, threshold adaptation, candidate association and retention. Each stage can introduce correlations or losses. The investigator should preserve the exact processing order, time-stamped configuration history and source identifiers connecting each alarm with its originating raw

Copyright 2026, James M. Atkinson

interval. Where storage constraints prevent retention of the complete stream, the system should preserve independently selected audit intervals and a truthful record of unobserved or invalid periods. A later examiner can then distinguish a physical negative observation from an absence created by a selection policy.

For a practical acceptance campaign, generate isolated bursts at randomly selected times and determine how many frame-level threshold crossings each creates. Repeat with pairs of bursts whose separation approaches the clustering threshold, and with long transmissions whose tails span many windows. Include noise-only intervals and strong legitimate interferers to measure correlated false alarms. Estimate detection probability per independently injected physical event, not per triggered FFT frame, and report how that probability changes with the event's arrival position and duration. Where the claimed result is an average spectral-density estimate, calculate the estimator's uncertainty under its measured dependence. Where the result is an event count, examine missed, split and merged events separately.

The scientific conclusion should reflect the quantity actually tested. A receiver may process ten thousand overlapping FFT frames and thereby improve its temporal coverage compared with a non-overlapping design. It does not follow that it acquired ten thousand independent samples of the event population. A dense waterfall may assist discovery of a burst that otherwise falls near a window edge. It can also produce numerous correlated alarms from one internal artefact. For source attribution, independent receiver paths, controlled input interventions or other physical evidence may still be required. Statistical dependence and physical

Copyright 2026, James M. Atkinson

causation are distinct questions, but neither can be ignored when the analyst converts many numerical detections into one confident statement about an external emitter.

I would preserve, therefore, the frame geometry, the detector's event unit, the actual observation exposure and the covariance evidence supporting any uncertainty calculation. A short concise report can contain a clear performance statement, while its supporting audit file retains sufficient details for replication. Where the covariance cannot be characterised, one should not falsely attach the confidence of independent trials to correlated data. The honest conclusion may be a bounded estimate with an explicit dependence qualification. That is the appropriate use of mathematical statistics in a technical surveillance countermeasures doctrine. I invite Dr Hamming to ask whether this level of dependence analysis can be implemented practically in a wideband receiver without overwhelming its storage and processing budget.

Richard Wesley Hamming | Peer question 1 to Maurice Stevenson Bartlett

Professor Bartlett, the theoretical covariance problem is well stated, but I wish to examine practical implementation. A monitoring receiver may process many millions of samples per second across several digital channels, each with overlapping FFT windows, adaptive thresholds and candidate-association algorithms. It is not always feasible to retain the entire raw stream or calculate a complete covariance matrix for every frequency and receiver state. What compact statistics and validation records would you regard as sufficient to support a bounded claim about the independence of detection opportunities? Could the laboratory

Copyright 2026, James M. Atkinson

preserve representative noise-only intervals, the hop and window parameters, a correlation summary and a sample of raw candidate intervals? How should it assess the danger that the selected audit intervals fail to represent the same interference environment as the material detections? Above all, where should an investigator place the boundary between a scientifically defensible reduced record and an archive whose apparent precision cannot survive independent forensic examination?

Maurice Stevenson Bartlett | Immediate answer to Richard Wesley Hamming

Dr Hamming, the required archive should be proportionate to the claim, but proportionality is not a licence to omit the variables upon which the claim depends. If the purpose is to establish only that the detector produced certain alarms under a documented configuration, a compact event log and a versioned record of the processing chain may be adequate. If the claim concerns the rate of independent physical emissions, the laboratory must also demonstrate the performance of its event-clustering and exposure rules. If the claim involves a narrow uncertainty bound based on many apparently repeated observations, the dependence of those observations becomes a material part of the evidence. The operator should decide which of these propositions is intended before selecting the retention policy.

A practical system could preserve the window and hop definitions, timebase and gain-state logs, alarm-to-frame associations, clustering decisions, and a statistically designed set of untriggered audit

Copyright 2026, James M. Atkinson

intervals. The audit intervals should be selected independently of the detector's own alarm decisions where feasible, rather than chosen only from quiet-looking portions of the survey. This reduces the risk of evaluating performance exclusively on examples selected for their apparent success. Reference challenges with known injected events should be performed across representative receiver states to measure split, merged and missed events. They can provide a bounded operating characteristic without requiring a covariance matrix for every instant in the historical survey.

For an estimator's uncertainty, the laboratory may compute empirical correlation functions, use appropriate block-based resampling where its assumptions are met, or compare the uncertainty of estimates from separately acquired non-overlapping intervals. Each method has limitations and should be tested against the process being characterised. A brief noise-only laboratory test cannot automatically represent a field environment with strong intermittent interference. The report should state the admitted operating envelope and any evidence of nonstationarity. Where the source population changes abruptly, a single stationary covariance estimate across the whole session may be inappropriate.

I would also distinguish storage efficiency from evidential sufficiency. A derivative spectral file may be much smaller than a raw stream yet retain enough information to reproduce the specific detector result, provided its processing version and necessary configuration are preserved. It may not permit reanalysis of an alternative event definition or source hypothesis. The laboratory

Copyright 2026, James M. Atkinson

should state those limitations explicitly. Retaining raw candidate intervals and independent audit intervals may provide a workable compromise, but the unrecorded time cannot be treated as observed merely because the software issued no alarms. That distinction is as important as the arithmetic of the covariance estimate.

The principled boundary is reached when a proposed conclusion depends materially on information neither retained nor independently characterised. At that point the report should narrow the conclusion or acknowledge indeterminacy. A modest event count with a validated clustering rule can be useful. An ostensible count of thousands of independent transmitters derived from overlapping FFT detections without source identification would be misleading. Statistical discipline is compatible with efficient engineering when the measurand and acceptance criteria are defined in advance. I return the floor to Dr Shewhart for an examination of the way operating-process changes can imitate separate events even when the underlying electromagnetic source remains the same.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal response 2: Process stability, event segmentation and the evidential definition of an alarm

Dr. Atkinson, I approach this problem through the distinction between a process measurement and a decision made about a process. In statistical process control a succession of plotted points may help reveal a change, but the number of plotted points is not the number of distinct causes which have acted upon the process. An investigator looking at overlapped spectral estimates confronts a related difficulty. Each frame is a calculation using a window of observations; its threshold crossing is a decision under a rule; the underlying electromagnetic episode is a physical occurrence. Counting those three entities as though they were interchangeable creates an impressive-looking statistical report whose units have not been defined. The first task is therefore to specify whether the claimed measurand is a frame-level detection rate, a rate of discrete emission episodes, an estimate of occupied time, or a count of distinct transmitters. These are not synonyms, and their appropriate validation experiments differ. [S1]

Consider a persistent carrier which sits just below a detection threshold while its apparent power varies because of fading, antenna motion and the receiver's changing gain. A collection of overlapping spectral windows may produce a series of threshold crossings, then an interval without crossings, then more crossings. Software that treats every rising crossing as a new transmission may manufacture a plurality of events from one continuing source. A different clustering rule can merge two genuine short bursts into one episode. Neither error is corrected by taking a prettier average of the power spectrum. Both are failures to relate the statistical decision to the physical event one intends to count. Accordingly I would define a candidate

Copyright 2026, James M. Atkinson

event by a set of operational conditions: frequency tolerance, temporal adjacency, admissible modulation changes, receiver-state continuity, and the rules governing when an event begins and ends. These rules must be declared before viewing the strongest case examples.

An overlapping-window detector is especially vulnerable when adaptive thresholds respond to the very disturbances under examination. If a burst causes a short increase in the estimated noise floor, subsequent frames can fall below a raised threshold despite continued physical emission. When the disturbance ends, the threshold may relax and produce a fresh apparent alarm. The combination of adaptation and overlap can therefore split or conceal episodes in ways a fixed-threshold laboratory demonstration does not reproduce. Validation should observe the full temporal trajectory of the threshold, the input power and the alarm state. The resulting account must include the detector's memory, update constants, hysteresis and reset behaviour. A single entry saying 'alarm detected' cannot explain those causal transitions.

For a quantitative acceptance campaign I would construct a challenge population that includes stationary noise, drifting noise, strong innocent interferers, intermittent known signals and pairs of bursts with controlled separations. Randomise burst arrival relative to the FFT hop, and vary the timing independently of any operator intervention. Then calculate a confusion table in terms of the actual injected physical events: how many are correctly detected, omitted, split into several reports, or merged with a neighbour? An engineering laboratory may properly use hundreds of overlapping frames to produce a feature estimate, but it should evaluate the event-level performance against the number of deliberately generated

Copyright 2026, James M. Atkinson

events. An apparently excellent frame-level recall may coexist with poor episode segmentation, and an event-based metric can expose that distinction.

I would place the process in time as well as frequency. A receiver whose gain state changes halfway through a survey is not necessarily operating under a single statistical population. The distribution of its detection statistic may change with ambient temperature, ADC overload, automatic gain control, preselector insertion, oscillator retuning or an operator's intervention. Pooling all frames into one estimate of a stable false-alarm rate can hide those changes. A rational record would stratify performance by material receiver state and would mark invalid intervals. Where a stable process approximation is asserted, examine its residual evidence rather than treating stationarity as a convention supplied by software. Statistical control does not mean every small fluctuation is abnormal; it means the declared process can be evaluated against the behaviour it is supposed to exhibit.

There is also a danger of selecting thresholds retrospectively. An analyst may examine the saved waterfall, notice the desired burst, lower the threshold, then report the adjusted detector as having detected the event all along. That can be a useful exploratory procedure, but it is not independent validation of the threshold's prospective performance. The corrected procedure should be challenged on observations withheld from its construction, including negative controls. If several candidate detection rules are compared, the selection step belongs in the statistical account. It changes the meaning of a reported false-positive rate, particularly when the user regards many overlapping trials as opportunities for chance success.

Copyright 2026, James M. Atkinson

The practical report can remain concise without evading these distinctions. It should state the observation interval, frame length, hop length, taper, detector statistic, threshold rule, candidate-association policy, and the physical event definition. It should provide an event-based performance table or an explicit statement that such performance has not yet been established. A claimed transmitter count requires further source discrimination and cannot be inferred from a list of trigger records. If the investigator wishes to assert only that an indication recurred under specified receiver conditions, that narrower claim may be well supported. We must not dress up a record of dependent numerical decisions as if it were a record of independently confirmed external actors. I invite Professor Neyman to challenge how uncertainty should be represented when the event-clustering rule itself was chosen after examining the field evidence.

Jerzy Neyman | Peer question 2 to Walter Andrew Shewhart

Dr Shewhart, your event definition appears operationally rigorous, but it raises a design question which cannot be avoided by writing more careful software. Suppose an investigator selects among five clustering gaps after seeing the same set of field recordings, choosing the gap which gives the least embarrassing difference between receiver indications and the hypothesis of one intermittent transmitter. The selected gap may then appear stable on that same recording. Even if the FFT windows are described exactly, the event count is the product of a rule trained on the evidence. How would you separate exploratory selection from a procedure eligible for a confidence interval with its advertised coverage? Would you recommend an independent challenge population, a predeclared rule or a simultaneous account of all five

Copyright 2026, James M. Atkinson

alternatives? Further, if only triggered intervals were retained, what can be inferred about missed events in the unretained time? I ask because the difference between a confidence statement concerning one fixed algorithm and a statement concerning an algorithm chosen to make the data look favourable is not a nicety; it determines whether the numerical bound can be defended.

Walter Andrew Shewhart | Immediate answer to Jerzy Neyman

Professor Neyman, the selection you describe is itself part of the procedure under evaluation. If the investigator fixes a clustering gap using a development recording and then measures its performance on a genuinely separate and suitably representative challenge collection, the resulting validation statement can refer to that frozen rule and its stated conditions. If the same observations are used both to choose and to vindicate the rule, the nominal performance of the selected result is liable to optimism. One must then either account for selection, assess the range of conclusions across reasonable alternatives, or restrict the result to exploratory analysis without the stronger coverage claim. A report should not conceal the process by which the apparently decisive rule was obtained.

A good independent campaign would contain several physical event classes whose timings are controlled without reference to the detection output. The trial designer could assign isolated bursts, close-spaced pairs and continuous carriers with intermittent amplitude fading. The operator analysing the results should receive either a blinded challenge schedule or a protocol which does not permit trial-by-trial threshold tuning. The rule should be locked before

Copyright 2026, James M. Atkinson

the held-out population is processed. The acceptance result is then meaningful for the distribution of source types, amplitudes, clock states and interference conditions represented in that campaign. It does not automatically extend to every environment the receiver may encounter.

For a decision made after exploring five gaps, a sensitivity table is valuable even if an independent trial is unavailable. Report the event count obtained under all five gaps and identify cases that merge or split as the parameter changes. This cannot create the missing independent evidence, but it makes the dependence of the conclusion upon a modelling choice visible. The investigator may discover that the apparent number of transmissions is stable over a broad, physically justified region of parameter space. That would provide a more persuasive restricted claim than choosing a single gap whose attractive answer cannot be reproduced under modest perturbations. If the count changes radically, the correct conclusion is that event segmentation remains uncertain.

Triggered retention poses a different, severe restriction. The absence of retained samples cannot establish the absence of an event during a period the retention system did not preserve. A detector may have monitored the interval and produced no trigger, but the strength of that negative evidence depends on the detector's validated exposure and sensitivity in the particular operating state. A complete event schedule supplied in a laboratory challenge permits direct measurement of omissions. In historical field data, one may have no such external truth record. The report must distinguish

Copyright 2026, James M. Atkinson

prospective performance established by challenge tests from the count of events actually retained during the investigation, and it must disclose blind intervals, buffer losses and changes in threshold.

I would not deny the value of exploratory detection. Its purpose is often to find a plausible candidate, not immediately to assign a judicially defensible probability to a source hypothesis. The error occurs when a candidate chosen through extensive search is later represented as though it had been specified beforehand. The proper chain has distinct stages: discover the candidate, freeze the claim and method, challenge the method independently, and then report the result with its remaining conditions. In that chain, overlapping windows are an engineering choice; the statistically significant unit and the validation population are separate choices. A scientific report becomes stronger, not weaker, when it states precisely which of them has been established. I respectfully pass the token back to Professor Neyman for his own account of multiplicity and dependent trial opportunities.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal response 3: Confidence, multiple testing and conditional performance claims

Dr. Atkinson, the quantity of calculations produced by a receiver is not an adequate substitute for the sampling design required to interpret them. Suppose a monitoring programme makes K window-level decisions from one stretch of digitised input. The decisions may share input samples, common gain disturbances, a common noise-floor estimator and a common source waveform. The probability distribution of their joint outcomes therefore depends upon the dependence structure. A calculation which assumes independence without testing it can produce a compelling but unjustified false-alarm probability. The correct approach is to define the repeated experiment and the decision rule before assigning confidence language to the result.

For a fixed set of K tests, the probability of at least one false alarm is constrained by general probability inequalities even when the tests are dependent. If the individual false-alarm probability is p under a common null model, the union bound is at most Kp, capped at one. This is conservative and does not require independence, but its p must be relevant to the actual tests and environment. The familiar expression 1-(1-p)^K follows under independence and should not be quietly substituted for a dependence analysis. When a detector scans many bins, times, antenna states and candidate rules, the family of opportunities must be defined. The effective search may be wider than the visually reported set of alarms because unsuccessful comparisons were discarded from the report.

A second distinction concerns confidence in a detection probability. An investigator may inject n known physical emissions and observe that all are

Copyright 2026, James M. Atkinson

detected. That result does not establish perfect detection. Under independent Bernoulli event trials with a fixed success probability, a one-sided lower confidence bound can be calculated from the binomial distribution. But if nominally separate injections all occur during the same favourable gain state, or if the operator times them to coincide with detector windows, the independence and representativeness assumptions may fail. The count of injected physical events is more important than the count of FFT frames in which each event was visible. A protocol which duplicates one favourable event across twenty overlapping frames has not thereby performed twenty independent trials.

For estimation from dependent data, the variance of an arithmetic mean depends on all pairwise covariances. Under an appropriate stationary model, one may express that variance in terms of lag correlations. Yet this relationship is not a magic formula for converting every waterfall into an effective sample size. Different spectral bins, tapers, receiver states and signal classes can have different correlation patterns. An analytic expression calculated under stationary Gaussian noise may not remain valid during bursty interference, ADC overload or an adaptive threshold change. The investigator should test the model with relevant noise-only and source-present records; where the model is inadequate, empirical block-based methods or independent acquisitions may provide a more defensible uncertainty evaluation.

I would distinguish the purpose of a test from the interpretation of a particular alarm. A laboratory may establish an operating characteristic, such as the conditional probability of detecting a burst whose power, duration and arrival phase fall within a declared range. That does not give

Copyright 2026, James M. Atkinson

the posterior probability that any particular field alarm arose from an illicit emitter. The latter conclusion depends upon competing source rates, artefact mechanisms, environmental conditions, sensor architecture and additional evidence. A high reported sensitivity can coexist with a large proportion of false alarms when the underlying target events are exceptionally rare. Overlapping FFT frames make the confusion worse if the analyst treats correlated repetitions of one alarm as independent corroboration.

The experimental plan should include withheld challenge signals whose timing is deliberately varied relative to the FFT hop, together with noise-only controls that preserve realistic correlation and interference. Define the statistical endpoint beforehand: event-level detection, false alarm per observation hour, frequency-estimation error, or transmitter-attribution accuracy. Record how physical events are clustered from frame-level indications. If several detector designs or threshold rules are compared, hold out a final validation population rather than selecting the most flattering model and testing it again on the same data. Where the intended claim involves several operating conditions simultaneously, a family-wise coverage requirement may be more appropriate than reporting the best one-condition result.

A useful report should carry both an executive conclusion and enough detail for a challenger to test it. For example, it may state that a frozen receiver procedure detected a specified proportion of controlled bursts of a declared signal class over a defined temperature and interference envelope, with an interval calculated using clearly stated assumptions. The technical record would identify the number of independently injected events, the

Copyright 2026, James M. Atkinson

number missed, the hop and window parameters, the clustering rule, the exact threshold version and the confidence method. If some runs are invalid because of buffer loss or clock failure, the exclusion must be declared rather than quietly omitted. A bounded statement is not a concession to uncertainty; it is the appropriate consequence of scientific testing.

When the system lacks raw retention, the claims become narrower. A later examiner can inspect the archived event log and determine what the algorithm reported. The examiner cannot necessarily reconstruct alternative spectrograms, recover suppressed subthreshold bursts, or test a different clustering rule without the source samples. A software log containing hundreds of nearly identical frame detections is not a replacement for unrecorded physical evidence. Therefore the numerical confidence attached to the report must be evaluated at the level of preserved observations and validated model assumptions. We should avoid both extremes: demanding impossible universal knowledge and declaring certainty from dependent numerical abundance. I invite Professor Fisher to ask whether the inferential unit remains well defined when the same physical event appears in different detection channels with distinct frequency windows.

Sir Ronald Aylmer Fisher | Peer question 3 to Jerzy Neyman

Professor Neyman, the notion of one physical event is harder to apply when a wideband receiver divides an input into overlapping spectral channels whose outputs overlap in frequency as well as time. One burst may produce several peaks, perhaps at adjacent filter-band edges and at sidebands created by modulation. The analyst may use a clustering algorithm to combine these into one putative transmission, but the algorithm is itself a statistical classification rule. If all those outputs share

Copyright 2026, James M. Atkinson

the same analogue front end, how would you distinguish evidence that the signal belongs to one emitter from evidence merely that one receiver architecture repeats the same stimulus? I also ask whether the union bound you propose offers more than an intellectually safe but practically useless upper limit when the number of channels is enormous. What validation design would permit a meaningful family-wise statement while remaining computationally feasible and susceptible of independent verification by another laboratory?

Jerzy Neyman | Immediate answer to Sir Ronald Aylmer Fisher

Thank you for that question. Sir Ronald, one must distinguish the physical stimulus, the spectral representation and the source classification. A burst with modulation can legitimately occupy several adjacent output channels. Its appearance in those channels is not independent confirmation that several emitters exist, and it is not by itself independent corroboration of one emitter's identity. To test a clustering rule, use a challenge set containing physically known events deliberately placed near frequency boundaries, with separations, bandwidths and modulation structures selected to distinguish possible interpretations. Evaluate the rule at the physical-event level, counting both unjustified splits and unjustified mergers. A second sensor path or changed analogue preselection may then help test whether the inferred location in frequency and time follows a genuine stimulus rather than an internal image.

The union bound is a valid general protection against treating multiple tests as though they were one; it is not always the tightest available performance statement. If the tests are strongly dependent

Copyright 2026, James M. Atkinson

and their joint distribution is sufficiently characterised, a more informative calculation can be made under an explicit model. Alternatively, a whole-system empirical challenge can measure the number of false events emitted by the complete processing chain during representative noise-only observation hours. That approach avoids the need to derive an independence assumption for every FFT bin, though its validity still depends upon the representativeness of the trial conditions and the preservation of detector state. The unit of a whole-system false-alarm rate should be a validated candidate event, not merely a threshold-crossing frame.

For computational tractability, design a bounded experiment around the claims material to the intended investigation. A receiver advertised for intermittent emissions in particular bands should be challenged with representative bandwidths, duty factors, amplitudes, hop phases and interfering signal classes. A systematic design can identify sensitive combinations without exhausting every possible waveform. Hold back independent test cases to examine whether the final algorithm generalises. Document the randomisation, selection rules and invalid observations. Where extreme rare-event false-alarm rates are claimed, note that an ordinary finite test may not establish a sufficiently small rate without additional modelling assumptions. Precision beyond the trial's information should not be printed merely because a processor displays many decimal places.

If a single physical input produces ten correlated outputs, their useful content may be richer than one scalar output, because relative amplitude and spectral shape can assist classification. Yet the

Copyright 2026, James M. Atkinson

increased dimensionality does not multiply the number of independent causes. A well-designed report can exploit the multichannel pattern while retaining the distinction between information about one event and independent evidence about source identity. Calibration controls and sensor substitution are particularly valuable when the competing explanation is receiver-generated structure. The scientific objective is to make those alternative predictions different enough that an experiment can discriminate between them. I now pass the floor to Professor Wiener to consider history-dependent clustering and the feedback between acquisition policy and retained event counts.

David Slepian | Peer question 4 to Jerzy Neyman

Professor Neyman, the statistical unit becomes even less obvious when the filter itself is selected to improve concentration in time and frequency. A laboratory may measure the effective bandwidth of one taper, then implement a different taper under congested field conditions. It may average adjacent frequency bins or change the hop while monitoring remains active. Each choice alters the amount of sample reuse and can change correlation among spectral estimates. If a confidence limit is calculated for one specified window and hop, may the operator transfer that limit to another configuration merely because the total observation time and the nominal number of FFT calculations remain unchanged? I should also like you to examine the problem of edge arrivals. A brief emission centred upon one hop position can occupy most of a taper's effective support, while an equally strong emission near the edge may be represented in several frames with much lower peaks.

Copyright 2026, James M. Atkinson

How should a validation population sample these phase relationships so that a reported detection probability is not simply the performance of a favourable alignment?

Jerzy Neyman | Immediate answer to David Slepian

Thank you for that question. Professor Slepian, the confidence statement should be attached to an actual procedure and challenge population, not to a generic description such as FFT analysis. Altering a taper, hop or bin-combination rule changes the statistic and possibly its joint distribution. A result established for one configuration does not automatically carry over to another. A validated equivalence between configurations could support transfer, but equivalence is a substantive empirical or mathematical claim requiring evidence. The operator should preserve the active configuration for every material interval, including the coefficients of the taper when implementation details are relevant to the proposed conclusion.

For edge arrivals, a suitable design deliberately spans the full arrival phase relative to the hop. One may generate bursts at controlled offsets from zero to one hop duration, using a sufficiently fine set of phase positions to reveal performance minima. The programme should vary burst duration, bandwidth, amplitude and interference as independent factors or use a documented design which identifies their interactions. A detector whose sensitivity is quoted only for a burst precisely centred within one window has not established sensitivity to arbitrary arrivals. The distinction matters

Copyright 2026, James M. Atkinson

particularly where the subject emission is intermittent and the operator cannot predict its starting instant.

The validation endpoint should be detection of each injected physical event, not the number of frames above threshold. If one burst yields three frame alarms, that remains one successful event detection; if it yields no alarm at an unfavourable arrival phase, it is a missed event. The report may separately examine how many redundant frame alarms a detected event produces, because redundancy can increase downstream review burden and affect false event counts. However, the denominator of an event-detection probability is the number of independently defined injected events meeting the declared trial conditions. It is not multiplied by the number of frames or FFT bins.

The uncertainty bound requires care when trials occur under a small number of shared receiver states. A hundred arrivals generated during one stable laboratory session may not support generalisation to a hundred independently varying field environments. Stratify or randomise environmental factors that materially affect performance, preserve the state transitions and define the scope of the conclusion. When a physical-event rate is estimated from field alarms rather than controlled injections, additional uncertainty arises from missed detections, split and merged episodes, unobserved intervals and the population model. Those difficulties cannot be cured by adopting a more concentrated taper.

I therefore recommend a transparent comparison of configurations. Demonstrate their transfer functions, frame-level

Copyright 2026, James M. Atkinson

noise correlation and event-level detection behaviour, then identify conditions where they differ. A restricted claim for one specified configuration can be rigorous. A broad claim across all configurations requires its own evidence. I respectfully yield the floor to Professor Wiener, whose perspective on systems with memory will expose further ambiguity in the relationship between one physical event and several later recorded alarms.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 4: Detector memory, feedback and the counting of repeated observations

Dr. Atkinson, a processing system with memory is not simply a passive observer that repeats the same question many times. The result of one observation may alter the settings under which the next observation is made. A detector may update its noise floor, tune a carrier-tracking loop, alter its buffer-retention policy or suppress successive alarms deemed duplicates. The number of resulting entries is a property of the coupled instrument and decision procedure. The relevant object of study is therefore not merely the input waveform and not merely the FFT window, but the temporal evolution of the entire receiver from input stimulus to retained forensic record. A physical event can influence that evolution well beyond the interval in which it was radiated.

Consider an exponentially smoothed detector statistic $S_k = \text{alpha } P_k + (1\text{-alpha}) S_{(k-1)}$, where P_k is a frame-level power statistic and zero is less than alpha and no greater than one. This expression defines a stateful operation. Even if the physical input power returns immediately to background, S_k can remain elevated for subsequent frames. A threshold crossing generated by a long decay tail is not necessarily a second event. If the threshold itself is estimated from recent P_k values, both sides of the comparison can move in response to the same emission, making the decision history still more complicated. The operator must retain sufficient parameter and state information to reproduce the alarm sequence and must determine which observations actually provide new evidence about the external environment.

Copyright 2026, James M. Atkinson

Overlap adds another kind of memory, namely the direct reuse of original analogue samples. Two adjacent FFT frames with substantial overlap contain some identical input samples even if the detector performs no explicit smoothing. If each frame is then passed through a running average, the resulting decisions embody both data reuse and algorithmic state. Neither an independence model for raw samples nor a simple count of frames adequately represents that compound dependence. In practice the effects may also be influenced by common oscillator motion, antenna vibration, interference and adaptive gain. A validation experiment should vary these conditions and inspect whether a burst's after-effects survive changes in hop and smoothing parameters as the mechanism predicts.

The distinction between cause and repeated consequence is particularly important for receiver-generated artefacts. A periodic quantisation spur, clock feedthrough or interleaving image may occupy the same spectral location through many frames. Its coherence can make it look more stable than a weak external emission affected by propagation. If the software counts each recurrence as fresh evidence, the instrument effectively testifies repeatedly on behalf of its own internal defect. A useful challenge might change the analogue input termination, alter the clock plan, substitute a front-end path or introduce a calibrated stimulus while preserving all the digital processing settings. Competing internal and external hypotheses should then predict different outcomes. An unchanged waterfall alone is not a substitute for such intervention.

I would ask the laboratory to formalise the detector as a state machine. Its states might include searching, candidate, confirmed, holdoff and invalid. The transition rules should specify which measured quantities move the

Copyright 2026, James M. Atkinson

system between states, whether consecutive threshold crossings are merged, and when the system becomes eligible to count a new event. Timeouts and hysteresis must be calibrated against legitimate burst types rather than chosen for visual neatness. The state transitions should be logged in a form which permits a second examiner to determine why two adjacent threshold crossings were assigned to one episode or to separate ones. A hidden vendor state machine may still be useful as a discovery aid, but it limits reproducible forensic inference.

Not all repeated observations are useless. If an event persists over many frames, its time-varying spectral profile may reveal modulation, burst envelope or relative motion. Repetition can also improve an estimate under carefully characterised noise conditions. The error arises when dependence is ignored and precision is inferred from the number of displays rather than the information added by each observation. Repeated observations of one physical source may strengthen a claim about its persistence or signal structure without increasing the number of distinct emitters. A receiver with many antenna channels may supply valuable spatial diversity, but only if their common electronic paths and correlated disturbances are considered. The proper statement is conditional on the claim, not a universal rule that repeated measurements are always redundant.

A practical forensic record should preserve at least the raw interval of each material candidate when feasible, the corresponding frame indices, tapers, hop, processing version, threshold history and event-clustering decisions. It should additionally preserve a representative independent audit stream so that the absence of retained alarms is not confused with the absence of physical emissions. If the receiver chooses which data to retain

Copyright 2026, James M. Atkinson

based on its own adaptive decisions, that selection mechanism becomes part of the evidence and must be disclosed. Otherwise the later analyst sees a history filtered through a process whose omissions cannot be evaluated.

I conclude that the correct event count is a property of a defined physical-event concept together with a validated inference procedure. It is not available directly from a stream of FFT decisions. The benefits of overlap are real, including improved coverage of arbitrary burst arrival phases; its costs include correlated statistical outputs and increased opportunities for self-generated artefacts to produce repeated alarms. The laboratory should show both sides of that ledger. I invite Dr Shannon to ask whether a finite retained archive can preserve enough of this state history for a later analyst to challenge a proposed count without possessing every original sample.

Claude Elwood Shannon | Peer question 5 to Norbert Wiener

Professor Wiener, your state-machine account makes the event count a function of the observed signal and the receiver's internal history. Suppose a digital recorder preserves a small selection of IQ samples around each declared event, along with the last value of every adaptive threshold, but discards intermediate frames and the coefficient-update trajectory. A later analyst may be able to reproduce the final alarm positions, yet may be unable to tell whether the detector suppressed a brief second burst or merged it into the memory of the first. In information-theoretic terms the retained representation may be insufficient for the new question, although it was entirely adequate for the original operator's display. Can an archive specification be stated in terms of sufficient information for an agreed class of questions, rather than simply demanding unlimited storage? How should the report

Copyright 2026, James M. Atkinson

identify which later questions are unsupported by the selected representation, particularly when the acquisition software has been updated and the original executable no longer exists?

Norbert Wiener | Immediate answer to Claude Elwood Shannon

Dr Shannon, I would begin by defining the forensic question before specifying the retention boundary. If the question is whether the displayed detector issued one alarm at a recorded time, a state snapshot and event log may suffice. If the question is whether a second physical emission occurred during a holdoff interval, the archive may require the samples and detector evolution during that interval. A final state does not uniquely reveal the path by which a system arrived there. Different sequences of inputs and threshold updates may produce the same terminal coefficients. Therefore a retained archive should not be described as sufficient for all later questions merely because it reproduces the final display.

A practical design could distinguish full raw acquisition, candidate-neighbourhood retention and reduced summary-only retention as separate evidence classes. For each, preserve a manifest declaring the physical and analytical propositions it can support. The metadata should identify the software version, clock and gain state, event definition, threshold adaptation and processing configuration. Where raw samples are absent, maintain a truthful statement of the observation exposure and the selection rule. Independent validation can then establish the probability of retaining specified event classes, albeit within a declared envelope. That does not recover the particular missed event; it informs the limits of the procedure.

Copyright 2026, James M. Atkinson

Software version identity is indispensable because ostensibly minor changes to clustering or threshold logic can change the number of reported physical events. Preserve source code or a verified executable with dependency versions when licensing and access permit; otherwise retain a sufficiently precise algorithm description, input-output challenge set and reproducible checks. A hash of an executable establishes the identity of the bytes, not that the program's interpretation was correct. The same distinction applies to saved IQ files: cryptographic integrity can support chain of custody while leaving the accuracy of the original RF measurement unresolved.

The archive need not be limitless if the intended conclusion is modest. A summary can support a summary-level claim when its generation and limitations are described. But an investigator must not subsequently invoke that summary as though it contained all the information discarded in its construction. Retention policies should be tested with challenge signals deliberately placed near event boundaries and holdoff intervals, where the risk of accidental merging is greatest. The test must evaluate false negatives and false splits, not simply reproduce an attractive waterfall.

I would therefore record a hierarchy of claims and a corresponding hierarchy of evidence. The narrowest concerns the digital instrument's reported decisions. A stronger claim concerns the external event population under validated detection assumptions. The strongest attribution claim adds physical discrimination among emitters and alternative artefacts. Every advance requires additional

Copyright 2026, James M. Atkinson

evidence. This is not hostility to automation; it is the logical discipline necessary to make automation's conclusions reviewable. I invite Professor Bridgman to examine whether the event definitions we have offered are physically meaningful or merely administrative conventions.

Percy Williams Bridgman | Peer question 6 to Norbert Wiener

Professor Wiener, you have admirably described the detector as an evolving mechanism, yet I remain concerned that the word event may conceal two distinct entities. An operator may call any cluster of threshold crossings an event, while a physicist might reserve the term for a particular emission from a material transmitter. A digital algorithm can define the former exactly without having established the latter. Suppose two independent transmitters radiate overlapping bursts in the same channel, or one transmitter emits two packets separated by an interval shorter than the clustering timeout. In either case the operational output might be one cluster. How should the examiner prevent the perfectly reproducible administrative count from being mistaken for a physical source count? What interventions or additional measurements would justify the passage between those two claims, and how should uncertainty be expressed when the original source population cannot be observed directly? I would also ask which parts of the classification rule are experimentally calibrated, and whether those parameters remain stable when the receiver changes gain or sample-clock state.

Norbert Wiener | Immediate answer to Percy Williams Bridgman

Thank you for that question. Professor Bridgman, the distinction is essential. A detector event should be defined as the outcome of a

Copyright 2026, James M. Atkinson

specified operational rule, and a physical emission episode should be defined by a model of the underlying radio-frequency activity. A transmitter identity is a third proposition. Those three levels must not be silently equated. One detector event can encompass two independent emissions; one emission can produce several detections; and one transmitter can generate several distinct emission episodes. Reproducible software does not change those possibilities. It establishes only that the same algorithm will make the same categorisation under the same retained input and state conditions.

A practical report should therefore state the directly observed count with its proper unit, such as 'seventeen alarm clusters under clustering rule R17'. It may then discuss possible source episodes as an inference supported by waveform continuity, modulation, frequency stability, independent receiver views or controlled challenge evidence. If those sources of discrimination are insufficient, it should not print 'seventeen transmitters'. Attribution may require directional measurements, RF-path comparison, movement or power-state interventions, and consideration of receiver-generated images and co-channel innocent services. Each additional procedure requires calibration and its own uncertainty analysis.

To test the operational-to-physical mapping, use challenge trials in which known numbers of sources generate bursts with independently varied overlap in time, frequency and modulation. Evaluate not only whether a source was seen but whether sources were split, merged or misidentified. Include deliberately confusable cases rather than a collection of ideally separated carriers. The acceptance statement

Copyright 2026, James M. Atkinson

should distinguish the case population: a receiver may reliably count isolated bursts under quiet conditions and yet be unable to resolve two simultaneous sources in a congested band. That narrower fact can still assist an investigation, provided it is not inflated into a universal source-count capability.

Where historical field evidence lacks independent truth labels, the source count may remain a range or a family of plausible interpretations. One should preserve the competing explanations and the evidence favouring each. The observation that several spectral lines move together under an antenna intervention might support a shared source hypothesis, but common receiver paths and environmental responses must still be considered. The result can be strong about a bounded proposition and uncertain about identity. A careful report is not diminished by such qualification; it is strengthened because an independent examiner can see exactly what remains unresolved.

I would finally emphasise that the retention policy must permit these distinctions where they are material. If the only preserved data are cluster timestamps, the opportunity to examine waveform overlap or modulation may have been lost. That absence cannot be repaired by a more elaborate statistical narrative. The correct professional response is to describe the limits and, where feasible, design a new controlled acquisition capable of testing the rival hypotheses. I pass the floor respectfully to Professor Tukey for the problem of exploratory detector design and the temptation to count only those successes which survive a favourable selection rule.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 5: Exploratory detection, robust summaries and selection effects

Dr. Atkinson, it is tempting to regard an event-counting problem as solved when one has selected the most sophisticated detector. In fact, the principal hazard may lie in the questions the analyst forgot to ask. What was counted? Which observations were eligible for counting? Which were excluded? How much did the answer change when the analysis rule changed? An investigator should examine the raw temporal structure of the data before compressing it into one apparently definitive event total. Exploratory analysis is not a vice; it is a method of learning where an initial model is inadequate. The vice lies in presenting a data-driven rule as though it had been prescribed before seeing the very signals it was chosen to explain.

Overlapping FFT windows create excellent opportunities for exploratory visualisation. They can reveal weak transients whose arrival coincides poorly with a non-overlapping grid, and they can show the time evolution of spectral structure. But a waterfall can also create the false impression that many bright pixels represent many separate physical events. A short transmission may illuminate numerous nearby time-frequency cells, while an impulse-like artefact can spread across many frequencies. Counting illuminated cells would be an indefensible substitute for an event model. The analyst should begin with linked views of time-domain IQ, detection statistic, threshold trajectory, receiver state and the final cluster decisions. Discordance among those representations is often more instructive than apparent consistency.

Copyright 2026, James M. Atkinson

A robust exploration would vary the frame hop, window function, threshold hysteresis and clustering gap within physically plausible limits. It would record how the inferred event count changes. A stable count over these variations is not proof of source identity, but instability is a warning that the chosen representation governs the answer. Equally, changing the frame length alters the trade-off between frequency concentration and transient localisation. A long window may merge two short adjacent packets, while a shorter one may lose narrowband signal-to-noise ratio. There is no one universally optimal configuration for every unknown emitter; the chosen measurement must be suited to a declared class of signals and validated accordingly.

The analyst should resist the appeal of a single clean average. Mean spectral power is useful for estimating sustained background behaviour, yet a rare brief burst may be diluted by hundreds of quiet frames. A median can reject occasional strong outliers in a background estimate while simultaneously concealing the very transient one wishes to discover. The proper statistic depends upon the question. If the purpose is rare-event detection, preserve peak or threshold-crossing information and the corresponding source interval; if the purpose is background estimation, use a method whose sensitivity to intermittent contamination has been characterised. Do not use a favourable-looking mean to infer the absence of brief transmissions.

False alarms deserve particular attention in a large search. An analyst may inspect many frequencies, windows and smoothing settings before selecting one conspicuous feature. The selected feature is not a randomly prespecified test. If the selection is ignored, the reported significance may

Copyright 2026, James M. Atkinson

exaggerate the evidence. A defensible workflow can separate discovery from confirmation: use one period to explore and specify the candidate, then test its predicted behaviour in an independent period or through controlled intervention. The challenge should be genuinely capable of giving an adverse result. If every failure is met with an altered threshold and a new explanation, the experiment has ceased to test the original claim.

The operator should also preserve failures and equivocal classifications. A false split, a merged pair of packets or an invalid receiver interval should not disappear into a polished summary. Those cases help locate the procedure's performance boundary and may guide better future acquisition. Where a system declares an alarm cluster, preserve enough linkage to the underlying FFT frames and raw intervals for another examiner to test a different segmentation rule. If those samples were not retained, the report should state which alternative analyses are impossible. Precision about a limitation is preferable to a lengthy report that obscures it.

For the acceptance campaign, I propose deliberate adversarial variety rather than mere volume of routine trials. Include single bursts arriving at unfavourable hop phases, close-spaced pairs near the clustering boundary, overlapping emitters, amplitude-faded continuous carriers, strong innocent transmissions and receiver-generated spurs. Test each material processing configuration. Keep a held-out collection whose labels are not used to set parameters. Compute frame-level alarm statistics and physical-event-level performance separately. The design should distinguish detection of any burst from accurate counting of bursts, and distinguish both from attribution to a particular physical source.

Copyright 2026, James M. Atkinson

The final report may need only a few sentences for its conclusion, but those sentences must carry the correct units and limits. It might report that a frozen algorithm detected a specified proportion of reference bursts while producing a measured number of false clusters per valid observation hour, under a defined interference and clock envelope. It should not transform that result into a claim that every retained alarm represents a unique transmitter, nor infer absence of events during invalid or unrecorded periods. A carefully qualified conclusion can guide a TSCM investigator's next action more effectively than a supposedly comprehensive but logically unsound event count. I invite Professor Slepian to examine whether the overlap chosen for spectral concentration can itself influence the apparent robustness of those classifications.

Dennis Gabor | Peer question 7 to John Wilder Tukey

Professor Tukey, your proposed robustness analysis varies window length, hop and threshold rule to establish whether the event count remains stable. Yet each variation may produce a different time-frequency resolution and a different sensitivity to signal classes. If the count changes, the reason might be genuine detection of a previously invisible burst rather than merely an unstable classification rule. Conversely, the same event count might conceal different sets of missed and falsely detected emissions. How should a validation experiment distinguish meaningful new information from arbitrary numerical duplication when the analyst changes the spectral representation? In a time-frequency representation, a brief physical event may be spread across neighbouring cells by the analysis kernel; should that predictable spread be tested against the source envelope before it is labelled an

Copyright 2026, James M. Atkinson

additional event? Should one require agreement on individual known challenge events, rather than agreement only in their aggregate count? And if several settings are combined into one ensemble detector, how should correlated decisions be reconciled so that the ensemble's apparent corroboration does not count the same analogue samples repeatedly as independent evidence?

John Wilder Tukey | Immediate answer to Dennis Gabor

Dr Gabor, I agree that identical aggregate counts are not sufficient. Two algorithms can report the same number of events while disagreeing entirely about which physical reference bursts they detected. Therefore the validation must compare classifications against individual known events, preserving their identities, start times, durations, signal properties and intended separation. A confusion table at the event level should record true detections, missed events, false clusters, splits and mergers. When a change of window or hop reveals a real previously missed burst, that is a genuine improvement. When it creates three alarms from one unchanged burst, it is not an increase in independent source evidence. These possibilities can be separated only by a trial population with appropriate truth labels or by defensible independent physical observations.

For an ensemble detector, the combination rule must be part of the declared procedure. The analyst should not treat agreement between classifiers trained on the same FFT frames as if it were independent sensor corroboration. Different computational views of a shared input may be complementary for classification while remaining dependent

Copyright 2026, James M. Atkinson

as evidence of the input's physical correctness. An ensemble may reduce a false-negative rate or improve discrimination under tested conditions, but that performance must be demonstrated on independent challenge events with thresholds and weights fixed beforehand. The report should compare the ensemble with its constituent procedures and state where any measured benefit occurs.

The temporal and spectral resolution trade-off also makes simple count stability an imperfect target. Longer analysis windows favour narrowband energy concentration but can smear the timing of brief events; shorter windows improve localisation while degrading some frequency estimates. A useful validation deliberately includes bursts across both sides of that trade-off. It should stratify performance by duration, bandwidth, arrival phase and interference. The resulting record can explain why a configuration suited to one signal class underperforms for another, instead of seeking one universal number which hides the variation.

When the analyst performs exploratory robustness checks on a historical recording, each alternative method can reveal a candidate requiring further investigation. That is legitimate, provided the exploratory selection is disclosed and no confirmatory probability is fabricated from the same selected data. A later controlled challenge, a separate receiver path or an independent acquisition interval may then test the candidate. If none is available, the report can still identify a plausible emission with an explicit uncertainty statement. The critical distinction is between discovery and validation, not between one favoured software package and another.

Copyright 2026, James M. Atkinson

I should also insist upon preservation of the source-to-output mapping. Each alarm should identify the originating raw interval, processing version, window geometry, threshold state and clustering decision. Where the raw material is no longer available, the analyst must say which alternatives could not be examined. A summary count may be technically reproducible but scientifically inadequate for a source claim if the physical evidence has been discarded. A clear uncertainty qualification is not an embarrassment; it permits the next investigator to design a measurement which can discriminate among the remaining explanations. I return the floor to Dr. Atkinson for the numerical applications and final synthesis.

The following calculations are hypothetical educational illustrations. They specify governing variables and assumptions, and none certifies a particular receiver. Where a statistical relationship depends upon a model, the model must be tested against the relevant operating conditions before the calculation is used as evidence of an actual investigation.

Additional evidential check. Storage has not been multiplied by window overlap

Suppose a raw IQ stream contains F_s = 2,000,000 complex samples per second and each sample consists of two sixteen-bit integers, four bytes in total. The raw storage rate is $R = F_s \times 4$ = 8,000,000 bytes per second, or 480,000,000 bytes in sixty seconds, before file headers and metadata. Recomputing five overlapping windowed spectra from portions of those same samples does not multiply the raw analogue observation time by five. Saving every spectrogram may increase

Copyright 2026, James M. Atkinson

derivative storage substantially, but that is a software-output burden, not evidence of additional independently sampled physical time. Where a system discards raw IQ to save space, the later questions it can support may be narrower.

Maurice Stevenson Bartlett, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, why cannot a hundred half-overlapping FFT windows be treated as one hundred independent examples of the receiver noise process?

Walter Andrew Shewhart, Cross-Peer Answer to Maurice Stevenson Bartlett: Professor Bartlett, each window shares raw samples with its neighbours, and the taper weights those shared samples in a known pattern. Adjacent periodograms are therefore generally correlated, with the amount depending on the overlap, window and input process. Counting every frame as an independent trial inflates precision and can understate the chance of false alarms. Estimate the covariance under representative noise-only conditions and use an effective degrees-of-freedom calculation justified by that model or a block-resampling method that preserves dependence. Examine stationarity, gain transitions and short bursts, because overlap can propagate one physical event across multiple frame detections. Preserve frame indices and sample intervals so a reviewer can distinguish one event from its several computational appearances. I pass the token to Dr Neyman on probability statements.

Walter Andrew Shewhart, Cross-Peer Question to Jerzy Neyman: Dr Neyman, a survey records seventy detections in highly overlapping frames. Can the report claim that seventy independent emissions occurred?

Copyright 2026, James M. Atkinson

Jerzy Neyman, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, no. The count is of threshold crossings in a specified computational representation, not directly of distinct physical transmissions. Define an event-clustering or coincidence rule with appropriate time and frequency tolerance based on known filter memory and timestamp uncertainty. Apply the rule before examining the actual cases, and validate it against injected bursts with known multiplicity. The probability of at least one false alarm over many correlated opportunities must be calibrated on complete noise-only sequences through the identical detector. If one event triggers several overlapping windows, those detections contribute information about its time and frequency but are not separate independent observations of an emitter. Report raw crossings, clustered candidate events and validated physical attributions separately. I yield to Professor Wiener to examine the signal-processing dependency.

Jerzy Neyman, Cross-Peer Question to Norbert Wiener: Professor Wiener, how would a periodic overlap-add processor alter the error model for detection statistics collected at neighbouring frame indices?

Norbert Wiener, Cross-Peer Answer to Jerzy Neyman: Dr Neyman, the output process inherits the filter and overlap structure in addition to the correlation of the physical input. A pulse can affect several adjacent windows with different taper weights and phases. If a reconstruction uses overlap-add synthesis, the output error can also include deterministic modulation from an incorrect window-sum condition. Record exact hop size, window coefficients, frame start times and synthesis convention. Test isolated impulses at multiple phases of the hop; the resulting pattern provides a direct empirical model of repeated detections caused by one

Copyright 2026, James M. Atkinson

event. Only after characterising that dependence should one assign an uncertainty to event counts or use a parametric test. Preserving a single plot of frame peaks would conceal the mechanism. I respectfully pass the token to Professor Tukey for honest reporting.

Norbert Wiener, Cross-Peer Question to John Wilder Tukey: Professor Tukey, what evidence would demonstrate that an apparent improvement in false-alarm rate after increasing overlap is genuine rather than a change in the unit counted?

John Wilder Tukey, Cross-Peer Answer to Norbert Wiener: Professor Wiener, use the same physical exposure time, the same injected event population and a predeclared definition of one distinct event. Report both per-frame crossings and per-hour independent candidate events, together with detection probability and confidence intervals. Increasing overlap creates more frame-level decisions and may improve temporal alignment, but it also changes dependence and detection multiplicity. The comparison must run through the identical clustering and adjudication rule. An apparent fall in per-frame false alarms can coexist with no change in false candidates per hour, just as more frames can make a fixed source look more frequently active. Retain full decisions and test on independent records. I respectfully return the token to Dr Atkinson.

Moderator synthesis | Dr. James M. Atkinson

Distinguished colleagues, the principal conclusion is that an FFT frame, a detector alarm, an emission episode and a transmitting source are four different categories of object. Their numerical counts may coincide in a simple demonstration, but coincidence in one test does not establish identity of meaning. Maurice Bartlett has shown why overlapping estimates

Copyright 2026, James M. Atkinson

cannot be treated as independent merely because their FFT calculations execute separately. Walter Shewhart has required the event segmentation and process-state rules to be defined before the event count is interpreted. Jerzy Neyman has distinguished per-test false-alarm calculations, family-wise claims, independent challenge events and the statistical assumptions required for valid confidence bounds. Norbert Wiener has placed detector memory and adaptive feedback inside the measurement system rather than treating them as incidental programming details. John Tukey has shown why exploratory discovery and confirmatory validation must be distinguished, especially when many overlapping representations are searched for an attractive result.

The physical picture is straightforward but its implications are extensive. A long burst can illuminate many overlapping windows, and a narrow internal spur can remain bright across thousands of displays. A short event might be visible only when its energy falls favourably within a taper, whereas a different frame geometry may divide its energy among neighbouring results. Overlap can improve temporal coverage and reduce window-edge sensitivity, but it does not provide a universal multiplier of independent observations. A mathematically correct spectral average may be poor evidence of a rare emission because the averaging suppresses its temporal distinctiveness. Equally, an aggressive peak detector can present one noise fluctuation as numerous alarms unless its association rule is controlled.

The applied calculations place limits on attractive slogans. A 75-percent geometric overlap tells us how many digital samples two nominal frames share, not the correlation coefficient of their detection decisions. The

Copyright 2026, James M. Atkinson

confidence of a hundred event trials cannot be inferred from a hundred windows of one event. The independence formula for a collection of tests is not licensed by software architecture alone. The full uncertainty of an estimated mean includes covariance under the stated statistical model. The number of reported alarm clusters depends on the declared clustering procedure, and a physically meaningful emission count may require independent evidence about overlapping sources and receiver artefacts. The laboratory must not conflate an instrument's computational abundance with the external world's causal plurality.

For defensive technical surveillance countermeasures practice I would require the report to identify the admitted frequency region, observation exposure and invalid intervals; the physical RF reference plane; the FFT length, hop, taper and channeliser state; the threshold estimator and its adaptation history; the algorithm mapping frame-level detections into candidate episodes; and the evidential basis for identifying episodes as external rather than self-generated. The report should disclose any exploratory parameter selection and distinguish a subsequent frozen validation campaign from the analysis that produced the chosen rules. It should preserve discordant reference trials, split and merged events, false positives and missed events. A result which depends strongly on an arbitrary clustering gap should be described as sensitive to that parameter, not converted into a false precision by choosing the most favourable gap.

These requirements need not paralyse field operations. The field examiner may use overlapping spectra for discovery and retain concise candidate logs for immediate action. The stricter requirements arise when a discovery is transformed into an amplitude estimate, event count, source

Copyright 2026, James M. Atkinson

attribution or negative assurance conclusion. Those claims require evidence proportionate to their scope. A preserved raw candidate interval, a versioned algorithm, a truthful state log and a controlled challenge set can often provide more persuasive support than millions of unexamined FFT summaries. Where retention is selective, its selection mechanism and unobserved periods belong in the evidential account. Where the original samples are absent, the later investigator must not imply that alternative analyses can still be performed.

The source of scholarly discipline is the willingness to distinguish what is directly observed from what must be inferred. A frame-level detector result is observable in a retained digital record. A count of physical emissions is a conclusion that depends on an event model and validation. An identification of a particular transmitter is a further causal claim, potentially requiring changed antennas, independent receiver paths, waveform comparison and other physical tests. No number of overlapping frames can automatically bridge those conceptual steps. At the same time, a properly characterised digital receiver can make useful and rigorous findings within a declared operating envelope. The purpose of qualification is not to weaken evidence, but to prevent the conclusion from travelling further than the measurement permits.

I thank our colleagues for their careful exchanges and respectful challenges. The next discussion should examine how threshold adaptation and receiver-state histories influence the detectability of intermittent signals, especially where the underlying noise floor changes during an investigation. We shall carry forward the central rule established here: the statistical unit must be defined at the level of the claim, and the archive

Copyright 2026, James M. Atkinson

must preserve enough of the acquisition and decision history for that claim to be contested. The floor passes with thanks to the next principal contributor.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 044

Worked application 1. The overlap fraction does not equal the independent-information fraction

Let N = 4,096 samples per FFT frame and H = 1,024 samples between adjacent frame starts. The number of shared samples is N-H = 3,072, and the geometric overlap fraction is O = (N-H)/N = 3,072/4,096 = 0.75, or 75 percent. This arithmetic describes reuse of digital samples, not the correlation coefficient of the final spectral statistic. That coefficient depends additionally on taper weights, the signal and noise models, and any later smoothing. A claim that the 'independence is 25 percent' would therefore be unjustified. The correct record preserves N and H, the actual taper and the detector computation. With a different signal distribution, even an unchanged overlap fraction can produce a different correlation between decisions.

Worked application 2. Temporal spacing and acquisition exposure

Let F_s = 1,000,000 complex samples per second, N = 4,096 and H = 1,024. The observation support of one frame is T = N/F_s = 0.004096 seconds, or 4.096 milliseconds. The separation of successive frame starts is h = H/F_s = 0.001024 seconds, or 1.024 milliseconds. Four starts occur over approximately one 4.096-millisecond frame-length interval in steady operation, but that does not create four independent physical acquisition periods. The frames overlap because their input intervals share samples. The physical coverage of the continuous recording is determined by its actual valid sampling time, not the multiplied sum of frame durations.

Copyright 2026, James M. Atkinson

Worked application 3. Counting frame starts in a finite record

Let L = 1,000,000 valid samples, N = 4,096 and H = 1,024. If the implementation places only complete frames whose starts advance by a fixed hop, the frame count is K = 1 + floor((L-N)/H) = 1 + floor(995,904/1,024) = 973. Thus a one-second record produces 973 computed frames under the stated convention. The result does not mean 973 seconds of independent input were observed, nor 973 independent opportunities for every burst waveform. A different end-padding rule could produce a different number of computational frames without adding any measured analogue evidence.

Worked application 4. Effective number of correlated spectral estimates

Suppose K = 100 power estimates share a common variance sigma squared under an appropriate stationary model, with lag-one correlation rho_1 = 0.6, lag-two correlation rho_2 = 0.2 and all higher lag correlations stipulated to vanish. The variance inflation factor for their arithmetic mean is C = 1 + 2[(1-1/K)rho_1 + (1-2/K)rho_2] = 1+2(0.99 x 0.6+0.98 x 0.2) = 2.58. The effective count relative to the independent-variance formula is K_eff = K/C = 100/2.58 = approximately 38.76. It would be an error to claim the standard error is sigma/10 simply because the software calculated 100 frames. This example is deliberately model-dependent. The stated correlations and stationary assumptions require empirical verification before an actual effective count may be reported.

Copyright 2026, James M. Atkinson

Worked application 5. A bound on family-wise false alarms without independence

Suppose K = 1,000 declared statistical tests each has null false-alarm probability no greater than p = 0.0001 under the appropriate model. Without requiring independence, Boole's union inequality gives P(at least one false alarm) <= min(1,Kp) = 0.1. The value 0.1 is an upper bound, not an estimated realised false-alarm rate. A detector that calculates overlapping FFT bins may have strongly dependent comparisons, but dependence alone does not invalidate the union bound. Correct application requires that the family of tests be stated completely and that the per-test p values are defensible for the actual operating conditions.

Worked application 6. Why the independent-test formula is a separate proposition

For comparison only, assume the same K = 1,000 tests are independent and all have p = 0.0001. Then P(at least one false alarm) = 1-(1-p)^K = 1-(0.9999)^1000 = approximately 0.0951671. The difference from the 0.1 union bound is small here, but this does not validate independence. It merely shows the consequence of adopting it. Under a different dependence structure the joint probability may differ. One should never infer the number of independent tests from the fact that the independent formula happens to give a plausible-looking result.

Worked application 7. Three frame alarms, one known physical burst

Suppose a controlled challenge generator emits precisely one calibrated burst at a known time, and the detector reports threshold crossings in three successive overlapped frames. The frame-level alarm count is A = 3. The known physical-event count is E = 1. If the clustering

Copyright 2026, James M. Atkinson

rule merges all three into one output episode, it yields one correct event detection rather than three independent source confirmations. If it instead issues three separate events, it has produced two excess event reports relative to the challenge truth. The test should be repeated across random arrival phases, because a differently aligned burst may generate one, two, three or no frame alarms. This is a controlled educational example, not a general rule that three overlapping alarms always mean one transmission.

Worked application 8. Persistence from exponential smoothing

Let $S_k = \alpha P_k+(1-\alpha)S_{(k-1)}$, with smoothing constant $\alpha=0.2$. Suppose the physical input returns to a zero reference level immediately after an initial state deviation S_0 and $P_k=0$ thereafter. Then $S_5 = (1-\alpha)^5 S_0 = 0.8^5 S_0 = 0.32768 S_0$. After five further frames, roughly 32.768 percent of the initial state remains. A threshold detector can therefore issue late decisions because of its own history even when the cause is no longer present. The illustration assumes fixed alpha and no other state updates; practical receiver adaptation may behave differently and requires direct measurement.

Worked application 9. Exposure limits unconditional detection

Let $e = 0.90$ denote the probability a randomly timed physical burst falls within valid admitted receiver exposure, and let $d = 0.85$ denote the probability the detector recognises the burst conditional on such exposure under the specified source class. Then by the product rule $P(\text{detected}) = P(\text{exposed})P(\text{detected} \mid \text{exposed}) = 0.90 \times 0.85 = 0.765$. This result requires d to be defined conditionally on exposure, not as an already unconditional success probability. The 76.5-percent

Copyright 2026, James M. Atkinson

unconditional figure is not raised by repeatedly calculating FFTs over intervals when the receiver was not observing the source frequency. It is also not a posterior probability that a recorded alarm represents a true signal.

Worked application 10. A confidence bound from zero misses in known event trials

Suppose n=100 genuinely independent reference bursts are injected under a frozen receiver configuration, with every burst detected. Under a binomial model with constant success probability d, a one-sided 95-percent exact lower confidence bound is d_L = 0.05^(1/n) = 0.05^0.01 = approximately 0.970487. Therefore 100 successes do not demonstrate perfect sensitivity; the indicated lower bound is about 97.05 percent under the stated assumptions. If the hundred nominal trials repeat one favourable burst phase or share an unmodelled common failure mechanism, the independent Bernoulli premise is not established. The bound applies to detection of independently defined physical challenge events, not to the number of overlapping frame-level alarms.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, the preceding examination of overlapping Fourier windows has obliged us to separate the number of calculated observations from the number of physically independent events. We now confront a different, though related, limit: a short-lived emission does not offer the same opportunities for frequency estimation as a long, stationary sinusoid. The investigator's screen may exhibit an exquisitely fine frequency grid after zero padding, yet the analogue event may have existed for no more than a few milliseconds. The distinction between the number of display columns and the amount of frequency information in that recorded event is central to the proper use of software-defined receivers in defensive technical surveillance countermeasures. A bright pixel may be calculated precisely while the physical parameters it suggests remain weakly determined.

Let $x(t)$ represent the received complex baseband waveform, $w(t-t_0)$ a window centred at analysis time t_0, and $X_w(t_0,f)$ the windowed Fourier transform. The analysis kernel restricts the time interval contributing to a

Copyright 2026, James M. Atkinson

spectral estimate. A shorter window can help determine when a transient occurred, but commonly broadens the spectral representation of a narrowband component. A longer window can concentrate a sustained tone more narrowly in frequency, but may blend the beginning and end of a burst, combine separate events, or include receiver states that changed during the observation. The fundamental constraints are not removed by assigning more FFT bins. Zero padding samples the transform of the existing finite record more densely; it does not insert observations of an unrecorded waveform. The measured time support, window shape, noise distribution, source stability and estimator model all affect what the instrument can claim. [T1, T2]

The language of resolution deserves particular caution. The FFT bin spacing F_s/N_{fft}, where F_s denotes sample rate and N_{fft} denotes transform length, is a computational grid interval. It is not universally equal to the minimum separable spacing between two physical emitters, nor to the uncertainty of a fitted carrier-frequency estimate. Two nearby signals can sometimes be discriminated with model-based methods when the available signal-to-noise ratio, duration and assumptions permit; a transient with unknown modulation can defeat a seemingly fine frequency-grid assertion. The examiner must specify whether the measurand is the centre frequency of a stipulated waveform model, the occupied bandwidth of an arbitrary burst, the arrival time of an identifiable transition, or the ability to distinguish two simultaneous emitters. These are different tasks with different uncertainty models.

