A receiver's acquisition clock has an independently verified epoch at sample $n_0 = 0$, associated with 12:00:00.000000 on a declared time scale. A waveform feature is located at sample $n = 48{,}000$ in a continuously verified stream sampled at $f_s = 2{,}000{,}000$ complex samples per second. Let $\Delta n = n - n_0$ and let Δt denote the elapsed sample time. Then $\Delta t = \Delta n / f_s = 48{,}000/2{,}000{,}000 = 0.024$ s, so the uncorrected sample-derived time is 12:00:00.024000. This result identifies a time on the acquisition clock. It is not yet an antenna arrival time, because analogue group delay, the feature-picking algorithm and the epoch anchor's uncertainty have not been corrected. If the counter has a gap or the clock frequency differs from its nominal value, the simple mapping must be qualified.

Application 02. A buffer-completion timestamp incorrectly assigned to its first sample

An SDR fills blocks of $N = 8192$ complex samples at $f_s = 2{,}000{,}000$ samples per second. Let T_b represent one block's acquisition duration. Then $T_b = N/f_s = 8192/2{,}000{,}000 = 0.004096$ s $= 4.096$ ms. Suppose a host timestamp is generated precisely when a block becomes full and the application attaches that timestamp to the first sample without recording the block offset. Even if host delivery latency were zero, the first sample would be misdated by about 4.096 ms; a centre-sample assignment would differ by about 2.048 ms. Actual queueing adds a further uncertain quantity. This example demonstrates a deterministic position error due

Copyright 2026, James M. Atkinson

to timestamp semantics, not evidence that the receiver's physical signal propagation is delayed by exactly the block duration.

Application 03. Digital-filter group delay in microseconds

Consider an ideal causal odd-length linear-phase FIR filter of $L = 75$ taps, operating at $f_s = 4{,}000{,}000$ samples per second. Its constant nominal group delay in the relevant passband is $\tau_g = (L-1)/(2f_s)$. Substitution gives $\tau_g = 74/(8{,}000{,}000)$ s = 9.25 microseconds. If a detector timestamps the peak at the filter output but the intended measurand is an input feature, a 9.25-microsecond correction may be appropriate if the signal and estimator satisfy the stated assumptions. The result does not characterise analogue preselector dispersion, decimation-phase offsets or time walk. Those contributions require separate calibration. A different filter length produces a different delay; it would be a category error to use this value for an unrelated configuration.

Application 04. Cable propagation and the declared reference plane

A coaxial feed line has a measured physical length $\ell = 60$ m and velocity factor $v_f = 0.66$, defined as propagation speed divided by vacuum light speed $c \approx 299{,}792{,}458$ m/s. Assuming a uniform nondispersive line over the signal band, the one-way electrical delay is $\tau_c = \ell/(v_f c) = 60/(0.66 \times 299{,}792{,}458)$ s $\approx 3.032 \times 10^{-7}$ s = 303.2 ns. An event recorded at the receiver connector may therefore occur about 303 ns after the corresponding event at the antenna-end cable reference. Connector and antenna response remain additional terms. The uncertainty in length and velocity factor must be propagated if a sub-

Copyright 2026, James M. Atkinson

nanosecond conclusion is sought; this nominal calculation alone does not demonstrate such precision.

Application 05. Asymmetric network transit creates a clock-offset bias

A synchronisation exchange is analysed using the standard four-timestamp symmetry assumption. Suppose the actual network path delay from client to server is $d_f = 0.7$ ms and the return path delay is $d_r = 1.1$ ms, with other endpoint delays neglected. The asymmetry in the two delays is $\Delta d = d_f - d_r = -0.4$ ms. The offset inferred under equal-delay assumptions is biased by approximately $\Delta d/2 = -0.2$ ms relative to the true clock offset, with sign depending on the declared direction of the offset estimate. The round-trip delay is 1.8 ms. The example shows that consistent timestamps and a low measured round-trip time do not prove an unbiased absolute epoch. A host clock corrected by this exchange does not thereby calibrate an SDR's RF input-to-log delay.

Application 06. Oscillator frequency error accumulated over an observation

Let the nominal acquisition sample rate be $f_s = 4{,}000{,}000$ samples/s and suppose its realised fractional frequency offset from the reporting reference is $y = +2 \times 10^{-6}$ (two parts per million), approximately constant. For an elapsed reference interval $T = 40$ s, the first-order accumulated relative time error magnitude is $|\Delta t| \approx |y|T = (2 \times 10^{-6})(40) = 80$ microseconds. The sign depends on whether the mapping counts excess ticks as elapsed reference time or converts ticks using the nominal rate. A single frequency-offset estimate cannot reveal an intervening phase step, clock steering event or temperature excursion. The evidence should

Copyright 2026, James M. Atkinson

therefore contain periodic anchors, lock state and sample-counter continuity rather than relying on this linear approximation for all observations.

Application 07. Lost sample block and a false continuous timeline

Suppose an acquisition retains 4096-sample blocks at a constant 2,000,000 samples/s. One complete block is lost without a marker. Its missing temporal extent is Δt_{gap} = 4096/2,000,000 s = 0.002048 s = 2.048 ms. If the software simply concatenates blocks on either side and assigns times by file sample position, every event after the gap appears 2.048 ms earlier than its proper position on the original continuous sample counter. A later host clock comparison cannot determine which analogue samples were lost. The correct forensic record carries a discontinuity and, where known, its counter interval. Interpolated replacement samples may be generated for visualisation but must never be labelled original observations.

Application 08. Independent uncertainties and an explicit covariance warning

A hypothetical event-time estimate depends on three corrections with standard uncertainties u_{clock} = 0.8 ms, u_{filter} = 1.2 ms and u_{pick} = 0.5 ms. If these are unbiased and mutually independent, the combined standard uncertainty is $u_c = \mathrm{sqrt}(u_{clock}^2 + u_{filter}^2 + u_{pick}^2)$ = sqrt(0.64 + 1.44 + 0.25) ms = sqrt(2.33) ms ≈ 1.526 ms. This is a standard uncertainty, not automatically a 95 per cent bound. If two terms share an oscillator or filtering mechanism, the full variance includes 2 $\mathrm{cov}(X_i,X_j)$ for each relevant pair, and the simple root-sum-square result can be wrong. Every term's basis, distribution and potential correlation must be

Copyright 2026, James M. Atkinson

documented. A small displayed time increment does not reduce this uncertainty.

Application 09. Timing error as differential path-length error

For a far-field radio wave propagating in free space, let $c \approx 299{,}792{,}458$ m/s and let Δt be a differential arrival-time error between two receivers. The corresponding differential path-length error is $\Delta r = c\,\Delta t$, subject to the simple propagation model. For $\Delta t = 1$ microsecond, $\Delta r \approx 299.8$ m. For a host-timestamp variation of 20 microseconds, $\Delta r \approx 5{,}996$ m, or about 6.0 km. These are differences of propagation path length, not direct geographical position errors: the localisation geometry determines how such errors affect location. Unequal receiver group delays, shared clock defects and multipath must also be considered before assigning a bearing or position to an unknown RF source.

Application 10. Calibration mean, uncertainty and stress-state limits

A controlled input marker is applied 25 times under a fixed receiver configuration. The measured host-delay sample mean is 5.0 ms, with sample standard deviation $s = 0.8$ ms. If observations are approximately independent and drawn from a stable population, the standard error of the mean is $s/\mathrm{sqrt}(n) = 0.8/\mathrm{sqrt}(25) = 0.16$ ms, where $n = 25$. A rough normal approximation gives a two-standard-error interval for the population mean of 5.0 ± 0.32 ms. That interval does not bound an individual future delay or the maximum under untested heavy-load conditions. Applying the mean as a correction to a single event requires the much larger variability and possible bias relevant to that individual event, along with independent calibration of RF and filter delays.

Copyright 2026, James M. Atkinson

David Lennox Mills, Cross-Peer Question to Edsger Wybe Dijkstra: Dr Dijkstra, why is a timestamp written by an operating system when an SDR buffer completes not automatically the arrival time of the first RF sample inside that buffer?

Edsger Wybe Dijkstra, Cross-Peer Answer to David Lennox Mills: Dr Mills, the host observes a software event after acquisition, transfer, queuing and scheduling. The accumulated delay may vary with buffer length, device firmware, bus congestion and operating-system load. Recover the acquisition chronology from a hardware sample counter anchored to a characterised clock epoch, and retain the buffer sequence numbers and any known loss markers. A buffer-completion time can be useful as a bound or consistency check after independently measuring latency, but not as a precise RF arrival timestamp by default. Challenge the pipeline with externally timed pulses under different processor loads and buffer sizes. State separate uncertainties for the antenna reference plane, analogue group delay, ADC aperture, digital filtering and host timestamp. I pass the token to Professor Gabor on the short-event ambiguity.

Edsger Wybe Dijkstra, Cross-Peer Question to Dennis Gabor: Professor Gabor, can a software detector’s timestamp be corrected to pulse onset simply by subtracting one fixed FFT window duration?

Dennis Gabor, Cross-Peer Answer to Edsger Wybe Dijkstra: Dr Dijkstra, not in general. A detector’s threshold crossing depends on the window, taper, burst duration, pulse position within the window, filter memory and processing delay. A fixed half-window or full-window correction may be appropriate only for a specifically calibrated algorithm and signal class. Test known pulses at many relative sample phases and amplitudes, then quantify

Copyright 2026, James M. Atkinson

the onset-estimation bias and spread. Use a sample-index anchor and an independent timing reference before assigning a physical epoch. If a gap or dropped buffer interrupts the sequence, interpolation cannot make it observed. Report whether the timestamp marks window start, centre, maximum statistic or buffer completion. I yield the token to Mr Nyquist for the physical sample lattice.

Dennis Gabor, Cross-Peer Question to Harry Nyquist: Mr Nyquist, what does an ADC sample number establish when two devices share neither a clock epoch nor an externally verified frequency reference?

Harry Nyquist, Cross-Peer Answer to Dennis Gabor: Professor Gabor, each sample index identifies order within one acquisition sequence if counter continuity is proven. The nominal sample rate supplies an approximate relative interval, but absolute time and long-term rate error require external evidence. Two index sequences cannot be aligned reliably by matching decimal timestamps from separate host computers. Introduce a common physical reference event or traceable timebase and measure offset, drift and uncertainty; retain clock reset and synchronisation logs. If the clock rate changes between calibration markers, fit and validate an appropriate model rather than one untested linear interpolation. A claim of simultaneity should be framed as an uncertainty-bounded compatibility result, with physical path delay also considered. I pass the token respectfully to Dr Mills for the chain of custody.

Harry Nyquist, Cross-Peer Question to David Lennox Mills: Dr Mills, which records permit an independent expert to challenge an apparently microsecond-accurate timestamp in a seventy-two-hour monitoring archive?

Copyright 2026, James M. Atkinson

David Lennox Mills, Cross-Peer Answer to Harry Nyquist: Mr Nyquist, retain raw sample counters, hardware epoch capture method, clock-domain identifiers, oscillator or disciplining state, protocol synchronisation logs, sample-loss maps, buffer size, transfer events, clock steps, firmware revision and correction algorithm. Reference the same time scale consistently, including treatment of leap seconds and UTC conversion where applicable. A hash proves preservation after hashing, not original timestamp validity. Compare independent timing markers at multiple points across the archive and report estimated time error with its uncertainty, separately from the number of decimal places displayed. If a host timestamp is all that survives, its inference must be limited to host event chronology and a qualified latency bound. I return the token to Dr Atkinson.

Dr. James M. Atkinson. Closing synthesis of Question 051

Colleagues, our examination establishes a distinction which should govern every subsequent timing claim in this volume. A timestamp is meaningful only when its clock, its reference plane and the physical or computational event it denotes are known. The arrival of an electromagnetic disturbance at the antenna is not the arrival of a sample block at a host, and neither is the moment a detection algorithm completes its calculations. Those events may be linked by measured transfer functions, sample indices and clock anchors; they cannot be identified with one another by the typography of a log entry. The distinction is particularly important where a short transmission is used to infer another system's response, a source location or a sequence of actions in a protected environment. The apparent precision of the displayed time must not outrun the precision of the chain which supports it.

Copyright 2026, James M. Atkinson

Dr Mills has shown that clock synchronisation and measurement-chain latency require separate budgets. A host may agree with an external time standard and still report an RF event many milliseconds after it occurred. Dr Dijkstra has shown that concurrent software makes the distinction structural: completion of a callback, queue transfer or file write does not recreate the physical instant of acquisition. Dr Hamming has shown that even within the retained samples, a declared event time depends on filter group delay, template assumptions and onset-estimation method. Dr Nyquist has located the essential chronology in the sampling timebase and its continuity evidence. Rear Admiral Hopper has demonstrated that these distinctions will vanish from the legal and scientific record unless the acquisition software preserves them as explicit, independently reviewable facts. The resulting accounts do not compete; they address different boundaries of one system.

The required acceptance test should be built around a known, independently timed reference event applied at a declared RF or electrical input plane. The receiving system must preserve the sample counter and reference epoch, record each relevant analogue and digital filter state, and disclose any delay correction assigned to the feature estimator. The examiner should repeat the test with different buffer sizes, operating-system loads, receiver gains, channel selections and reference conditions. Deliberate clock loss, missing samples and retuning must be represented by validity or discontinuity records rather than concealed by interpolated data. If a system cannot pass a test in a particular state, its report should not assert the stronger time claim for observations taken in that state.

Copyright 2026, James M. Atkinson

I would require three dates or intervals where the evidence permits them: the raw hardware-associated acquisition coordinate, the best defensible estimate of the physical event at the stated reference plane, and the host logging or alarm time. Their relationship should be expressed through equations and uncertainty components rather than inferred from their closeness on a screen. For a single continuous recording, relative sample order may survive even when the UTC mapping is damaged. For geographically separated recorders, differential error, covariance, antenna geometry and synchronisation-path assumptions become essential. An investigator who cannot establish absolute arrival time may still provide valuable evidence of event existence, duration, spectral properties and relative order; those conclusions should be stated without embarrassment or unwarranted extension.

Our historical contributors have been represented here in a deliberately constructed academic exercise, not as speakers who encountered the software or standards of a later period. Their relevant intellectual achievements supply distinct methods for analysing a present engineering problem, and each modern application should be judged on its evidence rather than upon the authority of a famous name. The final proposition is therefore neither that software timestamps are useless nor that hardware timestamps are infallible. It is that the measurement must say what was timed, where it was timed, by which clock and with what uncertainty. This question is closed. The programme proceeds to Question 052, where frequency-reference traceability and phase coherence must be examined in their own right rather than treated as synonyms for accurate event dating.

QUESTION 052

Copyright 2026, James M. Atkinson

How should traceability of frequency standards govern coherent captures separated in time?

EDITORIAL CONVENTION: Newly authored academic dialogue moderated by Dr. James M. Atkinson. All interventions attributed to deceased historical scientists and engineers are constructed teaching reconstructions, not actual conversations or quotations. References to later SDR technologies, standards and forensic procedures are contemporary editorial applications of their genuine fields of expertise. Worked numerical examples are hypothetical and not certifications of any receiver.

Dr. James M. Atkinson. Opening of Question 052

Distinguished colleagues, two receivers may exhibit immaculate frequency readings and yet fail to preserve the phase relationship upon which coherent comparison depends. A synthesiser locked to a ten-megahertz reference can produce an output nominally equal to its intended carrier frequency while beginning at an arbitrary phase after a restart. Two independently disciplined references can each be traceable to the SI second and nevertheless exhibit an unknown relative phase. A reference-distribution network can introduce differential cable delay, clock-buffer skew or supply-dependent phase modulation; its outputs may retain satisfactory average frequency while their phase relation changes. The investigative temptation is to treat a manufacturer's phrase, *reference locked*, as if it also certified phase continuity, epoch alignment and waveform coherence. Our task is to refuse that category error without discounting the considerable value of an established frequency standard.

We must distinguish quantities before comparing them. Frequency is the rate of phase change measured over an interval. Phase identifies a point within an oscillatory cycle relative to a specified reference and is inherently

Copyright 2026, James M. Atkinson

periodic unless the observer retains an unwrapped, continuous history. Absolute time establishes the relation of an event to an external time scale. Frequency accuracy concerns the closeness of measured frequency to its intended value; frequency stability concerns its variation over specified intervals; phase noise characterises fluctuations of phase and may be described spectrally. None is interchangeable with another. A ten-megahertz output can be highly stable and offset from the correct frequency. Two accurate ten-megahertz outputs can have unrelated instantaneous phase. A clean average Allan deviation may not disclose a short phase step that destroys a retrospective coherent sum.

The term *traceability* must be used with metrological precision. It is a property of a measurement result connected to a stated reference through a documented calibration chain, with uncertainty contributed by each link. A traceable frequency measurement does not itself warrant a claim about an unmeasured phase relationship at an ADC input or an RF antenna. The clock reference, the synthesiser, the distribution path, the converter aperture and the post-processing transformations all must appear in the model appropriate to the actual measurement. An unexamined fan-out amplifier cannot be excused simply because the oscillator feeding it has an excellent calibration certificate.

Consider two recorded signals separated by hours. The investigator wishes to add their complex samples coherently, perhaps to expose a weak intermittent transmission beneath a fluctuating background. To align them, the engineer may need a common frequency scale, known temporal mapping, measured relative phase, and a physical model for propagation, Doppler shift and channel evolution. Merely using identical nominal ADC

Copyright 2026, James M. Atkinson

frequencies does not establish that these requirements hold. A host may also lose one sample, the local oscillator may settle at a new phase after retuning, or the received channel itself may change between acquisitions. Those effects cannot be corrected by asserting that both receivers use respectable reference clocks. A coherent integration which assumes phase continuity must either measure it, track it or disclose the resulting conditional hypothesis.

We shall examine the issue through five distinct disciplines. Professor Norman Foster Ramsey Jr. will consider oscillatory-field phase and frequency comparisons; Mr Louis Essen will examine the metrological calibration hierarchy and disciplined time standards; Professor Isidor Isaac Rabi will require experimental controls capable of separating oscillator behaviour from receiver and channel effects; Professor Charles Hard Townes will investigate oscillator coherence, spectral purity and the limitations of averaging; and Dr Harry Nyquist will explain the phase and sample-index transformations through which digital acquisition may preserve or destroy a defensible relationship. Seven colleagues will challenge them. The resolution must lead to an acceptance protocol in which known reference phase disturbances, frequency offsets, distribution changes and acquisition interruptions produce distinguishable recorded consequences. Professor Ramsey, I invite you to begin by asking what it means for two oscillations to have a measurable common phase history.

Copyright 2026, James M. Atkinson

Norman Foster Ramsey Jr.

Dr Atkinson, frequency agreement is a statement about the rates at which phases accumulate, while coherence concerns the relation of the phases themselves across the intervals of interest. In the language of oscillatory fields, one may represent a nominal sinusoid by $\cos[2\pi f_0 t + \varphi(t)]$, where f_0 is the nominal frequency and $\varphi(t)$ contains phase offset and fluctuation. Two signals with the same long-term mean frequency may begin at unrelated phases. If their frequency difference is small but nonzero, their relative phase evolves with time. If one suffers an abrupt phase step, an observer who examines only averaged frequency over a long period may scarcely notice the event, even though an attempted coherent combination across that step may partly cancel rather than reinforce the signal.

An elementary example is instructive. If the reference frequency difference between two oscillators is $\Delta f = 0.2$ hertz and they are otherwise stable, their relative phase accumulates at $2\pi \Delta f$ radians per second. After four seconds the accumulated difference is 0.8 of a cycle, or 288 degrees. The two clocks may have very similar frequencies by most ordinary specifications, yet a complex phasor sum that assumes zero difference is not generally coherent. At an RF carrier frequency, a very small fractional frequency error can accumulate many complete phase revolutions over a long observation. The phase measured modulo a complete turn at the end cannot disclose how many turns were accumulated unless the history was continuously observed or constrained by independent information.

The precision of a frequency reference is therefore not sufficient to establish the state of a frequency divider or synthesiser after interruption. A phase-locked loop may reacquire frequency lock while choosing an output

Copyright 2026, James M. Atkinson

phase which depends on an internal counter, a divided oscillator state or the time of a reset. To claim continuity, the engineer must show that the same phase relation was maintained or provide a measurement which allows the new relation to be reconstructed. A reference-to-output phase measurement at one instant can establish that relation locally, but the claim over a long unattended interval requires evidence that there were no unrecorded slips or a model bounding their consequences.

This is closely related to the interpretation of stability statistics. Allan deviation is useful for estimating characteristic frequency fluctuations over selected averaging times, and it is much less easily misled than a single conventional standard deviation by certain noise processes. Yet one should not read an Allan-deviation graph as a certificate that no phase discontinuity occurred. The statistic is computed from a set of observations under a particular sampling and treatment policy. A short event may be excluded, smoothed or diluted by averaging. A report addressing a short RF burst should therefore preserve the unaveraged phase residuals, the averaging intervals and an event log of any reference interruption, rather than presenting only a favourable summary curve.

Two receiver chains sharing the same reference create a further subtlety. A common disturbance may appear in both records with similar phase, producing an apparently satisfactory difference while moving each phase relative to an independent external reference. Some errors cancel in a differential comparison, but not all. A path-dependent delay in one fan-out branch shifts the phase of one channel; a common reference step may affect both, while a synthesiser that relocks asynchronously may affect only one. The correct observation is a vector of phase differences at specified

Copyright 2026, James M. Atkinson

points, not a statement that one cable feeds two instruments. At every branch the engineer must determine which errors are common and which are independent.

Suppose a ten-megahertz standard has a constant fractional frequency error $y = 10^{-9}$. Its frequency error is only 0.01 hertz, yet over an hour it accumulates thirty-six cycles of relative phase compared with an ideal ten-megahertz reference. Its associated clock-time scale error over 3600 seconds is 3.6 microseconds if the offset is constant. This calculation is not a condemnation of an otherwise useful oscillator; it demonstrates that a tiny rate discrepancy can have a substantial long-term phase consequence. To combine captures separated by hours, an investigator needs either a phase-continuous common reference with proven history or direct measurements permitting relative phase to be estimated anew.

It is worth distinguishing phase coherence of the receiver from phase coherence of the external signal. A source whose carrier drifts, a reflecting object which moves or a multipath channel whose geometry changes may alter received phase independently of the instrument. A receiver clock correctly held in phase will not compel the world to remain stationary. The aim of the calibration is to remove instrument uncertainty from the inference so that residual phase can be evaluated as a candidate property of the received field. Without that separation, a claim of transmitter motion might merely describe a clock slip, while a claim of clock instability might conceal a legitimate propagation change.

I would require simultaneous records of reference-to-reference phase, reference-to-ADC relationship, local-oscillator lock state and the phase of a deliberately injected calibration tone. Compare these during normal

Copyright 2026, James M. Atkinson

operation and after controlled loss-of-lock, power cycling and reference changes. Preserve the raw phase record because an apparently smooth fitted curve may hide a discontinuity near the event of interest. If the instrument cannot track phase across an interruption, declare a new coherent segment rather than joining two segments by wishful arithmetic. Frequency traceability is indispensable to some claims, but it is the beginning of a calibration hierarchy, not the end of the coherence question. I invite Mr Hewlett to challenge whether direct RF measurement is necessary when the distribution hardware is specified to a much finer tolerance.

William Redington Hewlett

Peer question 1 to Norman Foster Ramsey Jr.

Professor Ramsey, an equipment manufacturer may provide exceptionally low phase noise, stable connectors and a distribution amplifier specified for small channel-to-channel skew. If the inputs are driven from one calibrated ten-megahertz source, a designer might regard direct phase tests after installation as unnecessary repetition of factory measurements. Could a competent examiner accept the published component specifications as a bound on phase coherence, provided the system remains within the declared temperature and power range? Which features of the installed configuration would still require local verification, particularly when coaxial cables differ in length and the receiver synthesiser may be reconfigured during a survey? I also ask what evidence would distinguish a true synchronised phase change in the transmitted signal from a discontinuity introduced by a common reference or a single downstream branch. Please distinguish the accuracy of a specification at one frequency from the actual phase

Copyright 2026, James M. Atkinson

response across a useful bandwidth. An installed receiver may also select different local-oscillator multiplication paths during retuning, so a one-time ten-megahertz output comparison may conceal those path changes.

Norman Foster Ramsey Jr.

Immediate answer to William Redington Hewlett

Mr Hewlett, a specification is informative about the conditions under which its author claims a component has been tested; it is not direct evidence that an installed chain has the phase relation required by a particular experiment. A distribution amplifier's small nominal skew may be useful when a system is designed, but the phase at the converter also depends on cables, connectors, clock-domain transfer, dividers and synthesiser state. A small skew at the amplifier outputs says nothing definitive about the phase after those paths have been connected to dissimilar receiver architectures. A specification for stationary environmental conditions also cannot disclose a later intermittent connector fault or an unlogged reset.

I would use factory data to design a local test, not to exempt the instrument from one. Inject a coherent reference event into the receiver path and measure the phase difference at accessible points, varying temperature and cable configurations within the proposed operating envelope. Then deliberately power-cycle or retune one receiver to learn whether it returns to a known phase or an arbitrary one. Repeat the measurement with a second, independently traceable reference path. If the system retains coherence, the evidence will establish how it does so; if it does not, the resulting failure mode becomes part of the operating specification. The test should preserve

Copyright 2026, James M. Atkinson

uncertainty, not merely record that two waveforms looked aligned on one display.

As for a candidate transmitted-signal phase change, one needs observations with different sensitivities to the rival causes. A phase step appearing in a local injected calibration tone and in the unknown received signal suggests an instrumental origin. A step confined to the unknown signal while an independent calibration tone and reference phase remain continuous points elsewhere, though multipath and detection errors must still be considered. A disturbance appearing simultaneously in multiple channels sharing one clock but not in an independently referenced instrument suggests common-clock behaviour. Such comparisons do not prove a unique explanation by themselves; they narrow the possible mechanisms in a manner a specification sheet cannot.

I would also separate repeatability from absolute accuracy. Two receiver channels can repeat a stable phase offset for many hours, yet that offset may be wrong for a model that assumes zero differential delay. If the phase offset is measured and stable, it can be compensated for an appropriate narrowband signal, but the correction must be tied to the frequency and reference plane at which it was measured. A dispersive cable or filter cannot always be represented by one constant phase correction across a wide signal band.

The result is a practical acceptance rule. Use published component specifications to select reasonable instruments and define plausible error budgets; then challenge the assembled path under the exact

Copyright 2026, James M. Atkinson

operating modes on which the coherent claim will rely. The laboratory is not disparaging the manufacturer when it tests its own system. It is identifying the actual measurand and its chain of evidence. I return the floor to Dr Atkinson and invite Mr Essen to examine what traceability does, and does not, warrant in the language of standards and calibration.

Copyright 2026, James M. Atkinson

Louis Essen

Dr Atkinson, a frequency measurement is traceable through a chain of comparisons, each of which has a defined quantity, a reference and an uncertainty. The expression *a traceable oscillator* is convenient but imprecise when it replaces the description of a measurement result. A laboratory can own an oscillator whose frequency was compared to an external standard last year, yet the laboratory's current result depends on what happened to that oscillator since the comparison, its present environment and the instrument chain through which the frequency is delivered to the ADC. The relevant proposition is not that an object bears a respectable certificate. It is that the reported frequency or time quantity can be connected to a defined reference through an unbroken and sufficiently documented calibration hierarchy.

The SI second supplies a foundation for frequency measurement. If a laboratory measures a ten-megahertz reference by comparison against a higher-order standard, it must account for the reference's uncertainty, the counter or phase comparator, the comparison interval, possible loading effects and the environment. Each link contributes uncertainty. The resulting statement may establish the mean frequency of one reference during the time of observation, but it does not thereby establish that a different cable branch remained phase continuous or that the converter's aperture carried an accurate UTC epoch. A complete coherent-capture experiment commonly requires both the calibrated frequency scale and the relative-phase history of particular instrument paths.

A disciplined oscillator should be treated as a controlled physical system. A steering loop may correct mean frequency while introducing phase

Copyright 2026, James M. Atkinson

modulation or a transient when it changes mode. A reference can remain within its allowed long-term frequency tolerance yet exhibit a rapid phase disturbance unsuitable for short coherent integration. The engineer therefore needs measurements over the averaging times relevant to the intended observations. A carrier measured over one second, one minute and one hour may produce different descriptions of stability. None may by itself establish the instantaneous phase at the time of a rare burst if the data were reduced to averages or if interruptions were omitted from the record.

The traceability chain has a temporal dimension. It should state when each calibration applied and whether subsequent changes render it inapplicable. A precision oscillator transported between sites, warmed up after power loss or placed into a different thermal environment may no longer reproduce the calibrated value within the earlier uncertainty. Likewise, a fibre, cable or fan-out amplifier introduced after calibration can change the delivered phase although the upstream source remains traceable. The instrument's reference path should be documented as the one actually used for acquisition, not the one ordinarily installed at the laboratory bench.

Consider a receiver that samples at one hundred million samples per second, with time tags derived from a shared ten-megahertz reference. A single-sample interval is ten nanoseconds. A measured reference-branch delay of twenty-five nanoseconds therefore corresponds to two and a half sample intervals. It is possible for the two sampling clocks to have excellent relative average frequency and yet acquire a common waveform at sample indices differing by that much, depending on the phase and synchronization design. The remedy is not to declare that such skew is negligible because

Copyright 2026, James M. Atkinson

ten megahertz is lower than the ADC rate. The remedy is to characterise the phase relation between reference delivery and actual sampling aperture under the operating configuration.

A laboratory should be particularly careful when it claims *coherence across time*. If the receiver was powered down between two sessions, did its synthesiser return to the same integer phase relation? If the digital downconverter was reset, did its numerically controlled oscillator return to a known phase state? If the signal path was reconfigured, did the filter and delay model change? An accurate frequency source cannot answer these questions without further observables. A repeated measurement at two different times requires either proven continuity or a new calibration that determines the relation between the sessions. The two sessions can be compared for power or frequency without being coherently combined in complex phase; a measurement task should ask no more of the reference than the evidence supports.

I would preserve calibration results as part of each capture session. Identify the standard, the comparison route, the calibration date and uncertainty, the reference lock state, the output branch, the physical lengths and instrument settings. Record measurements of relative phase immediately before and after the capture, supplemented by continuous phase residual data when the intended claim requires absence of intervening slips. A series of references with a common upstream source should not be described as independent without considering their shared uncertainty components. If phase continuity is unobservable during a gap, the correct record must say so.

Copyright 2026, James M. Atkinson

This is not a recommendation to make every survey a national timing laboratory. It is a principle of proportionality. A survey that simply distinguishes authorised communications from an instrument artefact may require good frequency calibration but not nanosecond phase alignment. A coherent integration attempting to recover a very weak signal over long gaps requires a more demanding demonstration of relative phase, source stability and channel constancy. The quality of a metrological result lies in matching its calibration and uncertainty to its intended use. I invite Professor Gabor to question how the representation of a transient might create phase apparent continuity where the underlying data do not support it.

Dennis Gabor

Peer question 2 to Louis Essen

Mr Essen, suppose the receiving team stores only short-time Fourier transforms of several brief acquisitions, with each transform internally referenced to its own window origin. All captures use disciplined oscillators with a documented chain to the SI second, and the displayed carrier frequencies agree to many digits. An analyst proposes to rotate each complex spectrum by a fitted phase and sum the spectra, arguing that the fitted rotation recovers the coherence which was not explicitly retained. What must be known about window origins, local-oscillator phase, the target waveform and the gaps before that operation can be interpreted as recovering a physically meaningful phase relationship? Can a post hoc optimisation produce an attractive peak even when no coherent relation was ever measured? I would welcome a criterion separating an exploratory alignment procedure from a validated

Copyright 2026, James M. Atkinson

measurement. Suppose the analyst has optimised not only phase rotations but also the time-window positions and carrier-frequency shifts. The significance of the strongest peak would then depend on a search over many hypotheses, some strongly correlated, rather than on one predeclared coherent comparison.

Louis Essen

Immediate answer to Dennis Gabor

Professor Gabor, the ability to select a phase rotation that increases an output is not, by itself, a demonstration that the selected rotation corresponds to a physical relation between acquisitions. When the phase is chosen after looking at the same data that are later offered as confirmation, part of the apparent improvement is due to fitting degrees of freedom. A valid inference must identify the model under which phase alignment is meaningful and how that model is independently tested. It must also preserve the acquisition window origins, sample-clock rates, local oscillator configuration and an uncertainty statement for the relative phases. Agreement of displayed carrier frequencies does not supply these missing quantities.