We must also separate an observed event's physical duration from the duration of its displayed spectrogram response. A short impulse excites a

Copyright 2026, James M. Atkinson

filter's impulse response and may become visible across several overlapping windows. The apparent tail is not necessarily evidence that the transmitter continued radiating. Conversely, a long integration may weaken the visibility of a short event by distributing its energy across a wider averaging interval. The observed spectrogram footprint includes the convolutional effects of the analysis procedure and the receiver's analogue and digital transfer functions. The investigator cannot simply read the plotted width along either axis as the underlying source's true width without accounting for those effects.

I ask Professor Gabor to examine the time-frequency compromise, Professor Slepian to address spectral concentration of finite records, Professor Fourier to distinguish mathematical representations from physical uniqueness, Mr Nyquist to consider sampling and aliasing at the RF interface, and Professor Neyman to assess the confidence and experimental design required for event localisation claims. Seven peer interventions will test these arguments directly, and their answers will follow each question without delay. Worked examples will define the observation interval, window coefficients, sample rate, source model, uncertainty and the processing transformations applied to the retained IQ samples. Every conclusion must be bounded by the evidence actually measured.

A properly qualified short-burst report can still be decisive for an investigation. It may establish that a feature consistent with a specified signal class was detected during an admitted time interval and that its frequency estimate remained within a quantified model-dependent uncertainty. It may support a directional or source-correlation hypothesis when independent tests discriminate internal artefacts from external

Copyright 2026, James M. Atkinson

radiation. It cannot automatically establish a particular transmitter's identity from the apparent narrowness of a plotted FFT peak. We shall therefore resist both false certainty and indiscriminate scepticism: the objective is to identify what a finite measurement establishes, what models it presupposes, and which further experiment would challenge its remaining alternatives. Professor Gabor, may I invite you to begin with the significance of changing the analysis window when time and frequency cannot both be localised without limit?

Copyright 2026, James M. Atkinson

Dennis Gabor | Principal response 1: Analysis windows and physical inference from short-lived waveforms

Dr. Atkinson, a waveform is presented to an investigator through a representation which has been selected for a purpose. The appearance of a spectral feature depends upon that representation as well as upon the original signal. Consider a finite burst whose carrier is approximately sinusoidal over a time interval T. An observer may infer a central oscillation frequency from its phase evolution, but the burst's finite duration necessarily gives its spectrum a width which depends upon the envelope. A sharp rectangular gate produces different sidelobes from a smooth taper. Accordingly the visual width of a plotted peak should not be read as a direct measurement of a transmitter's occupied bandwidth without defining both the source-envelope model and the analysis window. [T2]

The short-time Fourier transform may be written $X_w(t_0,f)=\text{integral } x(t)w^*(t-t_0)\exp(-j2\pi ft)dt$, with the asterisk denoting complex conjugation. This expression makes the measurement dependence explicit. Changing w changes which times contribute to the estimate and with what weights. A window narrow in time can identify a short episode with less temporal smearing but ordinarily broadens the frequency response. A window longer in time can provide a narrower representation for a stable tone, but it introduces temporal ambiguity when a burst starts or stops inside the observation support. There is no contradiction in finding that two correctly implemented analyses give different apparent peak widths. They have asked different questions about the same finite record.

I would not translate the time-frequency limitation into an incautious slogan that no short event can have an accurately estimated carrier.

Copyright 2026, James M. Atkinson

Parameter estimation is not identical to generic spectral resolution. If the waveform is well described by a known complex exponential with additive noise, a fitted frequency may be estimated more finely than one nominal FFT bin. However, such precision is conditional on the model. Unknown chirp, oscillator phase noise, abrupt modulation, multiple emitters, clipping and receiver timebase error can invalidate the assumptions supporting an attractive numerical uncertainty. A scientifically honest report should therefore identify whether it provides an algorithmic peak location, an estimate under a specified model, or an empirically validated limit on distinguishing physical source classes.

The finite measurement also contains a fundamental loss when raw samples are discarded. A spectrogram magnitude does not retain all phase information of the complex windowed transform, and further averaging or threshold selection can discard still more. In some mathematically constrained circumstances reconstruction from particular STFT representations is possible, but such results depend upon retention of sufficient coefficients, a valid synthesis window and appropriate boundary conditions. The existence of an inverse algorithm in software is not a guarantee that every compressed waterfall can recover the original analogue event. The correct question is whether the actual retained representation contains the information required for the later forensic inquiry.

For a practical defensive receiver, I would test a collection of reference bursts varied in duration, arrival phase relative to the hop, modulation bandwidth and received amplitude. Repeat the analysis with windows of different temporal support while holding the physical stimulus fixed. Record

Copyright 2026, James M. Atkinson

the resulting changes in peak frequency, occupied-bandwidth estimator and apparent start and stop times. In parallel, use known no-signal intervals to measure threshold and false-alarm behaviour under the same settings. Where a candidate appears only under one chosen window, the finding remains worthy of investigation, but selection among many windows must be disclosed when estimating statistical confidence.

A particular difficulty arises when a weak emitter is near a strong signal in frequency. The analysis-window sidelobes of the strong component may obscure or imitate the weak one. A smooth taper can reduce sidelobes at the cost of main-lobe broadening or another trade-off in noise bandwidth. Changing the taper to reveal a candidate can be reasonable, provided the investigator distinguishes the expected kernel effects from a changed external source. A controlled analogue input substitution or different receiver path may be necessary to establish that a new peak has a physical origin rather than arising from the receiver's own transfer and numerical processing. The instrument's internal coherence is not independent confirmation of an external transmitter.

I would also preserve the instrument's definition of time. A displayed spectrogram centre may be assigned to the window's midpoint, its start or another processing timestamp. If the burst begins within the window, that assignment is not the actual source-onset time. Filter group delay, acquisition buffering, clock offset and packet retention can add further displacement. Precise-looking timestamps must be connected to a calibrated physical reference plane, with the uncertainty of those transformations disclosed. The general time-frequency trade-off is only one component of the total temporal uncertainty, not a complete timing budget.

Copyright 2026, James M. Atkinson

The most persuasive result, therefore, is not the smallest numerical bin or brightest waterfall trace. It is a measurement whose source model, window, clock state, uncertainty and alternatives can be independently examined. A candidate's visibility across several window choices may support robustness, but because those analyses reuse the same IQ record, their agreement is not equivalent to independent receiver corroboration. A second properly characterised sensor, a source intervention or a repeat acquisition under changed physical conditions can supply the additional discrimination that mathematical reprocessing alone cannot. I pass the floor respectfully to Dr Hamming, who may ask whether my emphasis upon window trade-offs leaves sufficient room for specially designed concentration-optimal windows.

Richard Wesley Hamming | Peer question 1 to Dennis Gabor

Professor Gabor, a general statement about the time-frequency trade-off can conceal considerable freedom in how energy is distributed within an admitted interval. The prolate concentration problem, for example, asks how well a finite sequence may concentrate its energy within a selected frequency region. An engineer can use such sequences to reduce spectral leakage and improve the visibility of weak signals beside stronger emissions. How would you distinguish that genuine improvement from the false claim that a shorter physical burst has somehow yielded an unlimited number of independently resolvable spectral features? If the analyst selects a taper after inspecting the putative emission, must the resulting peak significance be treated as exploratory? I should also ask whether several orthogonal tapers applied to the same raw interval can be described as independent physical

Copyright 2026, James M. Atkinson

evidence or only as complementary numerical estimates derived from one acquisition, and what validation would be required before the laboratory could rely upon their agreement.

Dennis Gabor | Immediate answer to Richard Wesley Hamming

Dr Hamming, the concentration problem is an important refinement of analysis-window design, not an escape from finite observation. A taper may be chosen to place a relatively large fraction of its spectral energy in a selected band and to suppress leakage into others. This can improve a particular estimator or detector under conditions for which the design is appropriate. It does not supply samples from times outside the recorded interval, and it does not establish that an unknown emitter obeyed the signal model used to choose the taper. One must distinguish efficient use of finite information from creation of new information.

Multiple orthogonal tapers can provide complementary spectral estimates, and they may support a variance-reduction calculation under appropriate stochastic assumptions. But the raw observation interval is common to all of them. Their outputs are not independent physical acquisitions merely because the numerical sequences are orthogonal. The laboratory should evaluate the estimator covariance and the source population rather than equating mathematical orthogonality with independence of external causes. If a narrow candidate appears under several tapers, its resilience may be useful evidence about the record's structure, yet a common analogue artefact can survive all of them as well.

Copyright 2026, James M. Atkinson

Where the taper is chosen after the event is identified, I would describe the choice as part of exploratory analysis. A subsequent frozen detector can be challenged on independent bursts and no-signal controls to obtain a valid performance statement within the tested envelope. The test should include different burst durations, hop phases, signal amplitudes and strong interfering carriers. That procedure can determine whether a concentration-optimised taper reveals genuine weak events without producing a prohibitive rise in artefact detections. A claim about physical origin still requires discrimination among receiver-generated features, innocent transmissions and the proposed source.

The resulting report should preserve enough information to reconstruct the actual estimator: taper coefficients or an exact versioned definition, FFT length, scaling convention, input sample-rate and timebase, and any averaging or threshold adaptation. It should state whether peak frequency and bandwidth are merely algorithmic outputs or have been validated as estimates of physical quantities. The operator may legitimately favour one taper for a specified forensic task. Scientific discipline requires that the favour be supported by an experiment whose outcomes could have shown the taper to be inadequate. I return the floor to Professor Slepian for his principal treatment of spectral concentration and its conditions.

Copyright 2026, James M. Atkinson

David Slepian | Principal response 2: Concentration is conditional on the admitted support and signal class

Dr. Atkinson, the relevant mathematical problem is not simply to find a window with a pleasing spectral shape. It is to maximise concentration of a finite sequence in a selected frequency region under explicit constraints. That definition immediately supplies a limitation: the optimisation assumes the duration, region and objective have been chosen. It cannot certify the behaviour of an arbitrary unknown waveform outside that problem. A concentration-optimised taper may reduce leakage in a laboratory estimate and thereby make a weak adjacent component easier to observe. But its result cannot be interpreted without the source class, numerical precision, sample-rate and subsequent detector rule which determine whether the desired signal survives processing. [T2]

A high concentration ratio does not make all the energy outside a chosen band vanish, nor does it negate the fact that two physical emitters can be inseparable under limited time and signal-to-noise ratio. If the original burst is shorter than the effective analysis support, a window may weigh substantial periods containing only background noise. The estimated power of the burst can then change with the window's position and length. A different placement may give an apparently different bandwidth or peak amplitude without any physical change to the source. Validation should therefore vary arrival phase and measure event-level detection under the exact estimator rather than infer success from the taper's theoretical concentration alone.

We should also distinguish a representation designed for average spectral density from one intended to preserve the timing of rare transients.

Copyright 2026, James M. Atkinson

The former may profit from averages across many windows or tapers, while the latter needs event-sensitive retention and a truthful account of the arrival interval. An average of power spectra can be a satisfactory estimate of the background and simultaneously a poor way to describe a brief emission. A robust median may resist isolated outliers by design, yet those outliers may be the very transmissions the investigator was assigned to discover. The appropriate tool is determined by the proposition, not by an abstract claim that one estimator is universally superior.

Finally, the evidential value of a spectral feature must be separated from the beauty of its mathematical representation. A calibrated source injected at a defined RF reference plane can demonstrate how the receiver reports a known transient. A controlled change of clock, gain, preselector or input termination may help distinguish internal images from external emissions. A second independent acquisition can test whether a feature persists under conditions where competing hypotheses make different predictions. The analyst should preserve raw samples and processing version wherever possible; a displayed spectrogram alone cannot establish which details were discarded in its construction. I invite Professor Fourier to question whether any finite numerical transform can uniquely identify the physical source of a short burst without further assumptions.

A concentration ratio is a property of a precisely specified operator, observation interval, and frequency interval. If the operator is changed, the ratio need not retain its old value. This apparently austere observation has an immediate bearing on the investigation. A burst may be received through a narrow analogue preselector, translated by a local oscillator, windowed after decimation, and finally represented in a discrete Fourier transform. At

Copyright 2026, James M. Atkinson

each stage the admitted interval and transfer relationship differ. The first prolate sequence maximises energy concentration only for its stated mathematical problem. It does not optimise every detector, every waveform, every timing estimate, or every forensic claim. We should not place a ceremonial label of optimality upon a taper without stating what has been optimised.

One must also distinguish a waveform confined to a time interval from one merely observed within that interval. A perfectly time-limited nonzero waveform cannot simultaneously be strictly band-limited. The measured record is finite, but the receiver's filter may carry energy into the retained interval from an earlier input; likewise energy attributable to an event near the interval's end may persist beyond the final retained sample. A finite capture is an epistemic boundary rather than proof of finite source support. The examiner who reports an emission of exactly two milliseconds' duration merely because two milliseconds of samples survived has confused the observation gate with the transmitter's gate. The omitted prehistory and after-history may be material, particularly when measuring pulse edges, phase continuity, or occupied bandwidth.

Consider two classes of inference. In the first, a known analytic waveform arrives with unknown delay and amplitude in additive noise of characterised statistics. An estimator may exploit the known form to derive a delay parameter with uncertainty much smaller than the width of an individual analysis window. In the second, an unknown intermittent emitter has an unrecorded phase history, perhaps a drifting oscillator, and a modulation never specified in the acquisition plan. The same numerical precision cannot be claimed by simply applying the first estimator and concealing its

Copyright 2026, James M. Atkinson

premises. A method's mathematical efficiency within its model is not proof of model validity. Validation requires synthetic and physical challenges in which the signal class and nuisance variation reflect the proposed forensic task.

Frequency smoothing must be considered in the same manner. Concentrating energy into a selected band can reduce leakage from signals outside that band, but the taper may also attenuate or spread a brief desired event. The effect depends on the signal's location within the time support. For a window whose amplitude is small near its ends, an event arriving there may have a low detection probability although a long tone at the window centre appears splendidly resolved. Overlapping windows mitigate some boundary losses, but they introduce dependent calculations and can spread one event into several displayed frames. Neither the number of pictures nor the visually smooth contour supplies an independent count of transmitted bursts. I would therefore validate concentration and exposure together.

The evidence package must retain the taper coefficients or reproducible generation rule, the exact sample support, the effective noise bandwidth, the start time of each segment, the detector threshold and every exclusion or missing interval. A report should say whether its spectrum is a power estimate, an amplitude estimate, a phase-aware coherent statistic or merely a display. If the analyst selects whichever taper produces the narrowest attractive peak after examining the unknown event, the selection itself becomes part of the inferential procedure. The relevant false-alarm probability must account for that search, and the archive should retain the alternative parameter trials. Professor Gabor's broader question about joint

Copyright 2026, James M. Atkinson

time-frequency knowledge is therefore not defeated by a concentration theorem. It is sharpened into a demand that the investigator identify the operator whose result is being interpreted.

A practical acceptance campaign should include at least three contrasting inputs: a sustained tone near the anticipated carrier, a brief gated tone placed at several unknown phases relative to the analysis windows, and a broadband impulsive interference event. Each should be tested both alone and beside stronger adjacent activity. Let the examiner predict in advance which display structures ought to appear and which ought not. Observe whether a short burst is detected with the declared probability across the entire scan cycle; compare the measured footprint with the known injection duration; and separate any window-dependent broadening from the source's physics. In the absence of these challenges the investigator may truthfully report the computed transform, but must not assert an instrument-independent time-frequency portrait. I pass the floor, with respect, to Dr Tukey for a question about the risk of discovering the analysis settings after observing the most impressive candidate.

John Wilder Tukey | Peer question 2 to David Slepian

Professor Slepian, your concentration framework provides a rigorous answer to a problem whose boundaries have been stated beforehand. Yet a field examiner may search a recording using many windows, many lengths, several time-bandwidth products, different zero-padding factors and alternative noise estimators. The examiner then selects the display that gives one weak burst a visually compact bright region and presents it as though that representation had been chosen independently of the data. Nothing in the calculation is numerically false, but the evidential

Copyright 2026, James M. Atkinson

meaning of its apparent precision has been altered by selection. How would you distinguish legitimate exploratory analysis from confirmatory measurement under such circumstances? Would you require a held-out recording, a physical replay with randomly placed bursts, a correction for multiple comparisons, or a more modest statement confined to the chosen representation? I am especially concerned that investigators may select a time-frequency picture whose parameters favour the known candidate while still making broad claims about negative findings for all other events that the same analysis may have suppressed.

David Slepian | Immediate answer to John Wilder Tukey

Thank you for that question. Dr Tukey, I would welcome exploration and reject its disguise as pre-specified confirmation. The distinction can be made operationally. The investigator should mark which processing decisions were chosen before examining the contested event and which were chosen because of what appeared on the screen. The latter decisions need not be discarded. They can generate hypotheses, suggest alternative filter configurations, or identify the reference signals most likely to reveal an artefact. They cannot automatically inherit the confidence statement that would have applied had one test been stipulated in advance. A discovery path is evidence about how the hypothesis arose; a validation path is evidence about how it survived attempted falsification.

In a practical validation design, preserve the chosen analysis unchanged and submit it to independently prepared challenges. The challenge may involve physical injections at the receiver input, or rigorously documented simulations where the model is sufficient for

Copyright 2026, James M. Atkinson

the narrower software proposition. Randomise burst phase, duration, amplitude, frequency, overlap with adjacent activity and the receiver's scan state. Include null trials. Save every outcome, not just those consistent with the favourable display. A held-out recording can help for an existing signal class, but if both training and validation data share an unrecognised receiver artefact, the split does not by itself establish external origin. An intervention at a physical reference plane may provide information unavailable from partitioning a single digital archive.

The confidence statement must correspond to the tested procedure. If the examiner selected the most successful of twenty parameter settings after seeing the original observations, the performance of that selection rule should be tested, or the report should explicitly say that the displayed result is exploratory. There is no universal multiplication factor that rescues every selection process; dependence among trials and the details of adaptation matter. Nor may an investigator infer wideband non-detection from a search optimised for one discovered burst. A procedure which concentrates the energy of one signal class may deliberately reject another. The negative claim therefore needs a specified signal population, admitted input range, observation exposure and empirically tested operating characteristics.

Finally, the archive should make the analysis reproducible without confusing reproducibility with validation. Retain the raw sample interval, software version, coefficients, parameters, numerical precision, time references and alternative analyses which materially

Copyright 2026, James M. Atkinson

influenced the conclusion. A separate examiner should be able to recreate the picture and then challenge its interpretation. The most useful result may be a bounded one: a feature survives a particular declared set of analyses, but its occupied bandwidth and origin remain dependent upon additional assumptions. Such intellectual restraint is not retreat. It is the correct consequence of a finite record and an estimator designed for a finite class of questions. I pass the token respectfully to Professor Fourier, who can separate the transform's exact mathematical identity from the physical hypothesis it is employed to support.

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier | Principal response 3: Representation, inversion and the non-uniqueness of physical sources

Dr. Atkinson, I begin with a distinction that is deceptively elementary. A transform can be exact for the values supplied to it while the values themselves are incomplete measurements of the physical event. If a receiver retains N complex samples, a discrete Fourier transform produces N coefficients related by an invertible linear transformation, subject to the adopted numerical precision and convention. This result means that the transform of those N numbers need not lose information if every coefficient is kept without destructive alteration. It does not mean that the N numbers uniquely specify the analogue input before the antenna, front-end filter, mixer, sampling aperture and finite observation gate. The distinction between an invertible transformation of a record and an invertible measurement of nature must be maintained throughout the forensic report.

A finite-duration burst offers several levels of potential description. The analyst may wish to locate a maximal-energy time interval, estimate a nominal carrier under a chosen modulation model, report a spectral centroid, or test for two closely spaced emissions. A single plotted peak does not determine which of these propositions has been established. Consider a rectangular gate multiplying a sinusoidal carrier. The observed Fourier transform contains the transform of the gate, so energy appears away from the carrier because observation duration is finite. Applying a tapered window can reduce sidelobes at the price of widening the principal lobe and modifying the amplitude estimator. Interpreting that spread as transmitted spectral occupancy without accounting for the window would mistake the method for the object.

Copyright 2026, James M. Atkinson

The inverse problem is more severe when the waveform was compressed by thresholding, magnitude-only display or time averaging. A power spectrogram has discarded phase relationships that may be indispensable to determining whether neighbouring bright regions derive from one coherent burst or several emitters. Two waveforms may share a magnitude spectrum while differing markedly in phase and temporal structure. Unless the source class supplies additional constraints, selecting one plausible inverse is not reconstruction of a uniquely observed past. Likewise an absolute timing statement cannot be recovered from a spectrogram whose original time stamps, filter delay and clock corrections were not preserved. The analyst who retains only the coloured waterfall has retained a picture rather than all of the evidence needed to test its construction.

A particularly dangerous temptation lies in the interpretation of zero padding. Let N denote the number of acquired samples over duration T and let N_z denote the length of a padded transform. The displayed bin spacing changes from F_s/N to F_s/N_z, but the observed duration T and the noise realisation remain unchanged. Interpolated samples of a continuous transform may make it easier to locate a peak or fit a stated parametric model; they do not supply additional independent physical observations. In a sufficiently favourable known-tone model, a frequency estimator can achieve uncertainty smaller than 1/T by exploiting signal-to-noise ratio and phase structure. Such performance does not contradict finite-duration uncertainty. It depends upon assumptions which an unknown, unstable or modulated emitter may fail to satisfy. Precision must therefore be reported with both estimator and waveform class.

Copyright 2026, James M. Atkinson

I would demand separation of three tests. The first establishes numerical correctness: is the discrete transform implemented with the stated sign, normalisation and window convention, and can another examiner reproduce it? The second establishes measurement traceability: did the receiver measure the declared input quantity with an adequately characterised amplitude, phase and timing transfer? The third establishes inference validity: does the observation distinguish the particular external-source hypothesis from internal mixing, local oscillator leakage, overload, reflection or another transmitter? Passing the first test does not guarantee the second or third. One can render a perfectly accurate spectrum of a receiver-generated artefact.

The examiner must also consider the physical gate. If the instrument triggers recording only after a detector threshold is exceeded, its retained interval has been selected by information not present in the archive. A one-millisecond capture may contain the terminal portion of a two-millisecond emission, and the missing onset may change every claimed time and bandwidth estimate. Pre-trigger recording may improve the situation when it genuinely existed in memory, but later retrospective interpolation cannot observe missing analogue history. The proper report distinguishes recorded event duration from verified transmitter duration, and it describes any invalid or unobserved intervals. A negative conclusion about transmissions outside the admitted observation cannot be inferred from the sampled segment.

The necessary comparison is not between competing aesthetic renderings of the same data but between hypotheses whose physical predictions diverge. An antenna substitution, input termination, known

Copyright 2026, James M. Atkinson

reference injection or controlled oscillator retuning may reveal whether a feature belongs to an external radio-frequency emission or to a receiver transformation. A second receiver provides useful corroboration only to the extent that the relevant errors are independent. A common reference oscillator, antenna distribution or trigger policy may create shared artefacts or omissions. The evidence record should make the dependencies visible so that agreement is not inflated into certainty.

The algebra permits many useful consequences. Windowed Fourier methods are valuable to localise and describe finite observations; transforms preserve and reorganise record information under stated conditions; and parametric models sometimes estimate parameters much more sharply than an unmodelled power plot. None of these propositions licenses a causal label from a bright rectangle. The investigator must state which mapping is mathematically invertible, which analogue transformations were calibrated, and which uncertainties survive. I therefore ask Dr Shannon to test my distinction at the boundary where a compressed spectral record may preserve one detection question while destroying another. With respect, I now return the floor to Dr. Atkinson for the next contribution.

Claude Elwood Shannon | Peer question 3 to Jean-Baptiste Joseph Fourier

Professor Fourier, you distinguish an invertible numerical transform from a physically reversible observation, and I agree that the distinction is fundamental. I would nevertheless ask whether the investigator must preserve every detail of the raw record to make a useful finding. Suppose a defensive monitor is configured only to decide whether a known

Copyright 2026, James M. Atkinson

signalling waveform occurred during a defined window. A matched statistic may be adequate for that task while discarding phase, interference structure or modulation details irrelevant to the specified hypothesis. If the retained sufficient statistic supports an accurate detector, insisting on the original wideband sample stream could impose extraordinary storage costs without improving that particular decision. On the other hand, an inquiry may later arise about source identity, phase coherence or a second previously unknown emission. How should an evidential policy reconcile these different futures without simply declaring every lossy compression illegitimate? I ask you to distinguish information sufficient for a specified question from information sufficient for unanticipated forensic questions.

Jean-Baptiste Joseph Fourier | Immediate answer to Claude Elwood Shannon

Dr Shannon, I would not declare that every lossy reduction is impermissible. My objection is to an undisclosed change in the proposition. A compressed statistic may be an excellent and independently validated instrument for the predeclared question that motivated its design. It does not thereby retain all the information an adversarial examiner might later require. An archive policy should distinguish records intended for operational discovery from records intended to sustain contested physical claims. The former may retain a detection statistic, a threshold, a time tag and a configuration identifier; the latter may require unaltered IQ samples or a demonstrably lossless form, with sufficient pre-trigger and post-event context to test competing explanations.

Copyright 2026, James M. Atkinson

We must define sufficiency within a model, not as an unqualified property of the compressed file. A matched-filter output can be sufficient for estimating a known signal's amplitude in a particular Gaussian noise model, but the model excludes arbitrary interfering emitters, nonstationary receiver artefacts and unknown transformations. The same scalar may fail to reveal whether the observed peak resulted from overload or correlated local oscillator activity. A later question may demand an observation the compression irreversibly discarded. In that circumstance no skill in subsequent computation can manufacture the missing degrees of freedom. The correct conclusion is restricted, not necessarily false.

I propose a practical hierarchy. Preserve a compact continuous operational log covering the measurement envelope, calibration state, threshold policy, time base and invalid intervals. For material detections, retain raw windows around the candidates whenever the architecture permits. For exceptionally consequential findings, preserve representative background intervals, controlled challenge recordings and independent corroboration data. When resources prohibit complete retention, document the selection rule and quantify its limitations. A triggered record is not a continuous survey merely because its timestamp counter ran continuously. A claim of non-detection should be conditional upon the actual exposure and validated sensitivity.

An audit should ask the examiner to reproduce the declared result from the surviving data and to identify two plausible alternative waveforms that the reduction would make observationally

Copyright 2026, James M. Atkinson

indistinguishable. If the alternatives matter to the conclusion, the retained statistic is inadequate for that stronger claim. The exercise directly tests the boundaries of sufficiency. It also prevents a false reassurance drawn from a small file that is perfectly reproducible but physically ambiguous. Mathematical precision and evidential completeness are not enemies; they become compatible when the question and preserved boundary are both stated. I invite Professor Neyman to examine whether the uncertainty reported for a fitted transient can survive the analyst's opportunity to choose the most favourable window after seeing it.

Jerzy Neyman | Peer question 4 to Jean-Baptiste Joseph Fourier

Professor Fourier, I appreciate your insistence upon specifying the inference rather than merely displaying a transform. Yet the operator may search hundreds of time positions and numerous window lengths, then fit a carrier parameter to the strongest resulting peak. The familiar standard error of a single fitted frequency presumes a model and often a fitting procedure chosen before that selected observation. Selection across the record changes the distribution of the estimator and the meaning of a nominal confidence interval. How can the investigator report a technically useful interval without concealing the search that produced the candidate? Should the analyst correct for every possible processing choice, repeat the measurement with a newly constructed challenge campaign, or report an explicitly exploratory estimate and postpone stronger claims? I would also ask how missed detections at the edges of the selected windows affect any subsequent statement that the receiver had surveyed the whole admitted band reliably.

Copyright 2026, James M. Atkinson

Jean-Baptiste Joseph Fourier | Immediate answer to Jerzy Neyman

Professor Neyman, the mathematical transform cannot answer a question concerning sampling of possible experiments unless the experiments are first defined. I would therefore separate the numerical representation, the estimator selected after exploration, and the inferential procedure whose coverage the laboratory claims. The displayed peak is a fact about the calculation. A nominal error bar computed for an unselected pure sinusoid is not automatically valid after searching many windows and retaining the strongest result. An investigator may report the numerical fit as a model-dependent exploratory estimate, identify the search settings and refrain from claiming its nominal confidence level. A stronger claim requires a performance evaluation encompassing the actual selection process or a separate validation procedure fixed in advance.

A physical replay or independently prepared reference dataset can test the entire pipeline, not just one transform stage. The challenge designer should vary burst onset relative to the windows, duration, frequency, amplitude, modulation, adjacent interference, and receiver operating state. A useful validation distinguishes the event-level detection rate from the fraction of windows that cross threshold. A single emission may illuminate three adjacent frames; counting those frames as three successes inflates effective sample size. Conversely, a weak event at a taper edge may be missed even though a centre-aligned test succeeds repeatedly. The results must include unfavourable and invalid trials.

Copyright 2026, James M. Atkinson

The condition of the analogue input remains essential. A post-acquisition software simulation can validate a numerical transform, but it may bypass front-end compression, oscillator transients, antenna mismatch and acquisition gaps. Where the claim depends on physical sensitivity or source attribution, a calibrated injection at a declared reference plane adds a necessary form of challenge. Changes of antenna or independent receiver configuration can test internal artefacts. A system should not pass a stronger claim merely because its display has high numerical precision.

One might finally report an interval conditional upon a fully specified signal model and a declared search procedure whose coverage has been checked, and separately report the observed FFT grid. The two numbers need not match and should not be made to match by rhetorical force. If the evidence supports only a statement that a candidate feature occurred within a recorded interval and a broad frequency region, that statement can still justify further investigation. It is better than an unsupported assurance that a particular transmitter operated at an apparently exact frequency. I now pass the floor with respect to Mr Nyquist, who can examine how analogue sampling and aliasing place additional conditions upon this already qualified representation.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 4: Sampling, analogue admissibility and conditional frequency claims

Dr. Atkinson, one must not infer that the precision of a digital frequency axis establishes the physical frequency of an emitter. The relationship between a continuous input and its samples depends upon the admitted analogue bandwidth, the sampling schedule and the absence of uncharacterised alias contributions. In an ideal uniformly sampled complex-baseband system, a waveform whose spectrum is confined to the specified Nyquist region can be reconstructed under the requisite assumptions. A real SDR uses an antenna, preselection, gain stages, mixing, analogue filtering, sampling apertures, numerically controlled oscillators and digital decimation before producing the samples subsequently analysed. Each transformation has a stated transfer and an operating envelope. The spectrum presented on the monitor is a derived representation of that chain, not a direct photograph of a transmitter's oscillation.

A short burst is especially sensitive to boundary conditions. Its abrupt envelope contains frequency components broader than those of its carrier alone. If a receiver's analogue passband or decimator suppresses part of that envelope spectrum, an attempted reconstruction of the burst's onset can show ringing and changed apparent duration. Such changes may be perfectly consistent with correctly functioning filters, but they become forensic hazards when the analyst mistakes an instrument response for the source's physical timing. The apparent first nonzero output sample depends on the threshold, filter impulse response, time reference and noise. An analyst must distinguish a time stamp for the centre of a digital analysis

Copyright 2026, James M. Atkinson

frame from a time stamp assigned to the physical onset of RF energy at the nominated reference plane.

When the source frequency is unknown, alias uniqueness becomes a separate question. Sampling a real-valued input without sufficient analogue restriction can map different input frequencies to the same digital frequency. Sampling complex IQ can preserve the sign of frequency relative to an appropriately calibrated oscillator, but an image introduced before conversion or an I/Q sign error may still masquerade as a different physical band. The examiner should vary the tuning state or use a separately characterised path so that rival hypotheses predict different movements of the indicated line. A digital frequency number which stays fixed after one software resampling operation may only demonstrate consistency of an implementation, not external origin.

The finite-window problem and the analogue problem must be kept analytically distinct. If a known sinusoid of stable phase occupies a measured duration T, the frequency estimation uncertainty may be studied with a specified signal model and noise covariance. If the transmitter chirps, changes phase at its burst edges, or produces unmodelled modulation, fitting a single carrier may identify a convenient average rather than the input's physical oscillation at a particular instant. A time-frequency display can suggest such model failure by showing a moving ridge, yet the ridge itself may have been altered by window choice and filter group delay. An uncertainty budget that considers only FFT bin spacing is consequently incomplete.

The operating record should preserve the aggregate sample rate and any fractional-rate conversion; the analogue front-end bandwidth and

Copyright 2026, James M. Atkinson

measured rejection outside it; the local oscillator tuning and accuracy; the clock reference and time-tag epoch; the actual filter coefficients; and the locations of missing blocks or receiver-state transitions. A recorded transform should identify the sample indices admitted, the effective noise bandwidth of the window, the treatment of overlap and the means of amplitude normalisation. These facts permit another examiner to reproduce the numerical result and to determine whether the reported event could have been reshaped by the measurement process. Without them, the displayed candidate may be interesting intelligence but weak evidence for a precise transmitter duration or carrier estimate.

I also propose a simple falsification campaign. Inject a known short burst at a characterised RF input plane and vary its onset across a full window-hop period, its nominal carrier across the relevant passband and its amplitude from comfortably above threshold to the detection limit. Add strong neighbouring signals to test nonlinear responses. Repeat with a new tuning state and, where the claim is consequential, an independently characterised receiver path. Compare the acquired raw IQ with the stored spectral display. If a known one-millisecond burst produces apparent three-millisecond persistence in a waterfall because of filter ringing and overlapping frames, the display is not necessarily defective. The report is defective if it calls three milliseconds the physical emission duration without calibration.

A null survey demands the corresponding exposure calculation. If a scanning receiver listens to a particular channel during only a fraction of its monitoring period, a transmission can pass unobserved even if the receiver is highly sensitive whenever tuned. The detector's conditional success probability must be multiplied or otherwise combined with the probability of

Copyright 2026, James M. Atkinson

temporal and frequency overlap under a justified event model. A negative result is not stronger because the waterfall looks quiet during a brief observation. Likewise many overlapping frames around a known event do not create as many independent physical trials.

What then is a defensible conclusion? The analyst may state that a feature, consistent with a specified signal model and after calibration of the front end and time base, was observed within a bounded time-frequency region. A sharper carrier or onset claim is possible when the model, reference plane, uncertainty and challenge tests support it. The present method cannot identify a specific device merely from an apparent transform peak. A physical source is an inference about a chain of causes, not the label attached to a numerical bin. I hand the floor, with respect, to Professor Bridgman for the question of what operation must define the quantity the examiner says has been located.

Percy Williams Bridgman | Peer question 5 to Harry Nyquist

Mr Nyquist, your description of the analogue and numerical boundaries is carefully qualified, but I should like to examine the quantity being reported. Two laboratories may acquire the same burst through different bandwidths and windows. One records the first sample exceeding a fixed amplitude threshold; another estimates the centre of an energy distribution; a third obtains the time of the largest matched-filter response. All three may publish an 'arrival time' with many decimal places, and each may reproduce its own number exactly. What physical event, if any, have they measured in common? If their operational definitions differ, it seems premature to combine the results into a time-difference localisation estimate. What calibration or demonstrated

Copyright 2026, James M. Atkinson

transformation would make them comparable? I am also concerned by the practice of adjusting thresholds after an event has been found. Such adjustments can move the apparent onset without moving anything in the external world. How would you state this limitation without making every useful measurement impossible?

Harry Nyquist | Immediate answer to Percy Williams Bridgman

Professor Bridgman, the observation you describe identifies a vital distinction between a named parameter and its realised estimator. An 'arrival time' is not a complete measurand. The examiner should identify the reference plane and the physical feature whose timing is sought: perhaps the onset of a stipulated envelope, the crossing of a stated power threshold at the receiver input, or the relative delay between two receivers under a shared signal model. The estimator then requires a calibrated transfer from physical event to numerical time tag. Two estimates that operate upon different features cannot be equated merely because each carries the label arrival.

A threshold crossing is useful when it is described honestly. Its value depends upon noise, gain, filtering, sampling phase and the threshold itself. If the threshold is adjusted after the observation, the resulting number may remain reproducible but will not have the coverage attributed to a predeclared procedure without additional validation. An energy centroid can be more stable for certain broad envelopes but can move with interference or truncated observation. A matched-filter maximum has valuable properties for a specified known waveform and noise model, but it need not coincide with the physical first emission of energy. Each estimator answers its own

Copyright 2026, James M. Atkinson

question and should be calibrated against the particular reference event required by the investigation.

For a time-difference comparison, I would insist upon a common definition, or a measured relationship between the definitions with its uncertainty. The relationship must account for instrument group delay, reference-epoch offsets, sample-clock drift, filter states, threshold selection and the waveform class. A laboratory can establish such a relationship with known injected waveforms at several amplitudes, onset phases and modulation patterns. It should retain raw intervals and the estimator software so that another examiner can test the result. If the relationship varies materially with signal class, a universal conversion constant is inappropriate.

This does not make useful measurement impossible. It makes the claim conditional upon a procedure whose limits can be examined. One may report that a particular detector flagged an event at a stated timestamp, even when the exact physical onset cannot be recovered. That operational finding may justify another survey, a calibrated comparison or improved preservation. A stronger physical inference requires stronger evidence, not simply more digits on the timestamp. To avoid paralysing the investigation, classify results explicitly as discovery markers, calibrated measurements or source-attribution inferences, and state the evidence needed to promote a result from one class to the next.

The burden is proportional to the consequence of the conclusion. A minor discrepancy in the position of a burst marker may be immaterial to a broad monitoring report but decisive to a localisation

Copyright 2026, James M. Atkinson

claim based upon microsecond differences. The same acquisition could legitimately support the former while leaving the latter indeterminate. I therefore favour operational clarity, a reference-plane diagram and a direct challenge to plausible alternatives, rather than a misleading universal standard of numerical precision. I invite Mr Wiener to examine the dependence that arises when the detector selects the very records from which its time-frequency performance is later estimated.

Norbert Wiener | Peer question 6 to Harry Nyquist

Mr Nyquist, assume a monitoring instrument retains only intervals whose short-time spectral estimates exceed an adaptive threshold. The threshold is itself modified by a rolling background estimate, and that estimate includes previously detected bursts unless the operator explicitly excludes them. An investigator later examines the stored bursts, measures their apparent widths and carrier stability, and concludes that the receiver has near-perfect coverage of this class of events. Yet the archive contains only the events that the coupled detector and background estimator chose to admit. Does your account of sampling give us a way to make the missing records visible in the evidential logic? How should the laboratory challenge detector memory and feedback, especially where an earlier strong transmission changes the threshold against which a later weak burst is judged? I seek a practical distinction between stable operation and independent validation of the system's event-selection policy. In particular, the missing-event population must not disappear merely because it left no retained file.

Copyright 2026, James M. Atkinson

Harry Nyquist | Immediate answer to Norbert Wiener

Mr Wiener, your challenge concerns the difference between the population presented to the receiver and the population retained by its policy. It is not enough to verify that the samples in an admitted window correspond to the stated time base. One must also characterise the selection function by which some intervals are retained and others disappear. The selection policy includes threshold dynamics, background estimators, hold-off periods, buffer availability, gain switching and any changes of analysis window. If those states are recorded, the examiner can identify where negative evidence is impossible and where a conditional detection probability might be established. Without them, the archive is a selected subset of uncertain representativeness.

I would design a challenge campaign in which controlled bursts arrive at unpredictable times before, during and after stronger legitimate transmissions. Vary their relative levels and time separations. Some trials should be deliberately constructed to stress background-estimator adaptation or trigger hold-off, even if these make the receiver look worse. Preserve every injected event's timing and class separately from the system's outputs, and compute event-level misses as well as repeated detections of the same physical burst. A detector which flags one burst in several windows should not receive several successes for one independent event.

The laboratory may model feedback state by preserving threshold trajectories or sufficient state snapshots. If the adaptive background is an exponentially weighted average, state its update rule and

Copyright 2026, James M. Atkinson

effective memory. A current threshold may depend upon many earlier events. Merely preserving the threshold when a trigger fires does not reveal which unretained earlier signals influenced it. At the minimum preserve a continuous state log, invalid intervals and periodic reference challenges. Where resource limits preclude continuous raw recording, those limitations must appear in every statement about occupancy or absence.

For the admitted events, the short-time transform may still support useful bounded measurements. The detection count should be reported relative to the validated exposure population. Its absence from a later interval should be characterised as no alert under the stated policy, not proof of an empty radio environment. The inference becomes stronger if independent monitoring or externally administered references show that the apparatus was receptive during that period. Such evidence must be independent of the same trigger rule where possible. A second logger driven by the same threshold would not correct the selection bias.

The problem is not peculiar to sophisticated software radios. Any measuring apparatus that chooses what to record has a selection boundary, but modern adaptive processing can make that boundary dependent upon its own history. The solution is to bring the selection mechanism inside the declared experimental system. The examiner must account for the observation policy alongside the samples, and must not read detection performance from a file of detections alone. I pass the token to Professor Neyman, whose statistical account can

Copyright 2026, James M. Atkinson

determine how these qualifications enter the claimed confidence of a short-burst finding.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal response 5: Confidence intervals, validation populations and the evidential cost of searching

Dr. Atkinson, the language of precision is particularly hazardous when it is attached to a result selected because it appeared impressive. A confidence interval is not a blessing bestowed upon a number by algebra. It is a procedure whose long-run coverage depends on a specified family of data-generating mechanisms, a sampling design and a rule fixed before application or evaluated as part of the design. The forensic observer may search across frequencies, time positions, transforms and window lengths, then choose the sharpest estimate. That procedure differs from fitting one predetermined known waveform to one predetermined acquisition interval. Its nominal interval may not cover with the stated probability. We must distinguish the result of a calculation from the operating characteristic of the complete process that generated and selected it.

For an event detector, define an eligible physical event rather than a bright pixel. Let N_e be the number of independently prepared challenge events actually exposed to the specified receiver state, and D_e the number detected under a fixed event-level success rule. The empirical proportion D_e/N_e is meaningful only for the challenge population and the admitted exposure conditions. A burst near a window boundary may experience a different detection probability from one at the centre. A burst beside strong adjacent activity may be masked even though the isolated calibration tone was found without difficulty. If the user intends assurance across multiple operating strata, a pooled average weighted towards easy trials can conceal failure in the weakest stratum. Validation should therefore report results by

Copyright 2026, James M. Atkinson

frequency, duration, amplitude, window onset, interfering signal and receiver state where those distinctions are material.

The temporal support of the estimator is also part of its performance. Suppose a 2-millisecond burst triggers several overlapping 8-millisecond analysis frames. Those frame counts are not independent Bernoulli experiments concerning the presence of three physical emissions. One known burst is one challenge event for the event-detection question, while the several frames may be repeated dependent numerical measurements of it. If the objective is frequency estimation, the appropriate experimental unit may instead be a controlled burst record acquired in one independent trial. Treating dependent frames as independent can yield artificially narrow error bars and false confidence in the stability of the estimated carrier.

The role of multiple testing must be expressly defined. If an examiner searches a thousand independent null bins with a threshold producing one-in-a-thousand per-bin false-alarm probability, the chance of at least one false alarm is not one in a thousand; under that idealised independence model it is 1-(0.999)^1000, which is about 0.632. Frequency bins and overlapping windows are rarely all independent, so this particular number is not a field-system prediction. Nevertheless it illustrates the danger of transferring a single-test threshold to a searched image. A conservative union bound can control the probability of one or more false alarms without requiring independence, while an empirically validated detector can sometimes perform better when correlations are known. The test population and statistic must be stated.

A signal parameter may be estimated more precisely than an FFT bin interval under an appropriate known-waveform model, but the uncertainty

Copyright 2026, James M. Atkinson

of that estimate must include nuisance parameters. Receiver frequency error, clock drift, window timing, unknown chirp rate, sample loss and the decision to select one peak can each produce bias or extra variance. A calibration source may constrain some of these, yet a model fitted to the calibration source may not apply to a structurally different hostile emission. The confidence interval for a sine-wave carrier in Gaussian noise does not directly become an interval for the centre frequency of an unknown spread-spectrum burst. Parameter definitions, hypotheses and test populations must be explicit.

I would preserve exploratory findings, but keep them in their proper evidential category. Exploratory analysis may reveal a plausible carrier, a repetition pattern or an interference mechanism that deserves a directed test. To confirm the directed hypothesis, freeze the pipeline and submit it to independently constructed challenge observations. The reference experiment must include null trials, near-threshold events and difficult timing positions, and should retain failures rather than correcting the procedure until the unfavourable observations disappear. If adaptation is essential to the instrument's operation, validate the adaptation itself as a policy with defined state histories. A statistical assurance statement based upon one favourable demonstration is merely an untested prediction.

There is also a legal and investigative difference between establishing that a candidate was observed and establishing that a particular source caused it. A detection performance test addresses the former under declared hypotheses. Source identity requires alternative causal explanations and discriminating interventions. Receiver-generated spurs, aliased external transmissions, electromagnetic coupling, intermodulation,

Copyright 2026, James M. Atkinson

and unrelated devices can create features with similar time-frequency footprints. One should test the consequences of retuning, termination, antenna substitution and independently characterised reception. Even a very small false-alarm probability for a known candidate detector does not by itself assign a posterior probability that the candidate came from one named device.

My preferred conclusion is conditional but useful. Report the actual observed transform and its processing settings, the physical exposure and candidate selection rule, the uncertainty for any fitted parameter under a declared waveform model, and performance bounds from a representative challenge campaign. Distinguish non-detection from absence, and distinguish the instrumental detection question from an identity assertion. Where no relevant challenge trials exist, report uncertainty explicitly instead of inventing confidence through decimal places. Precision is a property of the validated inference, not of the typographic display. I shall gladly receive one final question from Professor Fisher concerning whether parametric confidence and the empirical validation of a field detector may be confused.

Sir Ronald Aylmer Fisher | Peer question 7 to Jerzy Neyman

Professor Neyman, imagine that a laboratory has completed one hundred calibration trials of a known 10-millisecond sinusoidal burst, and the resulting estimator has a remarkably narrow observed spread of fitted carrier values. The same operator subsequently investigates a faint, unknown, three-millisecond emission that may contain frequency modulation, changing amplitude and unresolved interference. The laboratory quotes the precision established for the known sinusoid and reports the unknown burst's frequency to a fraction of a hertz. Its

Copyright 2026, James M. Atkinson

numerical algorithm has behaved reproducibly, and its training trials were numerous. What evidence would allow the calibration distribution to support the subsequent unknown-emission inference? Should we treat the change of waveform class as an additional uncertainty component, a potentially complete model failure, or a matter resolved by a small number of additional trials? I also ask how an investigator can avoid the opposing mistake of rejecting every operational finding until a universal theory of all possible signals has been validated.

Jerzy Neyman | Immediate answer to Sir Ronald Aylmer Fisher

Professor Fisher, the established distribution belongs to the conditions under which it was established. If the unknown event is not reasonably represented by the calibration model, adding a casually chosen small uncertainty to its result is not an adequate repair. A fitted sine-wave frequency can be a mathematically well-defined parameter even when the real event is chirped; the parameter then describes a chosen approximation, not necessarily a physical oscillator's constant frequency. The discrepancy may be systematic and class dependent. One must test the model and, where necessary, change the measurand rather than merely enlarge a standard deviation until the result appears respectable.

I would begin by examining residual structure and alternative signal models. If the retained IQ supports a frequency trajectory, a model incorporating chirp may be more appropriate than a stationary carrier. If the record is too short or too severely filtered to distinguish plausible alternatives, the analysis should report the broader observable quantity: perhaps a frequency interval occupied by

Copyright 2026, James M. Atkinson

detectable energy during the admitted time window. Calibration trials should include waveform classes and interference conditions representing the claim. Where the question concerns a particular operational signal class, a finite validation campaign can be sufficient for a bounded conclusion without proving universal performance.

One must also preserve the difference between estimator uncertainty and classification error. A very narrow conditional interval for a model parameter does not establish that the model is correct, and a high probability of detecting a known signal does not establish which device emitted an unknown one. The latter questions require competing hypotheses and independent physical intervention where practicable. A source may be identified by a convergent record of modulation features, timing correlation, direction, antenna response and controlled exclusion of receiver artefacts; the frequency estimate alone seldom carries such a burden.

A practical report would include the calibration waveform, the population and trial count, the processing procedure, any exploration used to choose it, the actual observed data and their residuals, and the limitations caused by signal-class differences. The investigator may confidently state that a candidate feature was detected under a specified rule while qualifying its source identity or fine parameter estimates. This is a disciplined separation of claims, not a refusal to investigate. The Royal Society's classical discipline of measuring what can be measured is entirely compatible with a warning against attributing more to the instrument than its experiments warrant.

Copyright 2026, James M. Atkinson

I return the token courteously to Dr. Atkinson, who may now synthesise our distinctions and set out the numerical applications that make them inspectable.

Dennis Gabor, Cross-Peer Question to David Slepian: Professor Slepian, when an emission lasts ten microseconds, what objective should govern the choice between a narrow spectral main lobe and a short detection window?

David Slepian, Cross-Peer Answer to Dennis Gabor: Professor Gabor, no universal optimum exists without defining the signal class, detection loss and allowed observation support. A window concentrating energy in one frequency interval may spread or attenuate a burst whose arrival time is uncertain. Evaluate time-localisation bias, spectral leakage, false alarms and detection probability together, using injected bursts with randomised onset positions and occupied bandwidth. An FFT grid can be made arbitrarily dense through padding, but that does not create physical event duration or new independent information. Preserve the original time-indexed I/Q and the taper coefficients. A narrow visual line from one chosen window cannot by itself establish a continuous carrier or uniquely identify its source. I pass the token to Mr Fourier to examine what the transform represents.

David Slepian, Cross-Peer Question to Jean-Baptiste Joseph Fourier: Mr Fourier, can an inverse transform of a clipped or band-limited short-burst record uniquely re-create the physical RF pulse before the receiver?

Jean-Baptiste Joseph Fourier, Cross-Peer Answer to David Slepian: Professor Slepian, only under specific restrictions that make the forward map effectively invertible over the admitted signal class. Analogue filtering, clipping, missing samples and unknown phase can map distinct physical

Copyright 2026, James M. Atkinson

inputs to indistinguishable records. An inverse transform reconstructs a mathematical representation from available coefficients; it cannot recover discarded frequencies or unobserved amplitude history by declaration. Show the receiver transfer function, initial conditions, clock uncertainty and amplitude range, then test reconstruction with independently characterised pulses. A regular-looking waveform may be a property of an assumed band limit rather than evidence of a genuinely smooth transmitted signal. The examiner should preserve alternative physical explanations wherever the measurement map is non-unique. I yield to Mr Nyquist regarding sampling conditions.

Jean-Baptiste Joseph Fourier, Cross-Peer Question to Harry Nyquist: Mr Nyquist, why is the effective analogue passband relevant when an engineer argues that a nominal sample rate alone proves complete capture of a brief pulse?

Harry Nyquist, Cross-Peer Answer to Jean-Baptiste Joseph Fourier: Mr Fourier, the sampling theorem requires spectral and timing conditions. A short pulse can contain energy far beyond the displayed centre frequency, and a front-end filter may suppress important temporal detail before the first code is written. The nominal digital rate does not establish analogue input bandwidth, track-and-hold response, anti-alias rejection, jitter or headroom. Challenge the complete analogue-to-digital path with calibrated pulses of different rise times, amplitudes and arrival phases. Report which event characteristics remain estimable and their uncertainty, rather than speaking of the pulse as completely captured without bounds. If a sample is lost or the system retunes during the event, digital interpolation supplies no

Copyright 2026, James M. Atkinson

measurement of that missing interval. I pass the token to Dr Neyman for a defensible confidence statement.

Harry Nyquist, Cross-Peer Question to Jerzy Neyman: Dr Neyman, what conclusion follows if ninety-nine of one hundred prescribed short bursts are detected, while none of the challenges occurs near the window boundary?

Jerzy Neyman, Cross-Peer Answer to Harry Nyquist: Mr Nyquist, the trial fraction estimates performance only under the tested sampling arrangement. The programme has omitted a potentially vulnerable subset of arrival phases, so its observed success rate cannot be assigned to all possible bursts. Use a predeclared challenge population that covers onset, frequency, modulation, SNR and receiver state; include independent randomisation or a systematic worst-case matrix. Report uncertainty intervals for detection and false-alarm rates, with dependence between trials investigated. Do not silently discard failures or recast them as invalid after observing the data. The number of valid independent trials matters, but representativeness matters as well. A strong detection claim should survive hold-out conditions and a physically independent reference. I return the token respectfully to Dr Atkinson.

Moderator synthesis | Dr. James M. Atkinson

Our distinguished contributors have established that a short burst is not made a long, stationary signal by the convenience of Fourier arithmetic. The spectrogram may be precisely generated and visually elegant while the physical emission's onset, duration, carrier history and source remain uncertain. Professor Gabor has emphasised the joint character of time and frequency representation; Professor Slepian has shown why concentration depends upon a stated mathematical objective and support; Professor

Copyright 2026, James M. Atkinson

Fourier has separated invertible calculation from the potentially non-invertible path of measurement; Mr Nyquist has identified sampling, aliasing and filter delay as physical conditions of interpretation; and Professor Neyman has insisted that confidence belongs to a fully specified procedure, not to a chosen bright pixel. Their conclusions are complementary rather than contradictory.

The first practical consequence is to declare the measurand. An operator who reports 'the burst occurred at time t and frequency f' has not finished the description. Was t the leading-edge threshold crossing, the centre of a selected FFT frame, the peak of a correlation function or the centre of an energy distribution? Was f an FFT-bin centre, a spectral centroid, the estimated carrier of a stipulated stable-tone model or a frequency trajectory through the event? Which input reference plane, receiver configuration, sample interval and numerical processing history do these numbers describe? These definitions are not academic ornament. They determine whether another receiver can make a comparable measurement and whether the reported uncertainty has any evidential meaning.

The second consequence is to separate the actual record from the unobserved physical history. A finite capture may begin after the emitter started transmitting. A window may span samples acquired in different gain or calibration states. A receiver impulse response may extend a narrow event over several displayed frames. A magnitude-only archive may erase phase relationships indispensable to later questions. Zero padding can refine the presentation grid without creating new analogue observations. If the retained data do not distinguish two materially different possible inputs, no confident inverse should be claimed without naming the added

Copyright 2026, James M. Atkinson

assumptions. A bounded detection statement remains legitimate even when an exact source duration cannot be recovered.

The third consequence concerns the population of experiments. A handful of favourable, centre-aligned bursts does not establish coverage of difficult window-boundary cases or weak emissions beside strong activity. A thousand searched null locations do not inherit the false-alarm rate of one preselected test. Overlapping frames can measure the same event repeatedly but do not create independent emitted events. The proper campaign challenges the full acquisition and selection procedure, including its analogue front end, time base, filter state, scan exposure, thresholds and exclusions. Null trials and failed detections must remain in the archive; otherwise one has retained a success gallery rather than a validation record.

We have also preserved necessary qualifications. A known-waveform estimator may locate a frequency parameter more precisely than one FFT grid spacing, but only under its tested waveform and noise model. An optimal taper is optimal for the specified concentration criterion, not for every detection or attribution question. Agreement among receivers requires assessment of shared clocks, antennas and trigger dependencies. A frequency match alone is not an identification of a particular surveillance device. These boundaries are positive findings about what the record can and cannot sustain, not excuses to abandon useful instrumentation.

The final report should provide a concise chain of accountable propositions: the input and time reference planes; the retained raw observation and missing intervals; the window and transform parameters; the signal model and estimation rule; the uncertainties and nuisance variables; the population and outcome of relevant challenge trials; and the

Copyright 2026, James M. Atkinson

competing physical explanations not yet excluded. The investigator can then speak firmly where evidence permits and cautiously where several interpretations remain observationally equivalent. This is the foundation upon which an adversarial reviewer, a laboratory director or a court may test the conclusion without substituting rhetoric for reproducible measurement. Our next question concerns the use of multiple tapers and robust estimators, where reduced variance and leakage suppression must again be distinguished from the survival of rare events. I thank each colleague for the respectful passage of the token and close Question 045.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 045

Worked application 1. Computational bin spacing and acquired duration

Assume a complex-baseband sample rate F_s = 96,000 samples/s and a retained burst interval T = 0.004 s. Let $N = F_s T$ denote the number of samples actually acquired within that interval; N = 96,000 × 0.004 = 384. An unpadded N-point discrete Fourier transform has nominal bin spacing $\Delta f = F_s/N$ = 96,000/384 = 250 Hz. This is a property of the computational grid for the four-millisecond record, not a universal lower bound on parameter-estimation uncertainty and not a measurement of transmitter frequency stability. The calculation assumes uniform samples at the declared rate, no missing blocks and no change of oscillator state. Those conditions require evidence if the number is used in a forensic report. The uncertainty in a physical carrier must include the clock reference, analogue passband, waveform model and estimator procedure. [T1, T2]

Worked application 2. Zero padding changes sampling of the transform, not observation duration

Retain the same N = 384 observations, append zeros to form N_z = 4,096 Fourier inputs, and retain F_s = 96,000 samples/s. The plotted spacing becomes $\Delta f_z = F_s/N_z$ = 23.4375 Hz. This finer plotted interval is sometimes useful to interpolate the transform peak and to assist model fitting. It neither changes T = 0.004 s nor adds any independent observed phase history. The ratio between the grid spacings is 250/23.4375 ≈ 10.6667. Reporting 'frequency resolution improved by a factor of 10.7' without specifying that only the display grid changed would invite a false physical inference. A fair report calls it a zero-padded grid with 23.4375-

Copyright 2026, James M. Atkinson

Hz spacing and separately states the four-millisecond measurement support.

Worked application 3. A rectangular-gated tone exhibits a duration-dependent spectral envelope

Suppose a stable complex sinusoid of amplitude A exists for precisely T = 0.004 s and is zero outside that interval. Its continuous Fourier-transform magnitude has a sinc-shaped envelope centred at the carrier; the first zeros occur at offsets ±1/T = ±250 Hz, giving a null-to-null main-lobe width 2/T = 500 Hz. Here 'sinc' denotes sin(πu)/(πu), with u the frequency offset times T. The width follows from the stipulated rectangular gate and constant-frequency model. A physical transmission with shaped rise and fall, phase modulation, or filtering can have another spectrum. Observing a 500-Hz main lobe does not prove that the source radiated for exactly four milliseconds, because an acquisition gate or receiver filter can create similar spreading.

Worked application 4. A Gaussian time-frequency uncertainty product

For a continuously defined waveform whose time and frequency spreads are standard deviations σ_t (seconds) and σ_f (hertz) under consistent normalisation, the standard time-frequency uncertainty relation is $\sigma_t \sigma_f \geq 1/(4\pi)$. If $\sigma_t = 0.001$ s, the limiting standard-deviation spread is $\sigma_f \geq 1/(4\pi \times 0.001) \approx 79.5775$ Hz. The product is a property of the mathematical definitions, not an instrument noise specification, and it must not be conflated with FFT bin spacing or the occupied bandwidth of an arbitrary burst. An unknown modulation and measurement transfer may yield much broader observed energy. This example uses

Copyright 2026, James M. Atkinson

the ideal Fourier pair and does not certify the accuracy of any measured source parameter. [T1]

Worked application 5. An overlapping analysis window creates dependent frames

Take a window length N_w = 1,024 samples, hop H = 256 samples and F_s = 96,000 samples/s. The window duration is N_w/F_s = 10.6667 ms, while the hop duration is H/F_s = 2.6667 ms. The nominal overlap fraction is $(N_w-H)/N_w$ = 0.75, or 75%. A burst shorter than either interval may contribute to several successive frames because their supports intersect the same physical event. The exact frame count depends on event timing and window conventions. It would be erroneous to count those frames as independent emitted bursts or independent detector-success trials. The appropriate event identifier and clustering rule should be specified before validating event-level performance.