A short-time Fourier transform of each capture contains phase relative to that capture's sample indices and analysis window. If the windows begin at different absolute times, the complex coefficients include the phase of the input oscillation and the phase shifts introduced by local oscillators, filters and the analysis convention. A post hoc rotation can make selected coefficients agree even when the true received phases were unrelated. For an exploratory detection

Copyright 2026, James M. Atkinson

statistic, this may be useful if the search procedure and its false-alarm consequences are stated. For a claim of measured physical coherence, however, one must obtain independent phase anchors or a validated model constraining the unknown rotations.

I would use a controlled reference tone admitted through the relevant receiver path during each acquisition and whose phase evolution can be traced across the intended gap. A common injected tone can reveal instrument phase changes, but its relation to the external emitter and antenna path must be evaluated separately. Alternatively, a reliable continuous clock-state record plus repeatable synthesiser phase-state control might permit reconstruction under a declared model. If the system cannot establish how many whole cycles accumulated through a gap, the absolute phase remains ambiguous even when the final phase modulo one turn is estimated precisely.

The analyst should then state which quantity was recovered. A coherent sum with known phase corrections can improve a measurement under a stationary or otherwise modelled target. An incoherent power combination can also improve detection under different assumptions, but its sensitivity and statistical interpretation differ. A maximised coherent-looking output from independently fitted phases is an optimised statistic, not automatically proof that the original recordings were phase coherent. That distinction should appear in the evidential report, together with the raw spectra or IQ data and the calibration chain that connects them to physical reference planes.

Copyright 2026, James M. Atkinson

Finally, the uncertainty budget must include the transformations through which the phase was inferred. If the emitter's phase wanders or the propagation channel changes, a flawless laboratory oscillator still will not secure the received signal's coherence. Conversely, an apparent phase discontinuity could originate in the receiver. The laboratory must test these rivals with a known injected waveform and with an independent environmental observation where possible. I thank you, Professor Gabor. I pass the floor to Sir Martin Ryle to examine whether a coherent antenna array can tolerate phase relationships that have been separately calibrated but not continuously watched.

Sir Martin Ryle

Peer question 3 to Louis Essen

Mr Essen, an interferometric receiver array may achieve excellent imaging or source discrimination while its phase corrections are obtained from periodic observations of a known calibrator rather than from uninterrupted monitoring of every oscillator branch. Suppose the instrument is stable enough between calibrations that a phase-interpolation model appears credible, yet an unobserved cable movement or synthesiser relock could occur between sessions. How should the array engineer distinguish interpolation of a measured smooth drift from an assumption that no phase step took place? Would independent calibrators, branch-swapping and simultaneous reference injection improve the evidential account, or merely add more shared dependencies? I should particularly like a decision rule identifying when a retrospective phase correction remains scientifically defensible and when

Copyright 2026, James M. Atkinson

the gap is too poorly constrained for coherent combination. A failed phase assumption might shift an interferometric image in a manner that appears physically plausible rather than simply reducing its brightness. Should the error budget therefore examine directional bias, not just reduction in coherent amplitude or the width of a fitted peak?

Louis Essen

Immediate answer to Sir Martin Ryle

Sir Martin, interpolation between phase observations is legitimate only under a model whose continuity assumptions have been justified for the interval and configuration at issue. If a system is known from independent trials to remain stable across typical calibration gaps, interpolation can support an uncertainty-bearing estimate. Yet the absence of an alarm about a phase step is not proof that none occurred. A gap containing an undocumented cable disturbance or a relock event may invalidate the smooth model, and a low residual on either side of the gap will not reveal that fact. The report should therefore include explicit validity conditions and a conservative treatment of unobserved interruptions.

Multiple calibrators can provide useful independent constraints if their relevant physical paths and error mechanisms differ. They can help distinguish a global instrument phase change from a source-specific propagation feature. But if every calibrator is observed through the same defective clock distribution, their agreement may preserve the common error. Branch swapping can be especially informative: if an anomalous phase change follows the hardware branch rather than the antenna or sky direction, an instrumental

Copyright 2026, James M. Atkinson

explanation gains support. Simultaneous injected reference signals may characterise a portion of the chain continuously, although the injection point determines which upstream effects remain untested.

I would define an acceptance envelope before evaluating the particular event. Measure relative phase wander over representative intervals and under controlled thermal, mechanical and reference disturbances. Establish the conditions under which phase can be interpolated with an uncertainty smaller than the scientific tolerance. Record any reference-state change which terminates the envelope. If a later capture lies outside the validated duration or operating state, describe the alignment as exploratory or conditional rather than presenting it as a traceable measured phase. This is especially important where the analyst's phase corrections were selected to optimise the very feature offered as evidence.

A defensible decision rule can be expressed in terms of predicted error. If the phase-uncertainty distribution under the justified model is small enough that the coherent-integration conclusion is insensitive to its variation, the correction may be fit for purpose. If plausible phase histories through the gap produce materially different conclusions, the original evidence does not select one of them. The correct choice may be incoherent combination, a shorter coherent interval or a new acquisition with more frequent calibration. A numerical threshold should follow the measurement's purpose, not a general rule that one calibration per day is always sufficient.

In summary, good metrology supports interpolation but does not abolish discontinuity. The engineer must account for both the

Copyright 2026, James M. Atkinson

calibration intervals and the failure modes capable of invalidating the interpolation. A transparent model can be challenged, revised and reproduced; an implicit promise of perfect phase continuity cannot. I return the discussion to Dr Atkinson and invite Professor Rabi to consider how controlled resonance experiments should distinguish source behaviour from an oscillator's own phase history.

Copyright 2026, James M. Atkinson

Isidor Isaac Rabi

Dr Atkinson, a resonance experiment teaches that an instrument's displayed answer may depend upon the phase and history of the fields used to interrogate the phenomenon. If we seek to distinguish a real change in an external signal from a change in the receiver reference, we must construct experiments in which those causes predict different observations. A statement that the instrument remains frequency-locked is an operating condition, not a demonstration that its phase relation to a physical signal is known. The experimental question is whether the receiver has preserved the phase-sensitive information required for the proposed inference. Without an independent control, an apparent shift can be attributed equally plausibly to the source, the propagation path or the instrument itself.

I would begin with a controlled source whose amplitude, phase modulation and frequency are characterised relative to an independent reference. Deliver it to the receiver's declared RF input through a measured path while also retaining a reference branch observed by separate instrumentation. Vary the source frequency by a known amount and confirm that the receiver reports the expected phase evolution. Then hold the source fixed and deliberately disturb the local-oscillator reference, synthesiser lock or frequency-divider state. If the apparent source phase follows those internal disturbances, the measurement has exposed an instrumental vulnerability. An investigation of an unknown emitter should not claim more precise coherence than such a controlled challenge demonstrates.

The experimental setup must distinguish the generation of a calibration signal from its delivery to the receiver. A pulse or tone produced by a well-

Copyright 2026, James M. Atkinson

calibrated generator can be degraded by the cable, switching network or injection coupler through which it enters the measurement chain. An apparently identical signal injected directly into the digitiser may bypass the RF preselector and local oscillator whose behaviour is in dispute. That test can validate the digital detector but cannot validate the untested analogue path. Conversely, a radiated calibration source tests antenna and propagation effects but may introduce environmental multipath which complicates interpretation. Both tests are useful if their reference planes are declared and the inference is confined to those planes.

The phrase *coherent across two sessions* should be resolved into observable conditions. First, the sample timebases must have a known scale over each acquisition. Second, the conversion chain must preserve the relation between sample indices and waveform phase within the relevant bandwidth. Third, the relative phase offset between the sessions must be determined or constrained by measurements. Fourth, the external source and propagation environment must behave consistently with the coherence model. The engineer may satisfy the first condition yet fail the second when a local oscillator is reset, or satisfy the first two yet fail the third when recording resumes after a long unobserved gap. The fourth condition belongs to the physics of the scene rather than to the clock laboratory.

A particularly instructive challenge is to inject two distinct coherent tones separated in frequency. A constant time delay produces a phase shift proportional to frequency; an arbitrary constant carrier-phase offset does not have the same dependence. If a receiver reports changes across the two tones consistent with a delay, that supports one model of the disturbance, provided filtering and phase unwrapping are controlled. If the phase shift is

Copyright 2026, James M. Atkinson

common across frequencies in a manner predicted by a synthesiser phase reset, a different explanation may fit. The purpose is not to create a universal classifier from two numbers. It is to choose perturbations that make competing models produce distinguishable predictions, allowing the data to decide within their measurement uncertainty.

I would also challenge claims based upon a calibrated timebase that was not monitored during the actual event. A long record may contain stable reference data before and after a gap, but that alone does not establish the absence of a phase slip in the interval. A receiver might reacquire lock with the same output frequency and a different phase, and a later comparison of average frequency would look satisfactory. The experiment must therefore record the phase through the interval, use an independent witness or accept that the number of lost cycles is unknown. A complete revolution of phase is invisible in a single modulo-two-pi measurement at the end, although it changes the unwrapped history necessary for coherent reconstruction.

When disagreement appears, it should not be resolved by preferring the most aesthetically pleasing plot. Compare raw complex samples and reference-state logs, investigate whether the phase correction depends on the processing algorithm, and see whether a known calibration signal displays the same feature. One receiver might show an apparent abrupt phase jump after retuning while a second, continuously tuned receiver does not. That difference can provide a strong diagnostic lead. It does not by itself identify the transmitter or establish that the second receiver is infallible; it creates a more specific testable hypothesis about the first receiver's clock and synthesiser behaviour.

Copyright 2026, James M. Atkinson

The final report should therefore include experiments designed to falsify its preferred interpretation. If the claim is that a phase shift belongs to an unknown emission, state what instrument controls would be expected to remain unchanged and which observations would contradict the claim. If the claim is that two captures are coherent, demonstrate how the relevant phase was tied across their interval and how possible missed cycles were excluded or bounded. The experiment's strength lies in its power to distinguish alternatives. I invite Dr Dijkstra to consider how an apparently continuous phase record can become discontinuous because of software state rather than oscillator physics.

Edsger Wybe Dijkstra

Peer question 4 to Isidor Isaac Rabi

Professor Rabi, an SDR may retain a nominally continuous hardware sample counter while its numerically controlled oscillator, polyphase filter or digital downconverter is reset by a software command. The resulting complex output can acquire a new phase origin even though the physical ADC and external ten-megahertz reference never stop. A programmer may then concatenate successive output blocks and present them as one coherent capture. Would your experimental method expose such a state discontinuity, and how should the system record the difference between continuity of raw samples and continuity of a derived complex baseband representation? I am particularly interested in whether the acceptance test should make state changes deliberately observable instead of inferring them indirectly from an unknown transmitted signal. If separate software layers each report internally consistent sequence numbers, they may still refer to different clock

Copyright 2026, James M. Atkinson

domains. The test ought to identify the exact sample index at which each phase-bearing transformation takes effect, rather than rely on a log statement that it occurred sometime during the block.

Isidor Isaac Rabi

Immediate answer to Edsger Wybe Dijkstra

Dr Dijkstra, the experiment must control the specific physical or computational state whose continuity is being asserted. An uninterrupted ADC counter establishes one form of sample chronology, but it does not establish that every subsequent mathematical representation preserves the same phase origin. A digital downconverter multiplies input samples by a phase-bearing numerical oscillator. If the oscillator's phase accumulator is reset, the resulting complex baseband signal can jump even when the analogue input and sample clock are perfectly continuous. The experiment should therefore retain the raw input samples and, separately, the phase-accumulator state or a reproducible record of the transformation applied to those samples.

One controlled test would feed a stable, independently referenced tone into the receiver while recording both raw samples and the derived channelised output. Issue a documented reset of the numerical oscillator or filter, and observe whether the raw tone remains continuous while the processed phasor changes. Repeat with a different downconversion frequency and initial phase, then verify whether the observed jump follows the predicted mathematical transformation. If it does, the discontinuity is a property of the processing state and can be corrected or segmented under an

Copyright 2026, James M. Atkinson

appropriate model. If the raw samples also change, the investigation must examine upstream causes rather than attributing the event solely to software.

The record should make phase-bearing state visible. Store the oscillator's initial phase, frequency word, reset event, decimator phase and the exact sample index at which each change became effective. A simple software command timestamp is insufficient if the command was queued and took effect at an unknown later sample. Where implementation details prevent an exact mapping, the affected interval should carry a validity qualification. A later analyst should not be forced to deduce state transitions from an unknown emitter, because the system was capable of recording its own state and failed to do so.

It is also important that the experiment cover different classes of change. A digital oscillator reset may produce a predictable constant phase rotation; a change of filter coefficients can alter frequency-dependent group delay; a dropped input sample can shift the time axis; an ADC clock event may create a genuine discontinuity in the sampled chronology. Those mechanisms call for different recovery methods. A correction valid for one must not be applied to another simply because all produce a conspicuous discontinuity on a plot.

I would require the software team to provide an input-output test vector for each phase-bearing operation and a trace that links the processing state to acquisition sample indices. The experimental team should then challenge that implementation by deliberate changes under a known signal and independently verify the predicted effects.

Copyright 2026, James M. Atkinson

Successful conformance does not guarantee that the unknown emitter's phase remained coherent, but it removes one major class of uncontrolled instrumental explanation. I thank you for the challenge and return the token to Dr Atkinson, inviting Professor Townes to consider the relationship between spectral purity and a useful coherence interval.

Copyright 2026, James M. Atkinson

Charles Hard Townes

Dr Atkinson, the study of highly selective oscillations draws attention to the limitations of a single number called *frequency*. An oscillator has a carrier frequency, but its field may also possess phase fluctuations and spectral sidebands. Two devices can agree in mean frequency while their phase fluctuations differ markedly, with consequences for how long their complex outputs can be combined coherently. Spectral purity is therefore pertinent to a coherent measurement, but it is neither the same as absolute calibration nor a guarantee that a particular receiver phase remains continuous after an interruption. A maser or any other stable source cannot retrospectively supply the phase of a receiver whose state was never observed.

An ideal sinusoid accumulates phase linearly with time. A real source may have a phase-noise process whose behaviour depends on the observation bandwidth and the time scale. Short-term random phase fluctuations can broaden spectral lines or reduce the average phasor obtained by coherent integration. Slow drift can rotate a phasor progressively until a fixed-phase summation partially cancels the signal. The practical problem is to identify an integration interval over which the residual phase after justified corrections is small enough for the intended detection or estimation. Increasing the duration may improve sensitivity to random noise only if the phase errors and signal dynamics permit the accumulation to remain coherent.

The engineer should distinguish power averaging from complex field averaging. If a measured complex signal has constant magnitude A but phase error φ, its coherent mean is related to the mean of exp(iφ). If φ is

Copyright 2026, James M. Atkinson

approximately zero-mean Gaussian with variance σ_φ^2, its expected coherent amplitude relative to A is $\exp(-\sigma_\varphi^2/2)$ under that particular model. With $\sigma_\varphi = 0.3$ radians, the factor is $\exp(-0.045)$, approximately 0.956. The corresponding coherent power reduction factor is the square of that amplitude factor, about 0.914. This simple calculation illustrates the sensitivity to phase noise but should not be treated as a universal law for oscillator slips, non-Gaussian phase processes, target motion or abrupt coherent segment changes.

A calibration must examine the phase-noise spectrum and the coherence time in the context of the receiver's own conversion chain. A frequency reference can supply an excellent ten-megahertz clock while the RF synthesiser introduces further phase noise, spurious modulation or a nonrepeatable phase after frequency changes. Two synthesiser outputs multiplied from the same reference may share correlated noise components, while independent internal components contribute separate fluctuations. The distribution paths and conversion factors determine the final relation observed at the RF or IF output. It would be a mistake to quote the reference oscillator's low-noise specification as the phase-noise specification of the complete instrument without measuring the conversion path.

The received signal's phase must also be distinguished from local oscillator noise. The field could originate from a moving or unstable source, or it could undergo varying multipath before reaching the antenna. A reference tone injected locally can track much of the instrumental phase path, but not the propagation effects that occur before its injection point. If one compares an external unknown emission with an injected tone, a

Copyright 2026, James M. Atkinson

difference in their phase histories can support a hypothesis about the external path, provided the signal models and receiver transfer functions are adequately characterised. An identical disturbance appearing in both may indicate an instrument path issue, though the independence of their downstream components should be examined.