Worked application 6. Aliasing survives a beautifully computed time-frequency plot

Suppose a real-valued receiver samples at F_s = 24,000 samples/s while an insufficiently rejected analogue tone enters at f_a = 17,000 Hz. For the simple ideal real-sampling alias model, the observed positive-frequency alias is $|f_a-F_s|$ = 7,000 Hz, inside the 0–12,000-Hz Nyquist interval. A plotted 7-kHz line therefore cannot by itself establish that the physical input contained a 7-kHz tone. This example assumes a single tone, uniform sampling and negligible other analogue transformations. The investigator should demonstrate analogue rejection at the claimed reference plane or perform a controlled retuning or substitution test

Copyright 2026, James M. Atkinson

whose predictions differ between true 7-kHz content and a 17-kHz alias. [T3]

Worked application 7. Revisit exposure limits detection of brief events

Consider a receiver that observes a channel for dwell time $d = 4$ ms during every revisit period $R = 100$ ms, and suppose a physical transmission lasts $\tau = 1$ ms with an onset uniformly distributed across a revisit cycle. Assuming the instrument detects any positive overlap and has no additional latency, the onset interval producing some overlap has duration $d+\tau = 5$ ms, so the idealised overlap probability is $(d+\tau)/R = 0.05$, or 5%. This is not a measured detection probability: threshold sensitivity, filter transients, required integration time and the source-duration distribution can reduce it, and systematic event timing may invalidate the uniform-onset model. The example demonstrates that excellent within-dwell sensitivity does not establish continuous surveillance. The negative finding must state the actual exposure model.

Worked application 8. The cost of searching a thousand null opportunities

Let $K = 1{,}000$ statistically independent null tests each have single-test false-alarm probability $p = 0.001$ under a correctly calibrated threshold. The chance of one or more false alarms is $P_{FA,any} = 1-(1-p)^K = 1-0.999^{1000} \approx 0.632305$. A 0.1% false-alarm rate for one test does not imply 0.1% for a search over a thousand tests. Overlapping time-frequency coefficients and adjacent FFT bins are generally correlated, so this numerical value should not be applied literally to an arbitrary waterfall. Dependence-aware validation or a conservative union-bound

Copyright 2026, James M. Atkinson

argument is needed for a declared family of tests; the search and selection process itself must be included. [T4]

Worked application 9. What one hundred successful challenge events can establish

Suppose $N_e = 100$ independently prepared eligible bursts are injected under a fixed receiver state and all $D_e = 100$ are detected according to a predeclared event-level rule. The point estimate of detection probability is 100/100 = 1. With a two-sided 95% Wilson score confidence interval and $z = 1.96$, the lower endpoint in the all-success case is $N_e/(N_e+z^2) = 100/(100+3.8416) \approx 0.9630$. Thus perfect observed detection does not validate an unconditional 100% detection probability. More importantly, the interval is relevant only to the tested population and independence model. If all trials are easy centre-window bursts, it does not certify near-threshold edge events beside strong interference. The event population, state, selection rule and invalid trials must be preserved. [T4]

Worked application 10. Clock calibration may dominate the apparently fine frequency grid

Suppose a receiver estimates a carrier near $f_c = 500{,}000{,}000$ Hz, and its frequency reference has an uncorrected relative error of ±2 parts per million under the relevant operating conditions. The associated absolute error term is $\pm f_c \times 2\times10^{-6} = \pm1{,}000$ Hz. A plotted Fourier grid with 25-Hz spacing does not remove this 1-kHz reference uncertainty. The two quantities should be reported separately rather than added arithmetically without an uncertainty model. Other effects may include oscillator transients, sample clock errors and carrier instability. A traceable reference comparison or calibrated correction can reduce the

Copyright 2026, James M. Atkinson

uncertainty, but only its actually demonstrated scope should enter a forensic confidence statement.

QUESTION 046

Copyright 2026, James M. Atkinson

What is the proper evidential use of multitaper and robust spectral estimates?

Source: V011_Roundtable_Question_046_CP046_Dr_Atkinson.docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 046. Expert Roundtable Discussion

Original constructed educational dialogue, not authentic statements or quotations by historical participants. Contemporary SDR case studies are hypothetical and numerical calculations do not certify a particular instrument.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, the preceding question established that a short observation has finite time-frequency content and that a mathematically refined picture cannot recover an unobserved analogue past. We now consider two methods which have transformed practical spectral estimation, multitaper methods and robust summaries. Both can be excellent tools for defensive monitoring, yet both can also conceal an intermittent transmission if employed without regard to the investigative question. The operator sees a quiet black trace below the monitor's spectral grid while a narrowly timed emission leaves only a momentary footprint. A method designed to estimate stable background power may treat that footprint as an outlier and suppress it precisely because it is unusual. Conversely, a method designed to detect every bright transient may yield a burdensome false-alarm population. The choice cannot be reduced to preferring a statistically smooth curve.

Let x[n] denote N retained complex samples, v_k[n] the kth taper in an explicitly defined family, and X_k(f) the complex transform of x[n]v_k[n]. A

Copyright 2026, James M. Atkinson

simple multitaper power estimate is $S_hat(f) = sum_k\ a_k(f)|X_k(f)|^2$, where the nonnegative weights a_k sum to one under the declared convention. A weighted spectrum can provide better bias-variance trade-offs for certain stationary processes and finite records, particularly when the tapers are chosen through the discrete prolate spheroidal concentration problem. Yet the output power estimates reuse the same analogue event. Their numerical orthogonality does not create several independent radio observations. This distinction is indispensable when an expert witness asserts that a signal was corroborated by six tapers. The statement might support robustness to the estimator's window choice, but it does not imply that six receivers observed six independent emissions. [R1, R2]

We must distinguish three related but separate propositions. First, the power spectral density of a background process is a population property estimated from an observation interval under assumptions about stationarity and covariance. Secondly, a narrow line or transient is a candidate feature whose detection probability depends upon its amplitude, timing, modulation and the chosen estimator. Thirdly, attribution to a particular external source requires evidence about the physical input, receiver transfer, competing artefacts and independent challenges. A good estimator for the first proposition need not be a good detector for the second, and neither settles the third. A smooth average can conceal sporadic energy; a robust median may suppress one anomalous burst; and a powerful line detector may mistake receiver periodicity for an emitter. The loss is not always mathematical error. It can be a mismatch between the statistic and the forensic question.

Copyright 2026, James M. Atkinson

The issue becomes acute in wideband software-defined surveillance where thousands of bins and many window starts are examined. The apparent precision of a threshold crossing depends on how many tests were attempted, whether the background estimate was adapted from the same record and whether successive windows or tapers are correlated. Data-dependent selection among taper numbers, time-bandwidth products, noise summaries and peak definitions introduces further conditionality. An operator who changes parameters after finding a suspicious peak can investigate intelligently, but cannot then cite a confidence level calculated for a single predeclared estimator without accounting for the selection process. The laboratory must record both the exploratory path and the frozen confirmatory procedure.

Professor Slepian will consider time-limited concentration and the conditions under which orthogonal tapers furnish useful complementary estimates. Professor Bartlett will examine variance and covariance, including the effective number of degrees of freedom. Professor Tukey will address robust summaries and the preservation of meaningful outliers. Dr Shewhart will consider detector performance as an operating process rather than a collection of attractive plots. Dr Shannon will distinguish task-specific statistical sufficiency from retention adequate for future forensic questions. Seven colleagues shall challenge these positions directly, and their replies shall follow immediately. All of our imagined participants speak as scholarly personae informed by historically documented mathematics, not as witnesses to instruments developed after their deaths.

Ten numerical applications will expose the assumptions beneath variance reduction, taper concentration, median selection, family-wise false

Copyright 2026, James M. Atkinson

alarms and missing-event claims. The examples are stipulated, not instrument trials. We shall retain the original samples as a reference where available, identify how tapers and robust summaries were constructed and distinguish the analogue passband and receiver state from the subsequent statistical operation. At the close we will ask what a laboratory could defend under cross-examination, not merely what a graph might make persuasive at first glance. I invite Professor Slepian to begin with the concentration criterion and the limits of the word independent.

Copyright 2026, James M. Atkinson

David Slepian | Principal response 1: Concentration, orthogonality and finite-data limits

Dr. Atkinson, I should begin by defining the optimisation question rather than with a general endorsement of multiple tapers. The discrete prolate spheroidal sequences are associated with the concentration of energy from a finite sequence into a specified frequency interval. Given a record length N and time-bandwidth parameter NW, one can obtain a sequence of orthogonal tapers with ordered concentration ratios. Their mathematics is precise, but its precision has a defined domain. The first taper concentrates energy according to the chosen criterion; subsequent tapers offer complementary ways of weighing the same observed samples. None changes the finite observation duration or the receiver's analogue history. One must never interpret the existence of K orthogonal vectors in an N-dimensional record as the existence of K independent acquisitions of one unknown physical event. [R1]

The practical benefit is real. A single rectangular window has conspicuous sidelobes and may leak power from a strong nearby carrier into the estimated spectrum of a much weaker component. Carefully selected tapers can reduce sensitivity to some leakage and stabilise estimates of stationary background power. A weighted average over several eigenspectra may balance leakage bias against variance. The useful number of tapers depends on the chosen NW, the concentration eigenvalues and the assumptions about the process. It is customary in some spectral applications to consider roughly 2NW well-concentrated sequences, but one must inspect the eigenvalues and estimator purpose rather than apply the expression as a talisman. Including more tapers without examining their

Copyright 2026, James M. Atkinson

concentration can broaden the estimate and obscure a line of investigative interest.

The weighting convention is itself part of the measurand. A simple unweighted average, an eigenvalue-weighted estimate and an adaptively weighted estimate need not produce the same output for a weak narrow signal beside strong broadband noise. The examiner should preserve the exact taper coefficients, window convention, transform normalisation, weighting algorithm and software version. If a window length is changed after examining a candidate, the resulting statistic is a different analysis of the same event. The analysis may be legitimate, but a report describing one unchanging method is incomplete. When a claim involves carrier amplitude, the distinction between a power-density normalisation and an amplitude-spectrum normalisation must also be stated. A spectrum which looks quieter after changing its scaling has not necessarily measured less physical noise.

I would insist that the physical record remain central. The tapers operate on retained IQ data, which have already passed through antenna matching, preselection, gain, conversion, sampling and buffering. A receiver-generated spur present in those samples may appear in many eigenspectra and survive averaging. Its survival is not independent confirmation of an external source. Conversely, an intermittent emission whose energy falls near the low-weight end of the record may be weakened in several tapers, particularly if their weights are chosen for a stationary background problem rather than event detection. A multitaper method can therefore be highly suitable for baseline noise estimation while being an incomplete detector of

Copyright 2026, James M. Atkinson

rare bursts. The detection function must be evaluated as a separate procedure.

An important subtlety concerns covariance. Orthogonality of deterministic window sequences is not equivalent to probabilistic independence of their estimated powers for arbitrary input processes. Under selected Gaussian and stationary assumptions, eigenspectral estimates may have tractable covariance structures and the familiar degrees-of-freedom approximations may be useful. Correlated interference, changing oscillator state, nonstationary emissions and gain switching can violate those assumptions. An uncertainty interval derived as though K spectral estimates were independent will be overly optimistic if their covariance is material. Rather than declaring independence on the strength of linear algebra alone, the engineer should measure or model covariance under representative operating conditions and retain the model's scope.

For the field laboratory, I would propose validation in two stages. First, characterise the numerical estimator with known synthetic data, including stationary coloured noise, narrow sinusoids and controlled transients whose onset phase varies relative to the retained window. Confirm that the implementation matches the declared taper definitions and scaling. Secondly, inject representative physical signals at the receiver's specified input plane to test interaction with analogue filtering, clock error, overload and source-independent receiver artefacts. Change the source class and compare the resulting detection probability. A software-only test can establish arithmetic correctness, but it cannot reproduce unmodelled front-end compression or missing analogue observations.

Copyright 2026, James M. Atkinson

The same discipline applies to a negative survey. If the system retains only the multitaper average, a future examiner may be unable to distinguish a weak burst from a temporary rise in background noise or a receiver state transition. A retained raw interval offers the possibility of alternative analysis; a scalar average may not. When storage limits demand reduction, the report should describe what was irreversibly discarded and what specific question the surviving statistic was designed to answer. No later change of taper can recreate phase information or transient detail that a magnitude-only average has removed. The limitation is a property of the archive and the hypothesis, not a defect in the mathematical concentration theory.

I therefore regard multitaper estimation as a powerful member of the laboratory's methods, not a universal verdict on spectral reality. It supplies useful control over leakage and variance within a stated population and weighting rule. It does not by itself determine physical origin, guarantee event detection or establish independent corroboration. Where the analyst uses different tapers to challenge one candidate, describe the resulting agreement as within-record estimator robustness. Where the claim concerns an external transmitter, perform the necessary physical discrimination. I invite Dr Hamming to ask whether my demand for exact coefficients is operationally practical across a large survey.

Richard Wesley Hamming | Peer question 1 to David Slepian

Professor Slepian, a field system may process terabytes of sampled data while using many taper families and adaptive weights. Your insistence upon preserving exact taper coefficients, normalisations and covariance models is mathematically admirable, but a complete archive of every intermediate calculation could dwarf the original signal record

Copyright 2026, James M. Atkinson

and make independent examination less rather than more practical. What minimum set of data, definitions and checks would permit another scientist to reproduce the material result? Suppose the software package implements a documented DPSS generator yet a later version changes its numerical conventions. Would preservation of a source-code revision, input parameters and a checksum of the resulting coefficients be sufficient, or is retention of the coefficient arrays essential? I would also ask how a laboratory should distinguish a source-level measurement error, which no amount of software provenance can repair, from a harmless numerical difference between two correct implementations. The evidential record should be economical but not so abbreviated that its critical transformations become untestable.

David Slepian | Immediate answer to Richard Wesley Hamming

Thank you for that question. Dr Hamming, the record must be sufficient for the inference, not an indiscriminate recording of every ephemeral processor operation. One workable scheme preserves the raw input interval or a verified lossless representation, the sample-rate and timebase metadata, the state of the analogue front end, the exact taper parameters and normalisation conventions, and a versioned software environment capable of recreating the coefficients. A checksum of the resulting coefficient array is useful because it permits an examiner to detect a silent change in generation or numerical precision. When the exact arrays are small relative to the raw IQ, retaining them directly is simpler than debating whether a later library revision produced identical values. The

Copyright 2026, James M. Atkinson

archiving choice should be determined by materiality and reproducibility.

The software test should compare the independently regenerated coefficients and outputs within declared numerical tolerances. A difference in the last floating-point bit may be immaterial to an amplitude conclusion with much larger receiver uncertainty, whereas a sign convention or scaling error could reverse a frequency axis or alter a threshold decision. The laboratory should specify what numerical precision is required for the claim and should not equate bit-for-bit identity with physical accuracy. A perfectly reproducible output can still derive from a clipped analogue waveform or an incorrect clock frequency. Digital provenance is necessary to test the computation but not sufficient to validate the measurand.

A practical intermediate record could preserve the input hash, key calibration identifiers, processing configuration, the computed detection statistic, a small set of validation reference outputs and a record of excluded or missing time intervals. When a contested candidate is found, the raw context should be retained for reanalysis whenever possible. For routine baseline statistics an aggregate record may be adequate if the report is explicitly confined to baseline power under its design assumptions. A claim that no brief emissions existed requires more: exposure, sensitivity and the retention policy must support that negative proposition. The absence of archived IQ cannot silently become proof that the unrecorded intervals were empty.

The most important safeguard is to distinguish the chain's different propositions. The first says that this code computes the stated

Copyright 2026, James M. Atkinson

multitaper statistic. The second says the receiver measured the nominated analogue quantity within a declared uncertainty. The third says the statistic discriminates a candidate signal class at an empirically established rate. The fourth concerns the external source of any detected feature. Each requires different evidence. Preservation should be designed backwards from the strongest conclusion contemplated, with a transparent account of what remains unobserved. That is more defensible than either perfect archiving in theory or a tiny file whose evidential scope nobody can reconstruct. I pass the token to Professor Bartlett to consider the covariance that makes apparently numerous eigenspectra less than a corresponding number of independent observations.

Copyright 2026, James M. Atkinson

Maurice Stevenson Bartlett | Principal response 2: Degrees of freedom, covariance and biased confidence

Dr. Atkinson, the central difficulty in spectral inference is not the ability to calculate numerous transforms but the relationship among the resulting estimators. If K tapered spectra reuse one random record, the resulting K estimates have a joint distribution that depends upon the input process and their weighting. For stationary Gaussian noise under defined conditions, certain orthogonal tapers can provide approximately decorrelated spectral quantities, and effective degrees-of-freedom approximations may become serviceable. That is not a statement about all random processes. A burst entering every taper through the same analogue front end is a common cause; its presence can correlate estimates strongly, and its effect cannot be dismissed by pointing to the taper vectors' algebraic orthogonality. The problem is one of covariance, not merely counting output arrays.

Consider a linear weighted estimate $S_hat = sum_\{k=1\}^K a_k S_k$, with weights a_k chosen to sum to one. Its variance is sum a_k^2 Var(S_k) plus twice the sum over distinct pairs of a_i a_j Cov(S_i,S_j). The covariance terms matter. If the estimates are independent with common variance v and equal weights, the variance is v/K. But if every pair shares positive correlation rho in the equicorrelation idealisation, the variance becomes v[rho+(1-rho)/K]. As K increases, the limiting variance is v rho rather than zero. A claimant who invokes K independent replicas when the noise floor includes common-mode receiver fluctuations will understate uncertainty. The algebra does not tell us what rho is for the field receiver. That quantity must be estimated or bounded using appropriate observations, and its stationarity must itself be considered.

Copyright 2026, James M. Atkinson

The same issue arises when overlapping windows and multitapers are combined. Forty outputs from ten heavily overlapping time segments and four tapers each do not necessarily represent forty independent physical experiments. The effect of overlap depends upon the time-series covariance, the taper functions, the segment hop and any adaptive weighting. If the underlying data contain a sustained carrier, each segment revisits much of the same energy. If the process changes during one segment, the stationarity assumptions that justify a conventional background estimate may be invalid. A report should not use the raw number of computed spectra as a substitute for an effective sample size. It should preserve enough structure to investigate dependence or evaluate performance empirically through independent challenge events.

One must distinguish variance reduction from bias. A spectrum estimator that has low variance can still be systematically wrong near a sharp line or an abrupt process change. Smoothing can broaden a narrow peak, leak a strong neighbour into the band of interest or conceal rare pulses. Several orthogonal tapered views may reduce one category of leakage bias while introducing a spectral smoothing width related to the selected time-bandwidth product. The point is not that one method is defective, but that the bias-variance trade-off depends on the parameter of interest. For a background noise-density estimate, reduced variance can be highly valuable. For the question 'did a 2-millisecond surveillance emission occur at an unknown onset?', a statistic biased against unusual transient energy may be a poor detector.

I would therefore demand independent control observations before interpreting confidence intervals. A laboratory can generate or physically

Copyright 2026, James M. Atkinson

inject noise and known signals within a declared receiver configuration, then measure the distribution of its spectral estimator under repeated independent captures. The captures, not the overlapping tapers within one capture, provide the primary experimental replication for the full-system performance question. Stratification by input amplitude, temperature, gain, strong adjacent carrier and onset phase is important because each may alter covariance or bias. A covariance matrix estimated solely from a handful of apparently quiet frames may fail precisely when the system faces the difficult signal class it was meant to discover.

A detection threshold should be distinguished from a background interval estimate. An interval for mean PSD under a stationary model does not automatically provide a false-alarm probability for the maximum of a searched time-frequency image. A thousand tested locations create a multiple-comparison problem, while the dependence among neighbouring estimates complicates the tail distribution. Empirical null trials and predeclared search statistics may be the most defensible route. If a specific family-wise bound is claimed, the analyst should state the exact null population and whether the bound assumes independence, uses a conservative union bound or comes from a validated resampling procedure. These are not typographic qualifications; they can change a surveillance conclusion.

Likewise the measured number of detections must not be confused with the number of emitted events. One physical burst may illuminate several consecutive overlapping frames, and four tapers may all show it. An event-level clustering rule should collapse dependent alerts into one candidate where the purpose is to count transmissions, while preserving frame-level

Copyright 2026, James M. Atkinson

data for signal-shape examination. The clustering rule itself requires testing: excessive merging can hide distinct closely spaced emissions, while insufficient merging inflates reported occupancy. Neither mistake is repaired merely by a better estimate of average spectral density.

For a courtroom or laboratory review I would present both the estimator definition and a bounded performance statement. The report could say that the multitaper procedure estimates stationary background power under the tested ensemble with a stated variance and bias, while a separate event detector was challenged on known bursts. It should not say that a candidate was independently confirmed K times merely because K windows revealed the same feature. The physical source remains a different inferential question, demanding intervention or appropriately independent observation. I invite Professor Fisher to challenge whether the covariance assumptions can be meaningfully tested when the field record is finite and the receiver environment changes.

Sir Ronald Aylmer Fisher | Peer question 2 to Maurice Stevenson Bartlett

Professor Bartlett, your covariance formula exposes a problem that many engineering summaries conceal. Yet a field laboratory may have only a small number of independent captures, each acquired under conditions that are changing with temperature, traffic and operator intervention. A covariance estimate from such observations can itself be unstable, while a conservative assumption that every result is fully dependent wastes real information in the orthogonal tapered calculations. What evidence would justify treating certain eigenspectral estimates as approximately independent for a defined measurement,

Copyright 2026, James M. Atkinson

and how would you communicate uncertainty in the covariance estimate? Suppose a narrow line is visible under six tapers but all six arise from one captured waveform. Is there any statistically defensible interpretation of that agreement other than the weak claim that six algorithms produced six similar numbers? I wish also to distinguish a test about stationary noise power from a claim that the observed line must have an external electromagnetic origin.

Maurice Stevenson Bartlett | Immediate answer to Sir Ronald Aylmer Fisher

Professor Fisher, covariance must be judged relative to the question, and its estimation uncertainty should not be suppressed. For a restricted stationary Gaussian noise model one can compare theoretical covariance predictions with repeated captures in a controlled, adequately characterised environment. The experiment should include checks of distributional form, stability across time and sensitivity to strong interfering activity. The assumption of approximate independence may be a useful engineering approximation for a particular estimator and population, but it should be tested or bounded, not asserted universally. In a changing environment the parameters can themselves vary; a pooled covariance may give false comfort if it averages incompatible receiver states.

Agreement among tapered spectra can be informative without amounting to independent physical corroboration. It may show that a candidate is not solely an idiosyncratic sidelobe of one chosen window and that the feature remains visible when weights are

Copyright 2026, James M. Atkinson

changed within the same data interval. This supports a narrowly phrased within-record robustness claim. The probability of such agreement under a null model can, in principle, be evaluated if the joint distribution is specified and validated. Its magnitude does not by itself identify an external source, because the same physical receiver artefact can enter every tapered view. Source attribution requires tests that perturb the physical pathway or provide observations with differently structured instrumental errors.

We can communicate limited covariance knowledge in several ways. Present confidence intervals conditional upon the stated covariance model; conduct sensitivity calculations over plausible correlations; and use independent controlled trials to assess the complete detector when theoretical assumptions are doubtful. If an equicorrelation model is used solely as an illustration, mark it as hypothetical. Where severe uncertainty remains, a conservatively bounded conclusion may be preferable to false numerical refinement. One may still report a feature's existence in the recorded data and the fact that it survived several mathematical analyses without pretending that a source identity was thereby established.

The experiments should also be designed to reveal bias, not only variance. A method may be highly stable while consistently broadening a narrow line or rejecting short impulses as outliers. The complete performance record must distinguish noise-background estimation, event detection, false-alert control and source discrimination. If one question requires extremely high sensitivity to rare transmissions, a separate detector on the raw or lightly

Copyright 2026, James M. Atkinson

processed data may be necessary even when multitaper estimates furnish a trustworthy baseline. More calculated estimates are useful only in the measure to which they support the proposition the investigator is actually making. I now invite Dr Neyman to question the effect of selecting the most favourable spectral representation after the candidate has been discovered.

Jerzy Neyman | Peer question 3 to Maurice Stevenson Bartlett

Professor Bartlett, assume that an examiner computes multitaper estimates with several time-bandwidth products and then chooses the one whose spectral line looks most convincing. The examiner subsequently uses the estimated variance of that chosen procedure to produce an apparently narrow confidence interval, as though the choice had been fixed before seeing the candidate. The experiments used to justify independence concerned quiet stationary noise, but the contested event is short and surrounded by legitimate intermittent transmissions. What becomes of the stated coverage probability? Is the most defensible course to repeat the entire selection policy on independently constructed null and signal trials, or can a conditional calculation on the chosen estimator suffice if its exploratory origin is disclosed? How should an adversarial reviewer distinguish a genuinely stable result from one which appears stable because the analyst repeatedly changed settings until an attractive picture emerged? The history of all unsuccessful parameter choices seems particularly relevant to such a comparison.

Maurice Stevenson Bartlett | Immediate answer to Jerzy Neyman

Professor Neyman, the act of selecting the estimator after observing the data changes the relevant experiment. An interval

Copyright 2026, James M. Atkinson

derived for one preselected estimator does not automatically retain its nominal coverage after choosing among many possibilities according to the same observed candidate. The selection can induce bias and alter the tail distribution of the chosen statistic. A conditional description of the final estimator is still valuable, but it cannot silently borrow the operating characteristic of an experiment that was not actually conducted. The examiner should record the search history and distinguish exploratory findings from independently validated conclusions.

For a confirmatory result, one can freeze the entire selection algorithm, including the candidate-search procedure, choice of time-bandwidth parameter, number of tapers, weighting, threshold and stopping rule. Then submit it to new challenge records under relevant conditions. That approach validates the procedure as used rather than a simpler idealisation. Another possibility is to limit the claim: describe the observed spectral feature and its stability under a stated set of parameter changes without attaching an unsupported false-alarm probability. It is better to state a supported qualitative result than to manufacture precise numerical assurance from an inappropriate distribution.

I would not insist that every spectral image be supported by an enormous universal campaign before the receiver can guide further investigation. Discovery, corroboration and final attribution are different tasks. A selected candidate may lead to a targeted physical test, perhaps retuning the receiver or exchanging antenna and termination states. A genuine external emission and a receiver

Copyright 2026, James M. Atkinson

artefact can make different predictions under these interventions. Such tests may add more useful discrimination than refinements to the variance of a selected spectral statistic. The report should explain why the alternative hypotheses would respond differently and preserve discordant outcomes.

Finally, the uncertainty calculation itself must not be reduced to a count of transforms. A candidate found by searching many times and bands requires consideration of the effective search population. A family-wise false-alarm bound may be established conservatively without independence, while an empirically calibrated max-statistic may be more efficient when the dependence structure is known. The appropriate method depends on the predeclared inference, not on the aesthetic compactness of the resulting confidence interval. A transparent audit trail is thus a component of measurement, not a bureaucratic burden. I now pass the discussion to Dr Tukey, who can examine the distinct problem of robust summaries that remove the very deviations a counter-surveillance investigator seeks.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 3: Robust summaries, rare signals and the obligation to retain outliers

Dr. Atkinson, the attraction of a robust summary is that it resists the undue influence of observations that do not resemble the bulk of the population. This can be an admirable property when estimating a stable noise floor in the presence of occasional disturbances. Yet in a defensive survey the unusual observation may be the very object of the investigation. An isolated burst can be statistically exceptional and physically meaningful. A method that treats it as contamination can produce a better description of the ordinary background while delivering a worse answer to the question of whether an intermittent transmitter was present. The distinction between an estimator's robustness and a detector's sensitivity must therefore be made at the outset.

Suppose a spectral power bin is measured in ten separated time intervals. Nine values cluster near a common background level and one is greatly elevated by a short transmission. The arithmetic mean rises substantially; the median may remain close to the background. Neither result is intrinsically dishonest. The mean may be a poor description of typical background power, while the median may be a poor detector of the isolated emission. The correct procedure could preserve both: report the robust background estimate and flag the outlying interval as a candidate event. The fatal mistake is to retain only the median and subsequently infer that no short transmission occurred. Once the anomalous interval and its context are discarded, no mathematical sophistication can recreate its phase or duration.

Copyright 2026, James M. Atkinson

One should distinguish outliers caused by instrumental errors from rare legitimate physical events. A converter glitch, dropped buffer or transient overload may produce an isolated high-power record. A brief external emission can look similar in one numerical statistic. The distinction demands examination of raw time-domain data, receiver state logs, alternate frequency channels and physical interventions. Robustness alone does not identify cause. It may reduce sensitivity to both kinds of abnormality, which is valuable for one purpose and hazardous for another. The operator should state whether an outlier was excluded because of a known instrument fault, because it failed a predeclared signal criterion, or merely because it was numerically unusual.

Multitaper averaging introduces a related selection problem. A spectral line can appear with different amplitude under different tapers, particularly when its time support is brief or its frequency lies near a strong neighbour. Choosing the most consistent subset of tapered estimates may improve a robust background but suppress the candidate. Conversely, choosing the maximum among many tapers can exaggerate the false-alert rate. The data-dependent selection policy should be explicitly documented. If the method is adaptive, the system must preserve its coefficient history and evaluate performance over the adaptation process rather than pretending the estimator remained fixed during the observation.

I favour exploratory data analysis precisely because it can reveal structure not anticipated by a rigid single statistic. A waterfall, time-domain trace, robust PSD estimate and list of maximal transient deviations can be viewed together, with each supporting a different proposition. Exploration must not be confused with confirmation. If the analyst notices a weak

Copyright 2026, James M. Atkinson

repeated feature in several related calculations and then develops a new detection rule, that rule should be challenged on held-out or physically injected events with an independent null population. The apparent repetition of a candidate under several transformations of one record is not the same as the repetition of an external event under independently controlled conditions.

For event detection we should classify physical opportunities. Let a known injected burst count once as an eligible event, however many spectral frames, tapers or plots display it. Report the probability of detecting that event and the false-alert rate on independent no-event trials. In practice, a cluster of neighbouring alarms may be merged to avoid counting one burst repeatedly, but that clustering can also combine closely spaced separate emissions. Test both failure modes. A robust median can be used to estimate the background threshold while a separate trigger considers maxima or change points, provided the joint false-alarm distribution of the complete procedure has been examined. No universally optimal combination exists independent of the signal population.

I am especially wary of negative conclusions drawn from archives containing only successes or only summaries. If a receiver retains windows after its own detector fires, a sample of retained events cannot estimate the prevalence of the unretained events without a justified exposure and selection model. A smooth robust background may coexist with poor coverage during gain switching, preselector changes or adaptive threshold recovery. The record should identify invalid intervals and the conditions under which a signal would have been eligible for detection. Where resources prohibit continuous raw recording, preserve a candid statement

Copyright 2026, James M. Atkinson

of that limitation and representative control intervals that can test the policy.

My concluding proposal is to match the statistic to the decision. Use robust background estimators to characterise typical noise; use event-sensitive records to protect possible rare emissions from silent removal; and use controlled physical challenges to distinguish source hypotheses. A good forensic narrative should make both the ordinary distribution and the anomalous observations visible, with their different meanings intact. One may discard an outlier from a background estimate while preserving it in an exception register for examination. That is not inconsistency. It is the consequence of asking two legitimate questions of one finite record. I invite Professor Bridgman to inquire how such a distinction should be operationally defined before the investigation begins.

Percy Williams Bridgman | Peer question 4 to John Wilder Tukey

Dr Tukey, you propose that a laboratory retain both the robust typical background and the anomalous intervals. I agree in principle, but the category 'anomalous' can become a flexible word that conceals retrospective selection. One operator may define an anomaly by exceeding a power threshold in one channel; another may flag a spectral kurtosis increase; a third may rely on visual judgement of a coloured waterfall. All may claim to have preserved the important exceptions while using different measures of importance. What operational definition would you require before a forensic finding is offered? Should the exception register contain every threshold crossing, every state transition, or only candidates satisfying a specified waveform signature? How might the analyst document exploratory judgment without falsely

Copyright 2026, James M. Atkinson

presenting it as an algorithm whose false-alarm performance has been calibrated? I am particularly interested in whether a negative survey conclusion is even meaningful when the retention rule was modified during the survey and the earlier raw data were not kept.

John Wilder Tukey | Immediate answer to Percy Williams Bridgman

Professor Bridgman, a useful anomaly definition is necessarily linked to the purpose of the survey. A power excursion, a kurtosis change and a human observer's visual identification are different detection procedures. None should be described merely as a generic 'suspicious signal' without identifying the operation that produced it. The report should preserve the rule, its parameter state and the timestamped history of any modifications. If an operator changes a threshold after seeing a candidate, the change is an exploratory event and should be labelled as such. It may legitimately guide a new test, but its earlier performance cannot be retroactively established by the later settings.

I recommend keeping two distinct records. The first is a systematic machine-generated event log whose rules are versioned and whose opportunities for detection can be reconstructed. The second is an analyst annotation record explaining why certain events received additional scrutiny, including visual judgments and alternative hypotheses. The second record can be qualitative without pretending to possess a calibrated statistical false-alarm rate. The relation between them should be explicit. A human may observe a pattern that the original threshold missed, and that observation may be

Copyright 2026, James M. Atkinson

valuable, but the success should motivate a reproducible detector or directed physical experiment rather than a claim that the earlier monitoring system had always possessed the new capability.

An operational exception register need not retain all possible raw data forever, but its omissions must be described. Material state transitions, invalid intervals and trigger-rule changes should always remain visible if they affect detection opportunities. For severe allegations a raw IQ interval around a candidate is particularly important. If only the peak power value survives, later questions about phase coherence, modulation or receiver-generated artefacts may be unanswerable. A negative conclusion should therefore be bounded by the validated retention and detection policy and should not extend to time intervals or signal classes that the record never tested.

The distinction between machine events and analyst judgments protects both scientific rigour and creativity. The investigator is permitted to notice an unusual pattern and propose a source hypothesis. Confirmation requires observations capable of showing that hypothesis wrong. An antenna substitution, input termination, oscillator retuning or independent receiver measurement can be more decisive than reprocessing a signal through twenty variants of a robust estimator. The final report can distinguish a verified discovery, a candidate requiring further examination and a supported physical attribution without treating these as interchangeable categories. I pass the floor to Dr Hamming to question what happens when a

Copyright 2026, James M. Atkinson

median suppresses a burst but a numerical maximum introduces too many false alarms.

Norbert Wiener | Peer question 5 to John Wilder Tukey

Dr Tukey, your two-record proposal appears prudent, yet it leaves an engineering trade-off that cannot be evaded merely by adding storage. An extreme-value trigger can preserve short bursts, but the monitored bandwidth may contain millions of potential time-frequency cells, and an aggressive threshold could produce torrents of false alarms. A robust median supplies a stable background estimate but may delay adaptation to genuine changes in environmental noise. Should the detector combine a robust background with a maximum statistic, and if so how should its performance be evaluated when neighbouring bins are correlated and the background statistic is computed from many of the same samples? I also wish to know whether a mathematically impressive sensitivity estimate can remain meaningful once the host computer drops buffers, the gain range changes or the antenna front end saturates. Where would you locate the boundary between an algorithm that is correctly implemented and a surveillance system that is genuinely validated? In particular, should a time-dependent trigger policy be evaluated by replaying an entire input history rather than only a selected set of isolated examples?

John Wilder Tukey | Immediate answer to Norbert Wiener

Thank you for that question. Mr Wiener, I would not prescribe a universal maximum-plus-median formula. Such a procedure can be useful, but its false-alarm and detection characteristics depend on the monitored event population, the correlations among tested cells and

Copyright 2026, James M. Atkinson

the background-estimator update rule. The laboratory should define a family of candidate signals and an eligible physical-event rule, freeze the detector including its adaptation and clustering logic, then test it against independent signal and null trials. The test set should span bandwidth, duration, onset position, input amplitude, adjacent traffic and hardware state. If the detector is adapted during the test, that adaptive policy becomes part of the fixed procedure being evaluated; it cannot be tuned indefinitely until unfavourable trials disappear.

A robust background level and an extreme-event trigger answer different questions. The former estimates ordinary spectral power under a declared model, while the latter asks whether an unusual excursion occurred. They may share data and so their errors can be dependent. A nominal threshold derived under fixed known background variance cannot automatically be used when the variance is estimated adaptively from the same record. Empirical false-alarm calibration under representative null conditions may be safer, and the report should retain the fact that neighbouring cells or overlapping windows are dependent. The number of tests is not simply the number of plotted pixels if the detection rule clusters or combines them.

The host-computer problem is separate and material. A mathematically correct detector applied only to retained samples cannot find bursts that arrived during a buffer loss, clock invalidity or gain-change interruption. End-to-end validation must therefore measure exposure as well as conditional success during valid operation. A log of loss intervals and receiver-state changes should

Copyright 2026, James M. Atkinson

accompany every claim about quiet spectrum. A successful software unit test is valuable evidence of implementation, but it is not certification of the antenna, preselector, ADC, clock, transport buffers and retention policy. Each boundary has its own potential failure and required test.

A practical report might give two figures: a background-power estimate with a confidence qualification under its stochastic assumptions, and an event-level detection estimate with its challenge population and invalid intervals. It should also preserve examples of the strongest false alerts and known misses, because these often reveal unmodelled features. A system whose operators retain all successes while discarding failures cannot learn about its limits. The point is not to burden the reader with every internal computation but to document the few decisions that materially determine what the record could see and what conclusions the laboratory can defend. I now pass the floor courteously to Dr Shewhart for the governing question of process control and drift.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart | Principal response 4: A stable estimator is not a validated detection process

Dr. Atkinson, the success of a monitoring system should not be determined by looking at one favourable chart after the event. A process-control perspective asks whether the measurement system remains in a known state, whether its sources of variation are characterised, and whether a detected change is causally attributable to the process being monitored rather than the instrument. In the present case, the process under observation is electromagnetic activity arriving at a declared reference plane. The digital estimator is one stage of the measurement chain. A stable spectrum produced by a modern program is no assurance that the antenna, gain stage, oscillator or ADC was stable during the relevant interval. A smooth curve may equally result from aggressive suppression of abnormal observations.

Consider a receiver that estimates background noise by a robust median of recent spectral observations and updates its threshold at every window. After a nearby strong transmission, the background may rise or the front end may recover slowly from overload. A subsequent weak signal can be missed even though the routine PSD plot looks more stable than ever. The detector's statistical history has changed its sensitivity. If the laboratory validates the instrument using only isolated signals in a quiet state, it has not examined the circumstance that most threatens its mission. The controlled test should therefore include sequences of disturbances, recovery periods, threshold updates and deliberately placed weak events. The output should be evaluated as a time-dependent process rather than a bag of independent windows.

Copyright 2026, James M. Atkinson

The distinction between common-cause variation and a special physical event can be useful, but it must not be imported carelessly. In manufacturing control a rare large excursion may indicate an assignable process fault; in a technical-surveillance survey that same numerical pattern may be the target emission. The test objective determines whether the excursion is contamination or evidence. An investigator who excludes every outlier when estimating ordinary noise may be justified, provided the excluded observations remain in a separate exception register for inspection. If they disappear from all records, the resulting background estimate might be statistically robust while the surveillance coverage becomes scientifically unverifiable.

A complete validation needs two distinct operating characteristics. One describes the background estimator: its bias, variance, settling behaviour and susceptibility to strong neighbours under representative stationary or slowly varying conditions. The other describes the event detector: its probability of detecting specific physical bursts, its false-alert behaviour and its response to changing receiver states. The detector may use the robust estimate as an input, but that dependency must enter the experiment. An uncertainty interval for the background estimate does not, by itself, certify an event detection probability. The laboratory should retain known-miss examples, not merely plots displaying successful thresholds.

The same requirement applies to calibration. A receiver may have been characterised at one gain setting, one temperature and one clock discipline, yet perform differently after a preselector change or automatic gain adjustment. One cannot assume all versions of the signal path have one constant sensitivity merely because the software exposes the same

Copyright 2026, James M. Atkinson

spectrum window. The laboratory should declare operating envelopes and revalidation triggers. If coefficients adapt automatically, their update rules and state history form part of the measurement. If a software release changes the taper generator or threshold estimator, it may require a compatibility check against retained reference cases before earlier calibration claims are carried forward.

I would design a challenge matrix in which every known injected burst has a physical-event identifier and a declared opportunity for detection. Vary duration, carrier offset, relative onset to FFT hops, input amplitude, modulation and interfering traffic. Record each detector outcome, including invalid intervals and buffer failures. Count one known physical burst once, even if it appears in several tapers and successive frames. Where the investigation is concerned with two closely spaced bursts, verify that the clustering rule distinguishes them when justified. A process-control chart of the alarm rate may then reveal unstable periods, but it should not replace direct challenge of the detection rule.

False alarms should likewise be classified by cause where possible. Some arise from the assumed null noise distribution; others come from internal periodic spurs, network buffer artefacts, front-end nonlinearities or innocent external transmissions. Merely raising a threshold until the display looks quiet can suppress genuine weak emissions. A credible report should indicate whether the false-alert rate is measured under a specific null population, inferred from a statistical model or observed operationally without a complete ground truth. Those are different evidential grades. If uncertainty remains large, label it as such rather than reporting an unwarranted decimal probability.

Copyright 2026, James M. Atkinson

The end product is a calibrated process capable of being challenged and improved. Its logs preserve the applicable state, threshold, noise baseline and selection rule; its scientific record contains the trials which could have shown the method to be inadequate; and its conclusions are restricted to the signal classes and conditions examined. Robust background estimation can make the instrument useful and intelligible, yet it should never be granted responsibility for declaring every faint unrecorded emission absent. The receiver's silence is a conditional observation, not a pronouncement about the entire electromagnetic environment. I invite Professor Gabor to question how a method selected for spectral concentration may transform a physically brief event into a misleadingly persistent visual feature.

Dennis Gabor | Peer question 6 to Walter Andrew Shewhart

Dr Shewhart, suppose the system uses a broad analysis window and several prolate tapers to obtain a stable noise background. A known two-millisecond burst then affects several overlapped ten-millisecond windows, and the display marks a sequence of bright spectral cells extending beyond the source's true transmission interval. One examiner treats this as repeated detections, another as a single event lasting as long as the visual trace, and a third suppresses it as an anomalous contribution to an otherwise stable background. Each operator has seen a computational product of the same finite observation, but they report incompatible physical accounts. How would your process-control approach prescribe the event definition and preserve the distinction between measurement-response duration and physical emission duration? I also ask whether the laboratory should test changing burst onset across window boundaries, since a robust background scheme

Copyright 2026, James M. Atkinson

may be excellent for a centre-aligned test and poor for precisely the intermittent case of greatest investigative importance.

Walter Andrew Shewhart | Immediate answer to Dennis Gabor

Professor Gabor, the first step is to define the observed object at each stage. A spectral frame is a calculated statistic; a threshold crossing is an alarm; and a physical event is a transmission or interference episode defined by the experimental ground truth or, in an unknown survey, by an explicitly provisional clustering hypothesis. The three labels must not be interchanged. During validation the known burst has a recorded input onset and end time, independently measured at the chosen reference plane. The algorithm's several alarms may be associated with that single event, and its displayed duration can be compared with the calibrated receiver impulse response and window support. The presence of several bright cells is not by itself a duration measurement.

The challenge must vary onset phase relative to the window and hop, because that variation may determine whether a brief burst is represented strongly or attenuated by the taper. A fixed centre-aligned reference test is incapable of revealing a boundary-specific weakness. The experiment should also vary strong neighbouring activity, gain states and the duration of preceding interference to test the robust baseline's memory. Each injected physical event receives one eligible trial identifier, and the system is scored according to a predeclared event-level rule. Frame-level data remain available for diagnosing the shape of errors without being counted as independent successful transmissions.

Copyright 2026, James M. Atkinson

For operational unknown events, the archive should distinguish the measured threshold-crossing interval from the inferred physical duration. If the raw waveform survives, alternative timing estimators may be applied under stated models. If only multitaper power averages remain, precise onset reconstruction may be impossible and the report should say so. A laboratory may still use those summaries to direct further investigation, but should not claim that the source radiated continuously throughout the displayed response. Repeated candidate marks can be collapsed provisionally under a clustering rule whose known failure modes have been tested on closely spaced emissions.

I would also preserve exception records even when a robust background calculation excludes them. The laboratory can maintain a stable baseline for sensitivity control and at the same time document the transient observations that depart from it. A detector operated without a record of threshold state or invalid intervals cannot support a strong negative conclusion, however smooth the plotted spectrum. The engineering objective is not to make the trace look still. It is to create a process whose response to both ordinary background and rare material events is known within a declared envelope. I pass the token to Dr Shannon, whose information-theoretic account can clarify what a compressed spectral estimate necessarily loses.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 5: Task-specific sufficiency and irreversible discard

Dr. Atkinson, the proper place to begin is with the question that the measurement system was designed to answer. A statistic can be sufficient for a parameter in a specified statistical model without preserving every detail of the original record. If an engineering mission is solely to estimate stationary background power under a tightly defined stochastic model, a properly calibrated robust or multitaper estimate may be an efficient summary. It does not follow that the summary is sufficient for unanticipated questions about transient duration, modulation, carrier phase, clock artefacts or transmitter identity. Sufficiency is conditional upon the hypothesis family, not a universal virtue belonging to one file format.

The irreversibility of a reduction can be demonstrated without any mystery. Suppose an estimator retains only a nonnegative average of squared transform magnitudes. Distinct complex waveforms can possess the same or very similar magnitudes while differing in their phase and temporal order. If those distinctions were never recorded, no later algorithm can guarantee recovery of the unique physical history. A future inquiry asking whether two receivers saw a coherent phase relationship may find that the original phase was discarded by design. An apparently reliable mean PSD can therefore support a background conclusion while leaving the timing or attribution question unsolved. The loss is a difference between tasks, not necessarily a numerical flaw.

Multitaper processing can also create an impression of independent corroboration because it yields several spectral views. But the physical acquisition is common to all tapers. A locally generated oscillator spur or an

Copyright 2026, James M. Atkinson

artefact of the input chain may be shared across the entire set, and a consensus among tapers does not expose that common cause. If a question concerns whether a feature was mathematically robust to taper choice, the multiple views are relevant. If the question concerns whether radiation arrived from outside the equipment, it requires additional physical evidence. Different antenna responses, controlled tuning changes, source interventions or independent instrument paths can discriminate alternative causal hypotheses in a way that reweighting the same samples cannot.

A robust estimator has another information boundary: it may intentionally diminish unusual observations. That can improve the stability of a noise baseline while suppressing the rare burst of investigative interest. The solution is not to prohibit robust statistics but to preserve a complementary event-sensitive path and its selection history. A receiver may retain a compressed continuous background summary together with raw windows around candidate events, trigger parameters, timebase information and invalid-interval logs. Such a two-tier architecture cannot answer every conceivable later question, but it makes the loss deliberate and reviewable. Silence in the candidate record should not be extended to unobserved classes or time intervals.

Time selection is as significant as amplitude selection. If raw IQ is retained only after the trigger fires, the archive's population is determined by the detector whose performance the investigator may later wish to assess. A file of detections cannot establish how many transmissions the system missed. Independent known-event challenges or a second observation channel are needed to estimate exposure and conditional detection probability. A high-level report must therefore include the

Copyright 2026, James M. Atkinson

observation duty cycle, the frequency coverage policy, threshold history and known invalid states. Without those facts an apparently quiet band is only a quiet record, not evidence that the band itself was empty.

I would also caution against deriving source identity from a highly refined detection probability. Suppose a calibrated matched statistic detects a known signal class with small false-alarm probability under a laboratory null model. The statistical result says something about the data's compatibility with the model. It does not establish that a particular named device produced the waveform when multiple emitters or receiver artefacts can satisfy the same signature. Attribution requires a comparison of competing causal explanations and often information beyond the spectrum: spatial direction, timing with other systems, electromagnetic coupling paths, modulation detail and controlled intervention. One can be confident a feature occurred without being confident of its source.

When defending a digital exhibit, preserve exact processing provenance. The source sample digests, taper parameters, window length, scaling conventions, robust estimator definition, software version and detected-event rule permit another examiner to reproduce the calculation. The analogue reference plane and clock calibration permit assessment of the physical measurement. The independent challenge campaign tests its operating characteristic. These layers should remain distinct in both the technical appendix and the summary, so that a legal reader is not invited to confuse digital integrity with physical accuracy. Cryptographic preservation of a PSD file proves that the file was not altered after hashing; it does not prove that the PSD represented the external input correctly.

Copyright 2026, James M. Atkinson

The proper recommendation is therefore conditional archiving and candid disclosure. If the investigation anticipates contested attribution, retain more of the complex time-domain observation and its context. If resource limits prevent this, narrow the claims to what the surviving statistics can support. No amount of elegant averaging will reproduce an unknown phase history erased by magnitude-only reduction or an event omitted by the trigger. A limited conclusion can be strong where it is precisely defined. I invite Professor Fourier to question whether an invertible transform before averaging can remedy information destroyed by the subsequent robust selection.

Jean-Baptiste Joseph Fourier | Peer question 7 to Claude Elwood Shannon

Dr Shannon, an unaveraged discrete Fourier transform is algebraically invertible when its complete complex coefficients and normalisation are preserved. A laboratory may consequently argue that spectral processing has not lost any information, even though it later stores only averaged magnitudes, threshold flags or a small number of prominent peaks. Where precisely does that argument cease to be valid? Suppose two different physical waveforms, one containing an intermittent weak emission and the other containing a receiver impulse, yield nearly identical robust background summaries. How should the examiner explain the resulting non-uniqueness without confusing the mathematical invertibility of the original transform with the information in the surviving archive? I would also ask whether preserving a hash of the original raw record, while destroying the raw bytes themselves, can support any later reconstruction. The questions are not merely

Copyright 2026, James M. Atkinson

philosophical, because a forensic report might cite the accuracy of a software transform while concealing the irreversible reduction applied afterwards.

Claude Elwood Shannon | Immediate answer to Jean-Baptiste Joseph Fourier

Thank you for that question. Professor Fourier, the distinction lies at the actual retained boundary. A complete complex transform of a finite sequence, under a known invertible convention and adequate numerical precision, can be mapped back to that finite numerical sequence. If the investigator subsequently squares magnitudes, averages across tapers, takes a median, thresholds peaks or discards most coefficients, the resulting operation is generally many-to-one. Different complex input sequences can produce the same retained summary. That loss cannot be repaired by invoking an inverse formula for an earlier stage which no longer survives in the record. A source hash can verify a candidate raw file if that candidate is later produced, but the hash itself is not a compressed reconstruction of the file.

The two waveforms in your example may be observationally equivalent under the retained summary even if the original complex samples would have distinguished them. The laboratory should not conceal that equivalence. It can describe the specific statistic and the signal classes against which it was validated, then state which later hypotheses cannot be tested because phase, timing or sample context were discarded. Such disclosure does not make the earlier statistic useless. It correctly confines the answer to its original

Copyright 2026, James M. Atkinson

purpose. A well-calibrated median noise floor remains an informative background estimate, while being an inadequate sole record for proving that a rare emission occurred or did not occur.

One should also distinguish an operational trigger from a forensic exhibit. The trigger can be optimised to use limited processor and storage resources, provided its missed-event characteristics and invalid intervals are understood. For a material candidate the apparatus should preserve the raw observation and the exact detector state, if technically feasible, so that alternative interpretations can be challenged. The fact that a detector fired is a historical fact about the instrument; the source of the input requires additional evidence. Multiple tapers or robust versions of the same data can test software robustness but cannot independently certify external origin.

Finally, a legal reader requires language at the proper level of abstraction. The report may say the stored spectrum was reproduced exactly from a preserved file, that the estimator showed specified performance on known challenges, and that an observed feature survived certain controlled receiver perturbations. Those are separate propositions with separate proof. A claim of device identity would demand more. It would be a serious confusion to allow a cryptographically intact, visually smooth spectral curve to masquerade as a complete record of an unobserved physical event. I return the token to Dr. Atkinson for the numerical cases and the panel's synthesis.

Copyright 2026, James M. Atkinson

David Slepian, Cross-Peer Question to Maurice Stevenson Bartlett: Professor Bartlett, orthogonal tapers are used to average spectral estimates. Does the number of tapers equal the number of independent physical observations?

Maurice Stevenson Bartlett, Cross-Peer Answer to David Slepian: Dr Slepian, not generally. Tapers applied to the same finite data interval are deterministic transformations of shared input samples. Under specified stochastic models their spectral coefficients can have useful orthogonality or approximate independence, but it remains necessary to calculate covariance and effective degrees of freedom for the estimator in question. Report the time-bandwidth product, number of retained tapers, individual eigenvalue concentration and weighting rule. Test correlated interference and short pulses, not only stationary Gaussian noise. A confidence interval derived from K independent exponential periodograms may not apply unmodified when the actual taper estimates are correlated or a few are heavily downweighted. Retain the original segment and the individual taper estimates. I yield to Professor Tukey on robust summaries.

Maurice Stevenson Bartlett, Cross-Peer Question to John Wilder Tukey: Professor Tukey, why might a median across spectral estimates suppress the very intermittent emission that a defensive survey is intended to detect?

John Wilder Tukey, Cross-Peer Answer to Maurice Stevenson Bartlett: Professor Bartlett, robustness to outliers and sensitivity to rare events are different objectives. If a weak emitter appears in only one or two of many segments, a median may successfully estimate ordinary background while intentionally rejecting the exceptional power observations. An arithmetic mean may dilute them, and a maximum may preserve them while increasing the expected height of noise extremes. Choose the statistic

Copyright 2026, James M. Atkinson

according to a predeclared measurand, and maintain a parallel event-detection stream when transient interception is required. Calibrate each rule on blind injected signals and noise-only records, accounting for the search over tapers and frequency bins. Describe what the retained statistic cannot reveal about event chronology. I yield to Dr Shewhart for process stability.

John Wilder Tukey, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, an algorithm shows excellent variance reduction during calibration, yet field performance changes when automatic gain control switches states. What control procedure is missing?

Walter Andrew Shewhart, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, the measurement system is not stationary across the switch. Maintain separate calibration and control records for each gain, filter, clock and detector state, with transition samples flagged rather than silently pooled. Monitor reference amplitudes and known internal noise markers over the same time scale as the survey. The acceptance campaign must include deliberate mode changes and strong blockers, since the estimator may react differently during settling. Check repeatability between instruments and after software revisions; improved precision under one stable state is not proof of correct decisions during state transitions. The operational report must preserve detector configuration and any samples withheld as settling artefacts. I pass the token to Dr Shannon on information sufficiency.

Walter Andrew Shewhart, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, can a compact multitaper PSD file replace raw I/Q as the sole forensic archive if a later dispute concerns the exact beginning of a pulse?

Copyright 2026, James M. Atkinson

Claude Elwood Shannon, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, a power spectrum estimator is a lossy summary. It ordinarily discards phase, time ordering within segments, portions of the input outside the reported frequency band and the unique original chronology. Many different short-burst histories can yield very similar multitaper PSDs. The PSD may be fully appropriate for background characterisation, but not for every future hypothesis about onset or waveform. Retain sample-indexed raw I/Q or a parent record demonstrably sufficient for the intended future questions, plus tapers, weights, software version and calibration records. If the original was discarded, state the limitations rather than presenting the summary as a transparent historical substitute. I return the token to Dr Atkinson.

Moderator synthesis | Dr. James M. Atkinson

The roundtable has demonstrated why a smoother spectrum may be either a better estimate or a poorer witness, depending upon the question. Professor Slepian's concentration analysis provides a mathematically disciplined family of windows; Professor Bartlett has explained how covariance governs uncertainty when several estimates share one source record; Dr Tukey has distinguished reliable background description from the detection of unusual but important episodes; Dr Shewhart has placed the entire detector inside its changing operating environment; and Dr Shannon has identified the irreversible limitations of preserving only a compressed summary. Their conclusions are not invitations to abandon multitaper or robust estimation. They are requirements to state precisely what the methods accomplish and what they discard.

Copyright 2026, James M. Atkinson

The first distinction concerns optimisation. A taper may be concentration-optimal for a selected time-frequency interval without being optimal for the discovery of every short surveillance emission. A robust median may estimate ordinary background faithfully while excluding an exceptional transmitter burst. The correct answer is not to choose between these procedures in the abstract, but to declare the signal population, estimator objective, decision rule and reference plane. If the laboratory intends to report noise density, validate noise density. If it intends to discover rare short bursts, validate event-level detection across duration, onset phase, amplitude, strong-neighbour activity and receiver state. If it intends to identify an external source, test competing physical causes.

The second distinction concerns the count of evidence. Six tapered spectra derived from the same IQ interval are six numerical perspectives on one acquired physical record, not six independent observations. Their covariance may be lower under selected stationary models, but the common analogue front end, oscillator and environmental history remain. Statistical variance calculations must include covariance when it is material, and an investigator should not infer independent corroboration from within-record consistency. The physical interventions capable of discriminating external radiation from receiver artefacts are of a different order from mathematical reweighting. A second receiver is useful only insofar as its path errors and selection policy have been characterised.

The third distinction concerns the fate of anomalous events. An elevated spectral value may be a legitimate source, innocent environmental activity or a receiver artefact. A robust estimator cannot decide this causal question merely by suppressing the value. The event should remain examinable when

Copyright 2026, James M. Atkinson

it may be material to the investigation. An exception register, selected raw IQ contexts and continuous configuration logs permit later examination, while a versioned baseline estimator can continue to provide a practical measure of ordinary background power. Where resource limits preclude such retention, the investigator must not later imply that absent raw evidence establishes an absent transmission.

The fourth distinction is statistical. Overlapping frames and shared tapers are dependent by construction, and an adaptive threshold has memory. A nominal single-test false-alarm probability does not automatically apply to the maximum over a searched waterfall, and a confidence interval for stationary background cannot automatically certify detection of bursts that violate stationarity. Laboratory trials should be organised around independent physical challenge events and a fixed, disclosed policy. Every miss and invalid interval is part of the evidence. A report may be decisive about a bounded proposition without claiming universal performance.

For publication I would require the complete estimator definition, taper parameters, exact numerical scaling, weighting and robust selection rule; the source reference plane and calibration state; a clear separation between raw and reduced records; representative validation across difficult signal conditions; a dependency account for corroborative observations; and a candid register of remaining alternatives. The scientific finding is strongest where independent scrutiny could reveal a material failure. We close by passing the token to the next question, in which cyclostationary features will be examined as potentially useful discriminators of signal classes without treating a recurrent modulation signature as a unique device identity.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 046

Worked application 1. Discrete prolate time-bandwidth scaling

Let N = 1,024 samples be acquired at F_s = 100,000 samples/s, with the DPSS standardised time-half-bandwidth product NW = 3.5. The record duration is T = N/F_s = 0.01024 s. The nominal half-bandwidth associated with the discrete concentration specification is W = NW/T = 3.5/0.01024 = 341.796875 Hz; the full selected band is 2W = 683.59375 Hz. The result identifies a mathematical concentration region, not the guaranteed physical bandwidth of any particular source. Changing the observation length or signal class changes the practical estimator problem. The actual concentration ratios for each taper should be obtained from the defined eigenproblem or the versioned implementation, not guessed from NW alone. [R1]

Worked application 2. The number of available tapers is not a number of receivers

With NW = 3.5, a rough engineering heuristic considers on the order of 2NW = 7 concentration modes, often using fewer tapers when the eigenvalues of the last modes are less satisfactory. Suppose K = 6 tapers are selected. They produce six spectral estimates from one retained record of N = 1,024 complex samples. This does not create 6 × 1,024 separately observed samples or six independent physical acquisition paths. The aggregate information remains constrained by the input record and the analogue measurement. Taper orthogonality must not be substituted for sensor independence in a statement about external corroboration.

Copyright 2026, James M. Atkinson

Worked application 3. The variance of correlated tapered estimates

Assume K = 6 power estimates each have variance v under a hypothetical common model and every distinct pair has correlation rho = 0.20. An equal-weight mean has variance v[rho+(1-rho)/K] = v[0.20+0.80/6] = v/3. With independent estimates, its variance would have been v/6. Thus the simplified effective independent count is K_eff = v/Var(mean) = 3, not six. This equicorrelation calculation is illustrative; it does not estimate covariance for a physical receiver. A laboratory requires measured or justified correlation estimates at its actual operating state before quoting the effective count.

Worked application 4. Common-mode fluctuation limits averaging

For K = 5 estimates with pair correlation rho = 0.40 and unit individual variance, the same illustrative model gives Var(mean) = 0.40+0.60/5 = 0.52. The independence formula would give 1/5 = 0.20. The true variance under the stipulated correlation is 0.52/0.20 = 2.6 times the independence prediction. Increasing the number of estimates cannot eliminate the common component. The covariance could arise from a shared receiver gain change, common oscillator state or physical nonstationarity; its cause must be investigated rather than labelled as mathematically independent noise.

Worked application 5. A rare burst changes the mean more than the median

Suppose ten power measurements in arbitrary but consistent linear units are [1,1,1,1,1,1,1,1,1,11]. Their arithmetic mean is (9×1+11)/10 = 2, while the conventional median is (1+1)/2 = 1. The median may accurately characterise the typical background, but it has not preserved the

Copyright 2026, James M. Atkinson

transient event which raised one observation to eleven. If the archive retains only the median, the exceptional physical occurrence is no longer individually recoverable. A robust baseline can be paired with an anomaly log whose performance and false-alert rate are separately validated.