A receiver might attempt coherent addition of several bursts separated by many seconds or minutes. If phase was continuously tracked only within each burst, one may have several internally coherent segments without a known phase relation between them. One can still add powers or combine suitable noncoherent detection statistics, sometimes at a cost in sensitivity compared with ideal coherent integration. The choice should be made from the evidence, not from a desire to present a larger nominal integration time. Optimising the phase of every segment against the same noisy data can exaggerate apparent significance unless the search degrees of freedom are included in the false-alarm calibration.

The decisive experiment should compare a stable reference field with the receiver's output over the desired intervals and through relevant disturbances. Apply controlled oscillator offsets, phase steps and changes of RF tuning; observe whether the estimated phase follows the applied change, whether the residual phase noise agrees with the measurement model, and whether lock events are recorded. Repeat across signal levels and nearby interferers to test whether the detector introduces phase bias. An instrument which performs admirably under steady carrier conditions may still fail when an ADC clips, when a front-end gain stage changes or when a digital phase accumulator is reset.

Copyright 2026, James M. Atkinson

I would preserve a distinction between nominal purity and observed coherence. A low specified oscillator linewidth does not establish that two recordings hours apart share a definite phase. A record of phase continuity through that interval can establish a much stronger proposition, subject to the chain's calibration and its uncertainty. Where continuity has not been measured, a later fitting procedure may estimate a relative phase under a source model, but it must disclose its model dependence. The scientific question is not whether one can obtain a bright correlation peak. It is whether the reported coherence follows from independently controlled physical information rather than from an unreported freedom to fit the data. Dr Mills may now challenge the difference between an accurate time scale and a phase-coherent RF reference.

David Lennox Mills

Peer question 5 to Charles Hard Townes

Professor Townes, suppose two receivers are disciplined by network-derived time and frequency information and produce UTC timestamps which agree to within a small stated tolerance. Each also uses a nominally identical internal synthesiser. An analyst argues that the common UTC time scale is sufficient to align the phases of their recorded signals retrospectively, particularly if their complex sample rates are precisely known. But a timestamp can identify an epoch without establishing the local oscillator's integer-cycle state, and the network path may introduce variable or asymmetric delay. What additional measurements must relate the UTC epoch to actual ADC aperture and RF synthesiser phase? Is it ever legitimate to treat network clock offset estimates as a substitute for a phase-calibration measurement, or should

Copyright 2026, James M. Atkinson

they remain a separate element of the uncertainty budget? Suppose the epoch estimate is updated by a time-service algorithm during one recording session but not the other. Even an internally coherent sample stream can acquire different civil-time labels after a clock step, and a later analyst may mistake the resulting offset for phase information.

Charles Hard Townes

Immediate answer to David Lennox Mills

Dr Mills, the distinction is essential. A timestamp associated with a stated UTC epoch may position a sample boundary on an external time scale without establishing the carrier phase of the local oscillator at that boundary. A synthesiser can begin with different phase after power cycling even when its frequency derives from an accurate reference. An epoch alignment can therefore remove one coordinate ambiguity while leaving a phase offset which affects coherent summation. The analyst must either measure that offset through a calibration path or estimate it from the received data under a justified signal model, and the latter procedure has different inferential consequences.

The required measurement hierarchy begins with the time scale and its relation to the sample clock. It must then establish the receiver's sample counter origin, the converter aperture relation and the local oscillator phase at the relevant acquisition point. The phase accumulated through any gap must be tracked or its uncertainty evaluated. A network time estimate addresses only a portion of that chain. Even a protocol with excellent hardware packet timestamping is concerned with network event timing; it does not inherently carry

Copyright 2026, James M. Atkinson

the RF phase of a local synthesiser. One should not convert a network-clock accuracy figure into a guarantee of coherent RF phase without the intervening measurements.

If the system includes a stable calibration tone phase-referenced to the same source as the synthesiser, it may be possible to observe their relation continuously or at suitable intervals. If the calibration tone enters downstream of the antenna, the external propagation channel remains a separate issue. For signals with known modulation or pilot structure, the received data might permit carrier-phase recovery, but the fitted phase can be ambiguous, subject to cycle slips or affected by noise and multipath. A phase estimator's uncertainty and the number of hypotheses examined must accompany the result. The engineer must distinguish a measured calibration relation from a model-based phase recovery.

Network timestamping may be entirely adequate for event ordering at a coarse scale while the coherent phase requirement remains unsatisfied. Conversely, two receivers sharing a phase-continuous local reference could support precise relative phase comparisons even if their civil-time labels were imperfect. These are different scientific tasks, and the appropriate calibration follows the intended claim. I would report time-scale accuracy, local sample-rate uncertainty, synthesiser phase status and residual phase noise as separate entries, then describe which combinations of those quantities support the proposed integration.

The strongest experimental test would vary the network synchronisation while holding a local coherent RF calibration stable,

Copyright 2026, James M. Atkinson

and separately perturb the RF synthesiser phase while holding the network epoch stable. If the output distinctions follow the predicted interventions, the two timing domains have been separated in practice. If the receiver's report changes both under one intervention, the mapping requires further examination. A model claiming that UTC time alone determines carrier phase is not satisfactory until it survives such tests. I return the floor to Dr Atkinson and invite Mr Harrison to test whether excellent long-term rate stability can coexist with a loss of phase knowledge across an interruption.

John Harrison

Peer question 6 to Charles Hard Townes

Professor Townes, the keeping of accurate time at sea taught that a clock must be judged through changing temperature, motion and interrupted observation rather than only at an ideal laboratory moment. A modern receiver may contain a highly stable oven-controlled oscillator, but it can lose the external reference and coast for hours before returning to disciplined operation. Its average frequency after recovery might appear acceptable while the phase accumulated during holdover remains uncertain. What measurements should be retained during holdover if the examiner intends to treat recordings taken before and after it as one coherent observation? Is a bounded frequency error enough, or must an independent phase comparison be preserved at intervals? I am concerned that the phrase *held frequency* may conceal a lost chronology of whole oscillations. I would further ask whether the oscillator has remained within the temperature range used in the calibration and whether any observed ageing rate was measured before

Copyright 2026, James M. Atkinson

the interruption. A bound valid for an hour at constant temperature may not remain a bound after an uncontrolled warm-up.

Charles Hard Townes

Immediate answer to John Harrison

Mr Harrison, a bounded frequency error can place a bound on phase accumulation over a specified gap, but it does not necessarily identify the exact phase. Suppose the local oscillator's fractional frequency error during holdover is known only to lie between two values. Integrating that error over the holdover interval yields an interval of possible phase change. If the interval spans many complete turns, a later phase observation modulo one turn may be compatible with numerous different histories. The scientist cannot select the history giving the most favourable coherent result without disclosing the choice and its uncertainty. A return to the correct mean frequency does not reconstruct the missing cycles.

Holdover evidence should include the local oscillator's state, temperature and steering history, any available reference comparisons, lock loss and reacquisition epochs, and unwrapped phase residuals if these can be measured against an independent witness. A phase comparison made before and after a gap can help, but if its sampling is too sparse, a cycle slip can remain ambiguous. Frequent independent anchors may reduce that uncertainty, and a stable local free-running counter can preserve relative sample chronology. However, the instrument must still link its phase history to an external reference if an absolute coherent relation is claimed.

Copyright 2026, James M. Atkinson

In a receiver acquisition, the relevant phase may be multiplied from the reference frequency to a radio-frequency synthesiser output. A small uncertainty in the ten-megahertz source can therefore accumulate rapidly in the RF phase. Temperature changes can affect not only the oscillator but also the electrical lengths of cables and filters, so an otherwise stable frequency source may feed a path with changing phase. The acceptance test should include thermal cycling and deliberately interrupted references, with phase observation at points near the actual mixing and sampling stages, not merely at the reference generator output.

If the available data support only a bound on phase error, the coherent-integration analysis can propagate that uncertainty or divide the records into independently coherent sessions. If the plausible phase interval is narrow enough for the intended inference, the investigator may justify a controlled correction. If it spans numerous alternatives, an incoherent combination may be more defensible. A second reference or regular calibration tone can provide additional constraints, but the independence and uncertainty of that witness must be tested. Nothing is gained by replacing an honest unknown with a nominal value merely because the display asks for a phase angle.

The guiding discipline is to preserve the history rather than only its favourable endpoint. The clock's return to good operation is a new fact; it is not evidence that no phase error accumulated while it was unobserved. For an engineering or forensic report, this distinction governs whether the phrase *coherent across the interruption* is

Copyright 2026, James M. Atkinson

supported or merely hoped for. I thank you, Mr Harrison, and pass the token to Dr Nyquist to examine the digital transformations of reference phase in a receiver and the meaning of a cycle ambiguity in sampled data.

Copyright 2026, James M. Atkinson

Harry Nyquist

Dr Atkinson, a sampled signal is not simply a series of amplitudes that can be placed at arbitrary times without consequence. The mapping from a continuous field to a sequence of complex numbers depends on the effective sample times, analogue bandwidth and any local oscillator used in downconversion. A declared reference frequency helps establish the scale of that mapping, but coherent combination requires the relevant phases to be known as well. If two segments are recorded with equal nominal sample rates and then joined without preserving their clock and oscillator state, the resulting sequence may look continuous while concealing a phase discontinuity at the join. One must distinguish the legitimate mathematical act of resampling from the evidential assertion that the resulting samples represent a continuously observed waveform.

For a narrowband signal with carrier f_c, a timing offset Δt corresponds to a phase shift $\Delta\varphi = 2\pi f_c \Delta t$, modulo a complete cycle. At a carrier of one hundred megahertz, a one-nanosecond time shift corresponds to thirty-six degrees of phase. This can be large enough to spoil a phase-sensitive comparison even though the clock error appears negligible in an ordinary event log. At a ten-megahertz reference, the same time shift is 3.6 degrees. The engineer must therefore identify the frequency at which a timing uncertainty is converted into phase uncertainty. A tolerance quoted as a number of nanoseconds has no unique phase significance without that frequency and the model of the signal.

Resampling can compensate for a known ratio between clock frequencies. If one recorder's sample rate is related to another's by a measured factor, a suitable interpolation filter can express both on a

Copyright 2026, James M. Atkinson

common nominal time grid. Such a transformation cannot restore the integer-cycle phase history of an unobserved local-oscillator reset, nor can it reconstruct samples lost before recording. The interpolation may introduce group delay or edge effects that must be accounted for, and the input's bandlimit and alias rejection matter. A complex-valued output that looks smooth after interpolation is not evidence that its underlying RF phase was physically continuous throughout the observation gap.

A numerically controlled oscillator supplies an instructive example. Its complex mixing signal can be represented as $\exp(-i\varphi[n])$, where the phase accumulator advances according to a frequency word. If an accumulator is reset at the beginning of each capture, both captures can have the same output frequency yet different relationships to the external RF carrier. A phase reference applied to the ADC does not necessarily reset the numerical oscillator to a phase corresponding to the same real-world epoch. To claim coherence, the instrument must either retain the accumulator state and a relation to the epoch or measure the relative phase by another justified method. The software interface should record precisely which sample index was the first one affected by a reset or retuning operation.

A frequency divider introduces its own phase-state ambiguity. A clock multiplied or divided by an integer ratio may return with a phase determined by internal edge selection after a power cycle. The fact that the ratio is exact is not a guarantee that the absolute phase is repeatable. Two systems whose reference frequencies are both exactly ten megahertz can have their ADC clock edges separated by an unknown fraction of a period, and two synthesiser outputs can differ by an additional integer-cycle relation. The calibration procedure should therefore observe the edges or

Copyright 2026, James M. Atkinson

relative phases at the stages used in acquisition, not infer them solely from a calibration certificate for the upstream oscillator.

The interpretation of phase also depends on the signal. A sinusoid does not uniquely identify how many full cycles occurred between two measurements because phase observations naturally wrap modulo two pi. A distinctive wideband waveform may support an unambiguous delay estimate over a wider interval, but only within the waveform's bandwidth, signal-to-noise and model limitations. An intermittent unknown transmission may supply no continuous phase information through its silent interval. In such cases the receiver can retain accurate sample times and still lack a determinate carrier phase relation between bursts. The inference must not silently assume an uninterrupted source oscillator which was never observed.

It is valuable to keep three separate records: sample-index continuity within a capture, reference-clock state across captures, and phase-bearing transformation state for every mixer, resampler and channeliser. These can be linked through explicitly defined conversions. A later examiner should be able to reproduce the relative phase predicted for a known injected signal and to identify the exact point where an unknown integer ambiguity enters. If the recording lacks those data, the uncertainty should not be repaired by filling an interval with invented samples or by fitting a phase that maximises an output without accounting for the search. Such fitting can be useful for hypothesis generation, but it is not the same as an observed calibration.

My preferred acceptance test is therefore a pair of controlled captures of a known waveform with a deliberately inserted interruption. The engineer should vary the interruption duration, the reference phase, the local

Copyright 2026, James M. Atkinson

oscillator reset state and the digital processing configuration one at a time. For each trial, predict the phase relation and sample-index mapping before viewing the result. A system claiming coherent continuity must recover those predicted relations within stated tolerances or identify the condition in which the relation becomes unknown. The experiment must also verify that no unintended sample loss or duplicated sample blocks occurred. When the measurement passes, the report can say something definite about the instrument's coherence; when it fails, it can still report valid frequency and amplitude observations without manufacturing an unsupported phase history. I invite Lord Kelvin to examine the relation between the reported unit, the physical reference and the uncertainty claimed at the final output.

William Thomson, Baron Kelvin

Peer question 7 to Harry Nyquist

Dr Nyquist, engineers may become so engrossed in digital phase accumulators that they neglect the metrological question of what, precisely, has been compared. An oscilloscope can report phase in degrees, a time-interval counter reports seconds, a network clock reports UTC offset, and a frequency counter reports hertz; yet each may be used to support the same claim of coherence. How should the measurement equation connect these different quantities without treating them as interchangeable? If the input phase is reported modulo one revolution, should the uncertainty be expressed in degrees or seconds, and how should the engineer treat the possibility of an unknown whole number of cycles between sessions? I should also like a decision procedure for when the accuracy of the reference, rather than its short-term stability, controls the final uncertainty. A narrow phase reading at one frequency

Copyright 2026, James M. Atkinson

could also be entirely inappropriate for a wideband pulse whose envelope delay and phase delay differ. Please identify the experiment which would establish that the selected phase-to-time conversion matches the actual waveform feature being compared.

Harry Nyquist

Immediate answer to William Thomson, Baron Kelvin

Lord Kelvin, the first obligation is to define the measurand and the reference plane. If the claim concerns relative phase at a specified carrier frequency, report the phase difference and its uncertainty, including the frequency at which it was measured and the method used to unwrap it. If the claim concerns time alignment, report a time difference and its uncertainty on a declared clock and physical path. The conversion $\Delta t = \Delta\varphi/(2\pi f)$ is valid for a specified sinusoidal frequency and phase relationship, but its interpretation must state whether $\Delta\varphi$ is an unwrapped phase change or a value known only modulo a cycle. An ambiguity of whole cycles produces a family of possible time differences, not one narrow Gaussian interval.

For instance, at one hundred megahertz a five-degree phase difference corresponds to 5/(360 × 100,000,000) s, approximately 139 picoseconds, if the five-degree value identifies the relevant phase branch. But if the phase was observed only modulo 360 degrees, alternative values displaced by complete cycles differ in time by ten nanoseconds each. The small local phase uncertainty does not eliminate the integer-cycle ambiguity. One could have a precise phase reading and a poor absolute time determination at the same

Copyright 2026, James M. Atkinson

moment. The report must show both the local precision and the global ambiguity.

Reference accuracy and stability enter differently depending on the intended interval. If an acquisition lasts only a short period and the reference has a small but constant frequency bias, that bias contributes a predictable accumulated phase or time-scale error. Random short-term fluctuation contributes another uncertainty over the relevant averaging time. Across a long gap, drift and possible unobserved phase steps may dominate. The uncertainty model should use the time dependence appropriate to each term rather than importing one overall oscillator number. A calibration valid for a short coherent burst does not establish coherence for recordings separated by days.

I would construct an explicit chain: the reference's calibrated frequency result, its delivered phase at each hardware branch, the sampling aperture relation, local oscillator and numerically controlled oscillator states, the digital processing transformations, and finally the event or carrier phase inferred from the captured samples. Each conversion must state its unit, sign, reference time and uncertainty. Where dependence exists, covariance terms should be retained. When a link cannot be measured, the final claim should be bounded to the strongest quantity the remaining chain supports. A correct unit conversion is necessary but not sufficient to identify the physical mechanism.

For acceptance, I would compare a known coherent input across deliberately separated captures and make predictions for the phase

Copyright 2026, James M. Atkinson

after each controlled change. If the instrument preserves the expected relation, the chain has passed a bounded test. If a reset yields an arbitrary phase, the system should open a new coherent segment. These conclusions are testable without pretending that an exquisite frequency standard can resolve every software or propagation ambiguity. I thank you, Lord Kelvin, and return the token to Dr Atkinson for the concluding experimental and numerical review.

Copyright 2026, James M. Atkinson

TEN WORKED ENGINEERING APPLICATIONS

Application 01. A small reference-frequency error accumulates many phase cycles

Let the nominal oscillator frequency be f_0 = 10,000,000 Hz and its constant fractional frequency offset relative to the selected reference be $y = +1 \times 10^{-9}$. Its frequency error is $\Delta f = f_0 y = 0.01$ Hz. Over elapsed time T = 3600 s, the relative phase accumulation measured in cycles is $\Delta N = \Delta f T = 0.01 \times 3600 = 36$ cycles. The equivalent time-scale error magnitude is $|y|T = 3.6$ microseconds. These results apply to the simplified constant-offset model; an unrecorded phase step or oscillator steering event cannot be inferred from them. The thirty-six cycles emphasise why excellent rate agreement does not, by itself, establish phase continuity across long separated captures.

Application 02. Relative phase from a nonzero frequency difference

Two otherwise ideal oscillators have a constant frequency difference $\Delta f = 0.2$ Hz over T = 4 s. Their relative phase change is $\Delta\varphi = 2\pi\Delta f T = 2\pi(0.2)(4) = 1.6\pi$ rad = 288 degrees. The phase is measured modulo a complete turn if only its endpoint is observed; the accumulated 0.8 cycles are known here because the controlled model provides the difference and interval. A coherent sum performed without this phase correction may attenuate rather than enhance the signal. The result concerns the oscillator relationship, and it should not be mistaken for evidence of the received emitter's identity or for a universally valid phase-recovery algorithm.

Copyright 2026, James M. Atkinson

Application 03. Coaxial reference branch creates a frequency-dependent phase shift

A reference-distribution coaxial cable has length ℓ = 25 m and velocity factor v_f = 0.66. With c = 299,792,458 m/s, its idealised one-way delay is $\tau = \ell/(v_f c) = 25/(0.66 \times 299{,}792{,}458)$ s ≈ 126.35 ns. At ten megahertz, the corresponding phase lag is 360 degrees × 10,000,000 Hz × 126.35 ns ≈ 454.9 degrees, or approximately 94.9 degrees when reported modulo 360. This calculation assumes a uniform nondispersive line. Cable length, connectors and temperature contribute uncertainty; the difference between absolute accumulated phase and modulo phase must remain explicit in any coherent alignment claim.

Application 04. A small time offset has a large radio-frequency phase consequence

A path or clock difference of Δt = 1 ns is interpreted at radio frequency f = 100 MHz. The corresponding sinusoidal phase difference is $\Delta\varphi$ = 360 degrees × $f\,\Delta t$ = 360 × 100,000,000 × 10^{-9} = 36 degrees. At ten megahertz the same delay gives only 3.6 degrees. These two answers are consistent because phase is frequency dependent. A manufacturer's 1 ns skew specification therefore cannot be translated into one fixed phase-angle tolerance for every RF or IF stage. The physical reference plane and the actual frequency of the relevant comparison must accompany the uncertainty statement.

Application 05. Differential reference error across a long coherent gap

Two acquisition chains differ in fractional sampling-clock frequency by a constant $\Delta y = 1 \times 10^{-10}$. If their relevant carrier-equivalent phase

Copyright 2026, James M. Atkinson

comparison is at f_c = 100 MHz, the corresponding differential frequency is $\Delta f = f_c \Delta y$ = 0.01 Hz. Over a gap T = 600 s, the phase difference accumulates $\Delta N = \Delta f T$ = 6 cycles. The final wrapped phase could appear identical even though the unwrapped histories differ by six full turns. The model presumes the offset was constant and does not account for possible target motion, propagating channel changes or resets. A single endpoint phase reading cannot recover those accumulated turns without more information.

Application 06. Phase uncertainty expressed as equivalent timing uncertainty

Suppose a carrier-phase measurement at f_c = 100 MHz has a small standard uncertainty of σ_φ = 0.1 radians, with phase errors sufficiently local that linear conversion is valid. The equivalent timing standard uncertainty is $\sigma_t = \sigma_\varphi/(2\pi f_c) = 0.1/(2\pi \times 100{,}000{,}000)$ s $\approx 1.59 \times 10^{-10}$ s = 159 picoseconds. The same phase uncertainty at ten megahertz corresponds to approximately 1.59 ns. This is not an absolute event-time uncertainty: the unknown whole-cycle branch, clock epoch and propagation corrections remain separate. In an investigation, the uncertainty must be associated with the actual frequency and phase observable rather than borrowed from a different stage.

Application 07. Expected coherent loss under a stated Gaussian phase model

Assume a constant-amplitude complex signal with independent zero-mean Gaussian phase error φ of standard deviation σ_φ = 0.3 rad. Under this specific model, the expected coherent amplitude factor relative to perfect phase alignment is $\exp(-\sigma_\varphi^2/2) = \exp(-0.045) \approx 0.956$. The

Copyright 2026, James M. Atkinson

corresponding coherent power factor is approximately $0.956^2 \approx 0.914$. The model is not appropriate for arbitrary phase slips, systematic Doppler drift or an unknown phase chosen by post hoc fitting. It illustrates why coherence claims should include phase-noise assumptions and why two accurate frequency references may still deliver less coherent gain than expected.

Application 08. Allan deviation measures variation, not the absolute calibration offset

Three equally spaced non-overlapping fractional-frequency estimates over averaging time $\tau = 1$ s are $y_1 = 1 \times 10^{-9}$, $y_2 = 3 \times 10^{-9}$ and $y_3 = 2 \times 10^{-9}$. Using the illustrative Allan-deviation estimator $\sigma_y(\tau) = \sqrt{\{[(y_2-y_1)^2 + (y_3-y_2)^2] / [2(M-1)]\}}$ for $M = 3$ observations gives $\sqrt{[(4 \times 10^{-18} + 1 \times 10^{-18})/4]} = \sqrt{(1.25 \times 10^{-18})} \approx 1.118 \times 10^{-9}$. This statistic describes variation across those observations; it does not certify that the mean frequency is correct or that no unobserved phase step occurred. The small sample is illustrative, not a robust oscillator characterisation.

Application 09. Combining independent delay uncertainties at a reference fan-out

Consider three independent zero-mean standard uncertainty contributions to differential timing: reference measurement $u_r = 0.4$ ns, distribution-branch delay $u_b = 0.7$ ns and sampled phase measurement $u_s = 1.1$ ns. Under the independence assumption, the combined standard uncertainty is $u_c = \mathrm{sqrt}(u_r^2 + u_b^2 + u_s^2) = \mathrm{sqrt}(0.16+0.49+1.21)$ ns $= \mathrm{sqrt}(1.86)$ ns ≈ 1.364 ns. This result is not a coverage interval without a distribution and coverage-factor justification. If the two receiver channels share reference noise, the correlation and

Copyright 2026, James M. Atkinson

covariance of their errors must enter the difference model rather than using independent quadrature indiscriminately.

Application 10. Wrapped phase cannot identify an unknown whole-cycle time delay

A carrier of f_c = 80 MHz has period $T_c = 1/f_c$ = 12.5 ns. A measured phase offset of 270 degrees is numerically equivalent to −90 degrees modulo 360; in the simple sinusoidal model these alternatives differ by one full period, 12.5 ns, in any converted time difference. Further alternatives displaced by two or three complete cycles remain possible if the history is unobserved. A phase meter can report a small uncertainty around 270 degrees while the true unwrapped delay remains ambiguous by integer multiples of 12.5 ns. A wideband calibration sequence, continuous phase tracking or another independent constraint is necessary before claiming a unique physical delay across separated captures.

Norman Foster Ramsey Jr., Cross-Peer Question to William Redington Hewlett: Mr Hewlett, two receivers each use a ten-megahertz reference advertised as highly stable. What experiment establishes that their complex captures remain phase coherent across a power interruption?

William Redington Hewlett, Cross-Peer Answer to Norman Foster Ramsey Jr.: Professor Ramsey, frequency stability alone does not guarantee continuity of phase through divider reset, oscillator reacquisition or synthesiser relock. Measure relative phase against a shared, traceable calibration tone before and after the interruption, with the tone injected through a known physical reference plane. Record synthesiser lock states, phase resets, distribution-cable delays and frequency-control settings. A small long-term frequency

Copyright 2026, James M. Atkinson

difference can accumulate many cycles between sessions; subsequent complex addition can therefore cancel rather than reinforce a real signal. Distinguish a common reference frequency from a guaranteed common phase origin. Repeat tests after power cycles and temperature excursions, then report residual phase uncertainty versus separation time. I yield to Mr Essen on traceability of frequency standards.

William Redington Hewlett, Cross-Peer Question to Louis Essen: Mr Essen, what does metrological traceability of a ten-megahertz frequency measurement establish, and what does it not establish about two separately recorded phase histories?

Louis Essen, Cross-Peer Answer to William Redington Hewlett: Mr Hewlett, traceability connects a measurement result to a stated reference through a documented, unbroken chain of calibration, each step contributing uncertainty. It does not by itself imply that two remote oscillator phases remained locked at all intervening instants. Record calibration dates, reference identity, frequency offsets, measurement intervals, uncertainty components and environmental dependence. Phase requires its own anchor and continuous or sufficiently sampled monitoring if later coherent combination is proposed. A frequency error of one part in a billion at ten megahertz corresponds to 0.01 hertz; over one hour it represents thirty-six relative cycles, despite a seemingly minute frequency difference. The actual phase path can be further altered by relock or distribution delay. I pass the token to Dr Mills for continuous timing records.

Louis Essen, Cross-Peer Question to David Lennox Mills: Dr Mills, if network time reports that both acquisition hosts agree within one millisecond, is that

Copyright 2026, James M. Atkinson

adequate evidence for coherent combination of a hundred-megahertz carrier?

David Lennox Mills, Cross-Peer Answer to Louis Essen: Mr Essen, no. Host time agreement to a millisecond is far coarser than the carrier period and does not establish ADC sample phase or local-oscillator phase. A coherent hundred-megahertz comparison requires an appropriately characterised phase relationship at the RF and sampling reference planes, with uncertainties expressed in units relevant to the wavelength or period. Network synchronisation can supply useful epoch information, especially with hardware timestamping, but it is only one part of the acquisition timing chain. Record oscillator phase, common clock distribution, divider resets, analogue delay and any interpolation used to align captures. Test coherence with a split calibration signal through independently calibrated paths, and report loss of coherence under the intended separation times. I pass the token to Mr Nyquist for the sampled evidence.

David Lennox Mills, Cross-Peer Question to Harry Nyquist: Mr Nyquist, can two captures be made phase coherent retrospectively by searching over every possible phase rotation until a desired weak line appears?

Harry Nyquist, Cross-Peer Answer to David Lennox Mills: Dr Mills, the procedure can produce a phase-aligned estimate under an explicitly chosen model, but searching over rotations is a statistical optimisation that can also align noise. The selected phase is not independent evidence of physical coherence. Define the search range and objective before examining the target, then calibrate the false-alarm consequences on noise-only records and verify alignment on an independently injected reference. Preserve the original separate captures, clock measurements and the chosen rotation as

Copyright 2026, James M. Atkinson

a derivative, rather than overwriting raw I/Q. Any conclusion about a common emitter must also address frequency drift, path-dependent phase, missing samples and alternative common-mode causes. A large combined peak is conditional evidence, not proof of uninterrupted phase traceability. I respectfully return the token to Dr Atkinson.

Dr. James M. Atkinson. Closing synthesis of Question 052

Distinguished colleagues, Question 052 establishes the obligations of coherent measurement over time. We have distinguished the accuracy of a frequency standard from the stability of its frequency, the continuity of its phase, and the integrity of the chain which delivers that phase to the actual sampling and mixing stages. A standard which is traceable to an appropriate reference is essential evidence for a particular frequency measurement, but its certificate does not establish all the temporal and phase relationships required by a separate receiver experiment. The measurement result, not the reputation of a laboratory instrument, must carry the traceability claim and its uncertainty. A frequency reference is therefore necessary to many coherent comparisons, but not sufficient by itself to warrant a claim that captures separated by a substantial interval can be joined in one coherent complex record.

Professor Ramsey has explained the distinction between phase rate and phase history. A very small frequency offset can accumulate many whole turns over a long gap; the final wrapped phase cannot identify the number of turns without additional information. Mr Essen has placed the calibration hierarchy and its time-dependent validity at the centre of the discussion. A result is traceable only through the stated measurement chain, with uncertainties and operating conditions attached. Professor Rabi has

Copyright 2026, James M. Atkinson

required experiments capable of distinguishing source behaviour from receiver reference faults. Professor Townes has shown why phase noise and spectral purity determine the useful coherent integration interval without certifying absolute phase. Dr Nyquist has shown where phase-bearing state can be altered by dividers, digital oscillators, retuning and resampling even when the reference oscillator remains excellent. Each argument applies to a different part of the same physical chain.

The required acceptance programme should begin with a reference whose frequency and phase relationships are measured against a declared standard. Characterise the distribution branches, converter clock domains, synthesiser states and digital processing origins. Inject a known coherent waveform into the declared RF path and record its relative phase over the intended integration time, not merely its mean frequency. Perturb the system deliberately: change a reference cable, interrupt discipline, restart a synthesiser, reset the numerical oscillator, retune a channel and repeat the test under thermal and load conditions representative of operation. If the measured phase follows the predicted changes, the model gains credibility. If a phase step appears, the record must identify it or terminate the coherent segment. An unobserved interval is not transformed into a measured phase history by later interpolation.

The forensic interpretation must further separate the instrument from the field. A change in received phase can arise from transmitter frequency error, target motion, multipath or propagation, as well as from the receiving reference and processing chain. A local injected calibration tone can reveal certain instrumental causes, but it does not automatically measure the full propagation channel before its injection point. Independent receivers and

Copyright 2026, James M. Atkinson

reference paths help only when their common dependencies are documented. Correlated errors must enter the uncertainty model where they are present. The appropriate conclusion may be that two records share a calibrated frequency scale but have no known absolute relative phase; such a result still supports valid spectral and chronological analysis within its stated limitations.

We must also distinguish an exploratory fit from a measured calibration. A rotation selected to maximise a weak apparent peak can be a useful research tool, but if its degrees of freedom were chosen after observing the very data used for confirmation, the statistical evidence must account for that search. The resulting alignment is not proof that the receiver actually preserved phase continuity during silence or shutdown. A more defensible report provides raw sample chronology, clock-state logs, calibration phase measurements and processing-state records, then specifies whether coherence is observed, model-estimated, or absent. The ten worked applications illustrate how seemingly tiny frequency, timing and phase errors can matter at the scale of a long coherent integration, and why their interpretation depends on defined units and reference planes.

The intellectual dialogue remains a constructed educational exercise. No historical contributor is alleged to have encountered the present-day receiver architectures or standards used for the modern applications. The value of their genuine metrological and engineering traditions lies in their ability to make a testable distinction between what a device displays and what the evidence establishes. Question 052 is therefore concluded with a conditional rule: coherent combination across separated captures is justified only when the necessary phase relationship is measured, retained, or

Copyright 2026, James M. Atkinson

bounded by an independently validated model whose uncertainty is adequate for the particular inference. We now proceed to Question 053, where the act of disciplining an oscillator may itself conceal a discontinuity if the observation system retains only an attractive long-term average.

QUESTION 053

Copyright 2026, James M. Atkinson

When can oscillator disciplining conceal rather than correct a phase discontinuity?