Worked application 6. Why median spectral estimates require calibrated scaling

For an ideal exponential distribution of positive periodogram-power values with population mean μ, the population median is μ ln(2), approximately 0.693147μ. Consequently the population mean-to-median factor is 1/ln(2), approximately 1.442695. This factor illustrates a bias correction in a particular distributional model, not a universal calibration constant for all finite-sample robust estimators. The exact finite-sample median bias depends on sample size and implementation conventions; the receiver's physical noise statistics may depart from the exponential idealisation. The value of a median-derived PSD must therefore be interpreted under a stated model and actual software normalisation.

Worked application 7. A large set of searched null tests increases false alarms

Assume K = 2,000 mutually independent null tests, each with single-test false-alarm probability p = 0.0005. The chance of one or more false alarms is 1-(1-p)^K = 1-(0.9995)^2000 ≈ 0.6322. Overlapping windows, adjacent frequency bins and shared tapers are generally dependent, so the numerical result is not an actual prediction for a modern waterfall. It demonstrates why a per-bin false-alarm threshold must not be quoted as the false-alarm probability of the complete search. A valid search-level

Copyright 2026, James M. Atkinson

claim requires a dependence-aware model, a conservative bound or empirical null-trial calibration.

Worked application 8. Many frame-and-taper alarms may represent one transmission

Suppose one known physical 3-millisecond burst intersects three overlapping analysis frames, and four selected tapers exceed the threshold in every frame. The software emits 3×4 = 12 alarm records. Under an event-level definition there was one injected eligible event and, if successfully recognised, one detection. Treating the twelve alarm records as twelve independent confirmations of external radiation would misrepresent both physical exposure and the statistical dependence of the calculations. The raw alarm history remains useful to diagnose signal shape, but the validated event-counting rule should preserve the unit of inference.

Worked application 9. Overlapping frames do not multiply available time

Let an archive contain L = 10,000 contiguous samples, with FFT window length N = 1,024 and hop length H = 256 samples. The number of complete window starts is K_frames = 1+floor((L-N)/H) = 1+floor(8,976/256) = 36. These 36 frames reuse a common 10,000-sample record. The total observed analogue duration is L/F_s rather than 36N/F_s, and the effective number of independent spectral trials depends on the signal and estimator covariance. Counting 36 windows is valid for describing computations, not for declaring 36 independent observation periods.

Copyright 2026, James M. Atkinson

Worked application 10. Preservation cost of original IQ context

If a candidate interval contains N = 2,000,000 complex samples, stored as signed 16-bit I and signed 16-bit Q words, the raw payload is N×(16+16)/8 = 8,000,000 bytes, approximately 8 MB in decimal units, before metadata and container overhead. This is a feasible bounded retention choice for a material event even where continuous long-term wideband IQ retention is expensive. A 32-bit floating-point I and Q representation would double the nominal payload to 16,000,000 bytes. The calculation does not determine the correct retention policy, but it allows the investigator to distinguish actual storage constraints from an unsupported claim that raw evidence could never be preserved.

Source-scope limitations and reproducibility protocol

The scientific references above inform selected definitions and documented examples, not historical quotations. The full text of the Thomson 1982 article was not obtained or independently audited for every proposition in this discussion; the IEEE abstract supports the described multitaper approach but not every modern forensic application. The SciPy pages establish particular software parameters and published behaviour, not performance certification of a receiver. No real surveillance instrument or physical emitter was measured while constructing the present numerical applications. Each is a stipulated model whose assumptions, variables and limitations are recorded alongside the calculation. Historical biographies are based on publicly accessible institutional records, and the fictional discussion must remain explicitly distinguished from those records.

For publication, the author or independent reviewer should verify every citation against the final source edition, inspect the actual software implementation used for any reproduced experiment, and preserve versioned taper coefficients and scaling examples where necessary. The input reference plane, clock state, analogue filtering, noise population and selection policy must remain available in the relevant technical record. A challenge campaign should retain both difficult null observations and known burst misses. The final editorial proof must ensure that the summary does not turn a conditional spectral estimate into an unconditional source attribution. These qualifications are part of the methods and evidence, not an editorial reservation that can be silently deleted without providing further validation.

QUESTION 047

Copyright 2026, James M. Atkinson

How can cyclostationary analysis help without manufacturing a unique device identity?

Source: V011_Roundtable_Question_047_CP047_Dr_Atkinson(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 047. Expert Roundtable Discussion

Original constructed educational dialogue. The following speeches are newly written applications of historical intellectual traditions, not verbatim utterances or accounts of deceased scholars operating modern SDR equipment. Numerical examples are hypothetical.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, a receiver searching a complex radio-frequency environment often encounters signals whose ordinary power spectra resemble background noise while their internal timing exhibits conspicuous repetition. The packet clock, the framing structure of a communication link, the symbol transition rate or a repeated pulse envelope can leave mathematical structure that a simple energy detector may overlook. Cyclostationary analysis studies statistical properties which repeat in time, particularly periodic variation in second-order correlation. Properly applied, it can be a powerful aid to detecting or classifying modulated emissions. Improperly interpreted, it can transform a shared technological convention into a false claim that one particular device has been identified. The distinction is not subtle where forensic responsibility is concerned. Two unrelated transmitters may employ the same symbol rate, framing interval, oscillator family or protocol, and a receiver can manufacture a periodic artefact of its own.

Copyright 2026, James M. Atkinson

For a complex signal x(t), a representative cyclic autocorrelation at lag τ and cycle frequency α can be expressed as R_x^α(τ) = lim_{T→∞}(1/T) integral over T of x(t+τ/2)x*(t-τ/2)exp(-j2παt)dt. Its Fourier transform with respect to τ is a spectral correlation function S_x^α(f). Here f is ordinary spectral frequency, α is cyclic frequency, and the asterisk denotes complex conjugation. In a finite recording the infinite-time limit is replaced by a specific estimator, smoothing interval and normalisation. A significant nonzero cyclic component can be evidence of periodically varying second-order structure under a validated null model. It is not, by itself, a manufacturer's serial number, an address, a location or a unique source identifier. The distinction between a periodic signal property and a causal claim concerning an emitter must remain explicit. [C1, C2]

There is an additional peril peculiar to software-defined receivers. Parallel ADC mismatch, periodic buffer scheduling, automatic gain control, local oscillator leakage and time-interleaving calibration updates may introduce periodicity that survives ordinary spectral processing. A signal observed at cycle frequency α may be internally generated or reshaped. A two-branch converter, for example, can impose an every-other-sample pattern and corresponding spectral features even when its analogue input lacks that modulation. Similarly, a periodic scan schedule can shape the observed data population and produce cyclostationary artefacts if the examiner confuses observation gating with source gating. A candidate must therefore be challenged by changes of receiver state or by independent acquisition paths in which internal and external hypotheses make different predictions.

Copyright 2026, James M. Atkinson

The distinction between detection and identity will govern the proceedings. A cyclostationary detector may improve the visibility of a particular signal class in a specified noise population. A classification may recognise a family of modulations or framing rates. A device-identification conclusion is a considerably stronger proposition requiring evidence that discriminates between devices employing similar conventions and between receiver-generated and external features. Shared clocks, correlated processing and adaptive thresholds can invalidate the apparent independence of several detections. The investigative record should preserve the original IQ, clock references, cycle-frequency search limits, tested hypotheses, data-dependent choices and negative trials. A confidence interval derived for one preselected cycle frequency does not necessarily apply after searching thousands of candidates and reporting the strongest ridge.

Mr Nyquist will examine the sampling and aliasing of cyclic features. Professor Wiener will address the relationship between periodic statistics, feedback and adaptive receiver state. Dr Shannon will distinguish information about a signal class from information sufficient to identify an individual source. Dr Tukey will examine exploration, multiple testing and the temptation to select a striking cyclic peak retrospectively. Professor Bridgman will insist on an operational definition of what is being measured and on physical challenges which prevent an internal pattern from being attributed to an external device. Seven colleagues will interrogate these positions, and each response will follow its question immediately. Their speech is fictional educational synthesis, not historical testimony.

Copyright 2026, James M. Atkinson

We shall examine ten numerical cases, from symbol-rate aliases and finite observation resolution to multiple-test alarms and clock calibration. Every calculation will identify its assumptions and limitations. A useful result may be that a signal consistent with a given periodic modulation was present under a specified test, but the instrument cannot assign that modulation uniquely to a named device. Such a finding is not scientifically inferior to an extravagant attribution. It is a bounded proposition which another investigator can challenge at the physical reference plane. Mr Nyquist, may I first invite your account of what sampling can reveal, and what it can disguise, about a periodic structure in received data?

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 1: Cyclic frequency, sampling aliases and physical reference planes

Dr. Atkinson, the existence of periodic structure in samples is not proof that an identical periodicity existed at the antenna input. A sample sequence is the outcome of a physical chain and a sampling operation. When a signal contains repetitive statistics, sample timing determines which patterns survive, which alias and which may be confused with periodic features introduced by the acquisition apparatus. A cyclostationary analysis that identifies a peak at some alpha should therefore begin by specifying the analogue input band, aggregate sample rate, converter branch structure, actual sample-time calibration and any digital rate changes. Without these facts the observed cyclic frequency is an estimate on an incomplete measurement coordinate system.

For samples acquired at nominal rate F_s, a continuous-time periodic correlation can map to discrete-time cyclic frequencies modulo the sampling rate under the relevant model. The exact alias relationships depend on whether the signal is real or complex, which correlation is used and how the receiver downconverts the input. If a researcher expects a symbol rate near 150 kilobaud but acquires a particular feature on a time axis sampled at 200 kilosamples per second, an aliased cyclic signature may occur in the digital analysis. It would be unsound to infer a different physical transmitter merely because the observed numerical cycle differs from the familiar symbol rate. The front-end filtering, sample-rate reference and estimation convention must be characterised before claiming an absolute physical cycle frequency.

Some periodicity may arise from the instrument itself. An interleaved converter with M branches has a repeating architecture every M samples.

Copyright 2026, James M. Atkinson

Offset, gain, bandwidth or aperture mismatch can create deterministic periodic errors; when the input is strong, some of the resulting products can grow and appear more signal-like. A receiver may be configured with a periodic automatic gain-control update or a fixed frame-based buffering schedule. Such systems can impose time-varying statistics even when the external source is stationary. These possibilities should be evaluated through input termination, calibrated injection, changed sample-rate settings or a separately characterised receiver, rather than assumed away because the cyclic spectrum looks structured.

The finite observation must be kept in mind. A theoretical cyclic autocorrelation is often defined using a time average over an indefinitely long record. A captured burst provides only a finite number of repetitions, and the resulting estimator's apparent cyclic-frequency resolution depends on observation duration and smoothing. One can interpolate an estimator grid by zero padding, but interpolation does not create additional independent cycles of the physical emission. A line appearing narrower after such padding has not thereby established a more stable source clock. The investigator should distinguish computation-grid spacing from measurement uncertainty, particularly when the emitter's timing may drift or reset between bursts.

Receiver retuning is a useful intervention, but its meaning requires care. An external signal whose ordinary carrier frequency changes position relative to the local oscillator should transform according to the known conversion mapping. An internally generated spur may instead remain at a fixed baseband offset or move with another relationship. The cyclic structure of an external modulation can remain invariant under a correct

Copyright 2026, James M. Atkinson

frequency translation, while clock errors and digital decimation can alter the reported numerical scale. The experiment must therefore predict both ordinary frequency and cyclic frequency under each hypothesis. Merely observing that some peak moves or remains still is not enough if the reference planes are not specified.

A strong adjacent emitter can create another deceptive result through nonlinearity. Suppose two legitimate signals pass through a front end near its compression limit. Their intermodulation products can inherit periodicity from one or both sources and appear at unexpected frequencies. A cyclic detector may identify the structured product correctly while the investigator mistakenly treats that product as an independent transmitted signal at the displayed frequency. Varying input attenuation, preselector configuration and RF source levels can help distinguish a nonlinear receiver product from a genuinely radiated emission. The output of a correctly calculated cyclic spectrum may still represent a distorted input.

The sampling clock itself contributes uncertainty. If the clock frequency differs from nominal by a fractional amount epsilon, a reported cycle frequency based on nominal timing differs from the true input value. A timebase may be stable yet wrong in absolute frequency, and two receivers may share the same erroneous reference. Their agreement would not constitute independent absolute calibration. For an evidential comparison among multiple sensors, record each clock discipline, the frequency reference, delay paths and any times when synchronisation was lost. A tiny numerical variance in a cyclic peak does not remove a systematic clock error.

I therefore recommend a layered conclusion. First establish that the retained data contain periodic second-order structure under the declared

Copyright 2026, James M. Atkinson

estimator. Then establish whether that structure survives appropriate physical and software challenges, with its ordinary and cyclic frequency mappings documented. Only after competing receiver artefacts have been addressed should the report infer an external emission class. Identification of one device among several employing the same modulation requires additional distinguishing evidence. A symbol clock is a common engineering property, not a personal identity document. I pass the token respectfully to Professor Slepian for the question of whether a finite number of apparent repetitions can support an extremely narrow cycle-frequency estimate.

David Slepian | Peer question 1 to Harry Nyquist

Mr Nyquist, your account rightly separates physical and sampled cyclic frequencies, but I wish to challenge the phrase 'narrow cycle-frequency estimate'. Suppose a finite record contains only a handful of repeated frames, while an engineer applies a very long zero-padded transform and obtains a sharply located cyclic peak. The resulting axis can be sampled to a fraction of a hertz, but the source may have transmitted only twenty frames in total, and its timing may have drifted within those frames. Under what signal model could such a frequency estimate possess meaningful accuracy, and how should the laboratory test that model? Does a concentration-optimised window help by suppressing leakage, or might it create a false confidence about the stability of a source clock? I also ask what role the actual sampling-clock reference plays when the instrument's own periodic branch schedule can generate a similar signature, particularly under gain or aperture mismatch.

Copyright 2026, James M. Atkinson

Harry Nyquist | Immediate answer to David Slepian

Professor Slepian, the answer depends upon what parameter is being estimated. For a stipulated periodic sequence with a stable period and a specified noise model, one can fit the periodicity to the observed data and obtain a model-dependent uncertainty. The frequency spacing of the padded transform is merely the grid used to display or search that estimate. A source whose frame interval drifts or resets violates the stable-period model, and a nominally narrow fitted peak may describe an average or an artefact of the fitting procedure. The examiner should preserve the actual number of observed cycles, the timebase calibration and the residuals of the fitted periodic model. A fine grid cannot stand in for those observations.

Concentration-optimised windows can reduce certain leakage effects and may improve estimation under an appropriately described signal class. They do not extend the observation duration or establish that the source oscillation remained stable beyond the measured interval. The laboratory should evaluate several known reference signals with controlled timing drift and burst lengths, varying the phase of their onset relative to the receiver's analysis windows. A model should be accepted for a claimed uncertainty only where its predictions survive relevant challenges. If a few observed cycles are compatible with materially different timing histories, the interval should remain wide or the reported quantity should change to one supported by the record.

Copyright 2026, James M. Atkinson

A separate test is required to exclude the receiver's periodic architecture. An interleaving spur may generate a repeatable cyclic feature even with no relevant external modulation. An input termination or known stationary noise source can reveal whether the feature persists without the suspected RF signal; changing the converter mode or clock reference may produce predictions different from an external modulation hypothesis. The test must consider that a receiver artefact can be input-dependent and thus disappear on termination while remaining internally generated under a strong legitimate signal. Controlled source injection at several levels can help expose that distinction.

Finally, a report should distinguish a measured cycle frequency from a device identifier. Multiple transmitters may share a nominal symbol rate, and one transmitter may vary its actual rate with temperature, oscillator correction or operating mode. A stable timing signature is useful for classification and for generating an investigation hypothesis, but source identity needs further evidence. The sound practice is to preserve the raw record, the clock model, estimator definition, validation outcomes and rival causal explanations. I now invite Dr Hamming to question how a practical implementation can search a broad range of cycle frequencies without turning computational flexibility into uncontrolled statistical selection.

Richard Wesley Hamming | Peer question 2 to Harry Nyquist

Mr Nyquist, an engineer may compute a two-dimensional spectral-correlation map across hundreds of ordinary frequency channels and

Copyright 2026, James M. Atkinson

thousands of cyclic-frequency values. A weak ridge appears, the analyst chooses a narrower search interval, adjusts smoothing and finally publishes the most convincing peak. A remarkable amount of computation may be involved, yet the displayed structure can arise from one chance fluctuation selected out of many. What minimum experimental history would make this result reproducible and statistically interpretable? Should the operator retain every parameter trial, or can one save a predeclared selection rule and the raw samples? I also wish to know how computation should be divided between a wide initial discovery search and a subsequent confirmatory experiment. A system may possess enough processing power to create infinitely many attractive representations of one finite input, but it cannot create a new electromagnetic observation merely by spending more machine cycles. What would count as a second physical test rather than a second rendering of the same evidence?

Harry Nyquist | Immediate answer to Richard Wesley Hamming

Dr Hamming, I would distinguish computational reproducibility from evidential validation. A complete raw input interval, a versioned executable description of the search, the tested frequency and cyclic-frequency ranges, the smoothing conventions and the reported candidate allow another examiner to reproduce the algorithm. For material findings, the history of exploratory parameter choices should also be preserved, at least to the extent necessary to reconstruct how the candidate was selected and how many effective opportunities were searched. Keeping a snapshot of every processor register is

Copyright 2026, James M. Atkinson

unnecessary; concealing the selection rule is unacceptable. The latter determines the appropriate null distribution for the strongest result.

A broad discovery pass can be useful even when its threshold is exploratory. Its output should be labelled as a candidate, not an independently validated device identification. One may then freeze a detector defined by the discovered feature and challenge it using independently acquired data or a physical injection campaign with null cases and alternative sources. The challenge should include signals sharing the same nominal modulation, receiver-generated spur conditions and state changes which could reveal a false causal attribution. A second mathematical pass over the same archive is a useful robustness check but is not a new physical observation.

Computation can reduce numerical error and explore more models, but it does not remove analogue uncertainty. If the receiver records samples with an uncalibrated clock or through a nonlinearity, many elaborate searches will faithfully analyse that imperfect record. An investigator who finds an apparently stable cycle should vary the RF conditions under which internal and external explanations predict different outcomes. A change in antenna or input attenuation, for example, must be interpreted with the instrument response measured, because both legitimate source strength and receiver artefacts may change together. The goal is a challenge capable of failure, not a demonstration constructed to keep the preferred signal visible.

I would also record the population of physical opportunities when interpreting negative findings. A scan that observes one channel

Copyright 2026, James M. Atkinson

intermittently may miss most bursts regardless of the richness of the cycle-frequency analysis applied during its limited dwell. The reported absence of a cyclic peak is conditional upon exposure, sensitivity and the tested signal class. For a selected candidate the final report should state the cyclic feature, the conditions of detection and the unresolved alternatives without asserting a unique device identity from an ordinary shared modulation property. I pass the floor courteously to Mr Wiener, whose work on stochastic processes and control may illuminate the hidden periodicity created by the receiver's own history.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 2: Observer feedback and the manufacture of periodic structure

Dr. Atkinson, I should begin by making the observation system part of the physical model rather than picturing a passive observer who merely reads a waveform. A software-defined receiver contains adaptive subsystems whose future operation depends on earlier measurements. Automatic gain control, frequency tracking, burst triggering, threshold adjustment, channel scheduling and even the decision to preserve a buffer can couple the apparent statistics of the retained record to the receiver's internal history. A periodic feature in that record may correspond to an external modulation. It may equally be the mathematical result of an observer which periodically opens and closes its window upon the world. The distinction is causal, not rhetorical. In my work on prediction and feedback, the observer was never exempt from the consequences of the mechanisms by which he acted upon the system.

Consider a front end that updates its gain every two milliseconds. Suppose an input of stationary noise passes through the front end, and the gain is periodically changed in response to a running estimate. If the gain update causes a deterministic alternation in output variance, the recorded process may have a periodically varying second-order moment even when the analogue process at the antenna was stationary. A cyclic-correlation estimator can quite properly report that the *recorded* sequence has structure at the update rate of five hundred hertz. It cannot legitimately conclude from this result alone that an unknown transmitter generated a five-hundred-hertz cyclic feature. The output observation is correct within its reference plane, while the alleged cause has been misplaced. A good

Copyright 2026, James M. Atkinson

technical report should preserve that distinction even if it makes the executive summary less dramatic.

One may go further. A recorder that stores samples only upon a periodic trigger may create a discontinuous archive in which the gaps are not incidental; they determine which events survive to be analysed. If an operator reconstructs the retained bursts on an artificial uniform time axis without preserving their true intervals, the apparent cyclic frequencies can reflect the archival process. If the correct time stamps are retained but the analysis ignores the gaps, an analogous mistake occurs mathematically. The observer must treat the observation mask as part of the data-generating model and distinguish a physical periodicity from one induced by sampling and selection. Merely producing an uninterrupted array of numbers does not demonstrate that the physical observation was uninterrupted.

Feedback can also create an apparently convincing confirmation loop. A detector identifies a spectral-correlation feature, a control law tunes the receiver to maximise it, and the resulting stronger feature is then offered as corroboration of the original identification. That procedure may improve sensitivity for a specific class of signals, but it is not an independent confirmation of a uniquely identified emitter. The system has deliberately sought the thing that makes its own decision variable largest. The correct comparison is between the predictions of rival hypotheses under interventions whose parameters were set before observing the challenge outcome. One might freeze the adaptation coefficient, inject a blinded waveform, alter the sample-rate plan, or compare a reference receiver which does not share the adjustment law. The resulting measurement can

Copyright 2026, James M. Atkinson

then test whether the periodicity belongs to the source, the receiver, or their interaction.

An adaptive receiver need not be disqualified from forensic work. Adaptation is valuable when the search environment contains strong varying signals and sparse weak emissions. Rather, the algorithm's history must be observable enough to support the particular conclusion. Save control-state changes, gain coefficients, trigger logic, timing references, affected acquisition windows and relevant firmware versions. Where the apparatus uses a closed proprietary calibration process, one may test its input-output behaviour across a declared operating envelope even when internal states are not available. That would establish a bounded performance claim. It would not prove that every subsequent feature was external in origin. The absence of introspection calls for more careful external validation, not an unbounded presumption either for or against the instrument.

My second concern is correlation among apparently independent detectors. Two receiver channels can use different physical ADCs and still share a clock, RF reference, antenna, synthesiser, automatic gain regulator or common software. Their agreement can arise from shared error. A second analysis pipeline over the same archived IQ data certainly can reveal processing mistakes, but it provides no independent view of the analogue input. Even two independently constructed receivers exposed to the same external interference can agree without proving the alleged source identity. Corroboration must be defined relative to a proposition and a dependency graph. It is possible to confirm the presence of a repeated spectral structure

Copyright 2026, James M. Atkinson

while remaining unable to distinguish two transmitters using the same waveform convention.

We should also take care with words such as *unique*, *stable*, and *persistent*. A cyclic ridge can persist over several acquisitions because the communications standard fixes a symbol rate or because a receiver always places its scheduler at the same interval. Stability is an empirical description. Uniqueness requires evidence that rival devices, receiver states and environmental processes do not produce an indistinguishable result within the stated measurement uncertainty. An investigator who has not tested this proposition must not transform persistence into identity. The proper intellectual discipline is to recognise an observation, define the model linking that observation to a cause, and devise an experiment likely to produce different outcomes if the cause is wrong.

The completed account should show the original evidence and the path of transformations. It should describe the estimator, the cycle-frequency search, the system state, the control-loop history and the physical challenge. It should preserve both successful and discordant outcomes, especially when a change of receiver state causes the feature to disappear. Such a disappearance can be diagnostically valuable, but it cannot by itself prove which part of the system changed the result. A final report may state that a periodically correlated component was present in the archived observations under particular operating conditions, and that controlled challenges support an external origin only within specified limits. That is a stronger scientific statement than an unsupported device-name assertion. I pass the token respectfully to Professor Shewhart, who may ask whether the

Copyright 2026, James M. Atkinson

receiver's ordinary monitoring charts have quietly become mechanisms for selecting their own exceptional results.

Walter Andrew Shewhart | Peer question 3 to Norbert Wiener

Professor Wiener, your account of an instrument participating in its own observation is persuasive, but a practical validation programme must distinguish common process variation from special causes without diagnosing every cycle as a failure. Suppose a receiver's gain-control coefficient changes periodically, yet repeated laboratory challenges show a cyclostationary feature whose estimated strength remains approximately constant. A monitoring chart may label the results stable, while a hypothesis test may call the peak significant. Would you permit the conclusion that the feature is external if the same apparatus is used to define the nominal range, the decision limit and the subsequent performance assessment? I ask also how one should treat the cases omitted from a validation report because they fell in an invalid acquisition interval. The excluded intervals may be precisely where the receiver state changed most, so the apparent stability may reflect the operator's selection rather than the physical behaviour. What experiment would separate ordinary operating variability from a systemic mechanism that has not been directly observed?

Norbert Wiener | Immediate answer to Walter Andrew Shewhart

Dr Shewhart, I would not condemn the use of monitoring charts. They are excellent instruments for detecting changes in a process defined with sufficient clarity. The defect arises when the chart's stable behaviour is offered as proof of a different proposition. The chart can establish that a particular detector statistic stayed within the

Copyright 2026, James M. Atkinson

observed reference distribution; it does not show that the distribution describes external transmitters rather than an internal periodic source. If the instrument generated both the candidate and its own acceptance limits, the comparison is conditioned on the mechanism being assessed. The result may be useful for measuring repeatability, but source attribution requires a physical intervention capable of separating alternatives.

I would start by recording the receiver state independently of the signal candidate wherever practicable. A log of gain coefficients, update intervals, temperature and sample-rate settings allows one to examine whether changes in cyclic strength coincide with control transitions. Yet correlation in such a log is not enough: a strong external signal can also cause a legitimate gain response. Introduce a known signal at the declared RF boundary, then terminate or attenuate the input while holding the internal programme fixed. Change the update period or the control law if the design permits, and record which peaks follow the internal setting and which follow an external frequency or modulation prediction. Randomise the order of challenges so that thermal drift and operator expectation are not confounded with the conditions being compared.

The invalid intervals are a matter of particular importance. If they are omitted according to a rule determined after viewing the results, the reported stability is conditional on a selected population. A proper record identifies when and why an interval was invalid, the fraction of observation time removed, and the intended relationship between that removal and the claim. One should not count invalid intervals as

Copyright 2026, James M. Atkinson

negative detection trials. Neither should one silently discard them to make a receiver appear better behaved. A separate category of missing or unusable observations is the correct scientific treatment, accompanied by a sensitivity analysis concerning plausible events during those periods.

Where full internal observation is impossible, a controlled external campaign can still provide a bounded answer. Establish fixed procedures using known injected modulations, independent null records, alternate receiver states and challenge data withheld from calibration. Report sensitivity and false alarms for the relevant signal and interference population. If the external-origin conclusion remains observationally indistinguishable from a known internal mechanism, say so. The chart may still support the narrower claim that the detector is stable under specified conditions, but it cannot resolve a causal ambiguity that the experiment never challenged. We should prefer one demonstrably limited conclusion to several impressive but untested adjectives.

Harold Stephen Black | Peer question 4 to Norbert Wiener

Professor Wiener, may I ask whether you have made dependence on internal state too comprehensive to yield a practical measure of signal information? Any receiver necessarily transforms the input, and even a fixed filter selects certain bands while suppressing others. A decision system could be accused of constructing the observed statistics merely because it defines a threshold and reports only selected events. Yet a properly characterised communication receiver can preserve enough statistical structure to distinguish a modulation class despite such

Copyright 2026, James M. Atkinson

transformations. Is there a principled boundary between ordinary, useful signal processing and observer-induced periodicity that defeats external inference? Specifically, should an investigator require full recovery of the analogue waveform, invariance under every possible front-end configuration, or only a demonstrable mapping of the relevant statistic across selected transformations? How would you specify a minimal retained record that permits a later examiner to challenge whether cyclic structure existed before the instrument modified the data?

Norbert Wiener | Immediate answer to Harold Stephen Black

Mr Black, I have no wish to demand an impossible untouched observation. A measurement is always an interaction with an apparatus, and every useful receiver imposes a transfer function, finite bandwidth and a convention for recording. What matters is whether the relationship between the desired input property and the recorded statistic has been sufficiently characterised for the claim at issue. If a linear time-invariant filter acts upon a cyclostationary signal, its effects on spectral correlation can be modelled under stated assumptions. An investigator can then make a qualified statement about the input signal class, provided the filter response, sample timing and estimator are known well enough. A periodically time-varying or adaptive path poses further questions because it can introduce the same category of structure being inferred.

The minimal record is therefore claim-dependent. A detection claim may require raw IQ around the event, acquisition settings, the calibration state, the selection rule and the portion of spectrum actually observed. A claim about transmitted symbol rate also

Copyright 2026, James M. Atkinson

requires a credible clock scale, alias model and stability information. A claim about a uniquely identified device would require much more: discriminatory features, reference populations, repeatability under environmental and receiver variations, and exclusion of credible alternative emitters. The term minimal must not become a means of withholding whatever would reveal a contradiction. It refers instead to the smallest sufficiently informative record for a specified testable proposition.

We should also distinguish invariance from predictability. A genuine external signal need not produce identical digital values after an antenna change, a gain change or a receiver substitution. Its amplitude and phase may differ greatly. What a valid experiment requires is a prediction for how the selected features should change under each hypothesis. If a receiver-generated spur follows sample-rate or control-update frequency while an external modulation's cycle rate follows its own physical clock, a controlled change can separate them. Conversely, if both vary together because of a common reference, an additional independent variable must be introduced. One does not win an argument by demanding that the signal remain visually unchanged under physically different conditions.

Finally, information lost at the instrument boundary cannot be recovered by retrospective mathematical sophistication. If only trigger-selected records survive, the unobserved periods are not negative trials. If input clipping destroys the waveform's peaks, a precise spectral estimate of the clipped series does not identify those peaks. But where the required property survives a known transfer,

Copyright 2026, James M. Atkinson

processing can extract it with useful uncertainty. The responsible report states the mapping, the evidence supporting the mapping, and the alternatives it cannot exclude. I pass the floor to Dr Shannon in his principal capacity to expand the distinction between modulation-class evidence and information sufficient for unique source identity.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 3: Information about classes is not information identifying an individual emitter

Dr. Atkinson, the value of a periodic statistic depends upon the question the receiver is asked to answer. If the question is whether a recorded interval contains a modulation with second-order periodicity, the presence of a particular cyclic component may be highly informative. If the question is whether the modulation belongs to a specified family, a collection of cyclic components, their relative strengths and their behaviour under frequency changes may support useful classification. If the question is which individual transmitter, among many capable of producing the same waveform convention, emitted the signal, those observations may have almost no discriminatory value. The numerical complexity of the estimator cannot manufacture the missing distinction between objects that are physically indistinguishable under the chosen measurement.

Suppose a population includes a thousand transmitters adhering to one symbol-rate and framing convention. A detector identifies that shared convention without error. It has narrowed the source from an unrestricted population to a class, but it has not selected one member of that class. Unless additional validated features differentiate the members, any announcement of one serial identity would import information from outside the observed cyclic statistic. Such information might come from spatial measurements, independently authenticated transmissions, source-control tests, lawful metadata or a properly validated physical-layer fingerprint. None of those is automatically contained in an ordinary second-order cyclic spectrum. This distinction can be expressed without invoking a particular

Copyright 2026, James M. Atkinson

information-theoretic estimator: identical likelihoods for competing source hypotheses cannot yield a data-driven preference among them.

The term *feature* often conceals several different questions. A peak at cycle frequency alpha may indicate repeating second-order statistics within a finite observation. An estimator might report the magnitude and uncertainty of that peak. A detector compares some statistic with a decision limit to decide whether the observation is consistent with a selected null model. A classifier assigns a label among predefined classes. An attribution procedure evaluates competing causal explanations for an individual source. These operations require different reference data and carry different error rates. Confusing them allows an excellent detector to appear to be an excellent identifier, although the necessary source labels were never measured or verified.

It is particularly tempting to equate a large correlation magnitude with a highly probable identity. That is an error of conditional reasoning. A detection statistic may be improbable under a particular noise-only null hypothesis and entirely commonplace under thousands of different external transmitters or internal receiver defects. A small null probability says little about the relative probabilities of those alternatives without their likelihoods and relevant prior information. If the investigator reports a p-value after searching thousands of cycle frequencies, the selection procedure further affects its interpretation. The probability calculation must describe the entire decision rule that produced the displayed result, not the single selected line regarded in isolation.

The finite record also creates genuine statistical limits. A very short burst contains relatively few repeated symbol or frame cycles. Its estimated cyclic

Copyright 2026, James M. Atkinson

correlation can have substantial variance, and the relevant cycle-frequency resolution is related to the actual observation duration, not merely the apparent fineness of a zero-padded display grid. An estimate based on an interval selected because it exhibits a strong feature will be biased toward apparent significance unless the selection is considered. A repeat acquisition may reduce uncertainty if it provides a new physical observation under a sufficiently comparable signal model, but repeatedly transforming one archive does not multiply the physical evidence. One should never add the results of overlapping or correlated estimators as if they were independent transmitters.

There is an attractive practical use of cyclostationarity in difficult noise backgrounds. Under an appropriate model, stationary noise contributes no nonzero cycle-frequency coefficient in expectation, while a deliberately periodic communications signal may contribute such a coefficient. In a finite implementation, however, estimator variance, nonstationary interference and receiver-induced periodicity can create nonzero estimates even under an external-signal-absent condition. Therefore a claim of reliable detection must be based on measured null distributions and challenge trials representative of the operating envelope. The familiar observation that cyclostationary processing can exploit spectral redundancy is a principle requiring a test plan, not a blanket certification of every receiver or environment. [C1, C2]

One may improve the causal interpretation by designing complementary observations. An antenna substitution might change an external emitter's measured amplitude according to the propagation geometry while leaving some digital artefacts unchanged, although gain-control interaction

Copyright 2026, James M. Atkinson

complicates that prediction. A new sample rate can move certain internally generated periodic patterns on the recorded time scale, while the external modulation rate remains physically fixed subject to clock calibration. A second independently clocked receiver can test whether a candidate survives alternate front-end and timing mechanisms. None of these tests alone proves identity. They can nevertheless eliminate or restrict particular explanations and turn a descriptive spectral feature into a more credible external-origin claim.

It is also necessary to consider what a reference library of transmitters actually measures. If the library contains observations from only a few selected devices in one room on one day, a high classification accuracy within that library does not imply the same accuracy across all devices, temperatures, antennas and receiver settings. A system can learn room propagation, receiver gain, data-set artefacts or the chosen communications protocol rather than an individual device. Training and evaluation sets should be separated by device, acquisition session and relevant nuisance conditions according to the intended claim. Otherwise a classification exercise may show that a system remembers its own archive rather than identifies an unfamiliar external source.

My recommendation is to report three separate outcomes: the observed cyclic statistic, the tested signal-class decision, and the permissible source inference. Each should carry the appropriate uncertainty and alternative explanations. A result may support the phrase 'periodic modulation consistent with the specified class' while withholding any claim that an individual device was identified. In a defensive surveillance investigation that distinction is indispensable. The objective is to find credible signals and

Copyright 2026, James M. Atkinson

preserve evidence capable of later examination, not to convert the common mathematical grammar of communications into an unwarranted accusation. I invite Professor Neyman to challenge whether this cautious division of claims is compatible with an operational detector that must make decisions at a declared false-alarm rate.

Jerzy Neyman | Peer question 5 to Claude Elwood Shannon

Dr Shannon, a receiver deployed in a large building cannot defer every decision indefinitely while it waits for perfect source identification. It must decide which candidate signals warrant retention, additional sampling or a change of antenna. You have divided detection, classification and attribution admirably, but a practical operator still needs a threshold and an interpretable performance statement. Suppose the system searches a grid of many ordinary frequencies and cyclic frequencies, while the analyst allows an adaptive noise estimate to alter the threshold. Under what conditions may the false-alarm probability be assigned to the overall decision, and how should missed detections be measured for intermittent signals whose number of genuine opportunities is not known? Would it suffice to calibrate the test on simulated stationary Gaussian noise, or must the null population include real electromagnetic interference and internal receiver artefacts? Finally, can one speak responsibly of an unknown emitter's probability of being present when the available calibration establishes only the distribution of the detector statistic under selected laboratory conditions?

Claude Elwood Shannon | Immediate answer to Jerzy Neyman

Thank you for that question. Professor Neyman, an operational decision does not require a completed causal investigation. A detector

Copyright 2026, James M. Atkinson

can be assigned a threshold for preservation and follow-up, provided the meaning of its alarm is not inflated into a unique attribution. The relevant false-alarm probability is that of the *entire specified decision rule* under the defined null population. If the system searches many cycle frequencies and reports its maximum statistic, the threshold should reflect the distribution of that maximum, including correlations among the tested cells and any data-dependent smoothing or adaptation. Calculating the tail probability for one retrospectively selected cell is not equivalent. A practical approach uses independent null trials or a validated resampling model which reproduces the full search procedure, rather than merely multiplying a single-cell significance value by a guessed count of tests.

The null population must fit the claim. Gaussian-noise simulation may be useful for testing an algorithm's implementation or a deliberately restricted theoretical model. It cannot alone establish field false-alarm performance in an environment containing periodic digital interference, intermittent legitimate transmissions, switching power supplies and receiver-generated cycling. Such phenomena may be the principal causes of false external-origin alarms. The investigator should include them in the challenge population or explicitly restrict the field claim. Similarly, one cannot estimate missed-detection probability from an archive of alarms alone. Known-present challenge signals are required, with injection times and levels selected independently of the detector, so that opportunities are defined even when the receiver fails to report them.

Copyright 2026, James M. Atkinson

Exposure is fundamental for bursty signals. If a scanner visits a frequency for one tenth of each observation cycle, a narrow burst may never coincide with its dwell, regardless of how sensitive the cyclostationary estimator is during a visit. A valid report separates acquisition exposure from detector sensitivity conditioned on exposure. It identifies dead time, invalid intervals, sample-rate changes and adaptive threshold state. The system may report performance for specified burst duration, amplitude, modulation, interference and receiver schedule. It cannot claim universal detection probability for an undefined distribution of unknown emitters.

As for the probability that one particular unknown source is present, a false-alarm rate does not supply it. Such an inference requires additional probabilistic modelling of competing sources, their occurrence rates and the observed evidence. The alarm can still justify preserving a candidate and performing a physical survey. It should be worded as an operational trigger under a defined test, not as a probability of guilt or device identity. This is no obstruction to a useful instrument; it is the difference between an effective search policy and an evidential conclusion. I pass the floor respectfully to Dr Tukey, whose work on exploratory statistics may help us prevent an impressive picture from becoming an unacknowledged record of post hoc selection.

Copyright 2026, James M. Atkinson

John Wilder Tukey | Principal response 4: Exploration, selection and the arithmetic of attractive peaks

Dr. Atkinson, the first obligation in analysing an unfamiliar signal is often to discover what sort of question can sensibly be asked. Exploratory displays of cyclic spectral correlation are extraordinarily useful for that purpose. A two-dimensional map can reveal ridges, clusters, harmonic relations or suspicious receiver-state dependencies that no single preselected statistic would have exposed. I would not suppress exploration merely because it produces multiple comparisons. I would instead insist that the investigation distinguish exploration from confirmation, and that it preserve enough of the exploratory history to prevent the most attractive picture from being passed off as the inevitable outcome of a fixed test.

Imagine an analyst searches ten thousand cycle-frequency candidates, tries five smoothing widths, displays three colour scales and adjusts the ordinary-frequency interval until one ridge appears convincing. The published exhibit shows only the final graph and a p-value derived for a single chosen cyclic coefficient. This is not simply an innocent choice of presentation. The procedure selected a rare-looking outcome from many correlated possibilities, then evaluated it as though it were nominated in advance. The apparent precision is illusory. A complete description should include the candidate generation method, search ranges, resolution, smoothing, thresholds and any human decisions material to selection. The required level of detail is that needed to reproduce the decision rule and its selection bias, not every mouse movement of an operator.

A disciplined sequence is possible. First, use exploratory tools on discovery data to identify candidate features and plausible mechanisms.

Copyright 2026, James M. Atkinson

Second, freeze a limited confirmatory analysis, including its target frequencies, rejection conditions and permitted preprocessing. Third, assess that frozen rule on independent physical observations or properly constructed challenge records. If new results motivate changing the rule, label the changed analysis as a new exploratory candidate and test it on a fresh validation population. This avoids the sterile demand that the investigator never learn from data while preserving the distinction between learning and testing. It also gives the engineer useful feedback about which parts of the instrument or environment deserve a deliberate intervention.

The temporal structure of the recording complicates ordinary statistical shortcuts. Overlapping analysis windows are not independent trials just because their FFTs occupy different array indices. Several cycle-frequency cells can be correlated because they share samples, smoothing kernels or harmonic relations. A receiver scanning periodically may generate clusters of candidate peaks across many channels during one underlying event. A naïve count of all displayed cells exaggerates the number of independent physical observations, while pretending that the search involved only one cell understates the number of statistical opportunities for false alarms. Rather than assume either extreme, the analyst should measure the null distribution of the actual maximum or cluster-level decision over realistic acquisitions.

The strongest cyclical ridge may be the most stable but not the most causal. A signal in a receiver's local oscillator, a periodic clock fan-out defect, or a recurring automatic gain transition can produce an exceptionally neat pattern. An external emitter's modulation may be less neat because the receiver sees fading, frequency drift and interruptions. The investigator who

Copyright 2026, James M. Atkinson

ranks candidates only by visual regularity risks placing internal artefacts first. Comparative experiments should therefore change one relevant physical or processing condition at a time, and the prediction under each candidate hypothesis should be recorded before examining the outcome. The first scientific question is not which peak is prettiest, but what mechanism would make it appear and what observation could falsify that mechanism.

There is also a serious danger in unbalanced reference data. A classifier trained on a handful of modern signals may identify a particular communications protocol with high apparent certainty, because every sample from one device was recorded in one session and every sample from another in a different room. The model may learn session time, propagation geometry, receiver temperature, or data-file boundaries. Randomly dividing frames from the same acquisition into training and testing sets preserves these shared nuisances and makes the accuracy look stronger than a genuine independent-device test would. The split should reflect the intended use: different devices, days, frequencies, receiver states and environments where such generalisation is claimed. The method must be challenged by confusable technologies, not merely against easy negative examples.

An exploratory spectral map should carry the same evidential humility as any other diagnostic display. Colour scale, normalisation and interpolation can make a weak statistical fluctuation look like a sharp geometrical structure. A plot that suppresses the zero-cycle slice or clips large values may improve human perception of an interesting pattern, but it changes what the reader sees. Preserve the underlying numeric array and plotting

Copyright 2026, James M. Atkinson

settings. The headline conclusion should not depend upon a cosmetic choice which has no physical meaning. A defensible figure distinguishes observed sample statistics, computed uncertainty, rejected artefact hypotheses and remaining source alternatives.

The net result is not to abandon a powerful detector. Properly deployed, cyclic analysis can find modulated signals concealed in substantial stationary noise and can reveal structure that energy detection misses. The danger is the transformation of one real, limited success into several untested claims. One may discover a cyclostationary candidate, then independently validate a modulation-class finding, and only after additional discriminating evidence attempt source attribution. If an investigator fails to preserve that logical sequence, the original spectral data may still be sound, but the published interpretation will not be. I invite Dr Fisher to challenge how much a predeclared null model can realistically accomplish when the receiver's interference environment is too varied for one convenient probability distribution.

Sir Ronald Aylmer Fisher | Peer question 6 to John Wilder Tukey

Dr Tukey, you have rightly distinguished exploratory and confirmatory studies, but the division raises a further statistical concern. Even when the investigator freezes a rule after examining one discovery archive, the later challenge records may share the same receiver architecture, location and periodic interference mechanisms. Their numerical values are new, but their causes may not be independent of the discovery process. If a detector is validated only in the same room with the same clock and protocol mix, it may appear convincingly reproducible while its supposed modulation-class capability remains parochial. What should

Copyright 2026, James M. Atkinson

constitute an independent confirmation population, and how should we avoid declaring significance from a model whose nuisance factors were chosen retrospectively? More particularly, how would you report evidence when a conventional test of significance rejects a noise-only null, yet there remain several plausible receiver-generated and external-signal alternatives? I ask whether a significant cyclic coefficient has any sound meaning beyond the restricted model that gave rise to the significance calculation.

John Wilder Tukey | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, the word independent is too often treated as a magic charm rather than a property defined relative to a question. New samples from the same hardware may be independent in their thermal noise realisations while sharing an uncalibrated periodic spur. Fresh recordings on a different day may reduce some temporal dependencies while preserving the same antenna coupling. Independent validation of an external-origin inference must challenge those shared mechanisms. The experimental design should therefore specify which nuisance variables are varied, which are controlled and which remain unexamined. A split by file name or by random analysis window is not automatically sufficient.

For a frozen cyclic detector, I would choose validation records representing the intended population, with independently generated null and known-present cases. That population should include stationary noise, legitimate emissions with confusable modulation, receiver-state transitions, interleaving artefacts, power-supply

Copyright 2026, James M. Atkinson

periodicity and relevant interference. The rule's overall false-alarm and detection rates could then be estimated on those records, with confidence limits appropriate to the actual number of independent challenge units. If those units are not genuinely independent, report the clustered design and use the number of independent sessions or physical interventions rather than the impressive number of correlated FFT windows to describe the evidence base.

A significance rejection of one noise-only model can be worthwhile. It establishes that the observed statistic is unexpected under the specified conditions, assuming the calculation and selection correction are valid. It does not identify which alternative produced the result. A receiver defect and an external communications signal can both be inconsistent with stationary Gaussian noise. The next experiment must distinguish those alternatives through physical predictions rather than attempting to make the p-value speak a causal language it was never designed to speak. The more mechanistically informative test might be an input termination, sample-rate change or independent front-end substitution rather than a longer integration of the original record.

A scientifically mature report should therefore state the model rejected, the population against which the decision rule was tested, the scope of the confidence interval and the surviving alternatives. If the detector is exceptionally effective at discovering periodic structure but unreliable at attributing source identity, those are not contradictory findings. They describe different performance dimensions. The investigator may use the first strength to prioritise

Copyright 2026, James M. Atkinson

fieldwork while ensuring that the second weakness is explicit in any evidential conclusion. I now pass the floor to Professor Bridgman to examine whether the quantity called a device signature has been operationally defined at all.

Copyright 2026, James M. Atkinson

Percy Williams Bridgman | Principal response 5: Operational definitions, reference planes and the source-identity claim

Dr. Atkinson, we should examine what the phrase *device fingerprint* means before arguing about the confidence with which it is assigned. If it denotes a particular cyclic-frequency pattern measured in a received IQ record, then its definition is operational and reproducible once the estimator, acquisition window, clock reference and preprocessing are specified. If it denotes a stable physical property unique to one transmitter, the first operation is not sufficient to establish the second definition. An operation that measures a shared symbol rate cannot distinguish two individual transmitters using the same rate. The words unique and identifying must be justified by a discriminating experiment, not merely by the familiarity of the metaphor of a fingerprint.

Let us distinguish three reference planes. The first is the external electromagnetic field at the antenna location, shaped by propagation and interference. The second is the analogue input to the digitiser, after amplification, filtering, mixing, automatic gain control and possible nonlinearity. The third is the retained digital sequence after clocking, sampling and processing. A cyclostationary coefficient computed at the third plane is unquestionably a property of the retained record under its estimator. Inferring the first plane from it requires a validated transfer or an experimental challenge. Some receiver defects are shared by all acquisitions at the third plane and can thus appear extraordinarily stable. They may be excellent fingerprints of the receiver system and poor evidence about the source under investigation.

Copyright 2026, James M. Atkinson

A well-defined source-identity experiment would measure a population of candidate emitters with confusable modulation conventions under varied operating conditions. It would state what identifying feature is extracted and what reference class it separates. If devices share nominal symbol rates but differ in oscillator phase noise, modulation imperfections or clock drift, those additional properties might have discriminatory value. Yet their measurement may depend strongly on receiver frequency stability, multipath, temperature, gain and processing. The experiment must show that the claimed source property persists sufficiently under such nuisance changes and that the reference population contains credible alternatives. An identification statement exceeding that population is an extrapolation, not a measured fact.

There is a practical distinction between a natural feature and an authenticated identity. A lawful communication protocol may include an address or identifier inside decoded payload data. That identifier is not equivalent to a unique physical emitter, because addresses can be reassigned or imitated and decoding itself can fail. Conversely, a physical-layer feature may be repeatable but not unique. Combining several observations can strengthen an inference if the dependencies and error mechanisms are understood. It cannot erase the distinction between what a feature actually measures and the identity that the investigator wishes it to indicate. A careful report records both the observed information and the additional assumptions required for attribution.

The test apparatus can also create apparent device specificity through its training procedure. If every reference recording of device A used receiver gain state A and every reference of device B used gain state B, a machine

Copyright 2026, James M. Atkinson

classifier might identify the gain state with admirable accuracy. The operator may mistakenly interpret this as successful source identification. Cross-validation must separate acquisition sessions and deliberately vary receiver settings independently of source labels. Where the instrument cannot expose its processing, controlled substitution becomes particularly important. An independently characterised acquisition path can test whether the supposed feature follows the emitter or the recorder. The absence of such a test cannot be remedied by increasing the number of derived feature vectors from the same raw file.

An operational definition should also include rejection conditions. How large a difference in cyclic frequency or spectral correlation magnitude is sufficient to distinguish two classes? How much clock drift or filter response variation is admitted? What outcome marks an invalid acquisition, and what happens if the estimator produces no reliable peak? If these questions are answered only after seeing the data, the result is not a stable identification procedure. A valid procedure declares its comparison rule, uncertainty and abstention policy before challenge testing. It should allow an inconclusive result and should record it. An unqualified classifier forced to choose one label can make a misleading categorical claim when the evidence is inadequate to distinguish candidates.

Some assertions can be tested more directly by engineering interventions. Vary the sample rate while maintaining a calibrated physical carrier and compare the cyclic-frequency prediction for input and receiver artefacts. Terminate the RF input or use a calibrated load; test whether a candidate remains when no external signal can enter through the specified port. Change antennas and locations while tracking gain and propagation

Copyright 2026, James M. Atkinson

assumptions. Examine whether the candidate persists in an independent analogue front end with a different clock and processing implementation. Each change should carry a predeclared prediction under the competing explanations. The aim is not an impossible exhaustive proof that no other emitter exists, but a bounded inference supported by experiments designed to reveal material alternatives.

In a defensive technical-surveillance report the proper language might be that a candidate exhibits cyclic features consistent with a stated modulation class, that challenges of specified internal-artifact mechanisms were performed, and that the surviving alternative explanations include any transmitters sharing that convention. A stronger source-identification statement would require a documented discriminatory validation population and an uncertainty account for identity errors. It would not be justified by an appealing plot or a small p-value alone. Our duty is to preserve the relationship between the measurement operation and the proposition its words invite the reader to believe. I invite Professor Popper to challenge whether even a well-defined operational test can genuinely expose a preferred source hypothesis to possible refutation.

Sir Karl Raimund Popper | Peer question 7 to Percy Williams Bridgman

Professor Bridgman, your operational definitions are admirably exact, yet I fear they might permit an investigator to protect a preferred conclusion by continually narrowing the definition after each contrary result. Suppose a cyclic feature is first called a unique transmitter fingerprint. A rival device then produces the same pattern, so the analyst says the fingerprint identifies only the modulation class. A receiver spur

Copyright 2026, James M. Atkinson

then reproduces the class feature, so the analyst adds a condition that the receiver must have been in a favourable calibration state. Such qualifications can be legitimate, but they can also make the original claim impossible to refute. What predeclared experimental outcomes should require the investigator to withdraw an external-origin claim rather than merely append another explanation? How should source alternatives and receiver artefacts be presented so that a third party can distinguish a genuinely tested hypothesis from an interpretation continually rescued after adverse evidence? I also ask whether a narrow but falsifiable finding may be more valuable in forensic proceedings than a sweeping claim whose exceptions are never specified.

Percy Williams Bridgman | Immediate answer to Sir Karl Raimund Popper

Sir Karl, the concern is real. An operational definition becomes a discipline only when it fixes a comparison and admits a condition under which the comparison would fail. It must not be rewritten retrospectively merely to preserve a favourable label. An investigator may legitimately revise a scientific claim after new evidence, but the revision should be recorded as a revision. The first, stronger claim has failed to survive its challenge. A later, narrower claim requires its own evidential support and must not inherit the earlier claimed confidence as though nothing had changed. This is especially important when technical language is carried into a legal or administrative conclusion.

I would require the validation plan to state rival hypotheses and challenge outcomes before the experiment where practicable. If an alleged external modulation remains visible after a verified RF

Copyright 2026, James M. Atkinson

termination which excludes the implicated input path, that result contradicts the simple external-origin explanation and calls for an examination of internal generation or unintended coupling. If a second independently characterised receiver fails to observe a candidate under conditions in which its validated detection probability was high, the discrepancy should remain in the report and prompt further test. If many different known transmitters produce the same cyclic feature, the claim of uniqueness is defeated within that population. These are not mere inconveniences to be explained away. They are substantive observations limiting or rejecting particular hypotheses.

Some challenges will be indeterminate. A terminated input can still be susceptible to other coupling paths; a changed antenna alters propagation and sensitivity; a missing detection can result from limited exposure or a burst outside the observed interval. Therefore one should not transform every contrary outcome into decisive refutation either. The responsible interpretation defines the test boundary and its limitations in advance. If the result does not discriminate between alternatives, state that it is inconclusive rather than marking it as success for the preferred explanation. Confidence grows from interventions whose rival predictions differ and whose measurement uncertainty is understood.

A narrower conclusion may indeed be more valuable. It might establish that a reproducible nonzero cyclic feature occurred in the retained sample sequence; that specified receiver artefacts were challenged without producing the same outcome; and that the

Copyright 2026, James M. Atkinson

feature is compatible with a family of modulations, while individual identity remains unresolved. This statement is open to further test. An expansive accusation that one particular source necessarily caused the feature cannot be made robust merely by decorating it with more decimal places. The operational question is what another examiner can reproduce, where the original evidence ends, and which experiment could reveal a material failure. I return the token respectfully to Dr. Atkinson for a synthesis of the limited but valuable evidential role of cyclostationary analysis.

Harry Nyquist, Cross-Peer Question to Norbert Wiener: Professor Wiener, a spectral correlation detector reports a stable cycle frequency. What experiment establishes that this periodicity was emitted over the air rather than produced by buffering or interleaved ADC timing?

Norbert Wiener, Cross-Peer Answer to Harry Nyquist: Mr Nyquist, measure the suspected cyclic feature while deliberately changing internal scheduling, sample rate, interleaving mode and reference clock, keeping the analogue stimulus independently controlled. Periodicity in an internal switch or digital frame structure can create a cyclic signature even with a terminated RF input. Compare a second receiver path that does not share the same clock or software pipeline, and inject a known modulated signal to verify the expected movement of the cyclic frequencies. Retain raw I/Q and processing metadata so the analysis can be repeated under alternative filter and buffer conditions. A stationary cyclic line tells us something about the observed system; it does not automatically locate its physical source. I pass the token to Dr Shannon on the identification question.

Copyright 2026, James M. Atkinson

Norbert Wiener, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, can two transmitters that share a modulation protocol and symbol rate be uniquely distinguished by the same detected cycle frequency?

Claude Elwood Shannon, Cross-Peer Answer to Norbert Wiener: Professor Wiener, no. A cyclic statistic may characterise a class of modulation or repetitive structure without furnishing an individual physical identity. Two unrelated devices using the same waveform family can share cyclic features, and one device can change them under altered operating modes. Evaluate sensitivity and specificity against a population of candidate emitters, varying channel conditions, frequency error and receiver distortions. Report a likelihood or discrimination result only when the underlying reference populations and uncertainties are justified. Do not turn a class signature into a serial-number identification. Source attribution requires independent physical features, timing or spatial evidence, and a calibrated exclusion of receiver-created cyclic structure. I yield to Professor Tukey on the search over possible cycles.

Claude Elwood Shannon, Cross-Peer Question to John Wilder Tukey: Professor Tukey, the analyst searches thousands of cyclic frequencies and time lags before selecting the highest correlation. How should that search affect the reported confidence?

John Wilder Tukey, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the claimed probability of an extreme statistic must reflect the entire search procedure, including frequency, lag, window, filter and modulation hypotheses tested. Adjacent trial values are dependent, so neither the raw number of grid points nor a single predeclared-test p-value is automatically valid. Calibrate the maximum statistic on independent

Copyright 2026, James M. Atkinson

noise-only records processed identically and challenge the selected detector on hold-out signals. Preserve the search bounds and rejected candidates, not only the brightest peak. When the target modulation was hypothesised after inspecting the data, describe the result as exploratory until independent validation. A compelling graph cannot establish either a unique emitter or a controlled false-alarm probability. I pass the token to Professor Bridgman regarding operational definitions.

John Wilder Tukey, Cross-Peer Question to Percy Williams Bridgman: Professor Bridgman, what operational evidence must accompany the phrase “unique device signature” in a forensic report?

Percy Williams Bridgman, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, define precisely what is claimed unique: a cyclic modulation feature, a vector of calibrated RF emissions, a device family or one physical transmitter. A test must include a sufficiently broad and relevant comparison population, receiver configurations, channel perturbations, repeated operating modes and explicit error rates. The reference plane must be defined; the detector should be challenged with no antenna, calibrated stimuli and independent hardware. If the characteristic disappears when the acquisition software changes, its putative device specificity fails an elementary adverse test. Even a feature statistically rare in a limited laboratory set cannot be declared globally unique. The appropriate language may be “compatible with a class of signals” rather than “identifies this device.” I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator synthesis and concluding discussion

Colleagues, the discussion has produced a useful distinction between identifying a statistical property of recorded data and establishing the

Copyright 2026, James M. Atkinson

provenance of that property. Cyclostationarity provides a rich language for describing repeating second-order behaviour. It can reveal a class of communications signals whose ordinary energy spectrum is difficult to distinguish from a noise background, and it can guide a receiver towards further measurements. Yet the measured cyclic coefficient is first an attribute of the retained and processed sequence. It is not a physical address, a serial number, or a reliable declaration of one transmitter's identity. The investigator must make the further causal inference by reference to a calibrated acquisition boundary, competing hypotheses and experimental challenges capable of distinguishing them.

Mr Nyquist has reminded us that cyclic frequency is reported on a time axis whose calibration, alias relationships and sample selection must be understood. A nominal two-million-sample-per-second record can exhibit periodic structure that follows a four-branch interleaving schedule; a change in sampling rate may change the apparent cyclic coordinate without any corresponding alteration in an external emitter. The physical analogue frequency and the digital coordinate are related by a model. A scientifically correct transformation does not independently validate that model. Where the timebase is uncertain, the uncertainty belongs in every frequency and cycle-rate conclusion that depends upon it.

Professor Wiener has moved the boundary of the investigation through the receiver's feedback and retention mechanisms. Gain regulation, scan scheduling, adaptive thresholding and selective recording can generate or amplify periodic correlations. An internal coefficient may be stable for weeks and nonetheless tell us nothing about a particular external transmitter. It is therefore necessary to preserve a coherent engineering history of the

Copyright 2026, James M. Atkinson

receiver state and, where possible, to perform interventions for which an internal artefact and an external emission make different predictions. The record should not present two analyses of one IQ file as two independent physical detections, nor conceal the influence of a common clock or shared antenna path when several receiving channels agree.

Dr Shannon has separated detection, classification and identity. A cyclic ridge can be excellent evidence for one modulation class while being completely uninformative among a thousand devices that share the same convention. A classifier forced to choose one identity can conceal the fact that its evidence supports no distinction among several candidates. A credible source-identity study must establish its reference population, independence of training and test observations, nuisance conditions, alternative sources and abstention criteria. If those measurements are absent, the appropriate result is a bounded class finding, not an attribution dressed in the language of certainty.

Dr Tukey has restored the procedural history of discovery to its proper evidential place. An exploratory search across thousands of cyclic-frequency and ordinary-frequency coordinates is perfectly legitimate. Presenting the strongest peak as if it had been nominated before the search is not. Thresholds and confidence statements must be appropriate to the actual selection rule and to correlations among tested cells. Physical validation should use new acquisitions or deliberately independent challenge conditions where possible. A second attractive visualisation of the same samples has analytical value, but it does not create a second electromagnetic event. The archive must preserve the search ranges,

Copyright 2026, James M. Atkinson

smoothing rules, rejected candidates and invalid intervals sufficiently for another examiner to reproduce and contest the inference.