SCHOLARLY RECONSTRUCTION. The following dialogue is an explicitly hypothetical educational exchange. The named historical contributors did not meet for this discussion; modern SDR, GNSS and digital-logging applications are contemporary editorial interpretations of their established scientific work.

Dr. James M. Atkinson, Moderator: Professor Essen, a receiver may report a frequency reference as locked, disciplined and apparently stable, yet the continuous phase record needed for coherent evidence may have been interrupted. Would you explain how a control loop could restore an excellent long-term frequency result whilst obscuring the very discontinuity that an investigator must preserve? Please distinguish oscillator stability, absolute time, sample chronology and phase continuity, and identify measurements capable of separating them.

Louis Essen, Principal Contributor: Dr. Atkinson, the central difficulty is that a frequency standard and an evidential clock are judged by different observables. Long-term frequency accuracy concerns the rate at which phase advances; uninterrupted phase concerns the integral of that rate together with any discrete changes. A reference that eventually returns the correct rate may have crossed a discontinuity that cannot be reversed by declaring a subsequent locked condition. The analyst must therefore insist upon the original phase-versus-time history rather than rely upon a single status indication or a stability plot generated after the clock has recovered.

Copyright 2026, James M. Atkinson

Let $x(t)$ denote the clock time error in seconds, t the reference time in seconds, and $y(t)=dx(t)/dt$ the dimensionless fractional-frequency error wherever the derivative exists. An abrupt time step Δx at instant t_0 can be represented as $x(t)=x_{cont}(t)+\Delta x\, H(t-t_0)$, where H denotes the unit-step function. A difference of x over an interval containing t_0 will include that step, but intervals wholly before or wholly after it need not. If software rejects outliers, bridges missing intervals, or calculates only long averaging times well away from the event, its reported stability may look excellent. The report is then a conditional characterisation of the retained samples, not proof of an uninterrupted clock.

The frequency-domain counterpart is equally instructive. For a sinusoidal carrier whose nominal frequency is f_0 hertz, a clock-time step Δx corresponds to an approximate carrier phase jump $\Delta\varphi=2\pi f_0\Delta x$ radians, assuming the relevant signal phase is referred to the clock's time base. At $f_0=10$ MHz and $\Delta x=20$ ns, $\Delta\varphi$ is 0.4π radians, or 72 degrees. This numerical example is hypothetical. A 20 ns discontinuity can be immaterial to a coarse event log yet destructive to a phase-coherent combination of two receiver records. A phase jump measured at one observed RF frequency must not automatically be attributed to a reference-clock step, since local oscillator paths, mixers, synthesiser division, propagation and carrier motion may introduce their own phase changes.

A disciplined oscillator comprises at least an adjustable local source, a reference measurement, a controller and a state machine. During ordinary lock the controller acts upon measured phase or frequency error. When its external reference disappears, the system may enter holdover, using the local oscillator and saved estimates of its drift. On reacquisition, firmware

Copyright 2026, James M. Atkinson

may choose a rapid phase step, a gradual slew, a restricted-frequency correction, or an exchange between reference sources. These are different policies. A gentle correction can preserve monotonic displayed timestamps while changing the instantaneous rate; an abrupt correction can preserve the future absolute clock alignment at the cost of phase continuity. Neither policy is fully described by the phrase 'relocked successfully'.

The distinction between control action and observation is crucial. Suppose an independent phase comparator records an unfiltered time-error step of 20 ns at reference reacquisition, while a supervisory plot shows a smooth residual because its estimator resets an offset, suppresses the transition interval or reports only the filtered loop error. The difference does not imply that either record is fictitious. It implies that the records describe different quantities. A responsible engineer retains the comparator stream, controller command, phase-detector history, lock-state transitions, sample counters, reference-health indicators and the software version that produced each derived trace.

A credible test deliberately interrupts the reference for a controlled duration under lawful laboratory conditions. A second independent reference observes the local oscillator continuously. The investigator records the pre-interruption baseline, holdover interval and post-reacquisition transient, then repeats the experiment with different temperatures and interruption durations. The decisive measurement is not merely whether the output returns to its target frequency; it is whether the accumulated phase, timestamp mapping and sample chronology can be reconciled without unrecorded jumps. Cross-reference switching should be tested separately

Copyright 2026, James M. Atkinson

because changing to another apparently valid source can introduce a new phase offset without invoking a loss-of-lock alarm.

The Allan deviation is a valuable but insufficient summary. It measures a specified statistical aspect of fractional-frequency variation as a function of averaging time. Its inference depends upon sampling, dead time, treatment of trends and discontinuities, and the precise data intervals selected. A clean curve must not be cited as evidence that no single phase step occurred. Nor is every conspicuous Allan-deviation point proof of a phase step: a drift excursion, environmental disturbance, estimator reset or missing sample can create superficially similar statistical features. Preserve the underlying phase record and test alternative explanations.

The forensic significance becomes sharp when two receivers are combined for arrival-time, cross-correlation or coherent-array analysis. If their timing errors contain independent discontinuities, their calculated relative delay may jump even if each receiver individually shows a green lock indicator. If both are driven by the same defective reference, their errors may be correlated and falsely reassuring when the receivers are compared with one another. An independent timing witness, physically and electrically separated where feasible, is therefore more informative than a second instrument sharing the first instrument's clock tree.

I would conclude that a disciplining system corrects an identifiable error according to a specified control objective. It does not, by that fact alone, establish that the original measurement record retained continuous phase. The proper evidential statement is bounded: 'After reacquisition, frequency agreement was restored within the tested limits; continuity across the interruption remains established, unestablished, or contradicted by the

Copyright 2026, James M. Atkinson

separately retained phase and timestamp evidence.' Anything stronger must be earned by direct measurement rather than inferred from a favourable dashboard.

Dr. James M. Atkinson, Moderator: Dr. Dijkstra, would you examine the distinction between the oscillator's physical evolution and the state presented by the software controlling its clock?

Edsger W. Dijkstra, Peer Question: Professor Essen, an engineer may assume that a reported 'locked' state describes the complete system invariant. Yet a lock bit is ordinarily derived from a finite decision rule, sometimes with hysteresis, timeouts and exception handling. How would one specify a more meaningful invariant, and what tests could expose a program that silently repairs timestamps, reorders buffered data, or substitutes an inferred sample chronology? I would also ask whether the original phase observations can be reconstructed if the application has retained only a smoothed clock estimate and not the underlying counter or comparator readings.

If the stated invariant can be met by counters created in application software after data have already been dropped, its reassuring appearance is misleading. Would you distinguish device-origin counters from host-origin packet numbers and specify an end-to-end stimulus test capable of detecting a gap concealed by software reconstruction? I would also ask whether a preserved exception log is sufficient if the application permits the operator to exclude failed intervals from the exported evidential file without retaining the rejection policy.

Copyright 2026, James M. Atkinson

Louis Essen, Response: Dr. Dijkstra, a useful invariant is not 'lock remains true'. It is that the relationship between hardware sample index n, measured local clock time and a declared external reference remains known within a stated uncertainty for every accepted interval. Let t_n denote the reference-time estimate associated with sample n and let N(n) denote the hardware counter. A continuous acquisition should preserve counter order and disclose any missing or duplicated indices. A timestamp correction may be appropriate, but it must be represented as a documented transformation t'_n=g(t_n,state), not silently substituted as if it were the raw observation.

I would add that counter provenance can be tested with a stimulus whose markers are known independently of the receiving software. A predictable succession of phase-coded test pulses makes it possible to detect omissions which the application attempts to conceal by renumbering its own buffers. The experiment must compare received raw sample offsets against a device-side counter or an independent acquisition ledger. A log recording 'no errors' has limited evidential value if the software generating it did not observe the relevant hardware event. The operator should retain every failed test, timestamp mapping revision and excluded interval. These records distinguish integrity of stored data from completeness of the physical observation.

A phase-continuity finding should finally be expressed at the smallest justified reference plane. An uninterrupted external reference at the rack does not prove uninterrupted sampling inside the receiver, just as a complete device index sequence does not prove uninterrupted UTC traceability. The test report should state which property each control

Copyright 2026, James M. Atkinson

actually established and the permitted uncertainty range for the event in question.

The experiment should separately perturb reference availability, controller restart and host buffering. Before each perturbation, inject a benign known timing marker through the authorised test chain. Capture raw counters, device-side timestamps and host arrival times; compare the three streams. A counter sequence with no gaps alongside discontinuous host arrival times points toward buffering rather than missing RF samples. Conversely, an index gap that coincides with reacquisition deserves an explicit missing-data qualification even if interpolation gives a visually smooth trace. Where raw observations were discarded, reconstruction is not an evidential certainty; it becomes an estimate conditional upon a model, and the report must say so. A system should make discontinuities conspicuous rather than improve their appearance by deleting them.

Dr. James M. Atkinson, Moderator: Professor Rabi, what independent physical test would you require before accepting that a measured transient came from the reference and not the observed signal?

Isidor I. Rabi, Peer Question: Professor Essen, the phase of an RF measurement is not simply the phase of one standard. Propagation changes, carrier modulation, resonator behaviour, heterodyne conversion and the measuring apparatus itself may all influence a trace. If a receiver reports a sudden angular displacement exactly when its timing reference is reacquired, correlation in time is suggestive but cannot by itself determine cause. What comparison arrangements, controls and counterexamples would be sufficient to attribute the event to the receiver's reference chain

Copyright 2026, James M. Atkinson

rather than to the transmitter, antenna path or a separate instrument artefact?

Consider, in addition, the possibility that a phase-locked synthesiser introduces a transient only in the band under examination, while an independent reference comparator operates at the receiver's 10 MHz input. Which downstream test point would best discriminate these possibilities, and how can the investigator avoid disturbing the very oscillator path being measured? If the test requires opening the chassis, what qualification should the report state when that intrusive operation differs from ordinary field configuration?

Louis Essen, Response: Professor Rabi, one should preserve the event and then seek a controlled differential measurement. Observe a stable laboratory test tone through the receiver while an independent phase comparator examines the oscillator reference. Where possible, observe the same test tone through a second receiver supplied by an independently maintained clock. Vary the first receiver's reference state without changing the transmitter. If the first receiver's phase change follows the reference transition, while the independent receiver and transmitter witness remain continuous, the reference-chain hypothesis gains force. One should also swap receivers or references to determine whether the anomaly follows an instrument or a source.

A high-value control is to observe the last accessible synthesiser output and a representative downstream sample-trigger relation while the input reference is deliberately disturbed within the laboratory's safe operating range. If the phase step is generated inside the synthesiser, the upstream reference comparison may remain normal while the downstream waveform

Copyright 2026, James M. Atkinson

changes. The challenge must specify the frequency plan, loop lock state, gain configuration and cable geometry, because the result need not transfer between modes. If opening the chassis changes loading, grounding or shielding, the intrusive result is a diagnostic investigation rather than a direct reproduction of field behaviour. The report should distinguish those conditions explicitly.

Even a pair of independent instruments can be influenced by shared environmental conditions or reference distribution. A causal finding should rely on controlled swaps and the predicted response to a known perturbation, not on the impression that two screens show similar phase traces.

No isolated experiment eliminates every hypothesis. A reference cable movement can alter phase, and a nominally independent receiver may share power, environmental perturbations or distribution hardware. The test record should state its control boundaries and the observed phase relation at each reference plane. A measurement of the 10 MHz reference alone cannot prove continuity of a digitally synthesised local oscillator or the downstream sampling edge; a fault can occur after the monitored reference node. Hence the best corroboration includes a downstream timing observable, such as an externally measurable sample trigger or a known injected tone carried through the actual signal path. Attribution is a hierarchy of constrained comparisons rather than a single status flag.

Dr. James M. Atkinson, Moderator: Dr. Mills, please consider how network time services might make the evidential narrative appear smoother than the receiver hardware permits.

Copyright 2026, James M. Atkinson

David L. Mills, Peer Question: Professor Essen, software time correction commonly separates a clock's internal state from its user-facing timestamp service, and packet arrival uncertainty can complicate estimation. Suppose a network-disciplined acquisition host slews the system clock while its SDR device uses a local oscillator and independent hardware counter. Can host time alone establish sample chronology? How should an investigator interpret a monotonic time display during a reference outage, and what independent data would discriminate real sample continuity from software adjustment or queued data arriving later?

If the host's monotonic time remains continuous but the algorithm mapping it to UTC has been revised after a reference outage, what is the evidential status of the originally displayed UTC time? May a later analyst replace it silently with a refined estimate, or must the case record preserve both values, their algorithms and the state intervals for which each was applicable? Please distinguish correction of a known clock bias from interpolation across an interval during which no physical acquisition-time reference was available.

Louis Essen, Response: Dr. Mills, host time is one measurement channel, not a substitute for the receiver's acquisition clock. A monotonic host timestamp can be achieved by a software clock discipline policy while the hardware sample rate changes, pauses or loses lock. Conversely, the hardware stream may be continuous while network delivery times fluctuate significantly. The analyst should retain the sample counter, the hardware timebase calibration, the host's wall-clock and monotonic-clock records, and the conversion used to map samples onto external time. Whenever that

Copyright 2026, James M. Atkinson

conversion is piecewise, its boundaries and adjustment history are material evidence.

The original UTC label is part of the historical record, whether or not later calibration improves its accuracy. A corrected time should appear as a new derived value associated with its source observations, algorithm version and applicable validity interval. If the receiver lacked an external reference during part of the capture, the correction may require an explicit holdover model with growing uncertainty; it should not be presented as direct observation. A host which never stepped its clock may nevertheless have altered the rate of its wall-time mapping by slewing. That history belongs in the evidence package alongside hardware counters and original logs.

A necessary qualification is that a timestamp is evidence of when an event was assigned a time within a particular instrument system. Establishing physical acquisition time requires calibrated knowledge of the latency and reference-plane relationship. Without that bridge, apparently precise agreement between host times can be an agreement between software conventions rather than a measurement of electromagnetic simultaneity.

A useful diagnostic uses a periodic reference stimulus and a hardware capture counter to estimate the interval between detected markers. In parallel, network synchronisation logs reveal when the host clock was slewed or stepped. If marker spacing in the sample-index domain stays steady but wall-clock intervals change, the evidence points toward timestamp mapping. If the sample spacing itself changes, investigate oscillator behaviour and dropped-sample controls. Where the external reference was lost, describe the holdover quality and the uncertainty growth during the interval; do not attach precision to a timestamp simply because

Copyright 2026, James M. Atkinson

the operating system prints many decimal places. Calibration of one clock does not confer traceability on every downstream timestamp automatically.

Dr. James M. Atkinson, Moderator: Lord Kelvin, how should this uncertainty be expressed when a brief discontinuity has operational consequences disproportionate to its duration?

William Thomson, Baron Kelvin, Peer Question: Professor Essen, numerical exactness in a display is not the same thing as measured accuracy. A very short phase disturbance may dominate an otherwise long and successful observation, particularly when the inference depends upon cross-receiver delay or accumulated phase. How should one separate repeatability from systematic correction, form an uncertainty budget without inventing certainty, and decide whether a candidate phase step renders a localisation or correlation claim untenable? May an engineer use a single scalar uncertainty figure to summarise both ordinary running conditions and the rare reacquisition transition?

Suppose that the estimator's standard deviation during settled lock is only two nanoseconds, but a reference-selection event might have introduced an unobserved step of fifty nanoseconds. Would you add that possible step in quadrature as though it were an ordinary zero-mean random error, or should it be represented as a distinct systematic scenario? Please explain how a receiver can exhibit excellent repeatability before and after the transition while remaining incapable of supporting a precise comparison of events on opposite sides of it.

Louis Essen, Response: Lord Kelvin, it would be misleading to absorb an unresolved discrete phase event into the average standard deviation of

Copyright 2026, James M. Atkinson

otherwise orderly operation. The proper model distinguishes conditional operating states. Let u_run denote standard uncertainty in the normal locked state, u_hold(t) the holdover uncertainty after elapsed time t, and Δx_step an identified or bounded reacquisition step. If Δx_step is known with uncertainty, its correction and associated uncertainty should be treated explicitly; if the step may have occurred but is unobserved, the analysis should present alternative scenarios or a conservative interval rather than treat the event as zero-mean random noise.