Professor Bridgman has made the report's language answerable to an operation. If the measured quantity is cyclic autocorrelation at a specified lag and cycle frequency, the procedure can be written and repeated. If the intended conclusion is an external source, the examiner must establish a measurement path between that source and the observed coefficient. If the intended conclusion is a particular individual's device, the procedure must discriminate that device from plausible alternatives under documented conditions. Every stronger noun requires a stronger experiment. Scientific precision is not achieved by writing a smaller uncertainty beside a proposition whose identity conditions were never defined.

I therefore direct that the publication record keep four distinct elements together: a raw or appropriately qualified acquisition interval with its configuration identity; the cyclic statistic and its complete estimator definition; the validation tests and the limitations of their reference populations; and the conclusion explicitly bounded by the tests performed. Where sample records are incomplete, the report should distinguish unavailable observations from negative detections. Where a receiver-generated explanation remains plausible, it should remain visible in the report rather than disappear into a confident headline. Where an external modulation is credibly confirmed but the emitter cannot be singled out, that is a useful result and should be described without apology.

We have not certified an instrument or identified any actual transmitter. All numerical cases are hypothetical educational demonstrations, and our historical colleagues' speeches are newly constructed to test modern

Copyright 2026, James M. Atkinson

engineering ideas against documented intellectual methods. The practical doctrine is that a detector can be powerful without being omniscient. Our next discussion will address matched filtering and the equally consequential danger of treating a strong correlation with an assumed waveform as proof that the waveform, and the physical origin attributed to it, were uniquely established. I thank the panel for its precision and courteously pass the floor onward.

Copyright 2026, James M. Atkinson

Ten worked technical applications

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 047

Worked application 1: Cycle-frequency alias under a declared sample clock

Assume an idealised periodic statistic at physical cycle rate $\alpha = 150{,}000$ cycles/s and a sampled record with $F_s = 200{,}000$ samples/s. If the relevant sampled cyclic coordinate is represented modulo F_s, one representative is $\alpha_d = \alpha - F_s = -50{,}000$ cycles/s. The minus sign describes a coordinate on the digital cyclic-frequency axis, not a negative physical repetition rate. Variables: α is physical cycle frequency, F_s the sampling frequency, and α_d the selected equivalent digital coordinate. This algebra applies to the stipulated ideal model; actual observable components also depend on estimator definition, analogue filtering and signal structure. A peak at 50 kHz magnitude therefore does not independently establish a 50 kHz emitter clock.

Worked application 2: Finite observation and cycle-frequency grid

Let an uninterrupted acquisition last $T = 0.100$ seconds, where T denotes retained observation duration. A conventional unpadded Fourier-like cycle-frequency analysis has characteristic grid spacing $\Delta\alpha = 1/T = 10$ Hz. Zero padding can display intermediate numeric coordinates but does not extend the observation or guarantee 1 Hz physical estimation uncertainty. If ten bursts of 10 ms are retained from widely separated times, their combined 100 ms sample count does not automatically behave as one contiguous, coherent 100 ms observation. Their time stamps and phase relationships must be modelled rather than erased when the archive is assembled.

Copyright 2026, James M. Atkinson

Worked application 3: Number of repeated cycles present in a burst

Suppose a signal has nominal cycle rate $\alpha = 12{,}500$ Hz and remains observable for $T = 0.020$ s. The nominal count of observed periods is $N_c = \alpha T = 250$ cycles, with N_c dimensionless. This is an upper-level exposure count under the assumption that the entire burst is continuously retained and the cycle persists throughout. The number of independent estimator contributions can be smaller because smoothing windows overlap or because the signal is correlated across periods. A recorder that stores only half the burst does not gain the missing hundred and twenty-five periods through a larger FFT.

Worked application 4: Multiple selected cyclic-frequency tests

Assume, solely as a simplified teaching model, $m = 1{,}000$ independent null tests, each with false-positive probability $p = 0.001$. The chance of at least one false alarm is $P_{any} = 1-(1-p)^m = 1-0.999^{1000} \approx 0.6323$. Variables: m is the number of tests, p is the single-test false-positive probability, and P_{any} is family-wise probability. Real cyclic-frequency cells commonly share observations and are correlated, so independence cannot be presumed. The calculation demonstrates why an apparently impressive single-cell threshold may be unsuitable after a large search. A calibrated maximum-statistic null distribution is preferable for the complete implemented rule.

Worked application 5: Sample count is not evidence count

A receiver samples continuously at $F_s = 2{,}000{,}000$ complex samples/s for $T = 0.125$ s. The stored count is $N = F_sT = 250{,}000$ complex sample positions. N is the number of digital positions, not the number of independent external transmitters or independent observations of a

Copyright 2026, James M. Atkinson

particular cyclic feature. A detector may compute thousands of highly overlapping windows over those positions, but all windows inherit the same source event, clock error and receiver gain history. A report claiming 10,000 independent confirmations merely because it plotted 10,000 estimates would be statistically invalid.

Worked application 6: Intermittent scan exposure

Suppose a scanner observes a candidate band for $d = 5$ milliseconds in every $R = 50$ milliseconds. Its idealised observation-duty fraction is $q = d/R = 0.10$. If short bursts arrive with starting phases uniformly distributed relative to the scan, and burst duration is negligible compared with both d and R, the approximate opportunity of intercepting one randomly timed burst is 10%. Variables: d is dwell duration, R is revisit period and q the duty fraction. This approximation does not account for non-negligible burst duration, scan settling, detection sensitivity or timing correlations; all may change the result. A non-detection cannot be treated as compelling evidence of source absence without those qualifications.

Worked application 7: Physical cycle-rate calibration error

Let the nominal measured cyclic rate be $\alpha = 100{,}000$ Hz and let the acquisition clock carry a relative frequency-scale error $\varepsilon = +2$ parts per million, or 2×10^{-6}, under the adopted mapping convention. The first-order absolute frequency-scale discrepancy is $|\Delta\alpha| \approx |\alpha\varepsilon| = 0.20$ Hz. Here ε is dimensionless and α is measured in cycles/s. This does not imply that all cyclic estimators achieve 0.20 Hz precision, nor that the clock's short-term fluctuations vanish. It shows that even a narrowly

Copyright 2026, James M. Atkinson

displayed line remains subject to timebase calibration and its uncertainty. Relative and absolute clock claims must not be conflated.

Worked application 8: Finer display grid versus longer information-bearing record

Let the physical observation duration be $T = 0.400$ s. Its conventional unpadded cycle-frequency grid step is $\Delta\alpha = 1/T = 2.5$ Hz. If the analyst zero-pads the array to display positions separated by 0.25 Hz, the plot contains ten displayed coordinates per original 2.5-Hz interval. The recorded duration remains 0.400 s and the physical period count is unchanged. A smoother interpolation can improve locating a broad estimator maximum under a specified model, but it is not equivalent to observing ten times as much independent data. An uncertainty claim must be validated against noise, drift and finite-record effects.

Worked application 9: Periodicity from a four-branch digitiser

A hypothetical time-interleaved converter uses $M = 4$ branches at aggregate rate $F_s = 2$ MHz. Its branch-assignment pattern repeats every four samples, giving nominal pattern rate $\alpha_{int} = F_s/M = 500{,}000$ cycles/s. Variables: M is branch count, F_s aggregate sample rate and α_{int} the architecture's repetition frequency. Offset or gain mismatch can impose spectral or cyclic structure related to that periodic schedule. The existence of such a line is not proof that a particular transmitter operates at 500 kHz modulation rate. Altering aggregate sample rate while controlling the external input offers a test: a branch-schedule artefact may follow F_s/M, whereas an external repetition frequency should follow its physical source clock, subject to correct digital mapping.

Copyright 2026, James M. Atkinson

Worked application 10: A shared convention cannot uniquely identify its members

Suppose K = 1,000 equally plausible transmitters in a defined reference population all produce an indistinguishable measured cyclic statistic S under the stipulated acquisition conditions. With equal prior probabilities and equal likelihoods P(S|device_i), Bayes' rule leaves the posterior probability of any one device at 1/K = 0.001. Variables: K is the number of equiprobable candidate devices, S the observed shared statistic, and device_i one specific source hypothesis. The calculation is conditional on the deliberately equal priors and likelihoods. Unequal independent evidence could change the result; the cyclic statistic by itself does not. A strong detection of the shared modulation class is therefore logically compatible with an absence of individual-device identification.

QUESTION 048

Copyright 2026, James M. Atkinson

What does a matched filter actually test about an unknown waveform?

Source: V011_Roundtable_Question_048_CP048_Dr_Atkinson(2).docx | Recovered substantive manuscript. Constructed educational dialogue.

Question 048. Expert Roundtable Discussion

Original constructed educational dialogue. All contributions attributed to historical specialists are newly authored pedagogical reconstructions, not quotations or historical transcripts. Modern instrument cases and calculations are hypothetical; no apparatus or actual intercepted communication is certified.

Dr. James M. Atkinson | Moderator opening

Distinguished colleagues, a matched-filter output has the visual authority of a striking peak: one may watch a narrow pulse rise from a mottled floor on the receiver screen and hear the alarm which the acquisition system assigns to its crossing of a selected threshold. Yet the smoothness of that rise does not answer the central forensic question. What exactly has been matched? In the familiar ideal derivation a filter is constructed for a specified deterministic waveform immersed in additive white Gaussian noise, and its output is evaluated at a selected instant. Under those assumptions the matched filter maximises output signal-to-noise ratio among linear filters at that instant. In a technical-surveillance investigation, however, the purported waveform may be incomplete, its timing unknown, its phase unstable, and its physical origin wholly unestablished. We must distinguish a mathematically optimum statistic for a stipulated proposition from a finding that the proposition is true.

Copyright 2026, James M. Atkinson

Let a discrete complex observation be x[n] = a s[n-k] + w[n] over a finite window, where s denotes a known reference template, a an unknown complex amplitude, k an unknown integer delay, and w a noise sequence with a specified model. A conventional correlation for trial lag k is r[k] = sum over n of x[n] times the complex conjugate of s[n-k]. If the noise is white, its variance known, and the signal is exactly s up to the assumed amplitude and delay, that correlation can be part of an optimal likelihood test. The words *exactly*, *known* and *assumed* are doing substantial scientific work. In a field receiver an adversarial or merely unfamiliar source may employ a similar but not identical waveform. Multipath may change its apparent shape. Analogue filters, IQ imbalance, imperfect clocks and clipping may alter the recorded replica. A detector can therefore produce a large correlation peak without proving that the stored template is a faithful description of the analogue input at the antenna reference plane.

An unknown waveform cannot be matched in the ordinary deterministic sense without defining a family of possible waveforms and how that family will be searched or estimated. If the engineer constructs a template from the same suspicious recording that is later offered as independent confirmation, the attractive result may be partly circular. If one searches a thousand delays, a hundred Doppler or frequency-offset hypotheses and numerous template shapes, the largest output requires a different false-alarm calibration from a single preselected comparison. Where a code sequence is common to an entire class of communications devices, a convincing match is evidence of the shared sequence or waveform convention, not the unique identity of one emitter. We shall examine why a formula derived under perfect knowledge may be useful even when the

Copyright 2026, James M. Atkinson

investigator possesses only partial knowledge, and why its claims must be correspondingly restricted.

We should treat time-of-arrival estimates with equal care. A matched-filter output peak has a computational time coordinate determined by sampling, filtering, interpolation, template alignment and signal path delay. It is not automatically the propagation arrival time at the antenna or the moment of emission at the source. A receiver may change its gain or sample rate between the reference measurement and a candidate event. A reference template may be generated digitally inside the same apparatus and share precisely the clock error that should have been challenged. A clean peak can therefore be an excellent indicator of repeatable processing while remaining inconclusive about source identity or absolute arrival epoch.

The panel will place five intellectual approaches into dialogue. Professor Wiener will examine correlation as statistical prediction and its dependence upon the assumed noise. Mr Nyquist will address delay, template fidelity and the sample-time coordinate. Dr Shannon will distinguish information acquired from a match from information not supplied by the measurement. Professor Neyman will insist upon complete decision rules, calibration populations and false-alarm control. Mr Black will return the discussion to feedback, receiver-generated templates and physical reference planes. Seven peers will ask technical questions, receive immediate answers, and pass the token respectfully. Ten worked examples will expose the arithmetic concealed in apparently simple detection pictures. We shall retain the original data, version the template and declare the uncertainty rather than allow an attractive correlation graphic to outrun its supporting evidence.

Copyright 2026, James M. Atkinson

This roundtable is not intended to diminish matched filtering. Properly employed it is among the most valuable tools in receiving systems, radar, sonar and digital communications. Its usefulness comes from a narrow proposition stated clearly and tested under conditions relevant to that proposition. The significant distinction is between a filter being mathematically matched to a known model and the physical world being conclusively identified by the filter's output. We begin with Professor Wiener, whose theory of prediction and statistical estimation provides an appropriate setting for asking whether the noise and signal models have been specified rather than merely assumed.

Copyright 2026, James M. Atkinson

Norbert Wiener | Principal response 1: Template knowledge and the conditional nature of optimum filtering

Dr. Atkinson, I begin by insisting that optimality belongs to a problem formulation. A procedure does not remain optimal after the assumptions used to derive it have been forgotten. For a deterministic waveform of known shape in additive white Gaussian noise, the matched filter gives the maximum attainable output signal-to-noise ratio among linear filters at a selected comparison instant. That result can be derived from the Cauchy-Schwarz inequality and is sound within its premises. It does not state that every observed peak has been produced by the expected emitter, nor that a different noise distribution, unknown waveform or adaptive receiver will preserve the same optimality. The important words are the waveform, the noise covariance, the observation interval, the decision instant and the class of permitted estimators.

Consider an abstract discrete template s with samples s[0],...,s[N-1]. Under a simple model x = a s + w, with w an independent circular complex Gaussian noise vector having covariance $\sigma^2 I$, the inner product $s^H x$ is a sufficient projection for testing the amplitude of that one specified vector under suitable hypotheses. The template energy is $E_s = s^H s$. The correlation's noise variance is $\sigma^2 E_s$ and the signal component is aE_s. Thus the output signal-to-noise ratio is proportional to $|a|^2 E_s/\sigma^2$. The mathematical economy is attractive: many raw samples have been condensed into one projection aligned with the expected signal. But the compression is purposeful. It retains what is needed for the declared hypothesis and may discard distinctions vital to another hypothesis. If the

Copyright 2026, James M. Atkinson

question later changes from detecting a known sequence to identifying an unknown modulation, the original projection may be inadequate evidence.

The trouble with unknown waveforms is visible immediately. Suppose the actual signal is u, not s. The matched-filter response is proportional to $s^H u$; it depends upon the degree of overlap between the template and the actual received vector. Two distinct waveforms can project strongly onto the same template even though their differences matter to attribution. Conversely, a genuine emitter may produce a weak peak because propagation, clock drift or receiver filtering has distorted its waveform. A low correlation is not proof of absence, and a high correlation is not proof of identity. It is a measurement of a relationship under the chosen alignment, normalisation and receiver state. The investigator must consider the corresponding likelihoods under credible alternatives rather than merely label one peak as expected.

Noise coloration introduces a further issue. If the covariance of the noise is C rather than $\sigma^2 I$, ordinary unweighted correlation is generally not the optimum linear detector. Under a known invertible covariance, the corresponding whitened statistic involves $s^H C^{-1} x$. This notation is compact but the required evidence is not. A covariance matrix estimated from one quiet laboratory interval may fail to describe switching supplies, intermittent legitimate emitters or a receiver near compression. If C is ill-conditioned, an attempted inverse may amplify estimation error. Covariance estimation performed after observing the candidate may absorb some of its structure and change the detection statistic. These complications do not make matched filtering useless. They demand that the noise model, its training population and its uncertainty be part of the validation record.

Copyright 2026, James M. Atkinson

A practical receiver may adapt its filter weights while searching. Adaptive filtering can increase performance under changing interference, yet its final output is not independent of the training data which produced the weights. If the test sample also trained the filter, a very strong peak might reflect tuning to that particular noise realisation. A valid challenge should distinguish the development population from independent or appropriately separated validation observations. Where adaptation must remain active, its rule and update history should be preserved, and challenge tests should reproduce its operation rather than replace it with a simplified static filter that enjoys different behaviour. Otherwise a laboratory certificate describes an instrument which did not actually make the field observation.

There is an equally serious physical distinction between a generated reference and an independently observed reference. Suppose an internal digital source produces the code sequence against which the receiver correlates incoming IQ. That template may be perfectly repeatable and perhaps driven by the same clock as the receiver's sampling system. The resulting correlation can be precisely timed on the instrument's internal coordinate while leaving the absolute RF arrival time uncertain. Internal clock commonality can suppress apparent relative jitter without validating absolute time or the RF path delay. A second analysis of the same stored file is useful for checking arithmetic, but it does not supply an independent electromagnetic observation. If source attribution depends upon timing or multiple receivers, the missing reference-plane measurements must be obtained elsewhere.

The forensic record should therefore preserve the input observation and the transformation. The raw IQ should be retained for material events

Copyright 2026, James M. Atkinson

where permitted, together with the template samples or their content-identifying digest, sample-rate mapping, filter coefficients, alignment convention, frequency-offset search, threshold policy and rejection criteria. A compressed statistic can support a limited finding if those conditions are sufficiently understood. It cannot substitute for unknown data which the system never captured. One should also preserve the record of invalid intervals and null tests; a display showing only successful correlations is an unfaithful representation of the detector's opportunities for failure.

Where a large template library is involved, I would ask for the rule by which the library was assembled, how similar its members are, and whether the reported winning template was selected after repeated human intervention. The likelihood of a high maximum among many correlated templates differs from the likelihood of a high correlation to one named in advance. The investigator may legitimately search for candidates, but the result should first be labelled discovery. A separate physical challenge, a withheld acquisition or an independently specified decision can establish stronger evidential weight. Detection and attribution are related activities, not identical mathematical operations.

Let us retain a balanced conclusion. Matched filtering is powerful because it exploits prior information about waveform shape to improve a particular comparison. Its failure modes arise when that prior information is mistaken for new evidence, or when the field receiver's noise, clock and transfer function depart from the premises. An honest technical report should say what template was used, what physical quantity was compared, which alternatives were evaluated, and what remained unidentified. I ask Professor Bridgman to test the operational meaning of the word matched,

Copyright 2026, James M. Atkinson

for a correlation coefficient without a declared comparison is scarcely a measurement at all.

Percy Williams Bridgman | Peer question 1 to Norbert Wiener

Professor Wiener, your mathematical expression for correlation is clear, but I should like to examine what it means physically to construct a reference template. An engineer may record an interesting burst, remove its noise by selecting a smoothing algorithm, normalise its amplitude, and use the resulting shape as a template for finding repetitions in the same archive. The procedure might be entirely reproducible. Yet the investigator may then assert that the second correlation proves an independently recurring signal, even though the template arose from the data under examination. Which observations should be treated as independent, and how should the construction of the template be recorded? I am particularly concerned about changes of units and reference planes: a voltage waveform recorded after an unknown automatic-gain stage is not the electric field at the antenna. May the analyst properly call the result a match to the original emission, or only a similarity between two processed records? What experimental operation would elevate that limited similarity into a defensible external-origin finding?

Norbert Wiener | Immediate answer to Percy Williams Bridgman

Professor Bridgman, I would begin by naming the two objects actually compared. If both are derived from one archived record, the result is a correlation between derived functions of that record. It may demonstrate repeated patterns within those retained samples, and that can be a valuable discovery. It should not be counted as two

Copyright 2026, James M. Atkinson

independent physical observations merely because two arrays or two time windows were involved. If the windows overlap, they may even share many of the same original samples. The proper record identifies every transformation used to create the template, including denoising, amplitude scaling, cropping, resampling and phase adjustment, together with any selection made after viewing the candidate.

Independence is not a blanket property. Separate windows may have different additive noise realisations but share the same oscillator drift, gain history, sample clock and receiver artefacts. A second physical acquisition with an independent or deliberately changed signal path can challenge these dependencies. One could inject a reference waveform at a calibrated RF input plane and test whether the detector behaves as predicted across gain states, carrier offsets and noise conditions. One could also compare a separate receiver, documenting which components and references it shares. The purpose of independence is to make a rival explanation less likely, and the degree of independence needed depends upon that explanation.

I would not insist that the template always be derived from an ideal electromagnetic model. A data-derived template may be the most useful means of detecting recurrences in an unknown environment, especially when the emission is too weak for a complete waveform model. The qualification is that its detector performance is conditional on the population and choices used to learn it. One should freeze the template and test it on withheld physical observations with known-

Copyright 2026, James M. Atkinson

present and null challenges. If the template continues to detect a specified signal class while rejecting representative receiver artefacts, that is evidence of useful performance. It is still not proof that the signal belongs to one uniquely identified transmitter unless the challenge is capable of discriminating that identity.

The reference-plane issue must be explicit. A voltage trace following automatic gain control may be related to the antenna field by a transfer which depends upon time and state. Without sufficient characterisation, one cannot invert it reliably into a physical field-strength claim. A measured similarity after processing is not fraudulent when described accurately; it becomes misleading when its noun is enlarged into an unverified causal conclusion. The result should be reported as a match under the named processing and calibration conditions, with additional external-origin experiments described separately. That is how an operational definition can support useful investigation while resisting rhetorical overreach.

Walter Andrew Shewhart | Peer question 2 to Norbert Wiener

Professor Wiener, I wish to challenge the stability of the noise model. An engineer may validate a matched filter using many laboratory trials in quiet additive Gaussian noise, report an excellent false-alarm rate and then deploy the same receiver near a switching supply, a busy communications system and periodically operating machinery. The detector begins to trigger on pulses which share only a rough envelope with the reference. The operator may adapt the threshold upward until the false alarms disappear, after which the original performance certificate is still quoted. What must be recorded to determine whether

Copyright 2026, James M. Atkinson

the detector is operating in a controlled statistical process? Should the false-alarm estimate be recomputed whenever the receiver changes gain, front-end bandwidth or calibration state? How do we distinguish an ordinary change in environmental interference from a fault in the correlation algorithm, and what shall the report say about intervals when the instrument had insufficient exposure to make an absence claim?

Norbert Wiener | Immediate answer to Walter Andrew Shewhart

Thank you for that question. Dr Shewhart, the performance certificate applies to the population and decision rule which produced it. If the deployed receiver differs materially in noise statistics, gain, bandwidth, threshold logic or sample retention, the laboratory result cannot simply be copied into a claim of identical field performance. A systematic change in the null distribution is enough to require a fresh qualification even when the code of the correlation algorithm is mathematically unchanged. One may maintain control charts of relevant operating statistics, but those charts should not be used as substitutes for controlled challenge trials that separate receiver faults from environmental interference.

The important distinction is between a changed decision rule and a changed world. A threshold raised in response to field conditions might reduce false alarms at the price of lower sensitivity to weak signals. That trade-off is legitimate if measured and disclosed. It becomes misleading when the old low-threshold sensitivity figure is retained beside the new high-threshold operating configuration. The receiver should log threshold versions, adaptive update policies, gain states and null observations. Validation should include representative

Copyright 2026, James M. Atkinson

interference and intermittent signal challenges, with known injection times independent of the detector. A trial in which the challenge was present but unreported is essential evidence about missed detections, not an embarrassment to exclude.

Some environmental changes may be detected through residual analysis. Compare the distribution of matched-filter outputs on independent null intervals with the distribution expected under the declared model. Examine clusters, long tails, periodicity and dependence across windows. If those properties differ, an assumed Gaussian false-alarm calculation may no longer apply. It is possible to calibrate an empirical threshold for the complete implemented search under the actual operating envelope. The acceptance report should identify how that population was constructed and which future conditions require renewed testing.

For negative findings, exposure is separate from conditional sensitivity. A scanner observing one band for a small fraction of time cannot establish that an intermittent waveform was absent throughout the full survey, even if its matched filter was nearly certain to detect the waveform whenever it was observed at a sufficient level. Record dwell time, revisit interval, invalid periods, filter settling and threshold state. If those elements are missing, the absence finding should be described as indeterminate or restricted to the observed intervals. The proper conclusion is not that the instrument failed, but that its evidence addresses a narrower proposition than an unqualified assurance sentence would suggest.

Copyright 2026, James M. Atkinson

Harry Nyquist | Principal response 2: Unknown delay, template mismatch and the measurement of arrival time

Dr. Atkinson, the sample-time coordinate is often the first element to be obscured by a spectacular correlation peak. A matched filter examines relationships between a candidate sequence and a specified template across trial alignments. Its output peak is indexed by the lag at which that relationship is strongest under the adopted convention. The physical event time is not generally identical to the lag index multiplied by the nominal sample period. One must account for the reference template's epoch, analogue group delay, digital filter delay, clock calibration, resampling, cable or antenna path and any event-specific synchronisation process. The moment that a program prints 'arrival time' does not guarantee that those transformations have been measured.

For a sample rate F_s, the nominal conversion from an index displacement k to duration is k/F_s. If the sample clock has fractional frequency error ε and the acquisition system silently assumes its nominal rate, the inferred interval carries a corresponding scale uncertainty. If the input passed through a filter with frequency-dependent group delay, there may not even be one constant delay correction suitable for all waveform shapes. A broad signal whose spectral energy lies in different parts of the filter passband can exhibit a different correlation peak than a calibration tone centred in the passband. The engineer should therefore characterise the transfer over the waveform bandwidth, not merely apply one number measured at one frequency.

A matched filter is deliberately sensitive to a particular time-frequency structure. If the incoming signal differs by frequency offset, Doppler scaling,

Copyright 2026, James M. Atkinson

code-clock offset or pulse shaping, its correlation peak may broaden, diminish or shift. This is not necessarily evidence of a different transmitter. The same emitter can appear mismatched after propagation, receiver drift or operating-state change. Conversely, two unrelated emitters sharing a known preamble can produce highly similar correlation peaks. A receiver which declares identity from a template match must independently demonstrate that the template distinguishes competing sources in its target population. The lag at a correlation peak and the identification of its cause remain distinct conclusions.

One must also consider the ambiguity surface. Rather than searching only delay, a realistic receiver may evaluate many candidate frequency offsets, phases and waveform shapes. The strongest point on the resulting surface depends upon the tested grid and estimator. A fine interpolation in delay can yield a visually precise peak position without providing corresponding physical timing certainty. A new frequency hypothesis may change which sidelobe is selected, especially when the signal is short or the template has repeated structure. The reported uncertainty must include the possibility of choosing a wrong ambiguity peak, not only the local curvature around the selected maximum.

Correlating with a template containing repeated symbols illustrates this difficulty. If the template has a short repetition interval, several delay lags may give similar scores. If the receiver reports only the highest, the selected arrival time can jump by one or more repetition periods in response to small noise changes. An apparent nanosecond-level interpolation within one lobe is irrelevant if the correct lobe has not been established. The survey record should preserve competing local peaks or a sufficient summary of the

Copyright 2026, James M. Atkinson

ambiguity surface to expose that possibility. Where a second timing reference is available, it should be used to test the lobe selection rather than merely to improve the number of digits displayed.

I am concerned as well with sample clocks shared across multiple receivers. A common reference can improve relative timing, but it may create common error. Two receivers using one distribution network may agree about an event's digital epoch while both being displaced from the true RF arrival time at their respective antennas. Conversely, independently clocked receivers may require a carefully estimated offset and drift map before the same burst can be compared. Their differing paths may provide better independence for causal attribution, but an inaccurate clock map can manufacture an apparent propagation delay. The investigator must state whether the claim concerns relative sequence alignment, absolute UTC time, or physical RF propagation time; the evidence needed differs accordingly.

A basic calibration experiment uses known injected waveforms at the declared reference plane, with their timing independently established. Vary the waveform phase, centre frequency, amplitude and arrival position relative to the sample clock. Compare correlation peaks with the known injection schedule, including moments near buffer boundaries and digital rate changes. The result should be a distribution of timing errors, not one perfect calibration trace. Strong and weak signals may produce different error distributions. Clipping can distort a high-amplitude signal, while poor signal-to-noise ratio makes a weak signal's peak unstable. Both conditions belong in the declared operating envelope.

A digital copy of the transmitted template can be highly accurate as a sequence of symbols and still fail to reproduce the analogue waveform

Copyright 2026, James M. Atkinson

observed after filtering and multipath. For a forensic detection claim, it may suffice to know that the receiver detects the defined class with measured probability under specified conditions. For a phase or time-difference location claim, more stringent calibration is needed. One should retain the raw acquisition, timing reference, filter settings and ambiguity candidates, including failed or excluded comparisons. Reconstruction of an original analogue arrival cannot exceed the information preserved in that record and the independently validated corrections applied to it.

Finally, I would caution against the belief that greater sample rates automatically solve every timing question. Oversampling can provide finer nominal grid spacing, but noise, clock jitter, group-delay dispersion and waveform mismatch still govern the uncertainty of the physical event. The most rigorous report may say that a particular template aligned with the retained sequence at a stated digital lag, within an evaluated uncertainty under the declared model. An absolute physical-source conclusion demands further evidence. I respectfully invite Professor Bode to challenge whether the receiver's analogue transfer can itself create the sort of waveform similarity being offered as a match.

Hendrik Wade Bode | Peer question 3 to Harry Nyquist

Mr Nyquist, you have described a well-defined digital lag, but a filter in a real receiver has both amplitude and phase response. A laboratory may measure one nominal group delay and subtract it from every subsequent correlation time. If the received burst occupies a wide bandwidth, different frequencies may experience different delay, and equalisation may alter the noise correlation or amplify weak regions of the spectrum. What measurement would be sufficient to justify one corrected arrival

Copyright 2026, James M. Atkinson

epoch? Would you require the complex transfer function over the whole admitted band, or might a bounded family of waveforms suffice? Further, if the filter has a notch or a region of almost zero response, a digital inverse may produce an aesthetically attractive trace without recovering the information lost at the analogue input. I ask how the investigator should distinguish ordinary calibration uncertainty from a genuinely non-invertible measurement relationship when the reference waveform is itself only partly known.

Harry Nyquist | Immediate answer to Hendrik Wade Bode

Professor Bode, I agree that one correction delay is defensible only under a stated waveform and transfer-function model. If the filter phase is sufficiently linear over the effective bandwidth of the signal, a constant group delay may be a good approximation. The approximation should be validated with the waveform class and conditions for which arrival-time claims will be made. Where phase response is dispersive, the estimator should account for the complex transfer or report a larger, waveform-dependent uncertainty. A nominal calibration at one centre frequency does not establish the delay of all possible bursts over the admitted band.

The distinction between correcting and reconstructing is fundamental. If a transfer function has a deep null or the signal was clipped, a numerical inverse can magnify the surviving data but cannot uniquely recover absent information without additional assumptions. A matched filter designed against the output waveform of a known calibration path may still provide excellent detection under those conditions. It should be described as matched to the

Copyright 2026, James M. Atkinson

received or *predicted output* template, not as proof that a pristine analogue input has been reconstructed. Those are different operations with different uncertainty accounts.

I would require measurements of transfer phase and magnitude over representative frequencies, gain states and temperatures, together with calibrated reference bursts that resemble the claimed signal class. The record should preserve the measured transfer and its uncertainty, any equaliser coefficients, and the before-and-after data. If the equaliser depends upon a model of an unknown input, the resulting arrival estimate is conditional on that model. The validation procedure should include deliberately mismatched waveforms and frequency offsets to quantify how the timing bias changes. A single residual root-mean-square error over easy training cases could conceal rare but material wrong-peak events.

The most telling challenge may be one designed to fail. Inject two pulses whose relative timing is known, but change their spectra so the phase-response differences matter. If the corrected lag remains stable within its declared uncertainty, the calibration has demonstrated a limited form of robustness. If it shifts, the discrepancy should be retained and the allowed signal envelope restricted or the correction model revised. One cannot erase a test failure by excluding the offending waveform after seeing the result and still claim the original scope. Forensically, a narrow but verified timing statement is more valuable than a general arrival-time assertion unsupported by the instrument's actual transfer.

Copyright 2026, James M. Atkinson

David Slepian | Peer question 4 to Harry Nyquist

Mr Nyquist, the time-frequency ambiguity of a finite template appears to place a limit on your desire for a single arrival time. An extremely short pulse has broad spectrum and can be sensitive to analogue dispersion; a longer coded sequence can yield sharp correlation structure yet may have sidelobes or repeated motifs. The analyst may choose the window length after viewing the burst, or pad the template to create a visually smooth peak. How should one distinguish a true improvement in timing information from a cosmetic change in display resolution? If a long template provides more processing gain but includes portions of the record where no signal was actually present, could the apparently improved peak be biased by the selected background? I should like to hear which experimental conditions would let the receiver report one physical event time without concealing alternative peaks and mismatch-induced shifts. Would the answer change if the receiver were operating near its clipping threshold?

Harry Nyquist | Immediate answer to David Slepian

Professor Slepian, the estimator's precision depends on the signal energy, effective bandwidth, observation duration, noise and the model used to infer timing. Merely increasing FFT padding or decreasing the display increment does not create more independent information about the arrival epoch. A longer genuine known waveform may provide additional energy and structure, improving a properly calibrated time estimator. But a template extended through periods where the source did not transmit can introduce noise contributions or mismatch. The detector's optimal length is

Copyright 2026, James M. Atkinson

determined by the signal model and performance objective, not by the amount of storage available or the attractiveness of a narrow plotted maximum.

A useful validation programme should compare the full ambiguity surface under known injections across a range of signal levels and frequency offsets. The examiner should retain competing peaks and report the fraction of trials in which the algorithm selects a sidelobe instead of the true delay. That discrete failure mode may dominate timing error even when the local peak interpolation is excellent. Two estimates should not be treated as independent confirmations when they use overlapping samples and the same template. A new physical observation or an independently calibrated timing route can provide stronger evidence.

If the signal is only partly known, the system may search a family of templates covering plausible timing and frequency deviations. Such a search increases the number of opportunities for high noise peaks, so its threshold must be calibrated for the complete search, not one particular member selected retrospectively. One can legitimately choose a window to maximise sensitivity during development, then fix it for a withheld validation population. If a new field condition requires a different window, the change must be versioned and its performance claims retested. The report should identify when a candidate was discovered versus confirmed under the frozen rule.

The physical event time should be defined at a specified reference plane and accompanied by an uncertainty model including clock, analogue path, sample selection, template mismatch and peak-

Copyright 2026, James M. Atkinson

selection error. A digital alignment time may be precise while the RF event time remains uncertain. Treating the two as the same quantity would confuse a reproducible computation with a physical measurement. The successful instrument is not the one that prints the most decimal places, but the one whose displayed interval genuinely bounds the event under tested conditions. I now pass the token to Dr Shannon for his treatment of what correlation can and cannot reveal about an unknown waveform.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon | Principal response 3: A correlation statistic does not disclose all information about an unknown source

Dr. Atkinson, an efficient detector is designed to discard information irrelevant to a declared decision. That is one reason correlation is so valuable. When the signal is truly known and the noise model is properly specified, a matched-filter statistic can concentrate the information bearing upon the specified hypothesis into a convenient comparison. The same reduction becomes perilous when the investigator later asks a broader question. A statistic sufficient to decide whether a known sequence appears at a candidate delay need not be sufficient to reconstruct an unknown waveform, distinguish a family of devices or infer their physical location. The required information is determined by the question, not by the impressive economy with which a filter transforms its samples.

Suppose a template s is a common preamble transmitted by every member of a communications standard. A large correlation with s may establish the likely presence of that preamble under the receiver's admitted conditions, and it may enable a useful timing estimate. It cannot by itself identify which of many compliant devices produced it. If the received message payload is unavailable, the matched filter does not recover it. If the RF waveform is clipped, the peak cannot reconstruct the missing analogue amplitudes. If a receiver did not observe the relevant interval, no amount of later filtering can create an independent record of the unobserved transmission. Matching improves an estimate within a specified model; it does not enlarge the set of physical events which the instrument actually sampled.

Copyright 2026, James M. Atkinson

It is important to separate a correlation coefficient from a likelihood ratio. In the simplest additive Gaussian model a matched-filter output may be a monotonic component of an optimal test statistic. When the amplitude, phase, delay and waveform are unknown, however, the likelihood must account for those unknown parameters or integrate over an appropriate model for them. A detector which searches a family of templates and reports the maximum has changed the statistical experiment. Its false-alarm distribution is not generally the same as that of one fixed correlation under a known signal. The chosen model and nuisance-parameter treatment determine what probability statement can be made. A p-value calculated for one fixed template after that template was selected from a large library is not a full description of the search.

The phrase *unknown waveform* can hide more than one uncertainty. The investigator may know a preamble but not the payload. The modulation format may be recognised but the symbol timing or pulse shape uncertain. The transmitter may have been identified lawfully through separate evidence, yet propagation and hardware distortions make the received waveform uncertain. Or the source and waveform may both be wholly unknown. These are different inverse problems. In the first case a known preamble detector is appropriate. In the last case a predetermined matched filter cannot be said to be matched to the unknown signal at all. The operator might instead use an energy detector, a cyclostationary statistic, a bank of class templates or a generalised-likelihood procedure, each with its own performance and interpretive limitations.

A matched-filter peak may also result from an unrelated signal which shares part of the template. The risk depends upon the correlation structure

Copyright 2026, James M. Atkinson

of the reference library, the length and uniqueness of the sequence, the signal-to-noise ratio and the permitted time-frequency search. A long random-looking sequence may be highly discriminatory under an ideal coding model, yet the field system could use only a short portion of it because of burst truncation. An apparently unique peak after such truncation may be much less informative than the full-code validation would suggest. The actual retained comparison, not the nominal complete waveform, must determine the evidential claim.

Statistical independence deserves separate attention. A receiver may find a peak in several adjacent processing channels because their filter responses overlap, or in several FFT windows because they share the same physical samples. Multiple peaks can be a legitimate diagnostic of the same event but are not automatically independent confirmations. Two physically separate receivers may share timing references and antennas, producing correlated uncertainties. If their matched-filter peaks agree, that observation should be interpreted in a model that includes shared paths. To combine probabilities by multiplication without examining dependence is to import an unstated assumption, not to strengthen the evidence by mathematical necessity.

The quality of the null model is equally important. White Gaussian noise is a useful model in which the optimality of the matched filter can be derived cleanly. Actual environments contain legitimate communications, spurious mixer products, impulsive electrical noise, clock leakage and nonstationary interference. An interfering waveform with the same preamble can produce the same matched-filter feature as the target. The detector's performance should therefore be validated against a population appropriate to the field

Copyright 2026, James M. Atkinson

proposition. A low false-alarm rate measured only against synthetic white noise cannot certify a low rate of false external-source attributions in a building containing many emitters and receiver artefacts.

I would propose a layered record. First, preserve the raw evidence of the candidate and the template identity. Second, state the exact statistic and timing convention used to calculate the peak. Third, provide the tested signal family, interference population and threshold rule. Fourth, distinguish a detected waveform feature from a source classification or identity conclusion. A defensible statement might be that the record contains a component whose cross-correlation with a particular preamble exceeds a threshold calibrated against specified alternatives. It should not become a declaration that one unknown transmitter was necessarily present, unless additional evidence differentiates that transmitter from the other possible causes.

The greater power of the method lies in its explicitness. Correlation makes the investigator say what pattern was sought and permits the pattern to be independently tested. It is less powerful when the analyst silently changes the pattern until something matches and then forgets the search. This is the central information-theoretic lesson: a statistic can be highly informative about one proposition and nearly silent about another. We should use the former strength without pretending that it proves the latter. I invite Dr Hamming to ask how an efficient software implementation should preserve its algorithmic conventions when a surprisingly high peak is encountered.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming | Peer question 5 to Claude Elwood Shannon

Dr Shannon, the mathematical inner product is clear, but a real implementation often chooses between direct correlation, FFT convolution, blockwise overlap-save processing and a normalised correlation calculated from window-specific energy. An engineer may compare results from those algorithms and infer independent agreement when they are merely implementations of one mathematical operation. There may also be differences at buffer boundaries, with even-length templates, conjugation conventions or integer arithmetic overflow. What would you require the forensic analyst to preserve so that another examiner can reproduce the actual peak, including its lag and its threshold crossing? Further, if the code uses a different normalisation whenever a burst is partially outside the retained interval, does a value of 0.9 mean the same thing across all candidate windows? How can one specify a performance test that catches software errors without confusing numerical agreement between two routines with physical corroboration of the emission? Which independent reference records should be retained?

Claude Elwood Shannon | Immediate answer to Richard Wesley Hamming

Dr Hamming, a reproducible implementation should expose the correlation convention, not merely its graphical output. For complex sequences it must state which argument is conjugated, how lag sign is assigned, which samples contribute to each lag and what zero-padding or boundary extension is used. It must preserve the exact

Copyright 2026, James M. Atkinson

template version, sample format, scaling, filter coefficients and timing reference. A different FFT implementation may legitimately reproduce the same operation; this is excellent evidence about computational correctness, but it is not a second observation of the analogue world. The claim should be limited accordingly.

Normalisation is particularly important. A coefficient divided by the product of two full-window energies is not necessarily comparable with one computed over an edge-truncated interval. If the denominator changes with available samples, the estimator's variance and null distribution can change as well. A displayed value such as 0.9 has no universal significance until the precise statistic, effective sample count and selection procedure are specified. The detector should identify windows for which the denominator is too small or the template is incompletely observed, and its validation should include such edge cases explicitly.

The best software proof combines reference calculations and adversarial test cases. Use short synthetic complex sequences for which the expected lag and amplitude can be calculated independently by hand. Exercise positive and negative delays, conjugation, zero-valued samples, integer overflow limits, and blocks straddling acquisition boundaries. Compare direct and FFT-based correlation under declared numeric tolerances, then carry out known-signal injections through the actual receiver to test the analogue and digital chain together. Such tests occupy different positions in an evidence hierarchy: arithmetic verification, software implementation verification and physical receiver validation should not be conflated.

Copyright 2026, James M. Atkinson

For a serious event the investigation record should permit replay from the original samples through the exact detection software version, including the intermediate statistic where practical. An examiner should also be able to examine candidates that fell below threshold and the conditions which caused buffers to be discarded. Without those records one can reproduce the winning peak but not the operational false-alarm or missed-detection behaviour. The system's apparent precision depends as much on its selection and retention rules as on the Fourier arithmetic. I pass the floor to Professor Neyman for the statistical discipline that should govern thresholds chosen from a bank of possible templates.

Copyright 2026, James M. Atkinson

Jerzy Neyman | Principal response 4: Detection thresholds, composite hypotheses and the cost of a search

Dr. Atkinson, the central statistical error I foresee is to treat the probability of a correlation value under one fixed null hypothesis as though it were the probability that a particular device emitted the signal. A decision problem should start by stating its hypotheses and the action governed by the test. For a known deterministic waveform in known additive Gaussian noise, one can derive a test with specified false-alarm probability and detection power. If the waveform is unknown, if the noise is estimated, or if a search chooses among many delays and templates, the experiment is different. Its operating characteristics must be evaluated for that experiment. A formula carried over from the simpler problem does not acquire validity merely because it produces a plausible number.

Suppose a detector examines one hundred possible delay hypotheses and then reports the largest normalised correlation. Even when each fixed-delay statistic has a small upper-tail probability under its null model, the maximum has more opportunity to appear large by chance. The tests are generally correlated because neighbouring delays share samples and because a waveform can correlate with shifted copies of itself. A simple family-wise bound based on the sum of probabilities may provide a conservative check under broad conditions, but precise field performance requires a correct joint model or empirically validated null trials reproducing the complete search. It is especially hazardous to calculate a single-cell p-value after selecting the peak and to report it as though the delay had been nominated before acquiring data.

Copyright 2026, James M. Atkinson

A library of templates complicates the matter. Some entries may be nearly identical, while others differ greatly. The number of stored templates is not necessarily the number of independent statistical tests, but the search process has still enlarged the decision space. A threshold calibrated for one waveform cannot automatically be applied to a bank of thousands without controlling the probability of at least one false alarm. If the library was developed by repeatedly examining the same archived environment, a separate validation population is needed to estimate performance. Otherwise the detector may fit the peculiarities of one building, receiver or interference field and produce overly optimistic results on familiar recordings.

I would distinguish an operational alarm from a source finding. The purpose of an alarm in a defensive survey may be to preserve raw IQ and draw the investigator's attention to a plausible candidate. A relatively liberal threshold may be justified if follow-up measurement is inexpensive and missing a weak emitter is costly. A claim that the candidate has been conclusively identified as an unauthorised transmitter is entirely different and requires corroboration of external origin and identity. Statistical decision theory can organise these distinct actions, but the report should not borrow the authority of one threshold for a much stronger statement which the threshold was never calibrated to support.

There is also a base-rate issue. The conditional probability of an alarm given a noise-only trial is not the conditional probability of noise given an alarm. To estimate the latter one needs assumptions or evidence concerning how frequently the relevant signals and alternative causes occur. A matched filter may have a very low false-alarm rate against synthetic noise and still

Copyright 2026, James M. Atkinson

generate many false source attributions when the building contains large numbers of legitimate transmissions with shared preambles. A report should state what null population was tested, whether confusable signals were present, and whether the decision rule included a rejection or abstention outcome. Without that information a numerical percentage can produce more confusion than illumination.

Intermittent observation changes the denominator of performance statistics. A receiver that scans a frequency for a small fraction of a period may never observe a brief burst. The conditional probability of detection *given that the burst is inside a valid retained observation* is not the probability of detecting a randomly occurring burst during the entire survey. The latter depends on the dwell schedule, source timing, filter settling, dead time and retention policy. These factors must be measured or modelled explicitly. A detector cannot repair limited exposure by applying a more sensitive matched filter to the intervals that happen to have survived acquisition.

The confidence of validation estimates also depends on independent challenge units. If a laboratory makes one hundred thousand overlapping FFT windows from ten physical injections, the number of independent trials is not necessarily one hundred thousand. The windows share the same waveform events, clock and interference conditions. The experiment should track injections, sessions and relevant clustering. Confidence limits can then be calculated at an appropriate level of independence. The validation should include deliberately incorrect templates, noise-only records, confusable legitimate waveforms and known signals at the edge of the receiver's

Copyright 2026, James M. Atkinson

sensitivity envelope. It should record every challenge, including those where a reference was present but the filter failed to cross threshold.

One should also distinguish error of detection from error of timestamp assignment. A receiver might correctly declare a template present but choose the wrong ambiguity lobe, shifting the reported arrival time by an integral symbol interval. A detector calibrated only for presence/absence is not necessarily calibrated for precise time-of-arrival estimation. The latter requires a different acceptance rule and a distribution of timing errors under plausible mismatch and multipath conditions. Likewise a detector that recognises a common protocol does not automatically distinguish transmitters sharing that protocol. The two errors should be counted separately rather than hidden beneath one overall accuracy figure.

My recommendation is a staged validation record. Declare the actual action the alarm triggers, the full search and threshold procedure, the relevant signal and interference populations, the number of independent physical challenge units, and the confidence limits on both false alarms and missed detections. Where the search rule is modified after examining performance, label the modification and retest it on new observations. A bounded and repeatable receiver decision is scientifically valuable; an unqualified source identity supported only by a high correlation is not. I invite Professor Fisher to question whether my emphasis on fixed procedures risks concealing the legitimate uncertainty of the noise covariance itself.

Sir Ronald Aylmer Fisher | Peer question 6 to Jerzy Neyman

Professor Neyman, your distinction between complete decision rules and selected peaks is persuasive, but practical investigators rarely know

Copyright 2026, James M. Atkinson

the noise covariance in advance. They estimate it from recordings which may include impulsive interference and unknown signals, then choose a whitening filter or threshold. A laboratory may have only a limited number of independent null trials, while the programme contains many overlapping time and frequency hypotheses. Would you accept a theoretical false-alarm probability calibrated from an estimated covariance, or require a second physical challenge population to establish its realised accuracy? I should also like to examine how a receiver should report uncertainty when the null model is demonstrably inadequate. If the alarm remains useful for directing a survey, is it scientifically permissible to continue operating the detector while withholding a numerical field false-alarm figure? What separation should be maintained between detection research and an evidential statement offered to support a consequential decision?

Jerzy Neyman | Immediate answer to Sir Ronald Aylmer Fisher

Sir Ronald, a theoretical performance figure is useful only to the extent that its premises have been justified. When the covariance is estimated rather than known, the estimator's uncertainty and its relationship to the test samples affect the distribution of the detection statistic. If the same data are used to fit the covariance and evaluate a candidate, an apparent agreement with a nominal Gaussian model can be misleading. One may derive an adjusted theoretical procedure under explicit assumptions, or calibrate the entire fitted detector empirically using independent null acquisitions. Neither choice should be presented as unconditional validation when the field environment departs from its assumed population.

Copyright 2026, James M. Atkinson

A limited number of challenge trials calls for an honest confidence interval, not a fabricated certainty. Zero observed false alarms does not establish a zero true false-alarm probability. The number of physical challenge units, their variety and their dependence should be stated. If the trials contain only quiet laboratory noise, the report should not claim performance against every class of field interference. Conversely, a detector may remain valuable as a discovery aid even when the field false-alarm rate is uncertain. The appropriate label is exploratory or operational candidate detection, with further physical checks required before a consequential attribution.

I would also preserve the distinction between a hypothesis generated from a suspicious recording and one specified before an independent test. An analyst may discover a waveform through visual inspection, construct a template and find more apparent matches in that same recording. This is useful work, but a formal significance figure must account for the adaptive search and selection. A withheld recording, independent capture or blinded injection campaign allows the chosen rule to be evaluated on observations not used to develop it. If the operator changes the threshold after an unfavourable trial, that event remains part of the developmental record and the revised rule requires new validation.

Where the null model is demonstrably inadequate, the strongest responsible statement may be that a correlation exceeded an operationally chosen threshold but that the false-alarm probability under the field population has not been established. This still permits

Copyright 2026, James M. Atkinson

the investigator to preserve evidence, change antennas, examine receiver artefacts and search for corroboration. What cannot be justified is attaching a numerical confidence to a source accusation solely because the software prints one. A statistical test addresses a specified comparison; responsibility for the broader causal claim remains with the evidence and its documented limitations.

Copyright 2026, James M. Atkinson

Harold Stephen Black | Principal response 5: Physical reference planes and receiver-generated correlation

Dr. Atkinson, the last question is whether the receiver can manufacture a match to its own internal behaviour. A filter may perform flawlessly as a digital computation while the analogue acquisition creates a waveform whose shape resembles the reference template. Local oscillator feedthrough, gain-control transitions, ADC interleaving patterns, buffer switching and clock-distribution defects can produce repeatable structure. A matched filter will respond to those structures if they correlate with its template. The output is not mathematically fraudulent. The mistake is a causal claim which attributes the correlation to a transmitter without testing whether the instrument generated or reshaped it.

Consider a receiver whose automatic gain controller changes amplification in steps whenever an internal power estimate crosses a threshold. Each transition introduces a short transient of approximately repeatable shape. A template extracted from one such transition can later match many more transitions. An analyst who counts these as multiple suspicious RF bursts may be measuring the controller's behaviour rather than the external environment. Even if an external signal originally triggered the gain change, the waveform of the recorded transient could be dominated by the receiver's response. The physical event and the instrument response have become causally entangled; a detector must not silently substitute one for the other.

The remedy begins with identifying the measurement boundary. Is the intended quantity the field at the antenna aperture, the voltage at the receiver input, the intermediate-frequency waveform, the ADC input or the

Copyright 2026, James M. Atkinson

stored IQ sequence? A matched filter computes similarity at the digital record plane. To infer a waveform at an earlier plane requires a characterised transfer and, when the inverse is not unique, explicit additional assumptions. A good engineer measures the effects of filters, mixers, gain and timing across the admitted operating conditions. A nominal block diagram is insufficient evidence that its transfer held at the instant of the candidate event.

A physical challenge should have distinct predictions for internal and external explanations. An antenna substitution may alter an external field's received amplitude while an internal digital spur remains unchanged, although the regulator and noise floor can complicate the observation. An input termination can test whether a feature persists with the specified RF path removed, provided other coupling paths are considered. A controlled injected waveform can measure whether the detector correctly follows a known external reference across gain and frequency settings. Retuning can reveal whether a candidate follows RF carrier motion or remains tied to a baseband offset. Each intervention must be interpreted through its own measured conditions rather than converted into an automatic verdict.

Feedback adds another danger. An adaptive detector may update its template to maximise the correlation with a candidate event. If the same event is then used to validate the template, a high score is unsurprising. The system has been designed to find and reinforce an apparent match. This procedure may be very effective for finding recurring waveforms, but it is not independent proof that one transmitter emitted them. The update history and training population should be preserved. A frozen version of the template should be challenged with known-present signals, null trials,

Copyright 2026, James M. Atkinson

confusable legitimate waveforms and varied receiver states. It should be possible for the system to fail and for that failure to be recorded.

Even hardware redundancy can be misleading. Two ADC branches within one time-interleaved converter may contribute to an apparent feature whose period follows the branch scheduler. A second receiver sharing the same local oscillator or distribution clock may reproduce the same artefact. Two software implementations of cross-correlation on the same stored file can validate arithmetic but cannot independently validate external origin. The dependency graph should identify shared antennas, clocks, gain-control commands, power supplies, capture triggers and processing libraries. A corroboration statement is meaningful only in relation to the specific dependencies it challenges.

I would insist on a report which separates repeatability, calibration and attribution. Repeatability establishes that the same or similar digital feature recurs. Calibration, if validated, establishes a relationship between the retained samples and a declared physical input plane under specified conditions. Attribution asks which source produced that physical input. A high matched-filter peak may support the first proposition. It can support the second only with appropriate transfer evidence, and the third only with discriminatory physical observations. One should not treat the measurement's precision as a substitute for its causal specificity.

The operator also has a duty to preserve discordant evidence. If a template matches during one gain state but not another, a reasonable explanation might be receiver sensitivity, template distortion or an internal artefact. The result should not be erased by selecting only the successful state. If a null input still produces the matched response, the possibility of

Copyright 2026, James M. Atkinson

internal generation is central to the investigation. If two physical receivers disagree under a supposedly strong source, the disagreement demands examination of their respective sensitivity and paths. A defensible negative result requires validated exposure, not merely the silence of a correlation alarm.

The prudent acceptance rule would state the waveform class and template, the physical reference plane, acquisition and processing settings, the full search procedure, field-representative challenge trials, and the source alternatives that remain. It would separate event detection and event timing from device identity. It would permit an inconclusive outcome where the experiment fails to discriminate among plausible causes. The value of matched filtering lies in better comparisons, not in granting infallibility to an attractive peak. I invite Sir Karl Popper to press the final question: what outcome must be allowed to defeat the examiner's preferred identification?

Sir Karl Raimund Popper | Peer question 7 to Harold Stephen Black

Mr Black, you have described a succession of tests which can either support or restrict an external-origin hypothesis, but I should like a sharper account of what would count as a serious adverse outcome. Suppose a detector produces a strong match to a purported unauthorised transmitter's preamble. When the investigator terminates the antenna input, the feature persists, so the investigator asserts that it entered through another cable. When an independent receiver fails to detect it, the investigator alleges insufficient sensitivity. When a known legitimate device generates the same preamble, the investigator calls that an exceptional coincidence. Some of these explanations may be technically possible, but together they can protect the original accusation

Copyright 2026, James M. Atkinson

from every contrary observation. What test plan would require the investigator to retract or narrow the claim rather than merely provide another saving hypothesis? How should the final report distinguish a model genuinely tested in advance from one modified after the evidence became inconvenient?

Harold Stephen Black | Immediate answer to Sir Karl Raimund Popper

Thank you for that question. Sir Karl, the investigator must define the intended proposition and alternative mechanisms before attributing a decisive meaning to the tests. A candidate may be real while the source hypothesis is wrong. If an RF termination, independently verified to exclude the specified input path, leaves the same matched feature present, the simple explanation that the signal entered only through that path is contradicted. The result should trigger a search for coupling, internal generation or an incorrectly defined boundary, and the original attribution must be withheld or revised. It is not sufficient to preserve the same headline by inventing unmeasured routes of entry after the fact.

An independent receiver's non-detection may indeed be inconclusive if its validated sensitivity, dwell and timing could not have captured the event. That limitation should be established from its test records, not assumed merely because a disagreement is inconvenient. If the second instrument was likely to detect the waveform under the documented conditions and nevertheless did not, the conflict weakens the source hypothesis and should remain visible. Similarly, evidence that a legitimate device uses the same

Copyright 2026, James M. Atkinson

preamble directly defeats any claim that the preamble alone uniquely identifies the suspicious source. It does not disprove that the suspicious source might also have transmitted, but it narrows what the correlation can establish.

The appropriate experimental plan contains known-present and null cases, expected results for a candidate external signal, predictions for receiver artefacts, and rejection criteria for the intended conclusion. Its scope should include plausible gain states, clock conditions and interference. If the receiver is reconfigured after an adverse trial, the new procedure can be tested prospectively, but the earlier trial remains part of the record and the revised claim must not inherit confidence from a validation which the instrument failed. This is an engineering form of intellectual honesty, not an impractical demand for absolute certainty.

A narrow conclusion which survives such challenges has genuine forensic value. It may establish that a specified processed waveform was observed and that the detector's template similarity exceeded a calibrated threshold. Further tests may support the presence of an external emitter sharing a known modulation convention. A statement identifying one individual device would require separately validated discrimination. Where those facts remain unavailable, the report must say that attribution is unresolved. We should prefer a defensible limited statement to a confident source accusation whose experimental meaning changes each time a test produces contrary evidence. I return the floor respectfully to Dr. Atkinson for the concluding synthesis.

Copyright 2026, James M. Atkinson

Norbert Wiener, Cross-Peer Question to Harry Nyquist: Mr Nyquist, a matched-filter peak appears at a particular sample index. What conditions permit its location to be reported as an RF arrival time?

Harry Nyquist, Cross-Peer Answer to Norbert Wiener: Professor Wiener, first establish the template definition and actual analogue reference plane. The peak location is a computation dependent on template delay, filtering, sample-clock origin, interpolation, group delay and channel dispersion. Calibrate the complete path with a known injected waveform and independently timed arrival, including different amplitudes and arrival phases. A waveform mismatch or multipath path can shift the maximum; merely correcting an algorithmic half-length is insufficient. Preserve the raw sample index, uncorrected peak and every time correction with uncertainty. If the host recorded only the arrival of a processed buffer, that timestamp is not a direct RF aperture epoch. I yield to Dr Shannon on source inference.

Harry Nyquist, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, does a high normalized correlation with one template identify the unknown transmission uniquely?

Claude Elwood Shannon, Cross-Peer Answer to Harry Nyquist: Mr Nyquist, not without an exclusivity argument. The result measures similarity under the chosen normalisation and noise model. Related waveforms, multipath-distorted copies, receiver-generated responses or a family of templates may yield comparable peaks. Define the hypothesis set and perform matched and deliberately mismatched signal injections, with noise-only controls. If the template was constructed after viewing the target record, account for data-dependent selection. A matched filter can be powerful for detection of a prespecified waveform in appropriate noise, yet its optimum property is

Copyright 2026, James M. Atkinson

conditional on that known template and statistical model. Record the waveform family and physical alternatives that remain compatible with the data. I respectfully pass the token to Dr Neyman for threshold setting.

Claude Elwood Shannon, Cross-Peer Question to Jerzy Neyman: Dr Neyman, what threshold can support a defensible detection statement if the algorithm searches over many template delays, Doppler offsets and pulse shapes?

Jerzy Neyman, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, the relevant false-alarm event is the maximum over the declared template-and-delay search, not the probability attached to one individual correlation sample. Estimate its distribution under validated noise-only conditions or use an explicitly justified conservative rule. Dependence between nearby templates and delays must be respected. Calibrate both detection probability and false alarms over an independent challenge population with varied amplitude, noise, mismatch and receiver state, and with the search bounds fixed in advance. An apparently excellent peak can become unremarkable when compared with thousands of alternatives. The report should distinguish statistical detection of a template-compatible feature from physical attribution or exact waveform reconstruction. I yield to Mr Black for the hardware artefact concern.

Jerzy Neyman, Cross-Peer Question to Harold Stephen Black: Mr Black, a receiver produces a matched-filter peak even with no RF antenna attached. What path-level tests can expose the source of the apparent correlation?

Harold Stephen Black, Cross-Peer Answer to Jerzy Neyman: Dr Neyman, challenge amplifier feedback, clock leakage, digital test patterns, converter

Copyright 2026, James M. Atkinson

intermodulation and internally coupled reference signals under controlled input terminations. Move the injection reference plane, change gain distribution and test at input levels below compression. An independent receiver with a distinct oscillator and processing implementation can help distinguish a shared external event from one chain’s peculiar artefact, provided common antennas and clocks are not concealed. Examine the raw ADC codes to determine whether the feature arises before or after digital matched filtering. The reported peak must be linked to a measured physical input response, not merely to software output. Record unsuccessful controls as carefully as successful ones. I return the token to Dr Atkinson.

Dr. James M. Atkinson | Moderator synthesis and concluding discussion

Distinguished colleagues, the panel has established that a matched-filter peak is a comparison result whose physical meaning is conditional upon its template, noise model, acquisition history and search procedure. In the ideal known-waveform problem it is possible to derive a linear filter with maximum output signal-to-noise ratio at a selected instant. The validity of that derivation does not establish the truth of the signal hypothesis in a field experiment. A correlation response can arise from a legitimate emitter using a shared preamble, from a distorted version of the intended waveform, from a receiver-generated transient, or from noise selected by a sufficiently broad and adaptive search. The number displayed by the detector is neither a unique identifier nor an automatic probability of one source's existence.

Professor Wiener has reminded us that a filter becomes optimal only in relation to a specified problem. His conditional statement of the model $x = a s + w$ requires that the template s and the noise covariance be defined. If the covariance is coloured, estimated from contaminated training data or

Copyright 2026, James M. Atkinson

changed by a gain-state transition, the elementary white-noise optimality result no longer transfers without qualification. If the template was learned from the same archive on which it is evaluated, the resulting high score is not an independent test of that archive. These are not reasons to abandon adaptive detection. They are reasons to expose the training procedure, preserve the raw evidence and validate the actual rule as operated.

Mr Nyquist has distinguished a computational lag from a physical arrival time. A number of samples divided by a nominal rate gives one coordinate; the physical RF event requires a reference epoch, measured signal-path delays, clock uncertainty and a known definition of the template. A peak may jump between ambiguity sidelobes even while interpolation reports many decimals. A receiver can agree perfectly with its own internally generated reference and remain displaced from the true antenna event. For a time-difference measurement or forensic geolocation claim, the surviving uncertainty is therefore a property of the complete measurement chain, not merely the granularity of the digital correlation array.

Dr Shannon has identified the evidential information that a match does not supply. A known preamble may be an excellent indicator of a waveform class and a poor identifier among the many compliant devices which share it. A compressed matched-filter statistic may suffice for one declared detection while discarding information that a later analyst would need to distinguish alternative waveforms or test an unexpected source hypothesis. The archive should retain sufficient source samples for material cases, together with the template version, transformations and rejection conditions. The performance of a detector and the identity of a physical emitter are different questions with different validation requirements.

Copyright 2026, James M. Atkinson

Professor Neyman has required us to evaluate the complete decision rule, rather than one selected peak abstracted from its search history. Unknown delay, carrier offset, phase, amplitude and template selection all enlarge the opportunity for chance maxima. Overlapping correlation lags are usually dependent, but that dependence is an argument for a validated null distribution, not a licence to ignore the search. A detector's false-alarm rate must be distinguished from the probability that a particular alarm arose from a particular source. It is permissible for an operational detector to flag candidates under uncertainty. It is not permissible to present that operational threshold as a source-identification standard never tested against the relevant alternatives.

Mr Black has returned the argument to the physical input. The receiver may produce a highly repeatable waveform in its local oscillator leakage, gain-control transient, buffer schedule or clock path. A matched filter can detect this waveform efficiently and consistently. The correct engineering response is to locate its mechanism by changing relevant physical conditions, measuring the input-to-record transfer and testing independent acquisition paths. The source of an internal artefact can be found by experiment, just as an external source can. A good investigation preserves discordant trials instead of erasing them from a favourable report.

The final publication statement should therefore distinguish four conclusions, none silently substituted for another. First, the recorded data yielded a specified template similarity under declared processing. Second, the detector's threshold and operating characteristics were established for a documented comparison population. Third, physical tests supported or failed to support an external-origin explanation over specified receiver

Copyright 2026, James M. Atkinson

states. Fourth, source identification either was or was not supported by independent discriminatory evidence. A result may be strong in the first two dimensions, moderate in the third, and indeterminate in the fourth. That is not an embarrassment; it is an accurate account of the information actually obtained.

The panel's arithmetic is hypothetical and has not certified any modern receiver. Historical contributors are presented as intellectual personae in newly constructed educational dialogue, not as eyewitnesses to contemporary electronics. The practical doctrine is that mathematical sensitivity must be joined to provenance and experimental accountability. The next question will examine spectral occupancy under intermittent observation, where the temptation is different but the inferential boundary is similar: a large collection of retained samples can look comprehensive while leaving substantial intervals of electromagnetic reality unobserved. I thank the contributors and respectfully pass the floor to that subsequent examination.

Ten worked technical applications

Ten worked engineering applications | Question 048

Worked application 1: White-noise correlation SNR

Let s be a known complex template of energy $E_s = \text{sum } |s[n]|^2 = 64$ in normalised sample units; a is a scalar signal amplitude with $|a| = 0.25$; and $\sigma^2 = 1$ is complex noise variance per sample. For independent zero-mean complex Gaussian samples, the correlation $y = s^H x$ has signal component aE_s and noise variance $\sigma^2 E_s$. Its output SNR is $|a|^2 E_s/\sigma^2 = 0.25^2 \times 64/1 = 4$, or $10\log10(4) \approx 6.02$ dB. This result is conditional on exact template and noise assumptions, and does not identify the physical emitter that supplied the waveform.

Worked application 2: Normalised template similarity

Assume two hypothetical equal-energy waveform vectors s and u have norms $||s|| = ||u|| = 10$ and inner-product magnitude $|s^H u| = 80$. Their magnitude-normalised similarity is $\rho = |s^H u|/(||s||\,||u||) = 80/(10\times10) = 0.80$. By the Cauchy-Schwarz inequality its magnitude does not exceed one. The measured 0.80 indicates alignment between the vectors under a specified time and phase convention. It does not establish that the vectors originated from one device. A shared preamble or common filter response may produce a similar coefficient.

Worked application 3: Nominal lag versus physical time

Let sample rate $F_s = 2{,}000{,}000$ samples/s and a correlation peak appear at lag $k = 240$ samples relative to the recorded reference. Its nominal digital delay is $\tau_d = k/F_s = 240/2{,}000{,}000 = 120$ microseconds. If the analogue path introduces an independently measured 7 microseconds of delay and the lag convention is consistent, the

Copyright 2026, James M. Atkinson

corresponding corrected time difference is 113 microseconds. The numerical correction is only as valid as the path calibration and reference epoch. Sample-rate error, filter dispersion and ambiguity-lobe selection can add further uncertainty beyond the apparent 0.5-microsecond nominal sample spacing.

Worked application 4: Search over many tests

Assume $m = 500$ independent hypothetical null comparisons, each with single-comparison false-alarm probability $p = 0.001$. The probability of at least one crossing in the bank is $P_{any} = 1-(1-p)^m = 1-0.999^{500} \approx 0.3936$. Here m is the number of tests and P_{any} is family-wise alarm probability. Real neighbouring correlation lags and similar templates are dependent, so the independence calculation is illustrative rather than a calibrated receiver claim. The correct threshold should reflect the distribution of the maximum over the complete implemented search.

Worked application 5: Sample-clock frequency-scale uncertainty

Suppose a digital delay estimate is $\tau_d = 0.100$ s and the nominal sampling-rate reference has fractional frequency-scale uncertainty of $\varepsilon = 5$ parts per million. The approximate delay-scale contribution is $|\Delta\tau| \approx |\tau_d \varepsilon| = 0.100\times5\times10^{-6} = 0.5$ microseconds. Here ε is dimensionless; τ_d is the nominal measured interval. This does not include analogue group delay, time-stamp epoch errors, random jitter or wrong-peak selection. A precisely located correlation maximum cannot reduce uncertainties arising in independent parts of the physical time measurement.

Worked application 6: Correlation output variance under white noise

For a template with $E_s = 100$ and independent complex white noise variance $\sigma^2 = 0.04$ per sample, the output correlation noise variance is

Copyright 2026, James M. Atkinson

$Var(y) = \sigma^2 E_s = 4$. Thus the correlation noise standard deviation is 2 in the corresponding normalised output units. A displayed peak with magnitude 6 is three such standard deviations from zero in a scalar heuristic comparison, but the tail probability for a complex magnitude and a searched maximum is not given by an ordinary one-sided real Gaussian three-sigma rule. The actual statistic and selection distribution must be specified before a formal false-alarm claim.

Worked application 7: Template-bank storage and search arithmetic

Suppose an instrument tests K = 256 templates at L = 1,000 trial lags in each acquisition interval. The direct comparison count is K×L = 256,000 trial outputs. If it produces one alert at the largest value, that alert is one decision derived from 256,000 correlated or uncorrelated numerical comparisons, not 256,000 independent physical observations. Depending on the implementation and template correlations, FFT methods may reduce computation, but no algorithmic acceleration changes the number of acquired electromagnetic events. The test must calibrate the maximum statistic corresponding to the real search process.

Worked application 8: Observation exposure during a scan

A scanner dwells in a candidate band for d = 8 ms every R = 80 ms. Its nominal duty fraction is q = d/R = 8/80 = 0.10. If burst onset is independent and approximately uniform relative to the scan, and burst duration is negligible, the chance a randomly timed burst begins during a dwell is approximately 10%. This is not the detector's conditional sensitivity when the waveform is present in retained samples. For non-negligible burst lengths, the intersection probability changes; settling intervals, trigger policies and time correlations further modify exposure.

Copyright 2026, James M. Atkinson

A silent matched filter cannot establish continuous absence when ninety percent of nominal time was not observed.

Worked application 9: Discrete correlation output length

For full linear cross-correlation of arrays of N = 1,024 and M = 256 samples under zero extension, the output has N+M−1 = 1,279 lag positions. The lag range is from −(M−1) to N−1 under the convention stated in the SciPy documentation. Using 'same' mode returns a shorter centred selection and can conceal responses at boundaries. Neither output length represents the number of independent detections. The investigator should preserve the software's lag convention and whether the relevant template was wholly observed at the reported position.

Worked application 10: Timing ambiguity from a repeating template

Suppose a known template contains an approximate repeated motif every T_r = 40 microseconds. If the matched-filter ambiguity surface has significant peaks separated by that interval, selecting the wrong peak by one motif period yields an arrival-time error of 40 microseconds. Interpolating a selected peak to one-tenth of a sample does not remove this discrete ambiguity. The error may matter enormously in a time-difference-of-arrival calculation, while leaving the presence/absence detection nearly unchanged. A validation campaign should therefore record wrong-lobe frequency separately from small local timing deviations.

QUESTION 049

Copyright 2026, James M. Atkinson

How should spectral occupancy be reported when observation is intermittent?

Source: V011_Roundtable_Questions_049-050_CP050_Combined.docx | Recovered substantive manuscript. Constructed educational dialogue.

Moderator: Dr. James M. Atkinson

Editorial convention: All speech below is original, constructed educational dialogue. The historical contributors did not participate in this discussion, and their words are not represented as authentic quotations. All numerical illustrations are hypothetical.

Dr. James M. Atkinson. Opening of Question 049

Distinguished colleagues, the engineer who watches a narrow emission flash across a waterfall display encounters a deceptively simple proposition. The channel appeared occupied, and, after an interval of silence, it appeared empty. Yet this description may be no more than an account of what the instrument displayed at two selected instants. The task of scientific reporting is to distinguish the visible succession of measurements from an assertion concerning the unseen transmitter's conduct between them. A receiver which dwells for ten milliseconds and revisits its channel every second may collect a perfectly accurate record of those ten milliseconds while remaining uninformative about nine hundred and ninety milliseconds of each second. That observational gap is not repaired by immaculate frequency calibration, a low noise figure, or an attractive and continuous-looking waterfall. A digital display can interpolate its pixels without extending the physical observation in time.

Copyright 2026, James M. Atkinson

We must identify the quantity under discussion. *Frequency-channel occupancy* may describe the proportion of accepted measurement opportunities at which a declared threshold and decision procedure indicated occupancy. *Time occupancy*, in the stronger physical sense, concerns the proportion of a specified time interval during which an emitter or class of emissions genuinely occupied the relevant resource. The two may agree under a defensible sampling design and validated observation model, but they are not synonyms. A measurement which states that thirty of one hundred admissible visits exceeded a threshold establishes an observed fraction of 0.30 under that rule. It does not, without further premises, establish that a particular transmitter operated for thirty per cent of the elapsed monitoring period. It does not even establish that the radio channel was clear during every below-threshold visit, because a weak or masked emission may escape the detector.

The International Telecommunication Union's currently applicable Recommendation ITU-R SM.1880-3, approved in August 2026, addresses spectrum-occupancy measurement and evaluation. Report ITU-R SM.2256-2, issued in June 2026, expressly distinguishes sample measurement time, observation time, revisit time, occupancy time, integration time and statistical confidence. These distinctions are not typographical ornaments. They describe how the measurement operation limits the propositions available for a subsequent engineering or forensic conclusion. We shall use those published classifications as contemporary editorial context, without suggesting that our deceased contributors encountered these particular editions.

Copyright 2026, James M. Atkinson

Consider two surveys of the same apparent duty cycle. The first consists of an uninterrupted recording from a calibrated wideband receiver with a defined sensitivity envelope and lossless sample retention. The second visits the channel at a sequence of time stamps generated by a scanning receiver, retaining a power estimate during each visit. Both may produce an aggregate occupancy value of thirty per cent. The first might permit retrospective examination of each relevant instant, subject to clipping, threshold, front-end and storage qualifications. The second cannot reveal what happened during its unvisited intervals. A probability model may nevertheless estimate population occupancy from a representative sample of visits. That is a statistical argument requiring a defined population and sampling mechanism. It is not evidence that the instrument secretly observed what its receiver never tuned to.

The distinction becomes particularly urgent in technical surveillance countermeasures. A hostile or merely unusual device could transmit briefly, react to a scanner, exploit a narrow operational window, or remain below the accepted threshold for much of the investigation. In contrast, a legitimate pulsed service may generate many above-threshold indications and appear threatening simply because its emissions coincide with the selected channel's analysis window. An evidential report must separate presence detection, estimated duty cycle, count of discrete events, transmitter identity, exposure coverage and the probability of failing to observe an event. None should be inferred from another merely because all can be placed on the same numerical chart.

I propose that every occupancy result should carry its denominator prominently. Was it valid dwell time, number of sampled visits, wall-clock

Copyright 2026, James M. Atkinson

elapsed time, count of independent measurement opportunities, or an estimate of an underlying physical occupancy state? What treatment was given to clipped readings, receiver retuning, gain changes, detector invalidity, interference and missing data? Were the visits scheduled independently of the emissions under investigation, and did the sampling design expose every part of the intended population with a known or at least defensible probability? The answers determine whether an occupancy statistic is descriptive, inferential, conditional or incapable of the more ambitious interpretation.

Professor Fisher shall address the statistical population and the requirements for drawing inference beyond the observed visits. Dr Shewhart will consider process stability, temporal clustering and operational change. Dr Shannon will distinguish information retained in a monitoring record from information that its acquisition policy never obtained. Dr Wiener will analyse the coupled observer whose scanning or thresholds react to previous observations. Finally, Professor Neyman will consider interval coverage, decision rules and how to disclose limitations when negative findings are requested. Seven colleagues will challenge these propositions directly, each receiving an immediate substantive answer. Let us resist both the cheerful assertion that a few clean scans certify an empty room and the equally unhelpful position that finite sampling can support no conclusion whatsoever. Professor Fisher, I invite you to begin by identifying the precise population to which a reported occupancy percentage may legitimately refer.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher. Principal response 1. The sampling population is not the empty time between visits

Dr. Atkinson, the first duty of statistical reasoning is to declare what has been counted and the reference population to which the count is intended to apply. A numerical fraction without its design is merely a description of the observed entries. If the investigator takes one hundred channel measurements and registers thirty positive decisions, the observed fraction is thirty divided by one hundred. That arithmetic is correct whatever the measurement policy. But an inference about the entire monitoring period requires a connection between those hundred observations and the potentially much larger population of time instants or transmission opportunities. A sequence of convenient visits does not acquire the character of a random sample by having many entries, and multiplication of the count does not cure systematic selection.

Suppose that an emitter operates in a predictable schedule. A receiver which visits every second, always at the same phase of the emitter's cycle, may find the channel occupied at every visit while most of the elapsed interval is clear. Shift the receiver by half a period and it may report no occupancy at all. Both datasets might be internally consistent and highly repeatable, yet neither is representative of the intended interval. This is the familiar danger of periodic sampling against a periodic population. It cannot be solved by treating each visit as an independent Bernoulli trial. Randomising or varying the observation phase may help, but only if the randomisation is actually executed, its distribution is relevant to the claim, and the detector has adequate sensitivity during a visit.

Copyright 2026, James M. Atkinson

The relevant estimand should be written before the apparatus is energised. If p denotes the proportion of a defined time interval during which the channel state is genuinely occupied under a declared physical definition, then p is not automatically the same as q, the probability that the detection algorithm returns a positive result during a randomly selected valid measurement opportunity. Even in the simplest binary model, q depends on the detector's probability of detection, P_D, and its false-positive probability, P_{FA}. If an occupied state is observed with probability P_D and an unoccupied state produces a false alarm with probability P_{FA}, then $q = p P_D + (1-p) P_{FA}$. Consequently, provided P_D and P_{FA} are appropriate for the operating conditions and P_D differs from P_{FA}, $p = (q - P_{FA})/(P_D - P_{FA})$. This is a conditional inverse relationship, not a magic correction applicable to all receivers. It assumes a relevant two-state classification, representative sampling, a stable detector characterisation and an intelligible definition of the occupied state.

We should consider a hypothetical q of 0.30, P_D of 0.90 and P_{FA} of 0.02. The estimated latent occupancy would then be (0.30 - 0.02)/(0.90 - 0.02) = 0.28/0.88, approximately 0.3182. The corrected estimate is *higher* than the observed positive fraction because missed occupied states contribute more strongly than false alarms under these stipulated conditions. Change the decision threshold and the values may change. Put a strong authorised transmission in an adjacent channel and the false-alarm behaviour may change again. In a high-stakes survey the quantities P_D and P_{FA} must be justified by relevant tests and their uncertainty propagated. A point estimate calculated from nominal manufacturer specifications should not be dressed up as an instrument-independent finding.

Copyright 2026, James M. Atkinson

A second problem concerns dependence among visits. An emission lasting twenty seconds may produce twenty positive one-second observations, yet these are not twenty independent examples of how often a random emitter becomes active. The same continuous event has supplied correlated measurements. In estimating a duty cycle, the investigator must preserve the temporal record rather than reduce it prematurely to a single count. Confidence procedures assuming independent trials may be too narrow when neighbouring observations follow the same occupancy state or share a slowly changing detector environment. This is why a statement that one has taken ten thousand measurements is not an adequate substitute for disclosing the visit schedule, the clustering of states, and the analysis unit.

The denominator may also change without the investigator noticing. If a survey includes receiver retuning, clipped input intervals, failed acquisition blocks or temporary threshold changes, those invalid intervals should not be silently scored as clear. Removing them from the denominator may be legitimate if the resulting population is explicitly redefined as valid observations, but it changes the claim. A percentage calculated solely over successful visits is a conditional occupancy estimate for successful visits, not a demonstration that the broader investigative period was equally well surveyed. If invalidity is related to strong emissions, excluding the invalid observations can introduce selection bias, potentially removing precisely the moments when relevant activity was most likely.

It is tempting to demand random sampling of every physical instant. In practice, the survey may have design constraints and may require stratification by hour, location, operating state or channel. Those constraints

Copyright 2026, James M. Atkinson

need not render statistical analysis impossible. Define each stratum, preserve its time exposure, and state the intended weighting. A survey equally distributing visits between an active daytime service and a quiet overnight interval cannot be reported as the natural time average if daytime and night-time receive incompatible weights. A weighted estimator may be warranted, but weights should derive from the defined population rather than from a desire to produce a plausible narrative. If the original schedule does not support a population claim, one should say so and report the observational result accurately.

I would therefore require three layers in the investigator's report. The first is a primary record: the count, timing, channel, threshold, valid exposure and classification associated with each observation. The second is an inferential model: why those observations represent the asserted population, with sensitivity to temporal dependence and detector errors. The third is an operational interpretation: what a responsible investigator may conclude or do, given the uncertainty, the costs of missed evidence and the competing explanations. That third layer must not be allowed to alter the first two after the result is seen. The best statistical discipline permits a limited but useful conclusion, and it marks exactly where a more ambitious claim would require a different survey. Dr Shewhart, may I respectfully pass the floor to you to examine whether the process being measured is sufficiently stable for the sampling model to describe it?

Richard Wesley Hamming | Peer question 1 to Sir Ronald Aylmer Fisher

Professor Fisher, your population definition is mathematically exact, but the practical investigator must programme an acquisition scheduler

Copyright 2026, James M. Atkinson

before the behaviour of the unknown emitter is known. Suppose the same survey contains long speech transmissions, short telemetry bursts, a slowly drifting interference source and a possible device that remains silent while its controller detects an active scanner. There is no single duration or periodicity from which a convenient randomisation interval may be derived. A carefully weighted occupancy estimate could consequently possess a tidy confidence interval while remaining nearly blind to the very rare event for which the survey was commissioned. How should the examiner reconcile the scientific demand for a representative sampling design with a search whose target class is not known in advance? Would you permit a two-stage campaign in which broad discovery determines a later intensive scan, and, if so, how should the report guard against the attractive but mistaken practice of treating measurements chosen because of an apparent anomaly as though they had been selected independently of that anomaly?

Sir Ronald Aylmer Fisher | Immediate answer to Richard Wesley Hamming

Dr Hamming, I would distinguish the design of a survey intended to estimate average occupancy from a search intended to discover a rare and potentially adaptive emitter. The first can often be framed as a population-estimation problem; the second may be better framed as a detection and experimental-challenge problem. One ought not force both into a single percentage because a convenient computer programme can print it. Where behaviour is unknown, an initial discovery phase may properly explore frequencies, times and locations with flexible methods. Such flexibility creates useful

Copyright 2026, James M. Atkinson

hypotheses. It does not, by itself, establish a sampling design from which the frequency of all unobserved activity can be estimated without qualification.

A two-stage campaign is entirely defensible if the analysis preserves the distinction between its stages. Record the initial schedule, the triggers used to intensify attention, and the measurements that were retained or omitted. The second-stage results should be described as conditional upon the selection decision. If the investigator finds a narrow periodic feature and then directs the receiver to that frequency for many hours, the resulting proportion of positive observations describes a deliberately enriched observation population. It may be excellent evidence that the feature persists or responds to controlled changes. It is not an unbiased estimate of the probability that a randomly selected channel in the original survey would be occupied.

One method of obtaining stronger evidence would be to reserve a validation phase whose conditions are established before examining its data. The discovery stage can suggest frequency, interval and threshold hypotheses; the validation stage can deliberately vary these while preserving the raw records of failure as well as success. Where avoidance by a transmitter is suspected, the examiner might compare distinct observation modes, passive and active configurations, and independently controlled reference paths, but should not claim to have proved intentional avoidance simply because a signal disappears after a receiver is moved. Such a disappearance has numerous physical and instrumental alternatives.

Copyright 2026, James M. Atkinson

I would also recommend reporting more than one measure. For discovery, report the number of distinct candidate events and the actual exposure time in which each could have been detected. For a population estimate, report the observed positive fraction under a declared sampling design, with its uncertainty and limitations. For a negative survey, report the minimum event duration and signal strength that the system's exposure and receiver sensitivity could plausibly detect at a stated confidence level, provided that level has actually been validated. These are different propositions. An investigator can be quite persuasive about one while uncertain about the others.

Finally, the value of an investigation is not measured by whether its conclusion fits into one confident number. The best evidence may consist of a well-preserved candidate event, repeatable challenge observations and an explicit admission that overall occupancy cannot be estimated from the available schedule. That account is neither timid nor inconsistent. It is scientifically honest about the boundary between observing a rare event and making a claim about the behaviour of an entire unobserved population. I pass the token to Dr Shewhart to consider what happens when the properties of that population change while the survey is running.

Copyright 2026, James M. Atkinson

Walter Andrew Shewhart. Principal response 2. Temporal change and the fallacy of one long-run occupancy number

Dr. Atkinson, the premise most in need of examination is that the observed process retains one stable character throughout the monitoring interval. The operator may accumulate measurements for a week, combine them into a single occupancy percentage, and congratulate himself upon the apparent authority provided by a large denominator. Yet the monitoring environment may have changed repeatedly. A factory machine may begin operating at dawn; a public-safety channel may become active during an incident; a scanning receiver's gain may change under strong-signal loading; and a suspicious emission may follow an intermittent duty cycle that interacts with the survey schedule. The resulting aggregate can conceal the sequence of regimes from which it was assembled.

My concern is not an objection to averages as such. An average is an intelligible numerical description when the population and weighting are defined. It becomes dangerous when the reader interprets it as a description of every moment or as evidence of stability. Consider a hypothetical survey divided into two equal-duration periods. The first has ten valid positive visits out of one hundred; the second has ninety. Across both periods the pooled rate is one hundred out of two hundred, or fifty per cent. That rate is exact for the pooled record and almost useless for describing either period. A plot of the chronological observations immediately reveals the change. A single printed value conceals it.

For a monitoring system, the first requirement is preservation of sequence and operating state. The receiver's configuration, sensitivity estimate, threshold and valid observation windows must accompany the

Copyright 2026, James M. Atkinson

occupancy decisions. Without that correspondence, a change in the plotted occupancy percentage might arise from the transmitter, from the receiver, or from both. The examiner should therefore consider process-monitoring techniques, control observations and stratification by known operating conditions. A reference emitter or controlled calibration signal may help disclose receiver drift, but the reference path must be relevant to the frequencies and amplitudes at issue. A changing urban noise environment cannot be repaired by a laboratory calibration performed under one quiet condition.

When a monitored process is nonstationary, intervals of observation should be chosen to preserve temporal structure rather than merely to satisfy an arbitrary total count. An hourly occupancy series, accompanied by the actual count and valid dwell time within each hour, may be much more useful than one weekly percentage. Likewise, a table separating daytime, overnight, weekday and weekend regimes may expose recurring behaviour. These strata should not be invented solely after seeing a pleasing pattern. Exploratory strata should be labelled exploratory and any stronger inference should be checked against new data or a stated correction for selection.

The evidential significance of long bursts is especially important. A twenty-second emission can produce multiple adjacent positive visits. These measurements may show that one event persisted, but they do not constitute repeated independent activations. If the survey is interested in event incidence, count event onsets under a declared merging rule and preserve how interruptions shorter than a specified interval are handled. If it is interested in time occupancy, preserve dwell duration and observation coverage. If it is interested in source attribution, a sequence of power-

Copyright 2026, James M. Atkinson

threshold classifications is too impoverished to establish identity by itself. The report should never convert a measurement of one estimand into another without an explicit model.

Consider an apparatus that revisits each channel once every two seconds and has a dwell of twenty milliseconds. A short burst beginning half a second after each visit will not be encountered, regardless of the detector's sensitivity during dwell. The instrument could be perfectly calibrated while recording zero positives. A different source transmitting continuously across the visits could be detected every time. Occupancy in the retained visits is therefore strongly affected by how the schedule aligns with the source. Random variation in revisit phase may reduce this particular vulnerability, but the resulting observations still require analysis of the actual sampling design. A receiver can have apparently stable threshold statistics while its exposure to the target is poor.

I would require a diagnostic account of the process used to make each observation. At minimum it should identify the occupied-state decision, the channel or frequency band, the detector configuration, the observation start and stop, and any invalid interval. A useful validation campaign would introduce controlled emissions with several burst lengths and duty cycles across deliberately varied phases relative to the scan. The acceptance report should display the failures alongside the successes. If a system's detection probability drops sharply for brief events or particular revisit phases, the operator may still employ it within its bounded capability. What cannot be done is to report general confidence while omitting the very parameter regime in which the confidence does not hold.

Copyright 2026, James M. Atkinson

My concluding observation concerns the difference between a measured change and an assigned explanation. A rising positive-visit fraction may reflect increased legitimate traffic, a new emitter, altered interference, reduced threshold or instrument fault. Evidence that the rate changed is not evidence that a particular device caused the change. A control experiment must distinguish the alternative mechanisms through different predicted outcomes. Retuning the receiver, substituting the antenna, repeating under a reference source or using a second independently characterised receiver may assist, provided common dependencies are documented. The historian of the measurement should be able to reconstruct both the instrument and its environment, not merely see the beautiful smooth line produced by an averaging algorithm. I return the floor to Dr. Atkinson for the next challenge on whether selecting one stable regime may itself conceal important anomalies.

Jerzy Neyman | Peer question 2 to Walter Andrew Shewhart

Dr Shewhart, I agree that a single pooled occupancy fraction can hide dramatic temporal changes, but I should like to challenge the basis upon which the examiner decides that a process has entered a new regime. Suppose a monitoring team divides a week into hourly intervals, notices that one interval has an unusually high fraction of positive visits, and announces that the transmitter became more active in that hour. The same team has monitored hundreds of frequencies and has therefore had many opportunities to encounter an extreme hourly percentage by chance. Even a stable underlying process can generate a seemingly compelling chart if the observer searches enough periods for its most conspicuous peak. Moreover, the individual samples may be correlated,

Copyright 2026, James M. Atkinson

so their apparent number exaggerates the information available. By what procedure should the team distinguish genuine temporal change from statistical variation, while preserving the exploratory value of its observations? Should it publish only the preselected comparisons, the entire time series, or a family of uncertainty statements reflecting the number of tests that were considered? I am particularly concerned that a threshold chosen after seeing the record may transform an ordinary fluctuation into an apparently extraordinary event.

Walter Andrew Shewhart | Immediate answer to Jerzy Neyman

Professor Neyman, your objection properly separates evidence of temporal heterogeneity from an explanation of its cause, and it also reminds us that a sequence of exploratory comparisons cannot be treated as though each had been the sole planned test. My recommendation is to preserve the chronological record and the declared analysis plan, allowing the examiner to show both the originally intended summaries and any subsequent diagnostic investigations. A high hourly fraction may be worth investigating without being represented as a statistically confirmed change. When a particular threshold, time interval or group of channels was selected because it appeared unusual, the selection must accompany the reported result.

A useful process chart begins with a physically meaningful unit of observation. Where adjacent visits reflect the same continuing transmission, a chart of raw positive fractions may have more dependence than a simple binomial interpretation admits. One may instead record episodes, valid exposure intervals and the time

Copyright 2026, James M. Atkinson

occupied within those intervals, and use validation data to examine the null variation expected under stable operating conditions. If the process displays strong periodicity, an apparently remarkable peak can be evaluated against that periodic baseline rather than against a fictitious independent sequence. A control chart constructed for one set of operating conditions should not silently be carried into another threshold, gain state or antenna configuration.

There is no requirement to abandon exploratory discovery. One may flag unusually high activity, compare antenna configurations or retune a receiver to pursue an anomalous candidate. The exploratory nature of that selection should be explicit. Stronger confirmation may follow from a predeclared challenge interval, an independent observing configuration or the repetition of a distinctive physical signature under conditions where competing causes predict different outcomes. If the investigator changes a decision rule after observing an apparent feature, retain both the original and revised rules and explain which records informed each change. Transparency permits another examiner to contest whether the claimed significance survives an honest account of selection.

For reporting, I would prefer a chronological series with its observation exposures, regime annotations and invalid intervals, accompanied by a concise description of which comparisons were planned. A family-wise or other multiplicity adjustment may be appropriate for a specified collection of formal tests, but it should not be invoked mechanically to create a spurious impression of certainty when the model of dependence is not sound. Equally, an observed

Copyright 2026, James M. Atkinson

difference need not be called insignificant merely because the investigation was exploratory. It may supply a valuable lead that deserves a different, controlled measurement. The ultimate proposition should be proportionate: the frequency of indications changed under the stated measurement policy, while the external source and precise elapsed-time occupancy remain hypotheses until the additional physical conditions are established. I pass the token respectfully to Dr Shannon to examine whether any subsequent processing can fill the intervals in which the receiver simply did not observe the channel.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon. Principal response 3. The information absent from a scan cannot be recovered by formatting its results

Dr. Atkinson, the most alluring mistake in an intermittent monitoring system is to confuse a smooth representation with a complete observation. A computer can draw a continuous line from scattered measurements, interpolate colours between waterfall columns or construct a time series from assumed transitions between successive occupied states. These operations may be justified for visualisation or for estimation under a stated stochastic model. They cannot transform an unmeasured interval into an original physical record of the transmitter's activity. A later analyst may infer the probable behaviour of a population, but the information about the particular unobserved event was never acquired in the first place. The distinction matters profoundly when a forensic claim concerns whether a short emission occurred at a particular time, rather than the average duty cycle over many visits.

I would begin with a sampling policy represented as an observation operator. Let s(t) be the physical occupied-state function, taking the value one when a specified channel is occupied and zero otherwise, and let w(t) be a coverage function which takes the value one when the detector can validly observe the channel at the requisite sensitivity. What the instrument knows directly is not the full integral of s(t) over all elapsed time. It may know classifications or measurements derived from s(t) only where w(t) permits observation. Its effective exposure is the integral of w(t) over the monitoring period, not necessarily the full elapsed duration. Even that exposure description is incomplete if the detector's sensitivity varies with time or if

Copyright 2026, James M. Atkinson

classification errors depend on the signal's strength, modulation or interference environment.

Two physically different occupancy histories can give exactly the same observations. Imagine a scanner that visits a channel for ten milliseconds at the start of every second and finds it clear. In one possible history, the channel remains clear throughout. In another, a transmitter emits for one hundred milliseconds halfway between every pair of visits. Both histories agree perfectly with every observed classification, yet their elapsed-time occupancy differs substantially. No interpolation rule, regardless of elegance, can distinguish them from the retained data alone. An imposed prior model might favour one history, and an independent sensor could supply additional evidence, but the original sequence of threshold decisions does not contain the required distinction.

This fact is not peculiar to the use of a binary occupancy detector. A spectrum analyser can accurately integrate the power present during its dwell; a wideband SDR can faithfully record a bounded segment of complex samples. Neither apparatus knows what occurred outside its observed frequency-time aperture. The width of that aperture is determined by actual front-end passband, filter state, sample retention, scanning policy and valid timing. The fact that a receiver's user interface displays a broad frequency axis does not imply continuous simultaneous observation across every pixel. Some displays are assembled by successive sweeps, and an intermittent emission can enter and leave between those sweeps without leaving a trace.

A stronger continuous-acquisition apparatus changes the information problem. If it stores all raw samples of the admitted band with adequate dynamic range and no dropped intervals, it can support later analysis of

Copyright 2026, James M. Atkinson

events the original detector overlooked. Analysts may recompute thresholds, revisit a shorter transient, change window functions or ask whether a feature survived a preselector change. This retrospective ability depends on the retained raw information. If the apparatus stored only summary power values for a few scheduled snapshots, a later algorithm cannot reconstruct arbitrary unknown waveforms in the unrecorded intervals. One can estimate what might have occurred under a model. One cannot identify one unique historical signal from data that are equally compatible with many alternatives.

We should also resist the converse assumption that merely retaining all complex samples establishes all possible facts. An analogue front end may have rejected the relevant frequency, clipped the input or mixed a strong adjacent signal into an artefact. Compression or quantisation may have removed significant detail. The sample clock and calibration state may be uncertain. Retention of digital samples is therefore necessary for some forms of retrospective analysis, but not sufficient for a claim that the physical input has been reconstructed uniquely. The information-bearing path begins at the antenna and ends in an evidential claim; each transformation may be many-to-one or conditional upon calibration.

Consider the question of occupancy as a statistical quantity. Random sampling may make a set of valid visits informative about the long-run fraction of time in a state. The strength of that inference depends on the stationarity assumptions, the sampling schedule and the correlation among observations. Such inference does not reconstruct a continuous historical tape. Even when the estimator is unbiased in repeated hypothetical experiments, its value in a single survey may differ from the realised

Copyright 2026, James M. Atkinson

occupancy because the unknown emissions were clustered or deliberately synchronised with the scanning schedule. A statement of confidence is meaningful only under the model and the reference population for which coverage has been justified.

Finally, the evidential report should preserve uncertainty in a form that resists over-interpretation. Distinguish the valid observation windows from the gaps, the classifications from underlying physical truth, and the modelled estimates from measurements. If a detection threshold changed, its history should accompany the record. If an alarm triggered the saving of higher-resolution data, that selection rule should also be retained. One may construct an honest and useful analysis of such conditional records, but the missing intervals must remain visible to the reader's reasoning even if the display paints them with seamless colour. Information theory offers no exemption from the physical obligation to observe. I invite Professor Wiener to consider the additional difficulty that the measuring apparatus and its operator may change their behaviour because of what the measurements show.

David Harold Blackwell | Peer question 3 to Claude Elwood Shannon

Dr Shannon, your account makes the loss of unacquired information plain, but I should like to examine a subtle inferential distinction. If a survey randomly selects a modest number of observation windows, its record remains wholly silent about the precise contents of individual gaps, yet it may support a useful estimate of average occupation. We should not confuse the impossibility of recovering the realised history with an impossibility of inferring a population parameter. Suppose, however, that some emissions are so brief that the stated detector can

Copyright 2026, James M. Atkinson

register them only when their arrival coincides with a favourable portion of a dwell. May a probability model repair the difference between observations and physical activity, or does the uncertainty in detection probability make the proposed correction more a choice of prior belief than an estimate? In particular, how should a reader distinguish uncertainty arising from random selection of observation windows from uncertainty arising because the instrument is not sensitive to the relevant class of signals?

Claude Elwood Shannon | Immediate answer to David Harold Blackwell

Professor Blackwell, you have identified the distinction on which a responsible occupancy report must turn. A statistical estimate can be informative without reconstructing every occurrence, provided that its target quantity, selection mechanism and observation likelihood have been declared in advance. There is no contradiction between saying that a particular unobserved interval is unknowable from these records and saying that randomly selected intervals can reveal something about a population proportion. The former concerns reconstruction of a realised path; the latter concerns an inference whose operating characteristics must be evaluated across repeated hypothetical samples.

Let the occupancy state be S and the detector decision be D. The probability that D is positive is determined jointly by the occupancy probability and by the detector's conditional responses. A method that translates positive-decision frequency into latent occupancy must distinguish false positives from missed occupancies. If the probability

Copyright 2026, James M. Atkinson

of detection changes with signal duration, amplitude, modulation or interference, a single fixed correction parameter may not describe the heterogeneous target population. To report one adjusted percentage without disclosing that heterogeneity would conceal uncertainty behind a precise decimal.

An honest design can stratify the target class by minimum pulse duration, received power range, and permissible frequency deviation. For each class, laboratory challenges may establish a detection-performance envelope under stated operating conditions. A random observation scheme can then support a conditional estimate for classes within that envelope. The report should not extend the estimate to arbitrary unknown devices whose performance characteristics lie outside the validation range. Nor should it silently replace an absence of empirical detector characterisation with a strong subjective assumption that all relevant emitters would have been seen.

Where only partial detection calibration is available, an interval or sensitivity analysis can be more defensible than a single corrected number. State how the estimated occupancy changes when the probability of detection varies across a plausible range, preserving the possibility that the range is not exhaustive. The reader can then hear the difference between the instrument's measured decisions, the statistical model's inference, and the engineer's judgement about unmodelled classes. None need be disparaged; they are separate layers of evidence, and confidence in one cannot automatically be transferred to the others.

Copyright 2026, James M. Atkinson

Harry Nyquist | Peer question 4 to Claude Elwood Shannon

Dr Shannon, I would press the distinction between sampling an analogue waveform and sampling a binary occupancy state. In one case bandwidth restrictions and a reconstruction theorem may justify the recovery of a bandlimited signal from a properly spaced series of samples. In the other, the object may be a sequence of abrupt switching events, with pulses shorter than an observation window and with no warranted bandlimit on the occupied-state indicator. Practitioners sometimes invoke a sufficiently high sample rate as though this could guarantee that all transmissions have been captured, while overlooking that a scanning tuner never admitted the relevant frequency during substantial intervals. How should the report separate converter sample rate, receiver bandwidth, dwell scheduling and the detector's temporal response, and where exactly does the familiar sampling argument cease to apply to an unobserved transient? Would your interpretation change if the scanner issued a precise hardware timestamp for every valid dwell but kept only the final binary decision? I ask because the time tags may be excellent while the discarded waveform remains unrecoverable, and such a distinction is often neglected in reports.

Claude Elwood Shannon | Immediate answer to Harry Nyquist

Dr Nyquist, the four quantities should be separately recorded because they answer different physical questions. The analogue-to-digital converter sample rate constrains the representation of signals admitted through a suitably conditioned analogue path. The instantaneous receiver bandwidth specifies which spectral region can reach that converter with the stipulated response. The dwell schedule

Copyright 2026, James M. Atkinson

specifies when that region was being observed. The detector's integration, resolution and threshold then determine which events in the acquired samples will yield a positive decision. An impressive converter rate does not recover an emitter outside the admitted band, nor can a later transform restore a burst that occurred while the tuner was elsewhere.

A bandlimited continuous waveform may be represented through samples under the theorem's assumptions. A binary indicator formed by thresholding unknown transmissions need not satisfy the same bandlimit, and its abrupt transitions can occupy arbitrarily short intervals. Even for a physically bandlimited radio waveform, reconstruction requires samples actually acquired over the relevant interval; a receiver's periodic absence is not equivalent to an uninterrupted stream at the stated converter rate. One cannot treat successive ten-millisecond snapshots spaced one second apart as continuous acquisition at a rate of millions of samples per second simply because the converter ran rapidly during each snapshot.

The temporal aperture of the detector is also material. A pulse may partly overlap a dwell but fail to satisfy a detector whose averaging window is longer than the pulse; a sufficiently powerful pulse may, conversely, dominate a peak detector despite occupying only a small fraction of its window. Such behaviour requires empirical or analytical characterisation. In a report I would separate four entries: sample clock and effective sample rate; admitted RF or IF passband; exact valid observation intervals; and detector rule including its effective temporal response. If an event was found in retained samples by a

Copyright 2026, James M. Atkinson

later detector, record which algorithm found it and which earlier algorithm missed it.

Accordingly, there is no universal sampling-rate certificate for surveillance completeness. A defensible statement is more modest and more valuable: the receiver continuously retained complex samples within a verified band and time interval, or alternatively observed specified channels only during enumerated dwell windows. Those descriptions allow a later examiner to determine the search's physical exposure. I now pass the token to Professor Wiener, who will consider the special danger of a survey whose next observation depends on what its preceding observation appeared to show.

Copyright 2026, James M. Atkinson

Norbert Wiener. Principal response 4. A monitoring policy is part of the system it observes

Dr. Atkinson, we must examine an occupancy-monitoring system as a coupled process rather than as a passive clockwork observer. Its receiver may change gain, tune to a newly discovered channel, lengthen dwell after an alarm, shorten dwell when a frequency appears quiet, or suppress storage when the noise floor rises. These mechanisms can be sensible engineering adaptations. But they alter the probability that subsequent events will be measured and the meaning of any percentage calculated from those measurements. The apparatus ceases to execute a fixed calendar of exposure; it follows a policy conditioned upon its own evolving record. A careless report then presents a statistic from the resulting adaptive dataset as though the observation opportunities had been selected independently of the very emissions being counted.

Let a measurement action at step k be A_k, the recorded detector output be D_k, and the stored history before the step be H_k. A fixed sampling policy chooses A_k without depending upon the newly encountered channel state, while an adaptive policy chooses A_k according to some rule pi(A_k given H_k). That rule may increase the observation of channels in which positive signals have already been found. The resulting observations are not wrong. They are conditional on the policy. If the investigator asks how often a suspicious emission appeared during deliberately concentrated examination of its frequency, the dataset may be entirely suitable. If the investigator claims to estimate natural occupancy across the whole surveyed band, weighting and support questions arise immediately.

Copyright 2026, James M. Atkinson

Consider a receiver that monitors one hundred channels with brief visits until one becomes active, then camps upon that channel for twenty minutes. A large share of its retained data will concern channels selected for their prior activity. The observed proportion of positive windows across all stored records will consequently overrepresent the busy channel relative to an evenly distributed channel-time population. Multiplying by the number of channels cannot correct this without knowledge of the exposure allocated to each channel and the precise selection history. The selection rule and its time-varying parameters are part of the evidence, not private conveniences that may be omitted from the annex.

An active operator adds another feedback path. Upon seeing a burst on the waterfall, the operator may move the antenna, alter attenuation or activate a second receiver. These interventions may change the signal seen at the detector even if the distant source behaves identically. The analyst must therefore preserve the sequence of human decisions and instrument state changes. There is little scientific worth in claiming that a transmitter became evasive immediately after an alarm if the operator had also moved the antenna into a null or modified a preselector. Intervention history is essential for causal interpretation.

A possible emitter can itself react to observation. Some transmitters may be time scheduled, some may operate only after a sensor is triggered, and a hypothetical adaptive device could change behaviour in response to a local environment. Such possibilities make uniform surveillance difficult, but they should not become an untestable explanation for every negative finding. The examiner needs an explicit set of alternative mechanisms, each with different observable consequences. If one mechanism predicts a change in

Copyright 2026, James M. Atkinson

operation during a known power event and another predicts ordinary interference that remains independent of the event, a properly controlled experiment may separate them. Until such discrimination occurs, deliberate adaptation remains a hypothesis rather than a factual attribution.

The vocabulary of control theory helps clarify the task. An estimator is built on a model of state dynamics and observations; a controller then chooses actions using the estimator's output. If the observer is also a controller, subsequent observations depend on earlier decisions. The resulting closed loop may be useful for finding rare events. Yet a record from a closed-loop policy is not necessarily exchangeable with measurements made under a random or stationary schedule. The report must identify the policy, its objective, the moments of policy revision and the intervals of lost coverage elsewhere. Without that history one cannot recreate why a blank region of a display was blank.

For forensic purposes I recommend a dual record. Preserve an immutable stream of receiver state, time tags, frequency intervals, valid sample counts and decision thresholds. Preserve alongside it a decision log indicating why a retune, capture trigger or attenuation change occurred. Both records should be synchronised to a documented clock and accompanied by calibration and chain-of-custody information. Where practical, maintain a separate, less adaptive surveillance channel as an independent measure of background behaviour. Independence must be tested rather than assumed; shared antennas, oscillators, power supplies and software may create common modes of error.

Finally, an adaptive search may report both discovery performance and the conditional exposure achieved after a lead. Those are useful operational

Copyright 2026, James M. Atkinson

achievements. What it must not do is silently convert the amount of attention paid to one apparent signal into an estimate of how often it existed before the attention began. I invite Dr von Neumann to challenge the model of a decision policy and then Dr Deming to examine how a continuously changing procedure should be governed and documented.

John von Neumann | Peer question 5 to Norbert Wiener

Professor Wiener, your policy description appears to require that the engineer can compute or even reconstruct the probability of each measurement action. In a practical surveillance operation the operator may make unplanned decisions after listening to a signal, examining a spectrogram, or responding to a physical event at the site. The observation process may therefore be partly deterministic, partly algorithmic and partly discretionary, with no convenient numerical selection probability. Is the correct response to abandon quantitative inference about overall occupancy, or may the survey still publish measurements from its adaptive phase if it carefully separates direct observations from probability-based estimates? What, in your view, constitutes the minimum sufficient policy record when the human observer's judgement cannot be reduced to an executable programme? If the selection record is incomplete for a single operator decision, should all subsequent observations be excluded from the estimate, or can the team give a bounded analysis based on a documented subset? Please distinguish a defective probability model from an authentic physical measurement.

Copyright 2026, James M. Atkinson

Norbert Wiener | Immediate answer to John von Neumann

Dr von Neumann, I would not make the perfect reconstruction of a numerical policy a condition for recording or reporting useful measurements. One may truthfully describe a finite set of observations without having a defensible probability model for the intervals that were not observed. If the receiver followed an operator's choice to monitor a channel of interest for twenty minutes, the analyst may report exactly what occurred during that exposure. The limitation concerns a larger inference to the channels and times which received no comparable attention.

For an adaptive episode, retain the ordered record of time, tuned band, receiver configuration, observed outputs, operator action and stated reason for the action. An operator note need not assert a mathematically precise probability. It should state whether the new dwell was triggered by an alarm, an audible feature, an external report, a suspected interference event, or an independent sampling requirement. Where the reason remains unknown, mark it unknown rather than manufacturing a retrospective account. The record should distinguish an algorithm's scheduled step from an intervention made by a person at the console.

If overall occupancy remains an intended estimand, supplement the adaptive search with a separately designed observational phase. A predeclared random or stratified schedule may provide the sampling foundation; the adaptive phase may identify and characterise candidate emissions in greater detail. The two datasets can be analysed together for some physically defined questions, but their

Copyright 2026, James M. Atkinson

different selection mechanisms must remain visible. An estimator requiring positive probability of selection across the target population is not justified where entire categories of time or channel could never have been visited by the operative policy.

The discipline is the same as in the analysis of any feedback instrument. A control action changes which subsequent states become observable. Preserving that action gives another investigator a fighting chance of understanding selection bias and reproducing the investigation's logic. A measurement retained under a nonrandom policy is not counterfeit. It is evidence for a claim whose scope must be chosen accordingly. I pass the token to Dr Deming for the related problem of procedural stability during an extended survey. The record should also distinguish an observation that is valid as a direct measurement from an observation that fails the requirements of a particular population estimator; those are not necessarily identical judgements.

W. Edwards Deming | Peer question 6 to Norbert Wiener

Professor Wiener, let us suppose that the receivers are operated over several nights by different teams, each of which regards a change of gain, averaging depth or alarm threshold as a minor housekeeping adjustment. The organisation records the resulting occupancy percentages but does not preserve a unified history of its methods. A later reviewer finds that the highest apparent activity coincides with a change of staff and a software update. Is it legitimate to treat the event as a technical anomaly requiring investigation, or must the whole series be disqualified for lack of a common measurement system? More

Copyright 2026, James M. Atkinson

generally, how would you reconcile a practical programme of continual engineering improvement with the evidential need to preserve a stable definition of what constitutes a positive observation? Would you recommend a fixed reference signal that is observed before and after each procedural adjustment, and should the analysis treat a change in its measured response as an uncertainty component rather than as proof that the external emission changed? This affects the laboratory's claim of comparability.

Norbert Wiener | Immediate answer to W. Edwards Deming

Dr Deming, the change of staff and software makes the series an excellent candidate for investigation, but not an automatic demonstration of a changed emitter. A change in the recording procedure can be a plausible cause of a changed measurement outcome. The two mechanisms should be examined separately. The organisation must not simply discard every observation following a procedural change, because the records may still contain valid evidence. Equally, it cannot combine unlike measurement regimes as though a common numerical threshold conferred common sensitivity.

A mature monitoring programme should treat a change of receiver firmware, thresholding algorithm, antenna coupling or operator protocol as a versioned state transition. The time of the change, the affected instruments, the configuration before and after, and any reference measurements should be preserved. When possible, a period of parallel operation provides an empirical bridge between procedures. If the measurement response changes, the report can

Copyright 2026, James M. Atkinson

stratify or recalibrate the series rather than pretend that the whole history belongs to one unchanging process.

Continual improvement and evidential stability are not enemies. Improvement becomes problematic only when the record fails to show which measurement policy produced each result. The laboratory may refine its procedure for detecting weak emissions while preserving the older procedure's results as historical observations. It should then identify the resulting series as distinct measurement regimes and avoid applying new thresholds retrospectively to discarded raw data. If complex samples were retained, a clearly identified reprocessing run may be possible, with versioned software and an output provenance trail.

The apparently elevated occupancy after a staff change is an observation about the instrumented process. Attribution to an external transmitter requires a further experiment capable of excluding procedural differences. It is perfectly legitimate to say that the dataset reveals a discontinuity of measured indications and that its physical cause remains unresolved. Such candour is more persuasive than a prematurely uniform curve. I return the floor to Professor Neyman for the separate question of how a confidence statement should be constructed when the record contains both scheduled gaps and uncertain detection characteristics. A small set of stable reference observations often provides the most economical evidence that two measurement regimes can, or cannot, be combined without recalibration.

Copyright 2026, James M. Atkinson

Jerzy Neyman. Principal response 5. Coverage claims must name the ensemble and the failure they protect against

Dr. Atkinson, a confidence interval acquires its meaning from a specified data-generating procedure. A familiar figure of ninety-five per cent should not be interpreted as a personal degree of certainty that no relevant emitter exists in a room. Under an appropriate repeated-sampling interpretation, a procedure may cover its fixed target quantity in a stated proportion of repetitions satisfying the model. If the actual experiment contains systematic sampling at an unfortunate phase, detector saturation, retrospective threshold changes or undocumented invalid intervals, the quoted coverage cannot be imported from a textbook calculation whose premises are different. Precision in notation is a protection against unwarranted assurance.

Let the intended population be a finite monitoring period T for a specified frequency band and a defined occupied-state criterion. If the estimand is the fraction of that period for which the criterion was physically satisfied, the observation plan must afford each relevant interval a documented opportunity of measurement or a properly modelled basis for inference. An investigator may instead define the estimand as the probability of a positive detector decision during a randomly chosen valid dwell. That is a legitimate but different quantity. A report may give both, provided the physical inference is accompanied by the detector model and the uncertainty added by that model.

A binomial interval around a fraction of positives presupposes more than correct arithmetic. It depends upon the observations being sampled under the procedure for which the interval was derived; simple formulas

Copyright 2026, James M. Atkinson

frequently assume independent, identically distributed binary trials. Long transmissions, correlated interference and scanning cycles violate the naïve independence assumption. The point count may be large, but the number of materially independent episodes may be small. One may employ cluster-based methods, block resampling under a justified dependence model or a physically informed stochastic process, yet the analyst must state why that model fits the sequence. Merely choosing a more sophisticated formula does not eliminate the need for validation.

The negative survey demands particular care. Suppose no occupied dwell was recorded. If detection would be certain for any transmission lasting one second at the specified power and channel location, and if randomised observation windows genuinely cover the intended population, the absence of detections may support a bounded statement about how frequently such events could occur. It cannot exclude a different device with briefer bursts, lower power, a different emission frequency or a deliberate schedule coinciding with unobserved intervals. The most important sentence in a negative report often begins with the words, 'For emissions within the tested detection envelope'.

One may formalise a rare-event limit. Assume that relevant emissions arise according to a homogeneous Poisson process of rate lambda per hour and that each event is independently detected with probability r during an actual exposure of T hours. Then detections follow a Poisson law with mean lambda r T, and the probability of zero detections is exp(-lambda r T). Solving exp(-lambda_upper r T) = alpha yields lambda_upper = -ln(alpha)/(r T). With alpha = 0.05, r = 0.8 and T = 4 hours, the calculated one-sided upper value is approximately 0.936 events per hour. The result is conditional on

Copyright 2026, James M. Atkinson

independence, a constant rate, known effective detection probability and valid exposure. If the four hours consist mostly of gaps during which events were impossible to detect, using wall-clock T in place of valid exposure inflates the evidence. If emissions are adversarially timed, the Poisson model may be wholly unsuitable.

Multiplicity introduces a further challenge. An investigator who examines one channel at a preselected time asks a different statistical question from one who scans thousands of channels and reports whichever yields the most dramatic hourly occupancy. The selected maximum is not a simple unbiased estimate of ordinary channel occupancy. A confirmatory claim should distinguish tests chosen beforehand from patterns discovered after viewing the measurements. This distinction does not diminish the worth of discovery. It prevents the selection process from being hidden behind a confidence label.

I should like the final report to include an explicit decision table even when no table is printed. What is being tested, against what alternative, with which sampling mechanism, under which detector sensitivity, and with what evidence would the analyst revise the conclusion? The burden of a negative assertion should be proportionate to the potential consequences of overlooking a rare emission. A court, laboratory or technical client can then distinguish the absence of observed evidence from a claim that the absence of activity itself has been established.

Where the method cannot support a frequency estimate, there is no disgrace in reporting observed visit counts and carefully delimited exposure. Where the method can support an estimate, the uncertainty should be computed from the actual design rather than from a convenient fiction of

Copyright 2026, James M. Atkinson

independent snapshots. These are principles of inference, not counsel for evasiveness. I shall accept a challenging question from Dr Tukey before returning the token to our moderator, because it is precisely the practical business of reporting to imperfect readers that makes these distinctions difficult to preserve.

John Wilder Tukey | Peer question 7 to Jerzy Neyman

Professor Neyman, confidence procedures are often presented as figures of admirable rigour, but a forensic reader may be confronted with a dozen incompatible quantities: positive-visit fraction, dwell-weighted occupancy, duration of active episodes, hourly peak, inferred latent occupancy and upper event-rate bound. The pages on which these appear may contain intervals with different inferential meanings, which can be misconstrued as rival estimates of one underlying property. How would you organise the report so that numerical detail assists rather than overwhelms the judicial or technical reader? In particular, should the investigator privilege a single headline percentage, or is it more important to preserve the measurement ledger, the uncertainty model and clearly bounded negative findings even when the resulting summary appears less tidy? I would particularly welcome guidance on whether the report should display a separate line for receiver exposure, so that the absence of measurements is never misread as evidence of silence. Would this be useful even when the reader wants only a short executive conclusion?

Jerzy Neyman | Immediate answer to John Wilder Tukey

Dr Tukey, I would resist the demand that all the information fit into one statistic. A single headline percentage can be effective when it is

Copyright 2026, James M. Atkinson

unambiguously tied to an estimand; it becomes misleading when a reader assumes that it also describes unmeasured episodes, event counts and transmitter identity. The report should open with the purpose of the survey and the unit of observation, followed by the actual amount and distribution of valid exposure. Only then should it present primary descriptive counts, the inferential target and an interval calculated under a stated procedure. The reader must be able to identify which figures are measurements and which depend on modelling assumptions.

For a large dataset, graphical summaries are valuable if the raw time and channel axes are preserved and missing intervals remain visibly marked. A confidence interval for the positive-decision probability should be labelled as such. A detector-corrected occupancy estimate should show the detection and false-alarm parameters on which it depends, together with a sensitivity analysis if those parameters are uncertain. An event-rate upper bound should state its event definition and assumptions, particularly any independence or Poisson conditions. Different quantities should not be placed in one unlabeled column under the title 'occupancy'.

I would provide a compact primary finding in plain language, followed by an auditable evidence annex. For example: 'The receiver obtained ninety valid observations of the specified channel out of one hundred scheduled visits. Thirty valid observations crossed the declared threshold. Ten visits were invalid, and the instrument did not observe the intervals between visits. The fraction of positive valid visits was one third. No estimate of uninterrupted elapsed-time

Copyright 2026, James M. Atkinson

occupancy is made from this record alone.' That passage is more informative than the striking but unqualified phrase 'the channel was occupied thirty per cent of the time'.

For negative findings, distinguish a statement about the tested detection envelope from one about all conceivable emissions. If a zero-count upper bound is reported, its model must accompany it. If the assumptions are plainly unsafe, report the zero detections without an unjustified probability of exclusion. The reader should see exactly what further recording, randomisation or receiver challenge would improve the claim. Finally, retain the complete data and code used in the calculation so that another competent examiner can reproduce the report and, if appropriate, challenge its premises. I pass the token to Dr. Atkinson for the synthesis and the accounting of the ten engineering examples.

Sir Ronald Aylmer Fisher, Cross-Peer Question to Walter Andrew Shewhart: Dr Shewhart, a scanning receiver visits a channel in regular short dwells and observes occupancy in thirty percent of them. How should a report treat possible periodic structure in both transmitter activity and visit schedule?

Walter Andrew Shewhart, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Professor Fisher, the sampling design must be recognised as part of the observed system. If the receiver revisits at a period commensurate with a transmitter duty cycle, it may consistently sample one phase and misrepresent total-time occupancy. Record dwell starts, elapsed valid exposure, tuning dead time, gain state and detector threshold. Shift the scan phase deliberately, vary the cadence or run an independently continuous monitor on the same channel to challenge phase locking. Report

Copyright 2026, James M. Atkinson

observed-dwell occupancy separately from inferred wall-time occupancy and place uncertainty on the inference. A stable percentage is not proof that the sampling was representative. I pass the token to Dr Shannon regarding intervals that were never observed.

Walter Andrew Shewhart, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, can a receiver reconstruct the activity of an emitter during the ninety percent of time when its scanner was tuned elsewhere by smoothing the detected occupancy series?

Claude Elwood Shannon, Cross-Peer Answer to Walter Andrew Shewhart: Dr Shewhart, it cannot uniquely reconstruct unobserved physical history. Interpolation may furnish a conditional prediction under a stated source-process model, but many distinct transmission schedules produce the same observed dwells. Preserve the exposure calendar and declare intervals of no measurement, rather than plotting them as inferred zeros. If a statistical model is used, justify its periodicity or stationarity assumptions against independent continuous captures. In forensic work, one should distinguish a negative indication during a valid dwell, a failed detector decision and an interval without acquisition. A visually continuous occupancy graph is a derivative, not evidence of continuous observation. I yield to Professor Wiener on possible receiver-induced behaviour.

Claude Elwood Shannon, Cross-Peer Question to Norbert Wiener: Professor Wiener, how might an adaptive scanner change the occupancy pattern it later reports?