A discrete possible step does not behave like an ordinary contribution to white noise. If its magnitude is bounded but its sign unknown, a sensitivity analysis should examine the relevant positive and negative cases; if it is measured, apply a documented correction and propagate its own uncertainty. Treating the event as a zero-mean Gaussian merely to fit an existing root-sum-square worksheet could produce an unjustifiably narrow interval. The report should identify whether the timing claim spans a known discontinuity or a period of stable operation and compute its uncertainty from that actual scenario.

For example, a ten-nanosecond step at a 10 MHz phase reference corresponds to an idealised 36-degree phase displacement, but one cannot assert the exact phase error of every converted RF band without testing its signal path. A physically unobserved step cannot be eliminated by averaging many settled measurements taken afterwards. The quantities, assumptions and state boundaries should remain visible to a later examiner.

As an illustration, two independent receivers might exhibit 2 ns and 3 ns standard timing uncertainty while continuously locked. If those components are demonstrably uncorrelated, the standard uncertainty of their difference

Copyright 2026, James M. Atkinson

is sqrt(2^2+3^2)=sqrt(13) ns, approximately 3.61 ns. But if one receiver has an additional unresolved 20 ns step at reacquisition, the quoted 3.61 ns characterises only the continuous-state measurement model. A delay inference straddling the transition may carry a bias much greater than that nominal figure. The correct treatment is to exclude or separately qualify the affected interval until a bound on the discontinuity is established. Correlation between uncertainties must also be considered when references or environmental effects are shared.

Dr. James M. Atkinson, Moderator: Mr. Nyquist, can a system with adequate average sampling specifications nevertheless fail to preserve the required timing information?

Harry Nyquist, Peer Question: Professor Essen, a receiver's sample rate may comfortably meet the nominal frequency requirements of the signal, while its timestamping and phase bookkeeping remain defective. How should an engineer distinguish the conditions that protect reconstructable signal bandwidth from those that protect evidence of a short phase or timing step? In particular, what does a digital display's sample-rate specification establish, and what does it fail to establish about sample continuity, resampling, aliasing or coherent combination across a reference disturbance?

There is also a difference between a resampler which uses measured nonuniform timestamps and one which assumes a constant nominal sampling rate. What independent evidence is needed to justify phase unwrapping across an interval of uncertain sample spacing? If the carrier phase may rotate through several cycles while the instrument is unsynchronised, could two different unwrapped histories agree exactly with

Copyright 2026, James M. Atkinson

the recorded endpoints? I seek a criterion for refusing a unique phase conclusion when the data do not discriminate the alternatives.

Louis Essen, Response: Mr. Nyquist, the sampling theorem and the evidential continuity question address distinct requirements. A rate adequate for a bandlimited signal under the theorem's assumptions does not prove that the samples were uniformly spaced in physical time or accompanied by accurate timestamps. The actual acquisition may include timebase variations, transient clock corrections, missing samples or buffering delays. An ideal reconstruction based on nominal uniform intervals can therefore give a convincing waveform whilst shifting the timing of its components. One must establish actual clock behaviour and sample-index continuity independently of the configured sample rate.

A phase unwrapping decision requires a bound on phase advance between consecutive trustworthy observations. In an idealised continuous single-tone model, any phase interval greater than π radians between samples can create ambiguity in the simplest nearest-neighbour unwrapping rule. When the true sampling interval is itself uncertain or samples are missing, the method's condition may fail even though the saved endpoints look orderly. Independent phase markers or a credible bound on frequency excursion may reduce the set of compatible histories, but the exclusion of alternatives must be demonstrated rather than assumed. If several cycle counts remain possible, report that ambiguity explicitly.

The key distinction is between a data-processing convenience and a physical assertion. A resampler may produce a uniformly spaced estimated sequence for later spectral analysis, but it cannot prove that the instrument collected a sample at every synthetic time. When a phase-coherent forensic conclusion

Copyright 2026, James M. Atkinson

depends on an absent interval, the correct scientific result may be that continuity is indeterminate.

For test purposes, send an authorised reference tone, pulse marker or phase-coded sequence through the complete receiver chain and retain both raw samples and hardware counters. Compare marker phases and interval estimates across the suspected transition, including their uncertainty. A resampler may compensate slow oscillator error without restoring information lost during an unsampled interval. A phase-unwrapping routine can likewise choose a continuous mathematical branch without proving that the physical oscillator had no jump. The engineer should report whether the reconstructed sequence is an uninterrupted observation, a calibrated time-warp of an uninterrupted observation, or an interpolation over absent measurements. Those three statements must not be conflated.

Dr. James M. Atkinson, Moderator: I shall now pass the principal token from Professor Essen to Dr. Mills. The question is no longer whether the oscillator returned to lock, but whether an external time label can be reconciled with the surviving hardware acquisition chronology. Dr. Mills, please offer an independent principal assessment rather than merely repeating Professor Essen’s account.

Dennis Gabor, Peer Question: Professor Essen, I should like to distinguish an actual phase discontinuity from the apparent discontinuity produced when an analyst joins two observations made through different finite time windows. A short acquisition interrupted by a clock-reference switch can be displayed as adjacent spectrogram columns whose phase estimates each depend upon a window, filter and chosen carrier model. The analyst may

Copyright 2026, James M. Atkinson

then subtract two wrapped phase angles and announce an abrupt change although a continuous oscillator with a transient change of frequency could explain the same samples. Conversely, a phase reset might be smoothed by window overlap or by a postprocessing algorithm that enforces phase continuity. How would you construct an experiment that distinguishes these possibilities? I particularly ask how the hardware sample counter, the analogue waveform reference, the transform-window boundaries and the uncertainty of the comparison should be preserved. Would an apparently satisfactory reconstruction of the central carrier frequency have any evidential power concerning a brief discontinuity that was not actually resolved?

Louis Essen, Response: Professor Gabor, the first requirement is to state what was observed and at which stage a discontinuity might have arisen. The continuous input is not directly available after it has passed through a band-limited analogue circuit, a sampler, a buffering system and an estimator. I would preserve the original complex samples together with a hardware counter, the local reference-state log, and a chronology of every software operation that changed the sample-to-time map. A spectrogram, by contrast, is a derived representation. It is valuable for displaying changes in energy and local frequency, but adjacent displayed estimates are not independent measurements of instantaneous phase unless the underlying windows and estimator warrant that interpretation. The raw index sequence supplies a different kind of continuity evidence from a timestamp column: it can show that samples are consecutive in stored order, while leaving their exact physical acquisition times uncertain. Both facts should be reported separately. To test the competing hypotheses, construct an authorised

Copyright 2026, James M. Atkinson

reference experiment using a source whose phase evolution is observed independently at a second instrument. Keep a known unmodulated carrier and a controlled pulse or modulation marker in the reference input. Deliberately perturb the disciplined reference while recording the independent phase comparator, the SDR's physical sample-counter events and the actual acquisition state. Repeat with a deliberately introduced phase step, with an interval of frequency offset but no step, and with a known omission of samples. A blind analyst should examine those records using the proposed processing chain without being told which perturbation occurred. Preserve rejected interpretations as part of the validation evidence. In each case compare sample-domain phase differences, cross-correlation lag, and windowed frequency estimates, but do not use a common fitted model as though it were an independent witness. The mathematical distinction is elementary but decisive. If carrier phase is phi(t), instantaneous frequency offset is the derivative of phi divided by twice pi. A genuine phase jump is a discontinuity in phi that need not correspond to an ordinary bounded frequency offset. A finite frequency excursion instead accumulates phase continuously, although a narrow analysis window can make its boundary appear sharp. A sliding transform with overlapping windows can smear either phenomenon, and a reconstruction algorithm that interpolates across missing samples may favour whichever hypothesis it was designed to recognise. Record the window function, width, overlap, unwrap rule and reference comparison, and vary them during sensitivity analysis. A stable numerical frequency estimate after reconstruction confirms only the behaviour of that estimator on retained data. Where the independent reference cannot resolve the disputed interval, the final finding

Copyright 2026, James M. Atkinson

should say that phase continuity is unverified over that interval. It may still be possible to bound the maximum time or phase departure under additional explicitly justified constraints, but the boundaries must come from measured inputs rather than from the pleasant appearance of a waterfall. A phase-aligned display is never proof that an instrument experienced no reference interruption.

Claude Elwood Shannon, Peer Question: Professor Essen, a frequency-control loop can make the currently displayed frequency error small while having transformed or erased information concerning the trajectory by which the loop obtained that state. Imagine two acquisition histories. In the first a reference remains continuous; in the second the reference is lost, an acquisition buffer is filled with an alternate clock and subsequent firmware silently interpolates timestamps or discards duplicate counters. The final sample file may have the same nominal rate, the same size and an indistinguishable averaged spectrum in both histories. A reviewer who receives only that file cannot tell which history occurred. What minimal auxiliary record would allow the two experiments to be distinguished? Does a cryptographic digest of the postprocessed file establish the origin of its timestamps? Please explain the limits of reconstructing an unobserved phase history from frequency-domain summaries, and specify how an engineer should report the loss of relevant information without assuming that a strong clock-discipline algorithm can manufacture an independent observation.

Louis Essen, Response: Dr. Shannon, the two histories may indeed map to the same retained file. Once a transformation has mapped distinguishable physical histories into an identical stored representation, no later inspection

Copyright 2026, James M. Atkinson

of that representation alone can determine which history preceded it. This is not an allegation about a particular manufacturer's software; it is a statement about the information available to an inference. The defensible response is to change the acquisition record before the information disappears, not to invent a correction after the fact. In an SDR that must support coherent timing claims, the preserved evidence should include a monotonic hardware sample index at the earliest reliable boundary, identifiers and timestamps for reference changes, a record of phase-lock and holdover states, observed counter resets, and an explicit mapping between hardware counts and the reported external time scale. Those records should be sampled or captured with enough temporal resolution to expose the transient under examination. A host clock and a reference-frequency indicator are useful but cannot substitute for a direct record of sample continuity and phase behaviour. A cryptographic digest offers a narrower proposition. It can demonstrate, subject to the hash algorithm and custody process, that the bytes subsequently examined match an earlier recorded set of bytes. It does not demonstrate that the acquisition hardware operated correctly, that the encoded timestamps marked the true sample apertures or that a software programme never discarded and re-created data before the hash was calculated. The acquisition system needs an independently reviewable configuration record and an event log whose source and failure modes are characterised. A second counter with a different failure mode, or a simultaneous observation of a known RF reference, may provide additional discrimination. Where both rely on the same clock-distribution fault or the same firmware transformation, their apparent agreement is not independent corroboration. The limitation also

Copyright 2026, James M. Atkinson

has an instructive quantitative expression. A frequency-domain average is a many-to-one mapping: it commonly loses the time order or phase history required to reconstruct a transient event. Even a complex spectrum of one fixed-length transform does not necessarily identify events omitted by the recording system. If the samples themselves were lost, the uncertainty is not merely a larger least-significant-bit error. It is uncertainty about the existence and duration of an interval whose physical values were never observed. A defensible report should therefore distinguish observed sample coverage from nominal file duration, and verified phase continuity from continuity imposed by software. It should present alternative histories where both remain compatible with the evidence, rather than issue one preferred reconstruction as fact. I would require the qualification test to include injected clock failures and file-path faults whose start and end times are known to an independent controller. Test recording continuity with deliberate counter jumps, duplicated packets, phase resets, reference holdover, slews and reacquisition. Reproduce all derived displays with the disclosed algorithms and versions. The objective is not to obtain a perfectly smooth spectrum; it is to ensure that a reviewer can identify where the system observed, where it inferred, and where the surviving evidence cannot decide.

David L. Mills, Second Principal Contributor: Dr. Atkinson, a frequency-discipline system and a timestamp service have different control objectives. A clock can continuously advance its internal monotonic counter while a conversion layer applies a revised offset between the counter and a civil timescale. Conversely, a counter might stop, wrap or lose continuity while the visible wall-clock service remains superficially orderly. The practical test

Copyright 2026, James M. Atkinson

is to preserve an immutable map from sample index to the raw counter, plus each version of the later mapping to external time. I would obtain the exact pre-reacquisition and post-reacquisition counter readings, identify the oscillator and synthesiser nodes actually controlling sample acquisition, and measure an independent calibration pulse before and after reference recovery. I would not accept a computer time-service log as proof that an RF phase path remained uninterrupted. When the mapping is corrected after an outage, report the original record and the revised estimate separately, including the interval for which the correction is underdetermined. I invite Dr. Dijkstra to challenge the software implications rather than assume that the recorded chronology is immutable.

The hardware-to-UTC conversion should be documented as a succession of measured relationships, not as one eternal coefficient. Let n be a receiver's sample counter and C(n) the receiver-clock time represented by that counter. Define U_j(C) as the correction to external time accepted during validity interval j, with its independently justified uncertainty. A reproducible UTC estimate is t_UTC(n)=C(n)+U_j[C(n)] only when n falls in interval j and both mappings were actually observed or validly calibrated. If the oscillator reacquires a source and the correction model changes abruptly, the indices on opposite sides of the change belong to different intervals. A program that recalculates the entire file with the last known U_j can create a deceptively smooth chronology while concealing the historical change in the relationship between clocks.

This distinction is especially important during reference holdover. A disciplined oscillator ordinarily estimates its frequency and perhaps its drift from previous reference comparisons. Once the reference disappears, those

Copyright 2026, James M. Atkinson

estimates are predictions whose error may increase with time. For a simple constant fractional-frequency error y, the clock-time error accumulated over holdover duration T is approximately $\Delta t = yT$. If the unknown bias is one part in ten million, a 600-second holdover can accumulate approximately 60 microseconds of time offset. The arithmetic is illustrative. Actual drift is influenced by temperature, ageing, noise and controller history; an interval error bound must reflect those influences rather than simply multiply a catalogue specification by elapsed time. The quality of the estimator's previous lock does not remove the uncertainty created after the reference vanished.

A clock's ability to keep time monotonically should likewise be separated from its ability to represent an external timescale accurately. If the software clock is slewed, it may display an ever-increasing timestamp while advancing it at a rate slightly different from the hardware counter. If it is stepped, it may assign two adjacent stored events unexpectedly different UTC labels. Either policy may be acceptable for a particular computing service. The forensic requirement is to preserve the raw counter sequence and the clock-control decisions so that a later examiner can reconstruct the mapping applicable at the precise moment of acquisition. Host arrival timestamps introduce an additional queueing term and do not remove the need for hardware counter provenance.

Suppose the receiver delivers 4,000,000 samples per second with a hardware counter, and an external pulse-per-second marker is captured alongside the IQ stream. Before an interruption, successive markers occur 4,000,000 counters apart. After reacquisition one interval is only 3,999,980 counters, while the host's displayed timestamps remain separated by

Copyright 2026, James M. Atkinson

exactly one second. This hypothetical observation might reflect a temporary rate change, loss of twenty samples, a marker-detection fault or a counter mapping error. The correct conclusion is not yet that any one mechanism occurred. Counter overflow diagnostics, marker phase, simultaneous independent clock comparison and a known reference signal must be examined to discriminate them. A smooth host-time column is insufficient evidence of continuity.

When the reference path is shared by several receivers, common errors can survive comparisons between their UTC labels. Two instruments may agree because both used the same inaccurate time source or the same recalibration model. Their agreement does not establish independent evidence of absolute timing. A separate oscillator or timing witness with independently maintained traceability should observe at least one downstream point in the acquisition chain. The investigator must also consider whether the supposedly independent clocks share power, thermal environment, cabling or software. The evidential claim should identify which dependencies have actually been tested, rather than invoke independence simply because the instruments have separate serial numbers.

My recommended acquisition ledger therefore contains the device identity, original sample index, receiver frequency and gain configuration, raw clock status, reference selection, holdover and relock indicators, phase or frequency comparator measurements, host monotonic time, wall-clock time, hardware event markers and any subsequent calibration revision. No later transformation may overwrite the original values. A correction record should carry its effective range, algorithm version, source observations and uncertainty assumptions. The reviewer can then state whether an event was

Copyright 2026, James M. Atkinson

captured, whether its relative timing was preserved and whether its external UTC label remains supported across the reference transition. Those are different findings, and each deserves a separate evidential conclusion.