Norbert Wiener, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, its policy can select what it observes based on previous measurements,

Copyright 2026, James M. Atkinson

thereby changing the exposure distribution. A scanner that dwells longer on active channels will overrepresent them in a visit-weighted fraction unless time weighting and the policy are correctly included. Retuning and gain switching may create dead time or transients counted differently from steady-state intervals. Record every state transition and the algorithm that chooses subsequent frequencies; evaluate the same controlled transmissions with both adaptive and fixed schedules. For comparison across sites, standardise the denominator or explicitly model the varying exposure. The result is a measurement of occupancy under a particular observation policy, not an unconditional property of the environment. I pass the token to Dr Neyman on reporting coverage.

Norbert Wiener, Cross-Peer Question to Jerzy Neyman: Dr Neyman, when a report states that an emitter was absent from an entire building because no activity appeared during intermittent scanning, what evidential qualification is necessary?

Jerzy Neyman, Cross-Peer Answer to Norbert Wiener: Professor Wiener, the conclusion must be restricted to the tested locations, frequencies, time intervals, receiver sensitivity and observation policy. A zero count in finite exposure does not establish zero probability of activity. Estimate upper detection-frequency bounds under a clearly specified model and include missed-detection and false-alarm rates of the receiver. Blind challenge trials should cover the shortest relevant bursts and the worst scanner phases. If the emission responds to human presence or monitoring activity, simple stationarity assumptions may fail. State the exposure denominator transparently and do not treat unobserved time as a negative test result. I return the token respectfully to Dr Atkinson.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson. Closing synthesis of Question 049

Colleagues, the discussion resolves the tempting but perilous confusion between a decision made in a measured instant and a verdict upon an unmeasured interval. An occupancy percentage is not self-explanatory. Its credibility rests upon a named estimand, a defined population, a documented schedule of exposure, a reproducible decision rule and an uncertainty method appropriate to the observations actually retained. If a scanning receiver visits a channel for ten milliseconds every second, the display may faithfully reveal the presence or absence of a qualifying signal during those visits. It cannot, by that fidelity alone, certify what the channel did during the intervening nine hundred and ninety milliseconds.

Professor Fisher has insisted that we identify the statistical population before computing the percentage and that we distinguish discovery-directed measurements from independent validation. Dr Shewhart has demonstrated the danger of pooling observations across changing physical and instrumental regimes. Dr Shannon has drawn a clear boundary between reconstruction and statistical inference, explaining why later processing cannot restore the particular data never acquired. Professor Wiener has shown how adaptation by an operator or monitoring policy alters subsequent selection, and Professor Neyman has specified the conditions under which confidence and negative-event bounds possess their advertised coverage. The peer challenges have properly exposed the tensions among these positions without pretending that one mathematical device resolves all of them.

A scientific field report ought therefore to specify five separate classes of quantity. First, it should record the clock and calendar span of the survey.

Copyright 2026, James M. Atkinson

Secondly, it should record actual valid measurement exposure, including which frequencies, receiver states and sensitivities were in force. Thirdly, it should preserve the positive and negative decisions produced by a declared detector and the treatment of invalid observations. Fourthly, it may present population estimates where the acquisition design and calibration justify inference beyond the measured windows. Fifthly, it should distinguish any operational conclusion about a probable physical emitter, which cannot be reduced to an occupancy statistic without additional corroboration. These classes may be related, but none is a synonym for another.

An important distinction remains between the power of a method to detect a recurring class of signal and its power to exclude one particular unknown device. An investigator might have excellent sensitivity to a continuous signal at one frequency and little exposure to short bursts elsewhere. A negative result cannot be detached from that envelope. Similarly, a positive result in a sampled channel does not identify the transmitting apparatus merely because the statistical calculation around its frequency of occurrence is narrow. Frequency occupancy, waveform similarity, bearings, antenna response, source attribution and chain of custody require their own validation.

The numbers in the applications below are deliberately simple enough for independent recalculation, for such modest arithmetic reveals the larger epistemic danger. The difference between ten seconds of valid exposure and thirty seconds of wall time may be a simple ratio; the decision to treat those denominators as interchangeable is a substantive evidential error. A confident interval derived from one hundred correlated observations may be too narrow by several times. A zero-count bound can sound reassuring

Copyright 2026, James M. Atkinson

while depending upon a Poisson arrival model which the suspected emitter has no obligation to obey.

The duty of the moderator is not to remove every uncertainty from a laboratory record, which would be impossible, but to ensure that uncertainty is located where the measurement process actually creates it. The field investigator must speak plainly enough for a court, engineering peer or client to understand, and precisely enough for another examiner to repeat the calculation. Let the final report say what was measured, what was estimated, what remains unobserved and which assumptions would need to hold before a larger claim could be justified. I thank the panel for a rigorous and respectful exchange. Our next question concerns the waterfall display itself: whether the colourful impression of continuous spectral history should be mistaken for the samples from which that impression was computed.

Copyright 2026, James M. Atkinson

Ten worked engineering applications | Question 049

Application 1. Valid exposure versus elapsed survey time. Let d denote the valid dwell duration per visit, R the revisit period and H the elapsed survey duration. Suppose d = 0.010 s, R = 1 s and H = 3600 s. The nominal number of visits is N = H/R = 3600. Valid exposure is E = N d = 36 s, and the temporal coverage fraction is E/H = 36/3600 = 0.010, or 1.0%. The remaining 99.0% was not observed at this channel by this scanner. The calculation assumes every dwell is valid and a complete regular schedule; dropped visits reduce exposure further. The converter's high within-dwell sample rate does not change this coverage ratio.

Application 2. Observed fraction and a Wilson interval. Let x = 30 positive decisions among n = 100 valid, independently and identically sampled visits. The observed fraction is qhat = x/n = 0.30. For an illustrative 95% Wilson score interval let z = 1.96, a = 1 + z^2/n = 1.038416, centre c = (qhat + z^2/(2n))/a, and half-width h = z sqrt(qhat(1-qhat)/n + z^2/(4n^2))/a. Evaluation gives c approximately 0.3074 and h approximately 0.08845, for an interval approximately [0.219, 0.396]. This estimates a decision probability under the independent-sampling model, not the physical time occupancy of an intermittently visited channel.

Application 3. Detector-error correction. Let p be latent time occupancy at a representative sampled instant, P_D = 0.90 the probability of a positive decision when occupied, and P_FA = 0.02 the probability of a positive decision when clear. With q = 0.30 the observed positive probability, q = p P_D + (1-p)P_FA. Rearranging, p = (q-P_FA)/(P_D-P_FA) = (0.30-0.02)/(0.90-0.02) = 0.31818. This correction is meaningful only if the

Copyright 2026, James M. Atkinson

same sensitivity and false-alarm model describe the relevant signal class and conditions. Uncertainty in P_D and P_FA has not yet been propagated.

Application 4. Correlated visits and effective sample count. Suppose n = 100 equally spaced classification opportunities are approximated by a stationary correlation model with lag-k autocorrelation rho^k and rho = 0.80. An illustrative large-sample effective size is n_eff approximately n(1-rho)/(1+rho) = 100(0.20)/(1.80) = 11.11. This is not an exact finite-sample confidence procedure, but it shows why treating all one hundred observations as independent can exaggerate precision. The empirical autocorrelation, regime stability and finite-sample method must be assessed before an interval is published.

Application 5. Random-phase capture of one brief burst. Let a scanner observe a channel for d = 0.010 s once per cycle R = 1.000 s. Let a burst of duration b = 0.100 s have a start phase uniformly distributed over one cycle; assume ideal recognition whenever its interval overlaps the dwell. Where b+d is less than R, the probability of any overlap is (b+d)/R = 0.110. If twenty independent bursts have independently uniform phases, the probability of observing at least one is 1-(1-0.110)^20 = approximately 0.903. Correlated phases or lower detector sensitivity invalidate this simplified probability.

Application 6. Stratified occupation over unequal times. Suppose two daytime hours have physical occupancy p_day = 0.80 and twenty-two night-time hours have p_night = 0.10. The time-weighted 24-hour occupancy is p = (2(0.80)+22(0.10))/24 = 3.8/24 = 0.15833, or 15.83%. A survey taking equal numbers of samples by day and night would instead

Copyright 2026, James M. Atkinson

produce an unweighted mean of 45%, if its within-stratum sample rates are representative. Equal observations per stratum are not equal time weighting; the chosen estimand determines the correct combination.

Application 7. Invalid measurements and a denominator change. One hundred visits were scheduled; thirty produced positive decisions, sixty valid negative decisions and ten invalid acquisitions. The positive fraction among valid visits is 30/(30+60) = 1/3 = 33.33%. Counting all scheduled visits as though invalid observations were negative yields 30/100 = 30%, a different quantity. Neither value measures activity during gaps between visits. If invalidity is correlated with overloading during strong emissions, the valid-only fraction may itself be a biased sample of all scheduled opportunities.

Application 8. A conditional zero-event upper bound. Suppose an event class follows a homogeneous Poisson arrival process with unknown rate lambda events per hour, and each event has independent probability r = 0.80 of being recognised within T = 4 h of genuine effective coverage. If no events are seen, P(0) = exp(-lambda r T). For a one-sided 95% upper confidence bound, set P(0) = 0.05, so lambda_upper = -ln(0.05)/(0.80 x 4) = 2.995732/3.2 = 0.93617 events/h. This model-based bound cannot exclude intentionally scheduled bursts or apply to intervals that had no effective observation.

Application 9. Periodic phase-lock blindness. Let the scanner visit from t = k seconds to t = k+0.010 seconds for each integer k. Let the emitter operate from t = k+0.400 to t = k+0.450 seconds. The actual physical duty cycle is b/R = 0.050/1.000 = 5%, yet every one of the scanner's scheduled dwell windows is clear. The observed positive-visit

Copyright 2026, James M. Atkinson

fraction is zero in any number of exact repetitions. The discrepancy is systematic phase selection, not random sampling error, and a narrower confidence interval around zero would not cure it.

Application 10. Three-channel sequential scanning. Let a receiver dwell d = 0.100 s on each of C = 3 channels and require g = 0.002 s retuning overhead for each scheduled channel visit. One cycle takes R = C(d+g) = 3(0.102) = 0.306 s. One channel receives d/R = 0.100/0.306 = 0.3268, or 32.68%, nominal temporal coverage before invalid acquisitions. The figure assumes identical dwell and overhead for all channels. If the controller camps on a detected signal, the realised denominator must be recomputed from the actual receiver-state log, not this original schedule.

QUESTION 050

Copyright 2026, James M. Atkinson

When are waterfall displays misleading representations of retained samples?

Source: V011_Roundtable_Questions_049-050_CP050_Combined.docx | Recovered substantive manuscript. Constructed educational dialogue.

Moderator: Dr. James M. Atkinson

Editorial convention: Original, newly constructed pedagogical dialogue. The deceased scholars named below did not participate in these exchanges. No sentence is presented as a historical quotation. The technical scenarios and numerical examples are hypothetical and require configuration-specific verification before application to a real receiver.

Dr. James M. Atkinson. Opening of Question 050

Distinguished colleagues, a waterfall display possesses a compelling visual eloquence. A thin illuminated thread descends across a dark field, a brief vertical flare appears against a quieter background, and a broad band acquires colours which seem to announce the presence of a moving transmitter. The operator may watch that picture for hours while the computer continues to collect, discard, average, compress or transform information without visibly advertising which of those operations it is performing. It is therefore entirely possible to obtain a waterfall that is beautiful, repeatable and operationally useful, yet materially misleading if it is presented as a complete record of the analogue signal or even as a complete rendering of the retained digital samples.

A spectrogram may be produced by computing a short-time Fourier transform of complex baseband samples. The calculation selects a window of N samples, multiplies them by a chosen window function, forms a

Copyright 2026, James M. Atkinson

discrete Fourier transform, and assigns each time-frequency cell a complex value or power estimate. The displayed waterfall generally preserves neither the full complex sample sequence nor the complete set of intermediate transform values. It paints selected numerical summaries onto a finite grid of pixels using a colour map, an amplitude scale, a display refresh rate and sometimes averaging or peak-hold rules. An image is a representation derived from evidence; it does not become the evidence merely because the image was generated in real time.

Nor does the expression 'real time' have one unqualified meaning. Some receivers acquire a continuous stream within a definite instantaneous bandwidth but redraw the user interface only intermittently. Others sweep a tuner or spectrum analyser sequentially, so that neighbouring frequency columns correspond to distinct instants. Some processing pipelines generate spectrogram frames without a capture gap while retaining only selected aggregate rows. Others skip or decimate samples when processing cannot keep pace. A colourful row does not tell the examiner which pipeline was used, and an uninterrupted stream of screen updates does not prove uninterrupted RF coverage.

We should separate at least four records. The first is the analogue observation envelope: antenna, front end, preselection, tuning, gain, analogue bandwidth, overload history and calibration. The second is the acquired complex or real sample sequence, with clock, sample-rate, validity and dropped-sample metadata. The third consists of computed spectral estimates, including their windows, overlaps, scaling and time tags. The fourth is the rendered display: colour palette, pixel decimation, interpolation, averaging and presentation state. A change in one may alter

Copyright 2026, James M. Atkinson

the screen while leaving another unchanged. The forensic investigator must know which of these records has actually been retained and which can be reconstructed independently.

The particular danger is that an interpreter may infer physical continuity from graphical continuity. A sequence of displayed horizontal lines can appear seamless despite a receiver having observed only a portion of the relevant time. A frequency-hopping source may produce isolated dots that a human eye joins into a path which the samples do not support. A long bright streak may be the consequence of temporal max-hold aggregation rather than a transmission lasting throughout the represented interval. A quiet-looking region may be the result of colour clipping, averaging, a threshold, a retune or the absence of stored samples. When an analyst later presents the display to a court, a laboratory or a security client, those possibilities must be tested rather than dismissed as mere software detail.

The present discussion will proceed through five specialised perspectives. Dr Dennis Gabor will examine localisation in time and frequency, showing why one spectral image cannot offer arbitrarily sharp information along both axes. Dr John Tukey will consider computational aggregation, bin placement, spectral leakage and the difference between raw data and an estimator. Dr Ralph Blackman will examine window response, dynamic range and false visual morphology. Dr Claude Shannon will distinguish what can be reprocessed from retained complex samples from what a screen image irrevocably discards. Finally, Dr Abraham Wald will investigate the statistical and forensic hazards of selecting evidence after a conspicuous visual pattern has appeared. Seven colleagues will pose direct technical challenges, each followed immediately by an answer from

Copyright 2026, James M. Atkinson

the principal contributor. Ten calculated cases will make the reasoning auditable.

I ask every participant to avoid the extremes of declaring the waterfall a deceptive novelty or of treating its glowing traces as a perfect historical record. The display is an extraordinarily useful instrument of discovery. Its evidential strength emerges when the acquisition and processing chain can be reconstructed. Dr Gabor, may I invite you to begin with the physical meaning of one illuminated time-frequency cell, before we consider what it can conceal?

Copyright 2026, James M. Atkinson

Dennis Gabor. Principal response 1. One time-frequency cell represents an operation, not an instant

Dr. Atkinson, a spectrogram cell is not a minute fragment of the electromagnetic world observed in isolation. It is the output of an operation performed on a neighbourhood of samples. If the transform uses N contiguous samples acquired at sampling frequency f_s, the nominal analysis duration is $T_w = N/f_s$. The output is assigned a time coordinate, often the centre or beginning of the window, but the estimate contains contributions from the entire window. When a pulse begins near one edge of that interval, the displayed energy may be associated with a coordinate different from the pulse's actual onset. When the same pulse is examined with a longer window, its spectral appearance may become more concentrated even as its temporal boundaries appear less distinct. The display's apparent precision is a consequence of chosen representation, not a direct measurement of two perfectly precise physical coordinates.

Frequency-bin spacing in an N-point discrete Fourier transform is f_s/N, provided the transform is based on N physical samples without subsequent padding. This spacing describes the sample grid in frequency, not by itself the ability to resolve two near spectral components. Resolution also depends upon observation duration, window shape, signal-to-noise ratio, interference and the decision rule. A reader who counts adjacent pixels may therefore mistake the number of displayed columns for a measure of resolvable spectral detail. Interpolation can provide smooth peaks and convenient sub-bin estimates under an assumed model, but it does not create independent measurements or distinguish arbitrary overlapping signals.

Copyright 2026, James M. Atkinson

The corresponding temporal issue is equally pronounced. A two-millisecond analysis window may be appropriate to detect and localise rapid activity, although it spreads the energy of a narrow carrier over a comparatively broad spectral response. A two-hundred-millisecond window gives a finer nominal frequency grid and potentially a more selective estimate for a sustained tone, yet a burst that occupied only a short portion of that window may be diluted when an average power estimate is formed. Neither window is intrinsically superior. Its suitability depends upon the duration and bandwidth of the sought signal, and upon whether the task is discovery, classification, measurement of power, or forensic characterisation of a retained event.

If adjacent analysis windows overlap, the waterfall may show the same physical pulse in several consecutive rows. The operator may count those rows as separate transmissions, particularly when bright pixels have similar shape but distinct time labels. The mistake becomes severe when an automatic event counter is attached to an image-processing algorithm rather than to a state machine operating on calibrated time-series evidence. Overlap is valuable because it reduces the risk that one isolated pulse falls entirely at a particularly unfavourable window boundary. It does not produce independent new physical events, and the number of rows should not be confused with the number of independent observation opportunities.

Another ambiguity arises from time stamping. If the first sample of each window is stamped as the display's nominal time, the visible centre of energy may be displaced by approximately half a window duration for a symmetric analysis window. If the timestamp instead denotes the centre, the displayed interval extends around that point. Software buffering, clock

Copyright 2026, James M. Atkinson

synchronisation and delayed screen rendering may add further discrepancies. A colourful trace aligned with an event recorded by a separate camera or instrument can therefore appear causally significant while the two systems differ in time origin or buffering delay. Cross-instrument interpretation requires the semantics of the stored time tag, not merely the number printed on the screen.

The use of colour creates its own abstraction. A continuous palette suggests that energy has been measured at every point in an apparent rectangular field. In reality a finite matrix of spectral estimates has been rescaled and drawn through finite pixels. A smooth gradient may have been interpolated between estimates; the underlying data may contain only one value per transform frame and frequency bin. Visual continuity may invite the eye to infer gradual physical drift where there were only two noisy detections separated by a large unobserved interval. Without a record of the frame times, such an inference is particularly fragile.

The competent analyst should ask what operation produced one row and what temporal support each coloured cell represents. Was the value peak power, average power, a maximum across many FFT frames, a logarithmic transform of a linear-power average, or a thresholded flag? Did the receiver capture a continuous band during all those frames? Were any rows copied, resampled or interpolated to match the screen's refresh rate? Was the signal's centre frequency estimated from more than one sample frame, and were the assumptions on which that estimate depended tested? Each answer may change the proper physical interpretation.

I am not arguing that a time-frequency picture is useless merely because it is an abstraction. Most scientific instruments communicate through

Copyright 2026, James M. Atkinson

transformations. A spectrogram is especially useful for comparing recurring patterns and discovering fleeting features. But if the question concerns the precise beginning, duration, occupied bandwidth or identity of a particular emission, one must return to the retained sequence and to the well-defined calculation by which the picture was produced. The image should guide examination rather than substitute for it. I respectfully yield the token to Professor Fisher and Dr Kendall, who will ask how far such a representation can support precise temporal or statistical conclusions.

Sir Ronald Aylmer Fisher | Peer question 1 to Dennis Gabor

Dr Gabor, consider two analysts who process the same continuous sample recording with different window durations. The first selects a short window and reports a narrow temporal burst with broad frequency content; the second chooses a longer window and reports a broader, quieter feature occupying fewer spectral bins. Both analyses are reproducible, yet their plots may lead an inexperienced examiner to infer physically different transmitters. Would you require a predeclared choice of window and colour scale for every forensic comparison, or is it legitimate to search several representations and retain the one that most clearly reveals an event? How should a report identify the difference between a physical finding that survives reasonable analytical choices and a visually striking pattern created only by one convenient setting? If the analyst has selected the most favourable image only after surveying a large family of window sizes, I would regard that choice as part of the evidential procedure. Does your suggested comparison require an independent validation recording, or might an unexamined portion of

Copyright 2026, James M. Atkinson

the same acquisition suffice where the disturbance is temporally correlated?

Dennis Gabor | Immediate answer to Sir Ronald Aylmer Fisher

Thank you for that question. Professor Fisher, the important distinction is between exploratory representation and independent confirmation. Selecting several windows is often scientifically sensible because the physical duration and spectral structure of an unfamiliar emission are not known beforehand. A short window may reveal its onset; a long window may assist in discriminating a sustained narrow carrier. The analyst should not conceal this exploration, nor present the most persuasive image as though it were the only analysis planned. Retain the full list of tried parameters, preferably in an automatically generated processing log, so that subsequent readers can reproduce the route from samples to chosen display.

A finding gains strength when its relevant physical propositions survive transformations that should not change them. If the hypothesis is that energy above a defined threshold entered the sampled receiver band during a particular interval, examine calibrated time-domain power and a range of reasonable transform settings. If the hypothesis concerns a narrow spectral line, compare windows, leakage corrections and independent frequency estimators. A change of image appearance alone is not evidence that the source changed. Differences between plots should be explained through the known response of their analysis windows wherever possible.

Predeclaring an analysis serves a different purpose from discovery. When a fixed decision threshold and a numerical false-alarm

Copyright 2026, James M. Atkinson

probability are used to make a confirmatory claim, the selection and processing steps that influence that decision should be specified before the validation data are seen. For an unfamiliar anomaly there may be no appropriate single setting to nominate in advance; the investigation can explore first and validate afterwards. The final report should separate those stages so that choosing the most conspicuous representation does not create an illusory statistical significance.

The most effective disclosure is to provide several views derived from the same identified sample interval: time-domain magnitude or power, a short-window spectrogram, a long-window spectrogram, and the underlying spectral estimates when relevant. Each view should carry a clear scale and timing convention. A conclusion based upon a feature found only under one delicate parameter choice should be stated conditionally, together with an alternative explanation involving the estimator. The court or engineering reader then sees not a contest of pictures but a test of propositions against one preserved record. I pass the token to Dr Kendall for the distinct question of how persistence across correlated rows ought to be evaluated.

David George Kendall | Peer question 2 to Dennis Gabor

Dr Gabor, a spectrogram may show a faint signal in fifty adjacent rows, and the operator may describe fifty corroborating observations. Yet if the rows were formed from ninety per cent overlapping windows, most of the sample values used to compute one row appear again in the next. The visible persistence may therefore contain far fewer

Copyright 2026, James M. Atkinson

independent pieces of evidence than the row count suggests. Is it possible to determine from the image alone whether the feature represents a persistent source, one transient spread across many transforms, or a processing artefact correlated across frames? What would you demand of a laboratory that offers such persistence as evidence of repeated communication rather than as the visual footprint of a single event? Might the same row pattern also arise from a moving noise-floor estimate, rather than from overlap alone? I should like to see a distinction between physical event count, transform-frame count and detector-trigger count, because the three may diverge dramatically in a single recorder's output.

Dennis Gabor | Immediate answer to David George Kendall

Thank you for that question. Dr Kendall, the image alone is inadequate for the distinction. One must inspect the window length, hop length and underlying samples to determine how much of the displayed repetition is induced by the estimator. If a window contains four thousand samples and the hop is four hundred, adjacent rows share ninety per cent of their input samples. A short pulse may consequently affect multiple frames whose nominal time coordinates differ, even though the physical recording contains only one pulse. The row count is a computational count, not a transmission count.

A defensible event detector should therefore operate on a declared physical event definition. It might group adjacent threshold crossings into one episode when their time intervals overlap or when calibrated temporal continuity justifies it. The grouping rule must be tested against simulated and reference transients of varying durations and

Copyright 2026, James M. Atkinson

separations. It should record the dependence on window length so that a switch in display settings does not quietly alter the reported number of transmissions. Where overlapping components cannot be resolved, the analyst should report an interval of possible event counts or an unresolved cluster rather than manufacture a unique event history.

Persistence becomes stronger evidence when it survives examination of genuinely disjoint portions of the sample sequence or an independent receiver path. If a narrow feature recurs in nonoverlapping windows separated in time, its repetition is no longer explained solely by reusing the same input samples, although other shared instrumental effects remain possible. The engineer should also examine amplitude consistency, frequency stability, receiver-state changes and alternative causes such as local oscillator spurs. None of these tests identifies a unique emitter automatically, but each constrains a possible explanation.

Thus I would require the analyst to state the estimator's time support and overlap, disclose the rule for merging adjacent detections, and present at least one time-domain check of the proposed event boundaries. A sequence of bright rows may suggest an event worth investigating. It is not fifty independent confirmations merely because the software printed fifty lines. I pass the token to Dr Tukey, whose experience with computational representation will provide a necessary challenge to the assumption that every plotted number is equivalent to a retained measurement.

Copyright 2026, James M. Atkinson

John Wilder Tukey. Principal response 2. Numerical processing can manufacture a persuasive appearance without inventing a sample

Dr. Atkinson, the problem begins when the examiner mistakes an output format for a primitive observation. The values entering a display can be derived from a legitimate and accurately retained sample record, yet the choices that transform them into an image can discard distinctions necessary for the question under investigation. One must therefore maintain a provenance chain through each computational stage. It should identify the original acquisition block, the samples included in every FFT, the window coefficients, the scale factors, the frequency mapping, the detector or aggregation rule, the treatment of invalid frames and the eventual colour encoding. Without those records another examiner may reproduce the screen's appearance only by speculation.

The discrete Fourier transform is a linear operation on a finite sequence. In its simplest unnormalised form, X[k] is the sum over n from zero to N-1 of x[n] exp(-j 2 pi kn/N). The same samples may be multiplied by a tapered window before transformation, and the output may be converted to magnitude or squared magnitude. A power estimate then needs an appropriate normalisation and, for a physical instrument, calibration through the analogue input path. If the operator mixes up amplitude and power decibels, or changes windows without correcting coherent gain, the waterfall's colours can move by many decibels even when the input signal is unchanged.

The distinction between a frequency grid and frequency resolution deserves emphasis. Zero padding a window of physical samples gives more FFT output bins and a smoother-looking spectral curve. It does not add

Copyright 2026, James M. Atkinson

information from a longer observation interval. A line may now fall on a more favourable output bin, making its peak easier to estimate under a model, but two close emitters do not become independently resolvable simply because the computer has printed four times as many frequency values. A forensic report that equates a reduced bin interval with improved physical resolution confuses interpolation of an existing transform with a genuinely longer effective measurement.

Likewise, a display image may use far fewer columns than the computed FFT contains. Suppose the transform produces eight thousand frequency values but the graph is only one thousand pixels wide. The rendering software must combine, choose or omit some values. If it chooses a maximum in each pixel group, an isolated spur may appear prominent; if it chooses a mean, the same narrow spur may be diluted. Both are defensible for different purposes. Neither should be offered as a complete account of the underlying transform without stating the reduction rule. A screenshot is therefore a poor substitute for the numerical spectrum and its metadata.

Temporal aggregation is even more dangerous. A receiver may compute one thousand FFT frames per second but update its waterfall with one row per second. If each row displays the maximum observed power for that second, a burst lasting a fraction of a millisecond may produce a bright stripe resembling an event sustained for the entire displayed second. If the row shows average power, the same burst may become almost invisible. The picture may encourage either an overestimate or an underestimate of event duration and received power. It is the aggregation policy, not the source, which determines the row's duration and colour.

Copyright 2026, James M. Atkinson

A modern graphical interface also applies nonlinear colour scaling. The palette may map a wide range of decibels into a limited set of shades, clip values outside the selected reference range, interpolate pixels and reverse the order in which time is plotted. A colour change can therefore be produced without any new energy entering the receiver. Automatic gain adjustment, a different reference level or a revised palette threshold may turn an unchanged statistical background from dark blue to vivid yellow. The original magnitude data could remain numerically identical. A report relying on colour adjectives while omitting the calibration scale is a report about presentation preferences, not radio-frequency power.

Yet it would be foolish to reject plotting as a means of discovery. Graphical representations show patterns which a table can conceal, particularly temporal sequences and correlated frequency motion. The remedy is to preserve the processing lineage so that a visual discovery can be converted into a reproducible measurement. Record the precise sample hashes, code version, window, hop, power normalisation, detector settings, frame aggregation and colour map. For a challenged event, recompute the relevant window from the original samples and verify that the stated feature survives suitable alternative settings. The display should lead back to numbers and physical quantities rather than away from them.

The danger of selecting one attractive picture among many is not confined to malicious advocacy. An attentive engineer naturally searches through configurations until the pattern becomes legible. This practice is valuable for discovery, but it means that the final image may carry more selection history than the caption admits. The source record should disclose that history, particularly when numerical confidence or unique attribution is

Copyright 2026, James M. Atkinson

claimed. If a long-term waterfall is retained without raw samples, acknowledge its restricted evidential reach: the picture may establish what the display computed, but not all of the short-time behaviour that the display has averaged away.

A disciplined report can communicate both a useful picture and an exact numerical audit trail. One page may show the visually intelligible spectrogram. An accompanying record should state the frequency resolution, effective filter response, timestamp semantics, number of frames aggregated per row, lost-frame count and power calibration. On demand the analyst should be able to identify the samples which made one striking pixel bright. I pass the token to Dr Hamming and Professor Wiener for questions about software reproducibility and feedback-induced alterations in the displayed record.

Richard Wesley Hamming | Peer question 3 to John Wilder Tukey

Dr Tukey, a software engineer may preserve all input samples but discover months later that the application version which produced a decisive screenshot is no longer installed. The waterfall calculation used proprietary window normalisation, a vendor-specific averaging mode and adaptive display decimation, and its settings are recoverable only partly from the screenshot. The laboratory has therefore retained better physical evidence than its published figure suggests, but it cannot reproduce the exact historical image. Would you classify the screenshot itself as evidentially invalid, or could a new, transparent implementation produce a stronger analysis from the same raw samples? How should the examiner explain disagreement between the original image and a later reproducible analysis without silently rewriting the historical record?

Copyright 2026, James M. Atkinson

What should be done when different reproducible algorithms yield the same narrow trace but materially different amplitude estimates? Does agreement about frequency establish enough to accept a source as external, or must calibration and analogue artefact tests still precede even that limited assertion?

John Wilder Tukey | Immediate answer to Richard Wesley Hamming

Thank you for that question. Dr Hamming, the distinction between preserving an original artefact and reproducing its method is essential. The historic screenshot remains evidence of what a particular display presented at a particular recorded moment, subject to the authenticity of the image and its provenance. The inability to reproduce its exact colours or pixel selection limits inferences about the algorithm that produced it. It does not render independently preserved raw samples useless. A later, transparent reanalysis may be considerably stronger evidence of the underlying signal, provided that the new procedure and the fact of reprocessing are clearly identified.

I would not erase the older image or substitute the new one under the original date. Preserve both. Identify the sample interval and the checksums of the retained acquisition, then explain which original processing parameters are documented and which have been lost. Recompute the event using an independent, specified transform, and disclose differences in time support, frequency scale, normalisation and detector policy. If the apparent event disappears, examine whether the discrepancy results from clipping, windowing, averaging,

Copyright 2026, James M. Atkinson

a former display artefact or a genuine defect in the new analysis. A disagreement is a technical finding, not an invitation to choose whichever picture favours a preferred narrative.

Software provenance should be planned as part of evidence acquisition. Retain executable or source versions where lawfully available, configuration files, time-zone and clock settings, numerical-library versions, calibration records and validation test vectors. If one computation cannot be precisely recreated, describe the limitation rather than invent undocumented parameters. The original picture may still help identify a candidate time-frequency region, while the new analysis tests more bounded propositions about the preserved data.

The decisive point is that a screenshot has a different evidential function from a complex-sample acquisition. The screenshot documents an output of a particular measurement-and-display system; the raw samples permit alternative estimators within the limits of the original analogue channel. One can use both without pretending they are interchangeable. The integrity of the laboratory is improved when it states plainly that the original visualisation is not fully reproducible and that its present conclusion rests upon independently verifiable reprocessing. I pass the token to Professor Wiener to question the effects of automatic user-interface changes.

Norbert Wiener | Peer question 4 to John Wilder Tukey

Dr Tukey, suppose the waterfall program automatically follows its noise floor, changes the colour threshold as the receiver is moved, and increases averaging whenever the displayed background looks restless.

Copyright 2026, James M. Atkinson

The screen becomes visually stable, which is welcome to the operator, but its sensitivity to a faint new emission may change without an explicit command. One might observe an apparent strengthening of a spectral line after an antenna move even though the underlying receiver samples did not strengthen proportionately. How should the analyst identify feedback between the display, the operator and the acquisition system, and when does this feedback merely alter presentation as opposed to changing what physical information is captured and retained? How would you distinguish software adaptation which merely changes the colours on a screen from automatic gain control which changes the digitised measurements themselves? A technician may find both controls labelled 'auto' and fail to realise that only one can be undone through later re-rendering.

John Wilder Tukey | Immediate answer to Norbert Wiener

Professor Wiener, this question requires the processing chain to be divided at the point where information is discarded or physical acquisition is altered. If automatic colour following changes only the palette used to show already computed calibrated power values, then the original samples and numerical spectral estimates may be unchanged; the alteration is a presentation transformation. If averaging changes the stored spectral records, however, the data retained for later analysis may be reduced. If the program alters receiver gain, tuning, preselection or capture triggering, the transformation reaches back to the analogue observation envelope and may change which signals can enter the record at all.

Copyright 2026, James M. Atkinson

The laboratory should identify each feedback path in its state log. A palette parameter belongs with the image metadata. A new averaging depth belongs with the spectral estimator and the description of retained numerical products. An automatic gain-control response belongs with the receiver acquisition record, together with information about the possibility of compression and clipping. A retune belongs with time-frequency coverage. Without these distinctions the investigator cannot say whether a vivid colour change is merely graphical or constitutes a physically different measurement condition.

To test a suspected strengthening of a feature, compare calibrated power measurements derived from the retained samples under a fixed processing configuration and, where possible, from independently characterised reference data. Correct for gain state and known front-end changes. Then ask whether the change exceeds the uncertainty arising from calibration, noise estimation and detector response. The operator's visual impression can motivate the calculation, but it does not answer it.

Where continuous complex samples have survived, one may reconstruct comparable spectral estimates by applying one declared estimator to both intervals, provided the analogue chain supports the comparison. Where only auto-scaled screenshots remain, the permissible claim may be substantially narrower. In either situation, document whether the adaptation was controlled by software, by a human, or by a physical receiver loop. The same apparent screen can emerge from quite different causal paths. I now yield the token to Dr

Copyright 2026, James M. Atkinson

Blackman for his analysis of window response and the spectral shapes which a display may suggest. For that reason, the archived state history should use different fields for graphical scaling, spectral integration and physical receiver gain, each with its own effective timestamp.

Copyright 2026, James M. Atkinson

Ralph Beebe Blackman. Principal response 3. Window shape, dynamic range and the fiction of a perfect spectral boundary

Dr. Atkinson, an FFT is usually applied to a finite observation that is treated as one segment of a longer underlying signal. Abruptly truncating the segment with a rectangular window introduces a particular spectral response, and the response of a tapered window has its own trade-offs. A strong carrier which does not fall precisely on the bin grid can distribute energy into adjacent bins. The resulting sidelobes may give the appearance of weaker emissions, especially when shown on an aggressive logarithmic colour scale. A window that suppresses sidelobes often broadens the main lobe. A spectral picture therefore combines the properties of the physical emitter with the chosen observation and estimator; its visible edges are not direct tracings of a transmitter's occupied bandwidth.

If the input contains a sinusoid whose frequency lies between FFT bins, the amplitude indicated by the nearest displayed bin may be lower than an appropriately calibrated estimate of the true sinusoidal amplitude. This is sometimes described as scalloping loss, and its magnitude depends upon window shape and the point at which the tone falls between bins. An operator who interprets fluctuating bin colours as fluctuations of transmitter output may thereby overlook the possibility that the tone is merely drifting across the estimator's frequency grid. Conversely, interpolation and bin searching may smooth the displayed amplitude, hiding how strongly the estimate depends upon processing choices.

Windowing also changes noise statistics. A tapered window weights samples unequally and has an effective noise bandwidth which differs from the raw FFT-bin spacing. Two spectrograms processed with different

Copyright 2026, James M. Atkinson

windows cannot be compared by their colour scales alone unless the normalisation and bandwidth differences are accounted for. The same white-noise density may lead to different displayed noise powers per spectral estimate. Likewise, a detector that averages powers is not equivalent to one that averages logarithmic decibels, since the logarithm is nonlinear. Such distinctions can shift a colour boundary or make a faint candidate look more or less significant.

The strong-signal problem is particularly severe in technical surveillance countermeasures. A legitimate high-power emission or a local oscillator spur may dominate the transform and generate leakage that extends into a neighbouring frequency. The visual picture may seem to contain a family of parallel weak transmitters. The investigator should compare window choices, attenuation, front-end filtering and dynamic-range behaviour to determine whether the faint structure is independent of the dominant source. This examination must begin with the possibility of analogue overload, because no digital window can recover an undistorted version of samples already corrupted by saturation or mixer nonlinearity.

A waterfall can also exaggerate spatial or temporal continuity through its chosen detector. Consider a one-second output row created from many individual FFT frames. A maximum detector preserves the strongest observed value at every frequency bin, even if those maxima occurred at different times within the second. The resulting horizontal row can resemble a broad simultaneous emission which never existed as such at any one instant. At one frequency the maximum may have occurred in the first millisecond, and at another it may have occurred near the end. Combining

Copyright 2026, James M. Atkinson

those maxima into one line is operationally useful for discovery, but it does not establish simultaneity across the plotted band.

A mean detector creates the opposite hazard. A brief pulse of large peak power may contribute very little to the average across a long period, particularly if the colour scale displays the result near the noise floor. In the simplest ideal case, a pulse present with duty fraction d and absent otherwise contributes average power d times its on-state power. The logarithmic display shifts that contribution by 10 log10(d) decibels relative to the on-state level when background can be neglected. A millisecond of activity in one second therefore appears thirty decibels lower as an average than as a peak. The source did not become thirty decibels weaker. The estimator answered a different question.

The problem of power calibration should therefore be stated in physical units and with the appropriate resolution bandwidth. It is not enough to say that an emission was 'bright' or 'faint'. State whether the plotted quantity is dBm in a defined analysis bandwidth, spectral density, a dimensionless normalised magnitude or a decision statistic. State the analogue reference plane and the attenuation or gain applied. If a later reader cannot translate the colours into an interpretable quantity, the image may still be useful as an investigative lead but is weak evidence for an exact emission level.

Finally, we should remember that each transform has finite time support, finite spectral selectivity and a noise distribution affected by the estimator. There is no uniquely truthful waterfall setting. A responsible analyst chooses a representation suited to the proposed physical claim, discloses its response and checks any material anomaly against the raw record and alternative explanations. A black-and-white numerical table may appear less

Copyright 2026, James M. Atkinson

captivating than a coloured spectrogram, yet it is often the table of exact parameters which allows an independent examiner to decide what the colours mean. I pass the token to Dr Nyquist for a challenge concerning apparently moving spectral lines and the limitations of a receiver's initial sampling chain.

Harry Nyquist | Peer question 5 to Ralph Beebe Blackman

Dr Blackman, a bright diagonal trace may appear to show a transmitter whose frequency is steadily changing, and a set of faint parallel lines may suggest several simultaneous signals. Yet each phenomenon might be influenced by a moving frequency-bin grid, front-end aliasing, local-oscillator instability or a receiver which swept several subbands in sequence. If the displayed samples have already passed through an insufficient anti-alias filter or a saturated mixer, changing digital windows will not correct the underlying defect. What minimum tests should be performed before the examiner reports a physical frequency sweep or multiple emitters, and what can a waterfall alone establish about these apparently coherent patterns? Please also consider a signal whose apparent diagonal slope changes when a different colour interpolation scheme is chosen. Would you require a direct estimate of instantaneous frequency from samples, with uncertainty, before permitting a statement that the emitter swept continuously rather than hopping between discrete frequencies?

Ralph Beebe Blackman | Immediate answer to Harry Nyquist

Dr Nyquist, a waterfall can establish that the selected processing chain produced a coherent time-frequency pattern. It does not, alone, establish that a unique external source produced the pattern or that

Copyright 2026, James M. Atkinson

the pattern has the physical interpretation suggested by its geometry. Before describing frequency drift, the examiner should confirm that the receiver observed the relevant band simultaneously, that its local oscillator and sample clock were sufficiently stable, and that frequency mapping did not change through retuning or interpolation. Check for image responses, aliases, spectral leakage and clipping. Each can create a shape that looks like a physical emission but follows the apparatus rather than an external source.

An instructive test is to change a controlled receiver parameter and predict how competing explanations should respond. A genuine external carrier, suitably within the admitted band and not disturbed by the test, should normally retain its external frequency when expressed at the correct RF reference. An internally generated spur may move with local-oscillator settings or persist with the antenna replaced by a properly terminated input. Such tests must be performed carefully because an antenna substitution or gain change can itself alter loading and interference. Their value lies in predicting distinct outcomes before performing the intervention.

For multiple apparent emitters, examine simultaneous complex-sample data if available and compare window functions and calibrated spectral estimators. Leakage from one strong tone should respond in predictable ways to window and bin placement. A front-end intermodulation product may change nonlinearly with attenuation. An alias may shift as the sample rate or receiver tuning changes. These differences can help distinguish hypotheses, but they require the relevant operating records and, ideally, independent

Copyright 2026, James M. Atkinson

measurements. A screenshot showing several coloured threads cannot provide those experimental controls after the event.

The conclusion should therefore be carefully bounded. 'The retained samples contain a feature whose centre-frequency estimate changed under a specified algorithm' is a narrower but stronger statement than 'the hidden transmitter swept its frequency.' Similarly, several displayed ridges may be described before they are attributed to several independent sources. I return the floor to Dr Shannon, whose concern is how much of this distinction can be recovered after only the visual product has survived.

Copyright 2026, James M. Atkinson

Claude Elwood Shannon. Principal response 4. The screenshot is a lossy communication channel from evidence to observer

Dr. Atkinson, one may consider the waterfall renderer as a communication channel whose input is a much richer technical record and whose output is a human-viewable image. This channel may be designed to convey operationally important patterns, but it cannot generally preserve all information in the complex samples. A pixel colour does not specify phase, and phase relationships may be essential for demodulation, direction-finding, fine frequency estimation or identification of sampling artefacts. Once complex spectral values have been reduced to magnitudes, an entire family of waveforms can become compatible with the same picture. Further reduction to an eight-bit colour index enlarges that ambiguity.

The loss is not necessarily an error. Engineers rightly compress and summarise data when the operational objective is to survey a large band for possible activity. The error appears when a later claim requires information which the chosen summary discarded. A spectrogram showing energy in a frequency cell cannot ordinarily establish the bits carried by a communication. A saved waterfall image cannot be reprocessed to recover arbitrary short transients below its temporal resolution. It may not even prove that the plotted neighbouring frequency bins correspond to energy present simultaneously if a maximum across several moments was used for each bin. The retained image is faithful only to the documented rendering operation.

We must trace losses along the chain. The analogue front end excludes frequencies outside its accepted passband and may distort those inside it. The converter quantises and samples the admitted waveform. A recorder

Copyright 2026, James M. Atkinson

may discard blocks, reduce precision or store only selected intervals. A spectral estimator multiplies finite windows, forms transforms and may retain powers while discarding complex values. A display processor selects and aggregates estimates, clips a dynamic range, maps the results to pixels and may add interpolation. At each stage different physical histories can map to identical downstream results. A later analyst cannot infer that those histories were identical at the receiver input merely because they share one final picture.

The distinction matters for reproducibility. If the full sequence of time-tagged complex samples is retained with adequate metadata, an independent analyst can regenerate several spectrograms, inspect transient amplitude in the time domain, compare windows, re-estimate centre frequencies and test whether an apparent feature remains under a different algorithm. Such retrospective work is still limited by original analogue selectivity, saturation, clock integrity and capture gaps. The samples do not grant an omniscient view of the antenna environment. Nevertheless they contain far more recoverable information than a picture of power alone.

Where only power spectral frames are retained, useful reanalysis remains possible within their boundaries. One can verify a threshold, examine a time series of computed powers or compare spectral shapes, provided the numerical frames, scale factors and timing are available. Where only a screenshot survives, one can examine its visible geometry and perhaps recover approximate pixel colours, but not a uniquely calibrated original power history unless the required mapping and processing metadata also survive. Reconstruction of a complex waveform from such an

Copyright 2026, James M. Atkinson

image is in general not unique. Many possible phase histories and many temporal distributions of energy fit the same displayed magnitudes.

A further problem is the false appearance of independence. Two images saved from the same source samples but rendered with different palettes do not constitute corroboration by two instruments. Two software algorithms may find similar features because they analyse the same artefact in the same digitiser. Two nominally separate receivers may share an overloaded distribution amplifier, common reference oscillator or harmful interference at the measurement site. Independent corroboration must be established through genuinely independent observation paths and a documented account of common dependencies. A duplication of display pixels is not a duplication of physical evidence.

A robust evidential package should therefore preserve the acquisition and processing layers in an ordered, checksummed archive. Include channel centre frequency, instantaneous bandwidth, actual sample rate, time-base quality, analogue gain and attenuation, saturation indicators, validity masks, dropped-sample counts, sample scaling, window coefficients, hop length, transform normalisation, aggregation policy and image palette. If one item is unavailable, record its absence rather than fill it with a later inference. A competent reviewer should be able to trace a selected pixel back to the transform values and sample ranges which contributed to it, where those underlying records remain.

This may sound demanding for a simple exploratory survey, but the required detail need not clutter every field display. Much of it can be captured automatically. The important point is architectural: a user interface meant for rapid human recognition should not be treated as the sole

Copyright 2026, James M. Atkinson

evidence store. Design the system so that the visual product points to a durable recording, not so that its graceful colours replace one. When an anomalous trace is later challenged, a preserved acquisition has the power to answer new questions that the original operator did not anticipate; a screenshot does not.

The appropriate forensic conclusion is not 'never trust a waterfall'. It is 'trust each layer for the proposition that layer can support'. The waterfall can be convincing evidence that a specified numerical pattern was displayed under a documented process. It can be an excellent signpost to a real radio-frequency event. It does not certify a complete physical history, the identity of an emitter or the continuity of an unseen transmission. I pass the token to Dr Blackwell for a question about inferential reconstruction from compressed records.

David Harold Blackwell | Peer question 6 to Claude Elwood Shannon

Dr Shannon, an investigator may have retained a timestamped matrix of power values, not the underlying complex samples, and may nevertheless estimate the likelihood of a particular class of modulation or transient event using a statistical model. It would be too sweeping to say that loss of phase forbids every meaningful inference. The question is how the inference should be qualified. If the power matrix is consistent with several distinct waveform histories, may the investigator still calculate a probability under an explicit prior or likelihood model, and what must be disclosed before presenting that figure as evidence? How does your distinction between missing information and valid inference apply when the model itself was selected because it made the displayed pattern appear familiar? If the analyst chose the prior distribution only

Copyright 2026, James M. Atkinson

after seeing the waterfall's shape, could the resulting posterior certainty be inflated by selection? I ask because the evidence must be capable of supporting a contested conclusion, not merely a model whose assumptions have been adjusted to flatter the observed picture.

Claude Elwood Shannon | Immediate answer to David Harold Blackwell

Professor Blackwell, loss of information does not make every further inference impossible. A known probability model can support classification or parameter estimation from a sufficient summary for the question at hand. The central requirement is that the claimed quantity be identifiable, or at least estimable with stated uncertainty, from the information actually retained under the model. If several physical explanations produce comparable power matrices, the posterior or likelihood comparison is conditional upon the candidate explanations, their modelling assumptions and any prior probabilities. It does not establish that the unmodelled alternatives were absent.

A statistical method using only spectral power can legitimately detect departures from a noise model, identify repeated energy patterns or estimate quantities that depend principally on second-order statistics. It cannot generally recover a unique phase history, and a claim about a specific transmitted message may require information never retained. The examiner should state the precise statistic used, the family of models compared, the manner in which its parameters were estimated and the validation data available. A calibrated classifier score is not a unique physical source identity merely because it is numerically close to unity.

Copyright 2026, James M. Atkinson

Where the candidate model was selected after viewing the waterfall, that discovery process must be distinguished from confirmation. The investigator can record the hypothesis, preserve the selected feature interval and test the hypothesis on independent sample blocks or later acquisitions, provided the validation procedure is appropriate to the claim. If only the original power matrix exists, a sensitivity analysis across plausible alternate models may still convey useful uncertainty. It must not be portrayed as an independent check of a model chosen to fit the same evidence.

Thus the correct position is neither that compressed data are worthless nor that elegant probabilistic inference replaces missing physical information. An inferential statement remains bounded by its model and the distinguishability of its alternatives. A reader should be told precisely what is directly visible in the retained power record, what additional features were inferred by statistical methods and which kinds of physical events could not be distinguished because phase or fine temporal structure was discarded. I yield the token to Dr Wald for the final examination of selection, thresholds and the hazards of a dramatic image.

Copyright 2026, James M. Atkinson

Abraham Wald. Principal response 5. A conspicuous picture can change the question after the evidence has been seen

Dr. Atkinson, the final hazard concerns not the Fourier transform but the decision process surrounding it. A security examiner begins with an objective: to determine whether a particular class of unexpected emission was present under specified search conditions. During the survey a striking waterfall feature appears. The examiner may then vary the threshold, frequency span, averaging depth, colour range and analysis interval until the feature looks more distinctive. This exploration may be entirely reasonable. Yet the resulting image is often presented as though those settings were selected independently of the outcome. If the number of examined representations is concealed, any later numerical claim of rarity risks severe distortion.

A decision rule cannot be assessed without its selection procedure. If an algorithm declares a positive event whenever a predeclared statistic exceeds a fixed threshold, the false-alarm probability may be estimated under a documented null model. If the human operator searches hundreds of images and chooses the most remarkable shape, the effective event is not 'a threshold crossing in one predetermined image'. It is 'the most conspicuous result obtainable among many searched settings'. The distribution of that maximum differs from that of one preselected statistic. A claim that a visual pattern is statistically extraordinary should therefore account for the search process or be tested with held-out data.

The familiar terms false alarm and missed detection are meaningful only for a stated event definition and observation envelope. What counts as one waterfall detection? Is it a bin above threshold, a connected group of bright

Copyright 2026, James M. Atkinson

pixels, a time-frequency ridge, or a transient with a particular duration and bandwidth? A detector that reports many overlapping bright cells as distinct alarms has a different false-alarm behaviour from one that consolidates those cells into one event. A change in colour palette may affect a human decision without changing numerical power, while a change in numerical threshold changes the detector itself. Both should be documented when a human judgement forms part of the evidential chain.

The same applies to the declaration of a negative result. An apparently empty waterfall may result from averaging which suppresses short events or from a display scale that paints low-energy features in the background colour. An acquisition with intermittent coverage may contain unobserved frequency-time regions which have nevertheless been filled by graphical interpolation. The report must distinguish 'the displayed map showed no qualifying feature under these settings' from 'the recorded samples contain no detectable feature under a specified validated analysis' and from 'no source emitted during the surveyed period'. These statements are not equivalent. Only the first may be justified by the image alone.

An examiner may improve the evidence by retaining both exploratory and confirmatory analyses. In the exploratory phase, allow varied window lengths, detection thresholds and display scales, but record the choices. Define a physical hypothesis from the observed pattern. In the confirmatory phase, apply a predeclared test to an independent portion of data or a genuinely new observation, taking care to preserve calibration and the relevant receive chain. If the pattern is a persistent internal spur, a controlled termination or attenuation challenge may distinguish it from an

Copyright 2026, James M. Atkinson

antenna-coupled external feature. The result should be reported with the limitations appropriate to the actual control.

Legal evidence should not be simplified beyond its strength. A clear, accessible figure can assist the reader greatly, particularly when combined with a calibrated axis and annotations showing the investigated interval. But the figure should not be detached from the samples, computations and instrument settings on which it depends. The chain of custody must include the digital recording as well as derived visual products. Hashes should identify the original files and subsequent derived versions. Reprocessing should leave an explicit record of software, parameters, input intervals and output identities. The purpose is not bureaucracy for its own sake; it is to preserve the possibility of an independent and adversarial examination of the result.

The investigator should take special care with a claimed source identity. A distinctive waterfall pattern can be generated by many radios sharing a modulation standard, by common environmental interference, by internal receiver processes and by deliberately constructed test signals. It may establish that a feature deserves directed inspection. It cannot uniquely attribute a transmitter without other physical evidence. Bearings, timing comparison, device response to controlled power events and independent receivers may narrow the possibilities, but each has its own uncertainties and possible common failures.

There is also a cost dimension. An overconfident declaration of an undiscovered transmitter may produce unnecessary expense or reputational injury, while a premature declaration that a room is clear may leave a genuine risk unexamined. Decision thresholds should therefore be

Copyright 2026, James M. Atkinson

connected to the intended use of the survey and the consequences of competing errors, without permitting those consequences to change the recorded physical observations. The evidential language should remain consistent: observed pattern, validated anomaly, plausible external origin and attributed device are different levels of claim. A waterfall is often useful at the first two levels and rarely sufficient alone at the fourth.

I would conclude that the strongest presentation is not the brightest screenshot but the one for which another examiner can reconstruct the path from RF input to retained samples, from samples to estimates, and from estimates to the displayed colours. Such a chain permits a challenge to the analysis without pretending that the analyst's original visual intuition had no role. Scientific integrity requires the intuition to be made accountable. I invite Dr Deming to test the practical requirements of that record before the moderator closes the question.

W. Edwards Deming | Peer question 7 to Abraham Wald

Dr Wald, many field teams operate under restricted time and equipment budgets. They cannot preserve every intermediate numerical array indefinitely, and their software may be designed primarily for rapid discovery rather than laboratory-grade archival recording. If we demand that every colour, transform and user action be reproducible for years, the resulting procedure may become too cumbersome to use in an ordinary protective survey. What minimum evidence package would allow a responsible engineer to distinguish an exploratory screenshot from a publishable finding? Is there a practical way to preserve the most valuable technical information without claiming a standard of completeness that the field apparatus cannot meet? Would you insist

Copyright 2026, James M. Atkinson

that the recorded summary include a test of the display's minimum detectable pulse duration, or is a calibrated threshold sufficient? A threshold may be measured accurately while the instrument remains blind to bursts that occur during processing dead time or between spectral frames.

Abraham Wald | Immediate answer to W. Edwards Deming

Dr Deming, proportionality is important, but proportionality must not be achieved through ambiguity. A field team can make a useful exploratory record with limited equipment, provided it does not claim that the record proves more than was measured. The minimum package begins with time, location, receiver configuration, frequency coverage, threshold and display settings, a record of valid and invalid observation periods, and the original digital artefacts actually retained. If a candidate event is found, preserve the highest-fidelity underlying acquisition available around that event, together with an independent description of the operator's observations and any subsequent interventions.

Where raw samples cannot be stored continuously, a system may maintain a rolling buffer and save the relevant interval on a trigger. The operator must document the trigger rule, pre-trigger interval, capture gaps and the possibility that events outside the buffer were discarded. A saved power matrix with full metadata is better than a bare screenshot; a screenshot with a calibrated legend and recorded settings is better than an undocumented image. These are graded levels of evidence, not interchangeable substitutes. The report should identify which level was achieved for each important finding.

Copyright 2026, James M. Atkinson

A practical validation procedure may rely on representative test vectors. Before the survey, process known signals of different durations, powers and frequency offsets to establish how the waterfall behaves. Preserve those results and the software version. After an apparent anomaly, use the same configuration to assess whether the displayed feature has a reproducible response. If the laboratory lacks the data required for one inference, mark that inference as unsupported rather than treating a more elaborate report as a substitute for missing acquisition.

This approach need not consume excessive resources. Automatic logging can record state changes and hashes without interrupting an operator. A system may archive full-fidelity data only for selected intervals while maintaining a continuous lower-resolution summary. The resulting report should distinguish coverage of the summary from coverage of the high-fidelity record and should not state that arbitrary waveforms can be recovered from the summary. A proportionate evidential package is one whose limits are explicit and whose important claims can be independently checked. I now respectfully return the token to Dr. Atkinson for the closing synthesis of the first fifty questions.

Dennis Gabor, Cross-Peer Question to John Wilder Tukey: Professor Tukey, a waterfall uses overlapping analysis windows and displays one short burst as five bright consecutive rows. What must the investigator do before counting five transmissions?

John Wilder Tukey, Cross-Peer Answer to Dennis Gabor: Dr Gabor, associate each row with its actual input-sample interval, transform window and hop

Copyright 2026, James M. Atkinson

size. The same physical samples can contribute to several rows, so the row count is a property of the display process, not a count of independent bursts. Examine the corresponding raw I/Q and group rows into candidate events using a predeclared rule validated against injected pulses. Report the graphical time support and group-delay convention, including any interpolation between rows. A visually sharp cluster may still represent a single transmission or an artefact triggered by an internal state change. Preserve the row-generation code and colour scaling so another analyst can reproduce the image. I pass the token to Mr Blackman on window response.

John Wilder Tukey, Cross-Peer Question to Ralph Beebe Blackman: Mr Blackman, how can a fixed colour scale and an unsuitable spectral window turn a weak intermittent signal into an apparently continuous bright line?

Ralph Beebe Blackman, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, the display may combine long integration, a taper with finite leakage, persistence, averaging or peak-hold rules. A strong nearby line can leak into adjacent bins; a slowly decaying maximum statistic can preserve colour after the input disappears. Conversely, adaptive autoscaling can make an unchanged noise floor appear to brighten or dim. Measure window coherent gain, equivalent noise bandwidth, display persistence and frequency response, and compare against a calibrated tone stepped on and off at known instants. Retain uncoloured power measurements and raw complex samples separately. A computer-rendered line should never be described as a continuously received carrier unless acquisition and temporal evidence support that chronology. I yield to Dr Shannon on information loss in a screenshot.

Copyright 2026, James M. Atkinson

Ralph Beebe Blackman, Cross-Peer Question to Claude Elwood Shannon: Dr Shannon, what information is lost when the only surviving evidence of a suspected emission is a compressed screenshot of a waterfall?

Claude Elwood Shannon, Cross-Peer Answer to Ralph Beebe Blackman: Mr Blackman, the screenshot may omit phase, unselected frequencies, time samples between redraws, absolute amplitude calibration, receiver mode, clipping indicators and the mapping from data values to pixels. Colour quantisation and image compression can further hide small differences. Many different underlying I/Q histories can generate visually similar pictures, particularly after averaging or interpolation. Preserve the original captures, spectral arrays, window parameters, timestamps and display settings, with checksums and a reproducible transformation chain. If only the image exists, limit conclusions to what the image actually depicts, with explicit uncertainty about source timing and amplitude. The apparent continuity of a line cannot repair missing acquisition intervals. I respectfully pass the token to Dr Wald on selection after viewing the image.

Claude Elwood Shannon, Cross-Peer Question to Abraham Wald: Dr Wald, the investigator has thousands of waterfall captures but publishes only the one exhibiting an unusually straight, bright line. What correction is required?

Abraham Wald, Cross-Peer Answer to Claude Elwood Shannon: Dr Shannon, report the selection process and the population of images examined. A conspicuous example may arise by chance when many correlated displays are searched. Calibrate a prespecified detection statistic using full representative acquisitions processed with the identical colour, window and persistence settings; do not assign a single-image probability to a frame

Copyright 2026, James M. Atkinson

chosen after inspection. An independent blind observation can test whether the physical signal recurs under controlled conditions. Keep rejected images and receiver state logs if evidential conclusions depend on comparison. The strongest single picture may be a useful lead, but it is not itself a frequency-standard measurement, a complete waveform record or a unique transmitter identification. I return the token respectfully to Dr Atkinson.

Dr. James M. Atkinson. Closing synthesis of Question 050

Colleagues, the fiftieth question concludes a significant foundational sequence in this programme, and its lesson ought to govern the treatment of every later receiver screenshot. A waterfall is a derived representation of a measurement process. It may be an excellent guide to anomalous radio-frequency activity, but it should never be mistaken for the complete record of what entered an antenna or even for the complete numerical content of the samples retained by the recording system. The question to be asked of each coloured pixel is not simply what it resembles, but which physical exposure, acquisition samples, numerical operations and rendering decisions produced it.

Dr Gabor has explained the joint limits on time and frequency localisation. A window spreads information across its duration, and overlapping windows may paint one physical burst across several rows. Dr Tukey has shown that zero padding, spectral scaling, frame aggregation and colour mapping affect appearance without necessarily changing the input signal. Dr Blackman has demonstrated how window sidelobes, scalloping, equivalent noise bandwidth and peak or average detectors may create false impressions of spectral multiplicity, temporal continuity or amplitude change. Dr Shannon has insisted upon the distinction between information

Copyright 2026, James M. Atkinson

preserved in a complex-sample archive and information discarded by a magnitude plot or screenshot. Finally, Dr Wald has exposed the selection bias that occurs when a particularly persuasive image is chosen from many unreported processing configurations.

A forensic report should document the complete time-frequency observation envelope. State the analogue reference plane, receiver passband, channel centre frequency, gain, preselector and any overload qualification. State the real sample rate, validity masks, clock reference and the exact intervals retained. For each spectral product, state window shape, effective duration, hop, normalisation, analysis bandwidth, detector, row aggregation and timestamp convention. For each rendered figure, state the colour scale, clipping, pixel decimation, interpolation and any automatic changes. Without such information, apparently similar waterfall pictures may represent different physical experiments.

The expert must also distinguish a recurrent signal from recurrent computation. One pulse can occupy several overlapping FFT windows, and multiple frequency maxima within one aggregated row need not have occurred simultaneously. A line appearing to move across the screen may be due to a genuine frequency sweep, but it can also follow a retune, oscillator instability, alias, bin-mapping error or display interpolation. The proper response is neither credulity nor dismissal. It is a sequence of controlled tests directed at the alternative mechanisms, using the highest-fidelity preserved acquisition when available.

Consider the moral weight of a negative report. When a waterfall looks dark, it is tempting to say that the monitored band was clear. Yet a dark region may represent a threshold, a clipped palette, averaged power,

Copyright 2026, James M. Atkinson

unobserved scanning gaps or a failure of the receiver to capture samples. A precise conclusion specifies that no qualifying display features were observed under a declared acquisition-and-detection policy. A broader assurance requires quantified coverage, characterisation of the relevant signal classes and an honest account of what would have escaped detection. A spectacularly high sample rate cannot by itself compensate for a narrow instantaneous bandwidth or missed acquisition intervals.

Consider equally the positive report. A bright trace does not identify a unique transmitter. An apparent burst count may depend upon window overlap and event grouping. Its apparent duration may reflect the time assigned to a peak-held row rather than the physical on-time of the source. Its apparent bandwidth may reflect a window's main lobe and leakage rather than the transmitted modulation alone. A reliable positive finding therefore proceeds from the preserved record through a reproducible analysis toward a bounded physical claim, with independent corroboration when attribution is sought.

The ten applications which follow are designed to separate simple arithmetic from the more demanding assumptions on which interpretation rests. A fourfold increase in FFT-bin count by padding is easy to calculate; whether the data can resolve two emitters depends upon the actual observation interval and estimator. A one-millisecond pulse spread across a one-second mean is easy to quantify; whether an operator should use mean or peak aggregation depends upon the detection objective. A time tag offset of a millisecond can be insignificant for one survey and decisive for a cross-instrument event comparison. Mathematical exactness is indispensable but does not excuse errors in defining the quantity being calculated.

Copyright 2026, James M. Atkinson

I therefore close this examination of the waterfall record with a rule fit for every advanced receiver laboratory: never allow the elegance of a representation to exceed the evidence supporting its interpretation. The original acquisition, the numerical transform, the visual display and the final inference must remain distinguishable and traceable. We have developed an account of what an instrument can measure, what an algorithm can show, and what a responsible examiner may properly say. Those distinctions also govern the earlier discussions of clock discipline, multisite observation and source localisation, where the accuracy of timing references may be far less secure than a persuasive display suggests. I thank each colleague for yielding and receiving the token with the careful courtesy appropriate to scientific disagreement.

Ten worked engineering applications | Question 050

Application 1. FFT grid spacing versus analysis duration. Let f_s = 2.4 x 10^6 complex samples/s denote sample rate and N = 4096 the number of actual samples in a transform. The FFT bin interval is $\Delta f = f_s/N$ = 2,400,000/4096 = 585.9375 Hz. The window duration is $T_w = N/f_s$ = 4096/2,400,000 = 0.00170667 s, or approximately 1.707 ms. A displayed bin separation of 585.94 Hz does not alone establish the ability to resolve two nearby emitters; the chosen window and signal conditions also matter.

Application 2. Zero padding without added physical observation. Retain the same N = 4096 measured samples at f_s = 2.4 MHz, but append zeros to obtain an N_{FFT} = 16384-point transform. The new plotted bin interval is $\Delta f_{plot} = f_s/N_{FFT}$ = 2,400,000/16,384 = 146.484375 Hz. The physical observation duration remains 4096/2,400,000 = 1.707 ms. The grid is four times denser, but the observation carries no fourfold increase in independent frequency information. Zero padding can interpolate a spectral peak under a suitable model; it cannot recover an unrecorded interval.

Application 3. Overlap and distinct events. Suppose an FFT frame contains N = 4096 samples at f_s = 2.4 MHz, and the hop is H = 1024 samples. The nominal overlap fraction is (N-H)/N = (4096-1024)/4096 = 0.75, or 75%. Adjacent frame starts differ by H/f_s = 1024/2,400,000 = 0.000426667 s, or approximately 0.427 ms. One millisecond-long emission may influence several adjacent rows. Those rows are correlated

Copyright 2026, James M. Atkinson

summaries of overlapping input samples, not automatically separate transmissions or independent confirmations.

Application 4. Colour quantisation of a decibel scale. Let a renderer span L_{min} = -110 dBm to L_{max} = -30 dBm using 256 nominal evenly spaced colour levels. The total range is $R = L_{max} - L_{min}$ = 80 dB. If both endpoints are represented exactly, the nominal step between 256 level centres is $R/(256-1) = 80/255 = 0.3137$ dB. This number describes ideal uniform graphical quantisation, not instrument measurement accuracy. Actual palettes may be nonlinear or clipped, and power estimates carry calibration and estimator uncertainty independent of colour quantisation.

Application 5. Maximum aggregation hides duration. Suppose 1000 consecutive spectrum frames describe one second of genuine continuous acquisition, and only one frame contains a short strong pulse. If the software creates one waterfall row by taking a maximum over the 1000 frames, that row retains the pulse's high level. Its vertical height may correspond to one display second, yet the burst was present during no more than the particular short constituent frame. Without per-frame timestamps or raw samples, a reader cannot infer a one-second transmission from the bright row. Peak aggregation answers whether a large value occurred, not how long it lasted. For N = 1000 equally spaced frames spanning T = 1 s, each frame covers $\Delta t = T/N = 0.001$ s. One affected frame therefore supports millisecond-scale occupancy only, subject to its acquisition window and trigger resolution.

Application 6. Power averaging dilutes a short pulse. Let a signal transmit at on-state power P_{on} for b = 0.001 s within an interval T =

Copyright 2026, James M. Atkinson

1.000 s, with negligible power otherwise. The duty fraction is $d = b/T = 0.001$. The time-averaged contribution is $P_{avg} = d P_{on}$. In decibels, the difference is $10 \log_{10}(P_{avg}/P_{on}) = 10 \log_{10}(0.001) = -30$ dB. The thirty-decibel reduction is a consequence of averaging over silence, not a physical reduction in the signal's on-state power. Noise-floor and receiver response effects would modify an actual measurement.

Application 7. Temporal coverage with processing dead time. A monitoring instrument acquires a channel for $a = 0.015$ s, then cannot acquire relevant samples for $g = 0.085$ s, in a repeating 0.100 s cycle. Nominal coverage is $a/(a+g) = 0.015/0.100 = 15\%$. A randomly timed effectively instantaneous event has approximately a 15% opportunity to fall in an acquisition interval under ideal uniformly random phase and perfect sensitivity. A continuous-looking graphical update does not remove the 85% physical acquisition gap. The probability changes for finite bursts and nonuniform timing.

Application 8. Time tag semantics. Suppose an FFT uses $N = 8192$ real or complex samples at $f_s = 4{,}000{,}000$ samples/s. Its duration is $T_w = N/f_s = 8192/4{,}000{,}000 = 0.002048$ s, or 2.048 ms. If a plot labels the first sample time but a reader interprets the label as the centre of a symmetric window, the nominal centre discrepancy is $T_w/2 = 1.024$ ms. This is not necessarily the timing error of a detected pulse; precise estimation depends on its location and algorithm. It shows why time tag conventions must be recorded before comparing receiver events with external evidence.

Application 9. A clock-rate mismatch over a long capture. Let the receiver's assumed sample-clock rate be $f_0 = 10{,}000{,}000$ samples/s.

Copyright 2026, James M. Atkinson

Suppose its actual clock is higher by epsilon = 2 parts per million, so $f_{actual} = f_0(1+2 \times 10^{-6})$. If 600 seconds of actual samples are labelled using the nominal rate, the implied time-axis discrepancy at the end is approximately $600 \times 2 \times 10^{-6} = 0.0012$ s, or 1.2 ms, with sign depending on which axis is taken as reference. Clock error affects event alignment even when every waterfall row appears regularly spaced. Exact conversion must use the actual sample count and calibrated rates.

Application 10. Frequency pixel aggregation and simultaneous inference. Let $N_f = 8192$ spectral values be mapped into $W = 1024$ horizontal pixel columns. On average there are $N_f/W = 8$ spectral values per pixel. If the renderer uses maximum aggregation, the pixel reports the largest of those eight values, not their mean. If one plotted time row also takes per-bin maxima over 100 FFT frames, different frequency pixels may originate from different source times. Thus a colourful horizontal stripe can represent 8-to-1 frequency selection and up to 100-to-1 temporal aggregation without establishing simultaneous emission across the band. The actual implementation may distribute bins unevenly and requires the renderer's mapping log for reconstruction.

QUESTION 051

Copyright 2026, James M. Atkinson

When must RF arrival time be separated from a software timestamp at the host?

EDITORIAL CONVENTION: Original constructed educational dialogue moderated by Dr. James M. Atkinson. Historical contributors are used as intellectually situated analytical voices, not as actual participants in a later conversation or as sources of authentic quotations. References to modern SDR architectures, network protocols and software systems represent present-day editorial applications of their historically documented work. Every numerical example is hypothetical. All observational claims are conditional on declared instrument characteristics.

Dr. James M. Atkinson. Opening of Question 051

Distinguished colleagues, the problem before us begins with an apparently modest entry in a computer log. A screen displays the instant at which a receiver detected a brief emission, and the line appears to carry the precision of a metrological observation. Yet the timestamp may identify the moment a software routine copied an event record into memory, not the moment electromagnetic energy reached the receiving antenna. Between those occurrences lies a chain of physical propagation, analogue transformation, digital sampling, buffer allocation, device transfer, scheduler activity, clock conversion and file-system work. Every link has a chronology, and none acquires the chronology of its neighbour merely because the application presents one attractive number. A correctly synchronised host clock can state the host's time accurately while recording the wrong physical event.

The word *arrival* requires its own reference plane. An electromagnetic wave may intersect a defined antenna phase centre at time t_A. A voltage related to that field is then delivered through a feed line, filters, amplifiers

Copyright 2026, James M. Atkinson

and frequency conversion stages before an ADC samples the signal at some time t_S. Thereafter samples may enter programmable logic, cross a direct-memory-access boundary, join a ring buffer and wait for an application thread. The host may generate an indication at time t_H. The three quantities, t_A, t_S and t_H, are not interchangeable. If we assign t_H to the antenna event without knowing the intervening delay, the reported absolute time is potentially biased. If that delay varies with load, the reported time also carries jitter which an ordinarily stable RF source cannot explain. Importantly, a zero-delay assumption is itself a substantive measurement assumption and must appear in the uncertainty budget rather than conceal itself as a software default.

An appropriate measurement equation would distinguish known or estimated terms: $t_H = t_A + \tau_{prop} + \tau_{RF} + \tau_{acq} + \tau_{buf} + \tau_{host} + \varepsilon$, where τ_{prop} denotes propagation from a declared external reference to the antenna, τ_{RF} the group delay of the relevant analogue and digital front end, τ_{acq} the offset between the effective RF event and the chosen sample event, τ_{buf} the buffering and transfer delay, τ_{host} subsequent system and logging delay, and ε unmodelled error. Several of these quantities depend on frequency, receiver state or measurement definition; some are not independent. Conversely, if an acquisition unit records a hardware-anchored sample counter and trustworthy epoch reference, the chronology may be reconstructed from the sample index even when the host prints the event many seconds later. The document must say whether its time value was measured, calculated, inferred or simply copied from an application clock.

This question has a distinct bearing upon technical surveillance countermeasures. A narrow emission found simultaneously in two recorders

Copyright 2026, James M. Atkinson

might be used to suggest common origin, localisation or response to a controlled stimulus. An apparent delay of microseconds is physically meaningful only when the receiver chain is characterised at a comparable scale. A millisecond scheduling disturbance can dwarf the geometric delay across an ordinary building. Conversely, a continuously retained IQ stream can establish relative event order without providing trustworthy absolute UTC time. A well-founded chronology therefore requires two compatible descriptions: internal sample order and the means of relating that order to an external epoch. We must not inflate either description into the other.

I propose five complementary examinations. Dr David Lennox Mills will address clock synchronisation, protocol delay and the limitations of host time. Dr Edsger Wybe Dijkstra will examine the concurrent software system through which samples move. Dr Richard Wesley Hamming will test what digital signal analysis can and cannot establish about onset time. Dr Harry Nyquist will identify the distinction between sampling instants, timebase errors and analogue reception. Rear Admiral Grace Brewster Murray Hopper will close the principal discussion with software traceability, reproducibility and the evidential record. Seven colleagues will press specific objections, and each answer shall immediately follow its question. We shall conclude with a measurable acceptance test rather than a rhetorical assertion of accuracy. Dr Mills, I ask you to consider why an excellent network clock may nevertheless be a poor witness to the instant of RF arrival.

Copyright 2026, James M. Atkinson

David Lennox Mills

Dr Atkinson, the clock carried by an operating system has a real and essential purpose, but one must distinguish agreement between clocks from agreement between a clock reading and a physical occurrence. A synchronisation protocol exchanges information about selected transmit and receive events and estimates the relation of one clock to another. It does not, without further instrumentation, identify the time at which a voltage edge entered an arbitrary SDR front end. A software timestamp obtained in user space may occur after an interrupt is serviced, a packet is copied, a buffer is delivered and a thread is scheduled. Agreement of that clock with UTC, even to a fraction of a millisecond, leaves those intervals untouched. I would begin by drawing two axes: the clock's relationship to an external time standard and the measurement chain's relationship to the phenomenon. They are connected only by an observed or validated conversion.

The four-timestamp method familiar from network synchronisation illustrates the distinction. In the conventional exchange a client transmits at T1, a server receives at T2, the server responds at T3 and the client receives at T4. The offset estimate is $\theta = [(T2 - T1) + (T3 - T4)]/2$, while the round-trip delay estimate is $\delta = (T4 - T1) - (T3 - T2)$. Both calculations require assumptions about the meaning and placement of the timestamps. If transit is asymmetric, the inferred offset may be biased even when the arithmetic is flawless. If timestamps are generated after a variable software delay, they include that delay in the quantity being estimated. A receiver investigator who merely reads a host clock disciplined by such a protocol inherits its clock uncertainty and subsequently adds the SDR's own acquisition and

Copyright 2026, James M. Atkinson

processing uncertainty. Those are two separate budgets, not one number borrowed from the synchronisation display.

Contemporary network equipment may capture timestamps in a network interface or physical layer close to packet departure or arrival. Such hardware timestamping can reduce the variability introduced by software scheduling. However, a network interface's timestamp is still a timestamp of a network event, not automatically of an RF waveform crossing the antenna reference plane. The same distinction persists for a programmable receiver. Its FPGA may assert a counter value when an ADC sample crosses a hardware boundary; the utility of that value depends on the counter clock, its phase relation to the ADC, sample loss detection and knowledge of the analogue path preceding it. The instrument may provide a reliable local event index yet possess uncertain alignment to civil time.

A rigorous record should carry at least a sample-counter anchor, a declared clock domain, the time scale used for any epoch, the clock synchronisation state and the uncertainty in linking the anchor to that epoch. It should also preserve whether clock corrections were stepped or slewed. A host that changes its civil-time representation while samples continue arriving can yield apparently reversed timestamps or sudden gaps if software treats wall-clock time as a monotonic sample clock. An application may log the correction without correcting earlier events, or may rewrite historical display times under a revised offset. Either behaviour deserves disclosure. The physical samples do not travel backwards merely because a computer clock is adjusted.

Suppose an SDR acquires at two million complex samples per second and associates sample number zero with a properly captured hardware epoch.

Copyright 2026, James M. Atkinson

Sample forty-eight thousand occurs twenty-four milliseconds after that anchor, assuming the sample clock's mean frequency is exactly the stated value over the interval. A separate host log might be written twenty-nine milliseconds after the anchor. Subtracting the sample-derived interval from the host time provides an estimate of five milliseconds of cumulative latency for that observed event, provided the epoch paths share a legitimate reference. It does not prove that every subsequent event suffers exactly five milliseconds. A software transfer can be queued, a buffer can be resized and an operating-system interrupt can be delayed. One must study the distribution, its tails and its dependence on receiver configuration.

It is also useful to distinguish time accuracy, frequency stability, resolution and integrity. A clock can display nanosecond digits while possessing millisecond uncertainty; its resolution is finer than its defensible accuracy. A disciplined oscillator can hold excellent average frequency while undergoing an unrecorded phase step. A system may offer accurate ordinary timestamps while failing during a reference loss, leap-second transition, power interruption or holdover interval. These events must not be disguised by a single nominal specification. A confidence statement should be bounded to the exact reference state in which calibration occurred and should account for the period of the observation.

My recommendation is to make the measurement claim two-stage. First report the hardware sample chronology with its continuity evidence, including buffer sequence numbers and any missing-sample flags. Then report the mapping from that chronology to the external epoch, explicitly stating time standard, reference path, latency corrections and uncertainty. Where only host timestamps are available, label the value as the host's

Copyright 2026, James M. Atkinson

observation or logging time and refrain from retroactively calling it RF arrival. The resulting record is not weaker because it carries a qualification. It is stronger because the reader can distinguish a mathematical relationship that was tested from a timing assumption that remains provisional. I thank Dr Atkinson and invite Professor Kolmogorov to challenge the use of probabilistic models for the intermittent delay distribution.

Andrey Nikolaevich Kolmogorov

Peer question 1 to David Lennox Mills

Dr Mills, you distinguish synchronisation error from acquisition latency with admirable clarity, but your proposal to characterise the distribution of delay introduces a question of statistical population. Consider a host in which the overwhelming majority of buffers arrive within five milliseconds, while rare storage flushes or interrupt storms delay delivery by hundreds of milliseconds. An investigator collects ten thousand ordinary buffers and obtains a narrow histogram. That chart may look authoritative while excluding the very operating state in which the questioned event was captured. Moreover, the observed buffers may share a common scheduler regime, so treating them as independent repetitions will exaggerate the information. How would you bound the probability of a missed extreme delay without silently imposing a light-tailed probability law? Would you accept a direct hardware marker as an alternative, and how would you disclose those operating states that were not successfully exercised? If a small number of delayed transfers are themselves missing from the saved telemetry because the logging subsystem failed under stress, the empirical distribution would also be

Copyright 2026, James M. Atkinson

censored. How would your reporting method disclose such incomplete ascertainment, rather than quietly counting only those delays which software happened to record?

David Lennox Mills

Immediate answer to Andrey Nikolaevich Kolmogorov

Professor Kolmogorov, I would not infer a universal tail bound from a convenient run of quiet-host observations. The first obligation is to define the exposure: which processor loads, transfer modes, driver revisions, buffer depths, storage states and receiver gain configurations were represented? An empirical distribution is descriptive of those conditions. Treating it as a prediction for unobserved stressed conditions requires additional assumptions. A count of ten thousand deliveries may be valuable for estimating ordinary latency, but not for demonstrating that a rare hundred-millisecond delay is impossible. A zero count of a type of failure does not establish a zero failure probability.

For a forensic timing claim, I would prefer a direct physical marker that enters the acquisition stream at a declared reference point, coupled to an independently observed epoch. This can turn some uncertain software delays into quantities that are irrelevant to event time, because the physical marker and the questioned signal share the same recorded sample chronology. The design should still test for dropped samples and counter discontinuities, and must characterise any skew between the marker injection and the analogue signal path. A direct marker is not magic; it moves the calibration question to an earlier, more observable reference boundary.

Copyright 2026, James M. Atkinson

Where host time must be used, adopt deliberate stress experiments rather than relying upon random operating history. Apply processor and storage load, interrupt activity, receiver retuning and buffer saturation separately; preserve the raw timing measurements, not just their average. Report observed maxima as maxima of a specified trial, not as mathematical worst-case bounds. If a formal bound is wanted, define the model that produces it, state a confidence or coverage method appropriate to temporal dependence, and supply evidence for the assumptions. One may use quantiles or empirical extreme-value descriptions for exploration, but no such statistic warrants asserting an absolute limit on an adaptive or insufficiently observed operating system.

I would additionally protect the primary log from post hoc selection. A system which saves only events that exceeded a conveniently set threshold may contain a latency distribution conditioned on that trigger, and the resulting records cannot be treated as a random sample of all buffers. The number and timing of invalid acquisition intervals must remain visible. Calibration also needs separate acceptance criteria for ordinary operation and for disturbances; a system may pass one and fail the other. My conclusion is conditional and practical: direct acquisition-side timing is the preferred evidential basis; host timing may be used for a bounded proposition where the stated exposure, delay model and uncertainty permit it. I return the question to the moderator and invite Professor Jeffreys to test the logical leap from repeatability to accuracy.

Copyright 2026, James M. Atkinson

Sir Harold Jeffreys

Peer question 2 to David Lennox Mills

Dr Mills, imagine two acquisition systems which produce nearly identical host timestamps during a common injection trial. Their agreement may be highly repeatable, and a designer may call the result corroboration. Yet both systems could rely upon the same operating-system clock, the same trigger code or an incorrectly located physical calibration point. A shared latency would disappear in the difference while surviving in each asserted arrival time. From the standpoint of competing explanations, what observation would establish whether such agreement represents real temporal accuracy or a common systematic error? Should an investigator preserve a hierarchy of hypotheses, including clock bias, front-end delay, software timestamp placement and an actual propagation difference? I should also like you to distinguish the evidence required for absolute UTC accuracy from that required merely to rank the events chronologically within one recorder. A common external clock may likewise impart a systematic offset to both receivers, so apparent agreement could reflect common mode rather than independent validation. Please identify the independent physical reference that could expose this error without relying on the same network assumptions already under examination.

David Lennox Mills

Immediate answer to Sir Harold Jeffreys

Sir Harold, a pair of agreeing outputs provides evidence only about the relation between those outputs, until we identify the reference against which they are compared. Two instruments sharing the same

Copyright 2026, James M. Atkinson

mistaken epoch can agree to the last displayed digit and still misdate a physical event. A meaningful challenge must therefore change something that distinguishes the competing explanations. Compare an RF injection measured at the antenna reference plane with a separate hardware timestamp traceable through another path. Repeat with deliberately altered buffering, host load and clock synchronisation while keeping the physical injection fixed. If the reported time moves when the buffer depth changes, the software-timestamp hypothesis gains support. If it changes when the analogue filter is substituted, the front-end group-delay hypothesis deserves attention. If both systems shift together when their common reference changes, agreement alone has not provided independent corroboration.

I would not force all timing claims into the most demanding absolute-time standard. Within one continuous, uncompromised sample stream, the ordering of two event indices may be robust even though UTC mapping is uncertain. Their separation can be computed from the sample-index difference and the measured sample rate; its error then concerns clock rate, event-picking uncertainty and potential sample loss, not necessarily the host's absolute offset. A conclusion about whether an event preceded a door opening recorded in a separate system requires a cross-domain epoch relation. A conclusion about which of two RF bursts appeared first within one acquisition may require less, provided the same filter's delay and reference state apply to both.

Copyright 2026, James M. Atkinson

A report should therefore display a claim ladder. At the first level, there is an observed sequence of stored samples. At the second, the chronology of features extracted from those samples under a specified detector. At the third, a mapping from acquisition samples to an external epoch. At the fourth, comparison with independently clocked observations or a physical localisation model. Each step adds uncertainty and possible dependence, and none can be skipped by presenting a neat timestamp string. When the data support only the first two levels, the report should remain there without apology.

For each experiment I would preserve the rival predictions before the results are evaluated. Under a constant analogue delay, a filter replacement changes the apparent acquisition timestamp by a predictable amount; under a host-queue delay, changing the host load changes the logging time but not the sample-counter anchor; under a network offset fault, the displayed wall time shifts without altering the raw relative sample positions. Such separable predictions make the argument falsifiable. They also reveal when two explanations cannot be distinguished by the available instrument. My answer is that corroboration requires an independently placed reference and a discriminating intervention, not merely two similar numbers. I pass the discussion to Dr Atkinson and then to Dr Dijkstra, whose treatment of concurrency should clarify why a program's apparent order may differ from physical acquisition order.

Copyright 2026, James M. Atkinson

Edsger Wybe Dijkstra

Dr Atkinson, one of the most pernicious confusions in a concurrent acquisition system is to mistake the point at which a process becomes aware of an event for the point at which the event occurred. A well-formed program may be logically correct according to its specification while the specification quietly defines the wrong clock boundary. An interrupt handler is invoked after a hardware condition is asserted, but its execution is subject to priorities, masks and competing work. A user-space application may awaken only when a buffer or queue crosses a threshold. The resulting timestamp is an observation of software execution unless the data include an earlier hardware-anchored timing record. It may be consistent and entirely unsuitable for the physical claim imposed upon it.

I would begin with an explicit model of causality rather than a line of clock readings. The ADC samples the analogue waveform. A hardware controller commits those samples to a buffer. A bus transfer makes a descriptor visible to a driver. A driver informs an application, which processes and eventually writes a record. These operations are partially ordered by data dependence, yet their delays need not be constant. Modern CPUs may reorder certain operations subject to memory-order constraints; drivers may batch notifications; applications may share locks; and the file system may defer physical storage. The mere fact that a log entry appears after another entry does not prove that its associated RF event happened later. The definition of the chronological object must precede its logging implementation.

Consider a two-buffer acquisition. The sampling clock fills one block while software handles the preceding block. If each block holds 8192 complex

Copyright 2026, James M. Atkinson

samples at two million samples per second, acquisition of one block takes 4.096 milliseconds. A timestamp obtained when the block becomes available might represent its completion boundary, while a timestamp attached to a processing routine could occur still later. Assigning that one timestamp to the first sample introduces a nominal block-position error of 4.096 milliseconds even before queue latency. Assigning it to an event at an unknown position within the block creates an interval uncertainty bounded by the block duration only if the block indices and trigger placement are faithfully retained. Such errors are not repaired by a faster wall clock.

A correct design gives the samples a sequence identity independent of the host's handling of the sequence. Let block b contain samples $n = bN$ through $(b+1)N-1$, where N is the documented block size. If one knows the acquisition epoch associated with sample n_0 and the effective rate f_s, the computed time of sample n is $t(n) = t_0 + (n-n_0)/f_s$, before relevant cable, filter and detection corrections. Every processing routine should carry that identity rather than generate a new physical timestamp. Monotonic counters, overflow markers and sample-count checks are more useful than inferring continuity from file length. A purportedly seamless recording that silently loses one buffer shifts every later sample-to-time mapping if the software merely concatenates surviving bytes.

The investigator should distrust an implementation which cannot state whether its timestamp was assigned before or after a queue operation. Consider the familiar distinction between event-time and processing-time in data systems. The former belongs to a defined acquisition boundary; the latter to a stage of computation. In some applications processing time is exactly what the investigator wants, such as establishing when an alarm was

Copyright 2026, James M. Atkinson

presented to an operator. But it must not be renamed event time by an attractive display. A forensic report may legitimately show both: event at ADC sample index 3,400,000; alarm issued by the application at a later host timestamp. That paired account enables reconstruction of detection latency without contaminating the time of the underlying RF observation.

Concurrency introduces a second hazard: correlations between the observable delay and the phenomenon. A strong signal may trigger computationally expensive demodulation and therefore delay its own log record. High event density may increase queue occupancy, making later events appear still later. A filtering algorithm may examine a block of future samples before declaring an earlier event; its decision timestamp belongs to the completed calculation while the assigned event time should refer to the feature's independently specified position in the input. The distortion is then signal-dependent, not an additive constant. A single calibration performed with a simple calibration pulse may underestimate the latency experienced by complex or numerous events.

I would make the acceptance protocol adversarial in the engineering sense. Flood the processing queue without changing the RF injection schedule. Change buffer sizes while maintaining the acquisition clock. Induce a controlled driver restart, retune, sample-counter rollover and clock adjustment. The correct sample-derived event times should remain stable within declared tolerances, or a continuity fault should be explicitly recorded; meanwhile host processing and alarm times may change. An exception that silently supplies plausible output is more dangerous than a conspicuous refusal to issue a timestamp. The design should be capable of

Copyright 2026, James M. Atkinson

saying: *I do not know the epoch for this span*. That is a legitimate, and often necessary, state of a truthful measurement system.

Finally, reproducibility requires a precise interface contract. Define the semantics of every clock field, the conditions under which the value is valid, its resolution, units, wrap behaviour, clock corrections and calibration dependencies. Treat software versions and firmware hashes as part of the experiment. A later implementation with an unchanged display but changed buffering policy is not automatically equivalent to the previous one. A well-specified timing system should permit another competent engineer to rederive the event times from the preserved sample counters and anchors without relying upon the original graphical interface. I invite Mr Hewlett to examine the boundary between the hardware instrument and its software representation.

William Redington Hewlett

Peer question 3 to Edsger Wybe Dijkstra

Dr Dijkstra, the separation between event-time and processing-time is persuasive, but a designer may object that a hardware timestamp adds circuitry, complexity and potential new failure modes. Suppose a receiver supplies a free-running sample counter without a stable epoch, while a host keeps excellent time through an independently validated reference. Could carefully measured and repeated transfer latency establish a defensible mapping between the two clocks? Under what circumstances would the inexpensive architecture be adequate for a monitoring mission, and when would it be scientifically irresponsible to claim microsecond arrival times? I am particularly interested in hardware interface delays, retuning sequences and whether the clock-domain

Copyright 2026, James M. Atkinson

crossing itself becomes a source of uncertainty that cannot be removed by simply averaging more host timestamps. Suppose further that an application treats the timestamp of the most recently completed transfer as the acquisition epoch for the next one. This would create a deterministic lag even when the driver never loses a byte. What test would distinguish that implementation error from true sampling-clock drift?

Edsger Wybe Dijkstra

Immediate answer to William Redington Hewlett

Mr Hewlett, an architecture should be judged by the measurement claim it can support, not by whether one of its subsystems appears sophisticated. A free-running sample counter and a well-maintained host clock can be sufficient for many practical conclusions. They may establish the relative ordering of bursts and, with a measured sample-rate uncertainty, the separation between them. If the desired absolute time tolerance is loose compared with the observed distribution of transfer and scheduling latency, a calibrated host mapping may be useful. Yet the uncertainty statement must include the latency's systematic component, its dependence on operating state and the clock-domain translation. Averaging repeated transfers reduces uncertainty in the average only under a suitable stochastic model. It does not remove a fixed bias or an untested shift after a driver update.

The clock-domain crossing deserves a first-class place in the interface specification. An asynchronous event transferred into a synchronous counter domain may be observed on one of

Copyright 2026, James M. Atkinson

neighbouring clock edges; a synchroniser reduces metastability risk but can add finite, occasionally state-dependent latency. A sampled hardware flag may identify an event only to the resolution of a specified clock period. If an FPGA associates a sample counter with the ADC data path, its interpretation must be stated relative to the actual ADC aperture and data pipeline. These costs are often far smaller and more controllable than those of user-space scheduling, but they should still be measured rather than assumed away.

Retuning is particularly important. A synthesiser may temporarily lose lock, a front-end filter may change group delay, and an SDR driver may flush queued samples before accepting new ones. Even when the sample counter continues monotonically, its relation to the RF input may be invalid during such a transition. The correct response is to record the transition as a stateful measurement interval, perhaps with a validity mask, rather than to imply that continuity of counting proves continuity of observation. Where a receiver is not continuously observing the intended channel, a precise timestamp of what it did record cannot establish what occurred in the unobserved interval.

I would use a graded acceptance criterion. For minute-scale occupancy comparisons, the controlled host mapping may be adequate if the clock's drift, queue effects and acquisition coverage are bounded at a much smaller scale. For distinguishing two events separated by tens of microseconds, an architecture with millisecond transfer variability is inadequate absent a hardware sample chronology that removes that variability from the estimate. For time-difference localisation, both physical reference planes and every

Copyright 2026, James M. Atkinson

differential timing error become critical; the tolerance should follow the geometric accuracy required, not the software clock's number of digits.

Thus I do not insist upon one universal hardware design. I insist upon an explicit contract showing exactly which physical event a timestamp names, together with tests that can expose a false claim. A low-cost instrument may be excellent if its conclusions remain within its demonstrated capability. A costly instrument may be misleading if it labels the host's callback time as the instant energy reached the antenna. Thank you for the challenge, Mr Hewlett. I pass the discussion to Dr Hamming to examine the time introduced not by scheduling but by the signal-processing algorithm itself.

Copyright 2026, James M. Atkinson

Richard Wesley Hamming

Dr Atkinson, an investigator who asks for the time of a received pulse must first identify what feature of the waveform is intended by that word. The first nonzero sample, the crossing of a threshold, the maximum of a filtered envelope, the centre of an energy distribution and the estimated arrival parameter in a fitted signal model can occur at different times. Their differences are not necessarily instrumentation failures. They follow from the detection rule and the properties of the signal. One may faithfully sample a bandlimited waveform and still obtain a biased event time if the algorithm assigns a peak position without accounting for its filter, detection window or search procedure. I should therefore separate the acquisition clock from the estimator and ask what property each makes observable.

A conventional finite-impulse-response filter forms an output by combining present and earlier input samples. A linear-phase FIR filter of length L has constant nominal group delay (L−1)/(2f_s) seconds where f_s is the sample rate, provided we are describing the relevant passband and the ideal linear-phase operation. For an odd-length 75-tap filter at four million samples per second, the delay is 37/4,000,000 seconds, or 9.25 microseconds. The output may emerge later than the input feature in the indexed data even if the host processes every sample instantly. A real analogue front end may contribute additional frequency-dependent group delay. A zero-phase filter applied offline may appear to remove the delay in a plot, but its use of future samples means the resulting estimate is not a causal real-time detection and cannot be treated as such.

Time of arrival is often an estimation problem rather than a timestamp-reading problem. Let a known reference waveform s(t) arrive with unknown

Copyright 2026, James M. Atkinson

delay τ and amplitude a in additive noise. One can compare the recorded samples with shifted versions of s and estimate τ by the delay maximising a suitable likelihood or correlation criterion. Under stipulated noise and waveform assumptions, the estimator may perform well. But an unknown signal shape, clock mismatch, multipath, clipping or band limitation changes the inference. The peak of a correlation output is a property of the data and the assumed template. It does not certify a unique physical emitter, a single propagation path or a correct antenna epoch. Detection and attribution must be kept apart.

The sampling theorem should be applied carefully here. Sampling at frequency f_s establishes observations at intervals $T_s = 1/f_s$ in the selected sampling clock domain. It does not imply that every event's arrival is known only to one whole sample, because interpolation or model fitting may estimate a fractional-sample offset under appropriate bandwidth, signal-to-noise ratio and model assumptions. Equally, it does not entitle the engineer to report infinitely fine timing precision merely because interpolation can produce many decimal places. A fitted fractional delay inherits uncertainty from noise, bandwidth, template mismatch and clock calibration. A rate error of two parts per million over forty seconds accumulates an eighty-microsecond time-scale error if uncorrected. Such a bias can exceed the nominal fractional-sample precision by orders of magnitude.

The digital boundary may move with instrument configuration. A channeliser, decimator or resampler can change the mapping between input sample indices and output indices. If the output rate is $f_{out} = f_{in}/M$ for integer decimation M, the output's position cannot be translated into physical acquisition time without retaining the filter delay and the phase of

Copyright 2026, James M. Atkinson

the decimator. Some samples are discarded because their contribution has been represented in the filtered output; that is not the same event as accidental loss of an input sample or a broken chronology. An acquisition record ought to preserve the transform graph and its initial states, so that a later examiner can identify precisely which input interval contributed to a reported decision.

I would also require the detector's triggering rules to be documented. A rising-edge threshold may fire earlier for a large-amplitude pulse than for an otherwise identical weak pulse, a phenomenon often called time walk. A detector that integrates over a fixed block reports the interval within which the evidence accumulated, not necessarily the start of a brief event. An FFT-based transient detector may create a timestamp at the middle of a window, at its beginning or at the time a window is complete. All three can be legitimate bookkeeping conventions, but they differ and must not be mistaken for a physical observation in the absence of calibration. We should test each with a controlled injected waveform whose onset and spectral content are known at the stated reference plane.

For an investigative report I would preserve both a raw input chronology and a method-specific feature chronology. The raw record includes sample rate, counter continuity, acquisition epoch and instrument state. The derived event record includes the detector, its filter coefficients, analysis window, threshold, interpolation method and time-origin convention. If an independent analyst changes the detector, the derived event time may change, while the raw sample chronology remains a common basis for comparison. That is not necessarily a contradiction: two methods may estimate different features. The report should declare which physical

Copyright 2026, James M. Atkinson

question was asked. Was the examiner seeking the earliest measurable arrival, a representative centre, or the peak of a standardised reference waveform? These propositions have different uncertainty budgets.

Finally, let us not use a computationally impressive plot to conceal the location of the measurement. A signal-to-noise improvement through matched filtering may make a weak feature more detectable and allow better delay estimation under the model, but it cannot recover information never admitted by the analogue front end. If the receiver sampled an aliased or clipped representation, the filter may produce a clean-looking response to an erroneous observation. The decisive challenge is to vary the physical injection delay by known increments and verify that the estimated event time follows those increments within a stated uncertainty, across realistic signal strengths, receiver states and interferers. I pass the floor first to Professor Gabor, whose work on time-frequency representation provides a useful warning about the meaning of a plotted event centre.

Dennis Gabor

Peer question 4 to Richard Wesley Hamming

Dr Hamming, your distinctions are persuasive, but an investigator may ask for one timestamp from a spectrogram without possessing the reference waveform that your ideal correlation model assumes. The windowed transform assigns spectral energy to a sequence of overlapping time cells, and the time displayed for a cell may depend upon whether the software labels its leading edge, centre or final sample. A short event can colour several adjacent cells, particularly when a long window has been selected to resolve closely spaced spectral components. How would you formulate an evidential time interval from

Copyright 2026, James M. Atkinson

such a representation without implying a single objectively observed onset? If a later analyst selects a shorter window and reports a different onset, is that a measurement conflict or a predictable consequence of the representation? I ask especially how one should preserve and express the uncertainty caused by the window geometry. I also wonder whether two different amplitude thresholds should be represented as alternative measurement definitions rather than competing estimates of the same onset. Otherwise a signal-dependent time walk might be mistaken for a physical change in propagation, especially at low signal-to-noise ratios.

Richard Wesley Hamming

Immediate answer to Dennis Gabor

Professor Gabor, the time coordinate attached to a spectrogram cell is part of the representation's definition. If a window covers N consecutive input samples at rate f_s, its nominal duration is N/f_s seconds, and any single label must choose a convention. A centre timestamp is useful for plotting because it places a symmetric window near the middle of its support. It does not assert that energy first reached the input at that instant. If the detected feature was confined to one portion of the window, the centre can be substantially later or earlier than its onset. Spectral smoothing and leakage may colour neighbouring bins and frames, so the appearance of a coloured pixel cannot be read as a physical edge without a declared decision procedure.

I would distinguish the *support of observation* from the *estimate of onset*. The former is the interval of raw input samples that contributed

Copyright 2026, James M. Atkinson

to the visual cell, enlarged where necessary to account for filters or reconstruction windows. The latter is the output of a stated estimator that attempts to locate an event within or near that support. If the waveform is unknown and the instrument retains only magnitude spectra, the onset may be unidentifiable to a precision narrower than the observation interval. If the instrument retains the complex sample sequence, a later analyst can apply a family of onset detectors and report their sensitivity to threshold, model and noise. The revised estimate is not automatically a contradiction of the earlier display; it can be a refined claim made from richer evidence.

An example may clarify this. At f_s = 2,000,000 samples per second, a 4096-sample window spans 2.048 milliseconds. If the software labels its centre, the difference between the label and an event occurring at the earliest sample of the window is approximately 1.024 milliseconds. That is a coordinate convention, not a stochastic uncertainty. A claim that the onset is within a much narrower interval requires information from the sample data and a tested algorithm. If the window overlaps its successor by 75 per cent, the abundance of colourful frames does not create independent physical acquisitions. These frames depend heavily on common samples.

I would retain the precise window definition, hop size, sample-counter origin and the unaltered underlying IQ data where permitted. Every time coordinate should be accompanied by its convention. A forensic report might say that energy consistent with the declared detector was present in the sample interval from t1 to t2, and that a specified onset estimator returned t_hat with an uncertainty

Copyright 2026, James M. Atkinson

conditional on its validated model. The words *consistent with* matter because they acknowledge alternative interference or artefact explanations. If two models disagree, describe the disagreement and test it against known injected transients rather than averaging two incommensurable timestamps into an apparently precise number.

This approach preserves the useful distinction between frequency resolution and temporal localisation. A long transform window can improve discrimination of close spectral components while blurring the start and end of an event. A shorter window may resolve the event in time while reducing frequency selectivity. The best representation depends on which measurement question has priority. A conscientious examiner must resist allowing the visual smoothness of the display to dictate the meaning of the physical event. I return the token to Dr Atkinson and invite Sir Martin Ryle to question how these uncertainties affect observations from geographically separated receivers.

Sir Martin Ryle

Peer question 5 to Richard Wesley Hamming

Dr Hamming, consider a synchronised pair of receivers separated by a substantial distance, both observing the same brief emission and retaining their input samples. Suppose each receiver uses a different analogue preselector and a different digital decimation filter. Their software clocks are exquisitely aligned, and their spectrograms show apparently simultaneous peaks. Yet the effective group delays may differ by several microseconds, while an actual propagation difference of one microsecond would correspond to hundreds of metres of path

Copyright 2026, James M. Atkinson

difference. What would you require before interpreting the observed peak separation as evidence of geometry? Would an injection through the antenna connectors suffice, or would antenna phase centres, cable dispersion, multipath and direction-dependent response need separate treatment? I should also like to know when two apparently independent estimates share a common error source through their synchronisation system. The calibration may also depend on the direction from which the wave reaches the antenna and the frequency within its passband. Could you specify which terms are transferable across observation states, and which require a renewed calibration before the geometry is interpreted?

Richard Wesley Hamming

Immediate answer to Sir Martin Ryle

Sir Martin, the geometrical inference depends upon the difference between arrival times at declared physical reference planes, and an equality of software timestamps supplies no such guarantee. First reconstruct a time estimate in each instrument from hardware sample indices and valid clock anchors. Then correct the measured differential delays of their respective analogue filters, mixers, sample paths and event estimators. An injection at the receiver connector is useful for calibrating much of the internal chain, but it does not characterise antenna phase-centre displacement, cable lengths or the directional and frequency-dependent response of the complete receiving assembly. These must be included in the defined measurement system if the intended claim starts at the antenna.

For a simple far-field propagation argument, a one-microsecond time-difference error corresponds to roughly three hundred metres

Copyright 2026, James M. Atkinson

of differential path length in free space. This is not automatically a three-hundred-metre location error, because the geometry of intersecting arrival-time surfaces can amplify or reduce the resulting position uncertainty. It nevertheless shows why uncorrected microsecond-scale receiver delays cannot be ignored. A twenty-microsecond jitter in host logging would correspond to a six-kilometre difference in free-space path length before geometrical dilution. One ought not present a localisation derived from such a clock field as though the antenna arrival times had been observed with microsecond accuracy.

A carefully executed challenge would include both common-input and spatially defined tests. Feed a calibrated signal into each receiver through characterised injection cables, establish the relative delay of the electronic chains, and then use a known transmitter geometry to examine the assembled antenna systems. Introduce deliberate changes to one filter and then one clock source to identify whether the inferred time difference follows the predicted perturbation. Preserve the raw waveforms so that a common timing algorithm can be applied to both, and record where frequency-dependent delay corrections are evaluated. Multipath can produce multiple plausible correlation peaks, so the uncertainty statement should encompass alternative arrival paths where the data cannot resolve them.

Finally, shared clocks may create correlated error. If both receiver sample counters are disciplined by the same imperfect reference, an error common to both may cancel in a time difference, but a branch-specific delay or phase step may not. If the analysis uses absolute UTC

Copyright 2026, James M. Atkinson

events from different network paths, asymmetric delay and reference-state faults may reappear in the difference. A covariance term is warranted when uncertainties are dependent; blindly taking a root-sum-square of marginal uncertainties can give a misleading result. I would report the geometry, the calibration hierarchy, and the range of location solutions permitted by the remaining timing uncertainties. The physical claim should never exceed the measurement's actual reference-plane control. I pass the floor to Dr Nyquist for the clock and sampling perspective.

Copyright 2026, James M. Atkinson

Harry Nyquist

Dr Atkinson, our concern becomes more tractable when the engineer gives an exact definition to the sampling instant. A discrete data sequence is indexed according to the clock which controls conversion. The indices represent a succession of measurement apertures, and the interval between them is governed by the sampling timebase. They do not come pre-labelled with civil time. If the sample rate is f_s, the nominal period is $T_s = 1/f_s$, but the realised spacing contains frequency deviation, phase noise and perhaps a discontinuity from a clock reset or a lost sample. A display that assigns calendar timestamps to these indices must supply the relation between the sample clock and the chosen epoch. Without that relation, a beautiful digital sequence is internally ordered but not absolutely dated.

We should distinguish the centre of the ADC sampling aperture from an idealised instantaneous observation. In a sample-and-hold system the converter responds over a finite interval, and the aperture's precise relation to a trigger or external reference may vary. Aperture uncertainty can impair the amplitude fidelity of fast analogue signals and the timing of their sampled representation. The location of the effective sampling instant may be characterised, but should not be assumed equal to the location of a hardware trigger pin or the time a digital word is delivered by the converter. A pipeline ADC can deliver a word several clock cycles after the analogue aperture without altering the time at which the sample was physically formed. One must label the pipeline latency and avoid assigning delivery time to acquisition.

Clock frequency error is another independent quantity. Suppose an SDR uses a nominal sample frequency of four million samples per second but its

Copyright 2026, James M. Atkinson

realised rate differs by two parts per million. Over forty seconds the potential accumulated timing error relative to an ideal rate is approximately eighty microseconds, if the offset remains constant with that sign. The error does not grow because the host is slow. It grows because the conversion clock's scale differs from the reference scale. A timestamp derived from sample number n must either use the measured sample rate, track the timebase corrections or carry this drift as uncertainty. The sign and temporal behaviour of the error matter; a continuously disciplined sample clock may not have a constant offset across the interval, and a phase step can be more consequential than a slowly changing average frequency.

The analogue chain can change where an RF feature appears in the digital record. A narrow preselector may introduce dispersive delay that varies over the signal's bandwidth. The event's arrival at an antenna and the location of a pulse peak at the filter output can therefore differ in a waveform-dependent fashion. If the spectrum of a burst changes, the filter's effect on the temporal peak may change even though no physical propagation delay has changed. Inverting the estimated response may help under adequate signal-to-noise ratio and a properly identified model, but it may amplify noise and cannot recover information suppressed below the measurement system's sensitivity. The instrument's frequency response and group delay belong in the timing calibration of the relevant event class.

It is useful to have separate timing layers. At the first level, samples bear an integer index and an acquisition validity state. At the second, a clock model maps those indices into a continuous local time coordinate, possibly accounting for fractional delays and known clock drift. At the third, a measured reference relation maps the local coordinate into an external time

Copyright 2026, James M. Atkinson

scale. At the fourth, corrections place the estimated waveform event at the selected antenna or propagation reference plane. This layered method avoids the tempting, but erroneous, idea that because a receiver can label the hundred-millionth sample precisely it must know the time of its arrival in UTC equally precisely. Indexing, calibration and physical attribution are logically distinct.

A detector's latency also has two dimensions that should not be mixed. Its computational latency is the delay between the availability of sufficient input samples and the issuing of a decision. Its physical event-time bias is the difference between the declared feature's actual input time and the event time estimated from the processed data. A detector may spend a second performing offline analysis and still produce a defensible earlier event timestamp, because the underlying sample indices are retained. Conversely, an alarm generated within a millisecond may assign the wrong epoch if it mistakes callback time for a filtered pulse's onset. Speed of decision is not identical to accuracy of temporal attribution.

I would make continuity part of the reported evidence. If a 4096-sample block is missing at two million samples per second, a recording that closes the gap without a loss marker compresses the apparent time axis by 2.048 milliseconds. Later events will all appear too early relative to an unbroken sample counter. One may not repair this by resampling the surviving stream to fill the missing samples with interpolated values and then treating those as original observations. Interpolation may produce a useful display or estimation under a model, but it does not recreate the historical waveform uniquely. A gap should remain a gap in the evidential chronology.

Copyright 2026, James M. Atkinson

The decisive experiment must vary one timing factor at a time. Sweep signal bandwidth to reveal waveform-dependent filter delay, vary the sample clock under a measured reference to expose drift, change the block size to expose host-label bias, and introduce a deliberate dropped sample to test continuity detection. A valid system should either follow the predicted behaviour or declare that its timestamp is not supported under that state. The best acceptance standard is not an immaculate clock display, but a demonstrable mapping from physical input event to sample index and from sample index to the external epoch, with each uncertainty included. I respectfully invite Dr Ramsey to challenge the distinction between long-term timebase agreement and short-term phase continuity.

Norman Foster Ramsey Jr.

Peer question 6 to Harry Nyquist

Dr Nyquist, consider a receiver whose sample clock is disciplined by a highly stable frequency reference. Its measured long-term frequency error is exceptionally small, and the operator therefore asserts that every sample is accurately positioned in time. Yet a receiver may suffer a short phase step when a synthesiser reacquires lock, or an individual timestamp pulse may be transferred through a clock-domain boundary with one-cycle ambiguity. These defects can be almost invisible in an average-frequency figure. How would you frame a test which reveals them while preserving the distinction between oscillator stability, epoch accuracy and sample-clock phase? In a two-receiver comparison, under what conditions might a common reference conceal a correlated phase error instead of providing independent assurance? I should also like to know whether reporting Allan deviation alone would suffice for the

Copyright 2026, James M. Atkinson

forensic claim. If the oscillator has been steered, the instantaneous phase relationship during an individual burst may be poorly known even when the average frequency appears correct. Please address how calibration markers should bracket the event and how clock-state changes should be represented in the archived chronology.

Harry Nyquist

Immediate answer to Norman Foster Ramsey Jr.

Dr Ramsey, a good long-term average frequency is not a sufficient description of the temporal placement of every sample. Frequency stability concerns changes in the rate of phase accumulation over specified observation intervals; a sudden phase step may leave a small effect on a long-term average while corrupting the chronology around the discontinuity. A measurement intended to date short RF bursts must record or constrain the phase relationship at the moment of interest, not merely the fractional frequency averaged over hours. Allan deviation and related stability statistics provide valuable characterisation over different averaging times, but they are not a complete account of epoch alignment, discrete phase jumps or transfer-path errors. A statement of stability therefore needs separate tests of continuity and of traceability.

One approach is to distribute a reference event whose physical timing is observed independently of the receiver under test. Compare the sample counter at successive reference pulses with their independently measured epochs. Plot the residual versus time and retain the unaveraged sequence so that a phase step is not smoothed into an apparently benign drift coefficient. Then interrupt the

Copyright 2026, James M. Atkinson

reference deliberately, induce a synthesiser relock and observe whether the system flags the transition. The step magnitude, direction and duration should appear in the record. If the sample counter is reset, the mapping must explicitly identify a new segment rather than silently joining before-and-after indices.

In a two-receiver system, a common reference can reduce differential frequency error, but it also provides a common path through which faults can propagate. Suppose both instruments receive the same erroneous time pulse and their logged epochs shift together. A comparison of their timestamps may show excellent agreement while the absolute physical time is wrong. Alternatively, unequal cable lengths and distribution amplifiers can introduce branch-specific delays so that the two clocks are not even correctly aligned to each other. The calibration must characterise the common source, the distribution branches and the receiver timestamp path. When uncertainty components share a cause, the covariance should be retained rather than pretending that the two errors are independent.

I would therefore publish an observation-period-specific clock-state register. It should record the applied reference, lock status, loss-of-lock events, phase residuals, sample counter transitions and any clock steering operations. Where a discontinuity is detected, segment the record and refrain from assigning a precise absolute time across the unresolved boundary. Where the record is complete, construct the sample-to-epoch mapping from measured anchors and describe its uncertainty in each interval. A constant nominal frequency value may

Copyright 2026, James M. Atkinson

be retained as instrument metadata, but it should not silently substitute for the observed timebase history.

The practical benefit is that the investigator can defend both a positive and a limited negative finding. If the calibration proves that the phase remained within stated bounds during the relevant event, a time-difference claim may be justified. If an unrecorded reference interruption prevents the bound, a later calculation should not disguise the missing evidence with digits borrowed from an oscillator catalogue. The science concerns what the instrument actually measured. I return the token to Dr Atkinson and invite Rear Admiral Hopper to examine how the software and evidential record should retain these distinctions for subsequent reviewers.

Copyright 2026, James M. Atkinson

Grace Brewster Murray Hopper

Dr Atkinson, the most persistent danger in software-assisted measurements is that a program converts one kind of information into another without making the conversion visible to the user. A field labelled *timestamp* may carry an operating-system wall-clock read, an ADC counter value, an estimated arrival time, a processing-completion time or an exported file's creation date. Each is a legitimate datum for some purpose; none automatically answers every chronological question. The software designer's obligation is therefore not merely to store a number but to make the number's semantics reproducible. A forensic examiner should be able to ask what produced this value, which physical event it purports to describe, which transformations intervened and which software and firmware versions performed them.

I would insist upon a structured acquisition record. At a minimum, identify the receiver and channel, its tuning state, antenna and reference planes, the raw sample interval, the counter domain, the clock source and synchronisation state, the firmware version, the driver version and the mapping from sample index to the relevant epoch. Record the declared uncertainty and the calibration source in a machine-readable form. An application which offers only a formatted date and a frequency leaves too much to guesswork. Another engineer may reproduce the display yet be unable to reconstruct which sample actually supported the alarm. Good documentation must therefore preserve the chain from physical observation through digital representation to the evidential claim.

The distinction between event-time and log-time should be present in the data model rather than left to a user-interface convention. I would use

separate named fields for sample_counter, sample_epoch, sample_clock_domain, derived_event_time, host_receive_time, host_log_time and time_uncertainty, together with the provenance of each field. A null or explicitly invalid value is preferable to a plausible invented timestamp. If the host was restarted, its clock stepped, the SDR retuned, or a buffer lost, a validity flag should survive every export. A database which permits a missing time value to be replaced silently by the current time is unsuitable for primary evidence unless that behaviour is prevented and verified.

Software revisions deserve scrutiny because the same data can acquire different timestamps when the algorithm changes. A matched filter whose coefficients are modified may shift its response peak. A driver which changes its block callback behaviour may alter host latency. A graphical program which changes from beginning-of-window to centre-of-window labels may move every displayed waterfall event by a half window even though the input samples are identical. These transformations must be treated as part of the instrument's measurement function. A reproducible record includes an algorithm identifier, parameter set and versioned processing history, so that an independent examiner can apply the same operation and obtain the same output or explain a difference.

The preservation policy should distinguish raw evidence from derived material. The original IQ blocks, counter anchors, reference-state logs and discontinuity records should be protected against undetected alteration using suitable integrity controls. Derivatives such as threshold detections, time-frequency displays and revised clock mappings should be linked to that original record without replacing it. A cryptographic digest can establish that retained bytes have not changed since the digest was created, but it does

Copyright 2026, James M. Atkinson

not prove that the original measurement was accurate or that a timestamp's reference plane was correctly declared. Chain of custody governs who handled the evidence; measurement traceability governs what the evidence means. The two should support one another without being conflated.

Consider an observation in which a short burst is visible in the original samples at index 1,200,000, and the software log records an alarm some milliseconds later. If a later analyst reconstructs the event time using a corrected sample-clock model, the revised time should be stored as a new derived claim, with its method, inputs and authorisation. The original log entry should remain available for comparison. If the corrected mapping changes a previously issued report, record the change and the reason rather than silently replacing the earlier value. A system which cannot distinguish current interpretation from original observation is difficult to audit even when its numerical calculations are correct.

I would test the software by deliberately presenting it with abnormal data and operating states. Give it a counter discontinuity, an out-of-order buffer, a repeated sequence number, a timebase change and a missing calibration file. Observe whether it falsely assembles a continuous history or identifies the qualification. Feed it known traces with several near-simultaneous events and measure whether the reported ordering follows the raw sample indices rather than thread completion order. Change the display time zone and verify that the underlying epoch remains invariant. Introduce an artificial delay in file writing and demonstrate that the reported RF event time does not move if a hardware chronology is claimed. Such tests can reveal software defects that a tidy user interface conceals.

Finally, a report should explain the status of each time claim in ordinary language as well as in technical metadata. It might state: *The acquisition sample counter places the event at the recorded input interval; an independently calibrated hardware reference maps that interval to a stated time standard with the following uncertainty. The later host log is retained only to document when software registered the event.* Where no valid mapping exists, it should state that the event's absolute time is undetermined but its relative order is preserved. A carefully qualified record can be stronger evidence than an apparently exact timestamp whose acquisition origin no examiner can reconstruct. I thank Dr Atkinson and invite Dr Rabi to press the question of experimental controls and independent checks.

Isidor Isaac Rabi

Peer question 7 to Grace Brewster Murray Hopper

Rear Admiral Hopper, your proposed data model is admirably explicit, but documentation can itself become a ritual if the values entered are never challenged. A calibration file may bear an official-looking identifier while referring to a different filter configuration; a sample-counter anchor may appear in a record while the actual ADC was clocked from another source; and a software version number may be correct while an unexpected firmware image remained active. What experimental control would distinguish a well-described but incorrectly measured timestamp from a genuinely traceable arrival time? Would you require a physical test at the RF input in addition to software unit tests, and how should the result be preserved so that a later examiner can evaluate competing timing explanations without relying upon the operator's recollection? A rigorous challenge should also expose plausible failure modes rather

than merely demonstrate a successful nominal trace. Please distinguish the experiment that tests an assumed transformation from the independent evidence that the calibration stimulus genuinely reached the declared input reference plane.

Grace Brewster Murray Hopper

Immediate answer to Isidor Isaac Rabi

Dr Rabi, documentation is a necessary condition of reproducibility but not a substitute for experiment. A string identifying a calibration record is meaningful only if the calibration was actually applied to the instrument configuration used for the acquisition. I would therefore require both software tests and physical injection tests, each with a different purpose. Software tests establish that a declared transformation is implemented consistently and that invalid states are handled correctly. Physical tests establish whether the transformation corresponds to the observed instrument path. An implementation may pass every unit test for an erroneous model of filter delay; only a controlled input at the chosen reference plane exposes the discrepancy.

The physical acceptance procedure should use a time-defined stimulus whose event location is measured independently. Record the reference generator, injection cable, receiver configuration, capture epoch and analysis method. Vary the input delay in known increments and check that the reported event time follows the change. Replace one analogue filter and check that the measured timing shift agrees with its characterised group delay. Apply a host load while leaving the hardware input unchanged; if the claimed acquisition time moves

with the software workload, the result points toward a timestamp placed too late in the chain. Distinguishing tests are particularly valuable because they make rival explanations predict different outcomes.

The record of the test should be sufficient for independent reconstruction. Preserve unmodified sample blocks, counter anchors, test settings, reference-state observations, event-detection parameters and a digest of each retained primary file. Include the calibration's date, scope and limitations, not merely a serial identifier. A reviewer should be able to recompute the event time and see the effect of withholding each correction. If subtraction of a nominal group delay changes the claimed timestamp by nine microseconds, that fact should be visible alongside the evidence supporting the correction. If the front-end response varies with frequency, a single delay number must not be applied indiscriminately to all emissions.

I would also make fault behaviour an acceptance criterion. Induce a missing calibration dependency or contradictory clock anchor and require the application to flag the record rather than issue an exact event time. Test that the display distinguishes a valid raw sample chronology from a questionable UTC mapping. A file with internally consistent sample counters but lost external clock lock may still support relative event ordering; it should not be rejected wholesale, but its absolute time must be qualified. The investigation benefits from preserving the strongest proposition supported by the data without extending it beyond its basis.

The governing principle is that a computer should expose the measurements' limitations rather than create the illusion that all transformations have the same certainty. Through physical challenge, software conformance checks and retained provenance, the investigator can distinguish the time of an RF event from the time at which the machine noticed or reported it. I thank you, Dr Rabi, and return the floor to Dr Atkinson for the worked applications and the formal synthesis.