Edsger W. Dijkstra, Cross-Peer Question to David L. Mills: Dr. Mills, your proposed map is only useful if the software refuses to silently rewrite it. Suppose the application originally associated device counter 9,000 with a time estimate, then replayed the capture after reacquisition and produced a corrected UTC label. The operator sees only the latest view. What invariant must remain inspectable so that the post-hoc correction does not masquerade as contemporaneous observation? I am also concerned about the boundary of an overflow: a continuous sequence of host-assigned packet numbers does not prove that the instrument produced a continuous series of actual samples. Please distinguish provenance of the labels from provenance of the observations.

Would you also specify the minimal independent test that would catch a host which regenerates plausible UTC labels from the final clock state, thereby hiding the precise index at which the reference changed? I am concerned that a record may be cryptographically intact whilst its original time mapping was never preserved. An excellent digital signature authenticates retained bytes; it does not retroactively prove the scientific adequacy of the data model encoded in them.

David L. Mills, Cross-Peer Answer to Edsger W. Dijkstra: Dr. Dijkstra, store original hardware sample indices, the observed device-counter values, the device clock state and the exact transformation that generated each external timestamp. A later correction should be appended as a new

Copyright 2026, James M. Atkinson

mapping, never substituted in the raw acquisition ledger. If the device does not expose a counter that survives overflow, explicitly state that the host packet sequence is not an independent continuity witness. In laboratory qualification, inject known pulse markers while provoking both a reference interruption and an acquisition backlog; inspect which underlying records distinguish the two. A genuine clock correction may improve external-time agreement after the fact, but it cannot restore physical phase observations or samples never acquired. The contemporaneous record and the correction belong to separate layers of evidence, and an uncertainty interval should cover the unresolved transition rather than conceal it with numerical formatting.

A two-path timing witness makes the weakness observable. Capture a laboratory pulse-per-second marker and its device counter indices in the receiver, while an independent recorder timestamps the marker from a separately maintained reference. Interrupt the primary source, permit reacquisition and compare the raw hardware chronology with the host's corrected timestamps. Where the software silently reassigns the prior UTC values, the revised mapping can be compared against the preserved independent record. A cryptographic signature of the final file proves that the saved bytes were not later modified; it does not prove those bytes record what the operator saw before correction. The original and revised mappings must both survive, with evidence of the state transition which caused the change.

Louis Essen, Response to David L. Mills and Edsger W. Dijkstra: I accept that distinction and add a metrological qualification. Even a flawlessly preserved original counter is only a sequence until its time scale is independently

Copyright 2026, James M. Atkinson

established. A frequency standard may calibrate the interval between counts; a phase comparator may establish a transition step; neither substitutes for the other. The peer exchange therefore narrows the claim to what was observed at the relevant hardware node and separates it from subsequent clock estimation. I pass this additional question to the moderator: have we retained an independent downstream witness across the recovery interval?

Dr. James M. Atkinson, Moderator: Dr. Dijkstra, the previous exchange established that corrections to clock labels do not reconstruct lost observations. Would you develop the necessary software invariants, after which Mr. Nyquist may examine their sampling consequences?

Edsger W. Dijkstra, Third Principal Contributor: A clock transition is a state transition, not just a different numerical estimate. A well-specified acquisition program should preserve both raw and derived states and announce when a mapping loses validity. A robust design assigns one hardware index to each actual sample and never backfills missing observations with invented source data. An epoch boundary is a substantive event: subsequent timestamps may be accurate while the phase relation across that boundary remains unknown. My test would restart the acquisition software with a reference disturbance and compare the raw stream against a separately observed calibration marker. An invariant should fail conspicuously if evidence has been lost, rather than be restored cosmetically by a smoothly displayed clock.

One additional acceptance test should deliberately force an acquisition restart at the precise instant the reference state changes. The

Copyright 2026, James M. Atkinson

implementation passes only if it preserves both the prior and subsequent counter epochs, identifying which samples have no supported continuous-time correspondence. A restart concealed by renumbering constitutes a documentary defect even if the stored data remain syntactically valid.

I would specify the invariants before building the application. The first is order preservation: for any accepted sequential samples, the hardware index either increases according to the declared device contract or a gap, restart or wrap event is explicitly recorded. The second is provenance: a derived timestamp must be linked to its raw counter, source observations and conversion version. The third is state completeness: every transition between locked, holdover, reacquiring, unsynchronised and fault conditions must be represented with effective boundaries, including transitions that occur during a host communications outage. An ordinary status indicator cannot prove these invariants. They should be expressed as testable properties of the acquisition record and challenged under deliberate fault conditions.

Consider a state variable q with possible values LOCKED, HOLDOVER, RECOVERING and UNTRUSTED. A transition from HOLDOVER to LOCKED may require the controller to reacquire phase. The software must not infer that an earlier range was continuously valid simply because q now equals LOCKED. Instead, a transition event records the last index verified under the previous state, the first verified under the new state, and any unresolved interval between them. A state transition may leave the sample sequence intact while invalidating absolute timestamp mapping; another transition may invalidate both. Those outcomes should have different error codes.

Copyright 2026, James M. Atkinson

Collapsing them into a single Boolean is equivalent to discarding evidence needed to distinguish the competing physical explanations.

One verification rule could assert that every accepted IQ packet names a first sample index n and a declared sample count m, and that a following packet begins at n+m unless a documented exception is present. Yet an implementation might manufacture its own sequence numbers after discarded device packets; in that case the rule would merely certify software bookkeeping. The relevant counters must originate as near as practicable to the acquisition hardware and be qualified against known stimulus events. Packet duplication, reordering and counter wrap must be separately tested because an apparent arithmetic discontinuity may result from a legitimate wrap or a driver bug rather than missing physical samples. The verification report should identify the origin and integrity protection of every field used.

A second rule concerns transformation monotonicity. It may be valid to map a hardware counter sequence into corrected physical time using a piecewise function, but every change in mapping belongs to an explicit version. If a resampler creates synthetic samples on an even time grid, those samples are derived values with lineage to the original observed indices and an interpolation kernel. A missing segment cannot be silently filled by a filter prediction and then counted as an observation. In machine-readable evidence metadata, distinguish observed, resampled, interpolated and predicted states. A waveform that looks continuous after processing may still contain an interval in which the instrument was blind.

There is a profound distinction between checking program syntax and validating its scientific meaning. Unit tests can prove that an index field increments as designed, while the hardware actually stopped sampling for

Copyright 2026, James M. Atkinson

an interval. A fault-injection programme should therefore disrupt the physical reference source, hardware data transport, host processing queue, time-conversion process and storage path independently. For each disruption, a separate trusted recorder should establish what the device actually observed. The expected software result is not always successful continuity: sometimes the correct result is a conspicuous, bounded declaration that the record has become incomplete. An honest failure state is an essential product feature, not an embarrassment to suppress from the interface.

Finally, the evidential process must be reproducible. The analyst should retain a protected original file, event ledger and calibration configuration, then document each computation with a versioned executable and declared parameters. A checksum can detect later alteration of recorded bytes, but it does not prove that the bytes corresponded to correctly sampled RF at the time of acquisition. That requires instrument challenge tests and hardware provenance. A well-engineered archive consequently distinguishes integrity of storage, completeness of acquisition, validity of timing and support for physical attribution. These are independent propositions. None should be inferred solely from the attractive appearance of a retrospective phase plot.

Harry Nyquist, Cross-Peer Question to Edsger W. Dijkstra: If the device retains every index but varies its actual sample rate during recovery, may software still declare the acquisition sequence continuous? What happens to an inferred signal phase when a nominal constant sampling rate is imposed on the physically irregular clock?

Copyright 2026, James M. Atkinson

Please distinguish a sample-counter gap caused by lost transport packets from a genuinely irregular hardware sampling interval, since both may give the same discontinuity in an application's index series. Would the independent reference marker you propose make that distinction observable, and which records must survive to substantiate the result?

A variable-rate clock may also be accompanied by packet reordering or host buffering, so an index sequence which appears consecutive after software repair is not necessarily the original hardware sequence. How would you require the acquisition device to testify, in an engineering sense, to the generation time of the samples? Could a calibration marker expose a missing interval which a plausibly renumbered buffer conceals? And must every such correction be disclosed even if the final spectral picture appears unchanged?

Edsger W. Dijkstra, Cross-Peer Answer to Harry Nyquist: Physical sample continuity is not equivalent to calibrated temporal continuity. A retained sequence can be complete in index order while its mapping to elapsed time changes. The program must retain clock state or independently measured rate corrections. Resampling can construct a useful uniform representation of the recorded observations, but its interpolation model and uncertainty should be declared. If a discontinuity makes the phase path ambiguous, the system must preserve alternative plausible reconstructions rather than claim the missing phase was observed.

A hardware-time marker supplies a test of actual chronology only if its origin and capture method are independently characterised. A packet gap can occur downstream of a complete device capture, whereas irregular

Copyright 2026, James M. Atkinson

hardware sampling changes the reference marker relationship even when the transport delivers every packet. Compare both the hardware index and marker phase against an independent acquisition witness. When the driver hides its own errors, the software must disclose that the counter cannot certify acquisition continuity. A formally tidy index stream cannot substitute for the physical challenge test.

The capture protocol should require a hardware-origin counter or time marker whose generation precedes transport through the host, and each stored buffer should retain its relation to that origin. A separate test marker injected through the receiving path can expose a lost interval even if software creates a continuous index sequence. A driver that does not expose any such information must have its limitations documented; a post hoc software counter is weaker evidence. During a controlled reference fault, compare the count and phase of expected markers against the preserved raw stream, then challenge the record under packet reordering and host queue stress. If the gap was filled by interpolation, each derived sample must be tagged as such and excluded from a direct-observation count.

There is also an important reason to preserve failures that do not visibly alter a waterfall. An investigator may later ask a question about burst timing or coherent phase that was not contemplated during acquisition. A seemingly harmless interpolation for a spectral average can therefore destroy the evidence needed for another scientific inference. A complete acquisition record retains original samples, exception events and transformations so later experts can make that distinction themselves.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Rabi, may I pass you the token to examine the physical reference planes and the possibility of a synthesiser-origin transient? Professor Essen will then challenge the scope of the proposed measurement.

Isidor I. Rabi, Fourth Principal Contributor: The reference itself must be challenged as a physical component of the measuring apparatus. A phase jump in the displayed carrier may arise in a synthesiser, a mixer, a cable or an external field, even if it coincides with a clock status change. I would compare the oscillator output at the point of distribution with a second comparator monitoring a downstream sample-related event. A known local stimulus passing through the full receiver should be observed in parallel with the unknown RF signal. Switching only the external source, or only the receiver reference, supplies evidence about where the anomaly originates. The timing of coincidence is merely a clue until causal controls show which physical pathway produces it.

An independent phase comparison should also be repeated at more than one carrier frequency and over different receiver gain states. A transient seen only after frequency conversion may depend upon a particular oscillator or mixer path, and a successful test at the reference input alone cannot establish its absence. The conclusion must identify which downstream nodes were physically challenged.

A reference node is a physical measurement point, not a metaphor for the entire instrument. In a receiver containing a frequency synthesiser, analogue mixer and ADC, the input reference can be processed by several control loops and dividers before it influences the measured carrier phase

Copyright 2026, James M. Atkinson

or sample edges. A test that observes only the external 10 MHz terminal can miss a discontinuity generated inside an intermediate loop. It can also falsely assign an external phase change to the reference simply because the two events occur at similar times. The analyst must identify the complete transfer pathway, including any buffered control updates, phase-detector operating ranges and reference switching procedures relevant to the instrument's state at the contested event.

For an ideal frequency multiplier with ratio N, a deterministic input phase excursion may appear multiplied by N at the output under an appropriately coherent relationship. The familiar phase-noise power-density scaling of 20 log10(N) decibels is likewise conditional on the architecture and how noise is referred. A practical phase-locked synthesiser shapes input-reference noise differently across offset frequencies, while the local oscillator contributes its own independent noise. A sudden phase step is a transient rather than a stationary noise process, so one must not infer its exact waveform from a single catalogue phase-noise figure. The correct procedure measures the actual transient response of the deployed synthesiser or bounds it through a justified dynamic model.

An illuminating laboratory arrangement monitors three points simultaneously: the reference input, a downstream synthesiser or sample-edge witness, and a benign injected RF test tone traversing the receiver's full signal path. Introduce a controlled, small reference phase perturbation within component ratings, and record the response in all three channels with independently maintained time. Then repeat after substituting an external reference of adequate quality and after changing any authorised synthesiser mode. If the upstream reference is continuous but the

Copyright 2026, James M. Atkinson

downstream witness steps, the impairment lies beyond the monitored input plane. If both step together, further comparison is needed to distinguish source-origin phase from distribution or measurement-chain error.

A carrier burst complicates the comparison because it may not be present during every sampling interval. Suppose a fixed calibration tone remains visible while an intermittent external carrier shows a phase jump. A shared reference event should ordinarily leave some trace in the calibration path, subject to differing frequency conversion and channel transfer. If only one received carrier exhibits the disturbance, a propagation or transmitter hypothesis gains plausibility, but selective receiver artefacts remain possible. The calibration injection should span relevant frequency bands and avoid overloading the front end. One fixed test tone does not validate every receiver setting, filter path or gain state across a complex SDR's complete operating range.

The examiner must also preserve the chronology of switching. An instrument may report a relock time based on its control processor's status polling rather than the precise first hardware sample affected. A reference selection command might initiate a transient before the operating-system log acknowledges the change. Record both commanded and observed state changes and compare them with a hardware counter or event marker. A loss-of-lock indication after the suspected event does not necessarily exculpate the reference, just as a perfectly timely status flag does not prove the physical waveform of recovery. Discriminating evidence requires time correlation between independent physical observables, not timestamps read from the same control interface.

Copyright 2026, James M. Atkinson

My concluding evidential standard is a set of refutable alternatives. Could an input-reference interruption explain the observed phase? Could a synthesiser control transient do so while the reference remained stable? Could antenna-path motion, multipath or a carrier-origin phase change account for the pattern? State an observation that would favour each explanation and conduct as many lawful, reversible challenges as necessary to narrow them. If the relevant downstream sample phase was never recorded, say plainly that continuity remains unestablished. A proposed correction inferred from stable behaviour afterwards cannot retroactively create the missing observation. The proper outcome of an experiment may be a bounded uncertainty, not a reconstructed certainty.

Louis Essen, Cross-Peer Question to Isidor I. Rabi: Can the investigator use a single 10 MHz reference comparator to establish the phase continuity of a synthesised receiver that samples at an unrelated rate and translates several RF bands? How should uncertainty be transferred between nodes?

I would further ask whether the relevant phase transfer function is known at the moment of reference switching, rather than merely at settled lock. A recovery transient can briefly drive the synthesiser outside its usual linear operating regime, so a small-signal measurement conducted under normal operation may fail to predict the event. What qualification follows?

If different synthesiser paths derive phase from the same input through distinct division and loop-filter settings, a discontinuity may be suppressed at one monitored output and amplified or delayed at another. Would you require a matrix of tests across the relevant frequency plans rather than one successful check at the nominal band? And how should the investigator

Copyright 2026, James M. Atkinson

qualify a transient recorded through a probe whose capacitance or grounding potentially changed the oscillator under test?

Isidor I. Rabi, Cross-Peer Answer to Louis Essen: A comparison at 10 MHz measures that particular node. A synthesiser can introduce its own phase transients and a sampling clock can behave differently, depending on divider ratios and loop dynamics. One should measure or bound the relevant transfer function from the tested reference to the actual sample edge, including internal phase locking. The result must specify the observation node and state; otherwise it is a statement of reference-source stability, not of the whole receiving chain.

That qualification is essential. A linearised transfer function around settled lock describes only a local approximation. During acquisition or switching, a controller may saturate, reset an accumulator or engage an alternative divider. Such behaviour needs direct transient measurement or a bounded state-dependent model. The investigator must distinguish observations made under stable operating conditions from observations made during the transition and should retain any control-state records defining that interval. If the internal transition cannot be observed, one cannot claim that a quiet external reference terminal establishes the downstream phase history. The finding must identify this untested causal path.

A test matrix is appropriate because the transient transfer depends upon the frequency plan, lock state and internal configuration. At minimum compare representative synthesiser modes and downstream sample-edge observations, with traceable calibration at the chosen reference planes. A probing arrangement which changes the circuit loading cannot be assumed

Copyright 2026, James M. Atkinson

to reproduce untouched field operation. Its influence should be characterised using a non-invasive witness where possible, or by comparing operation before and after insertion of the diagnostic probe. The report must distinguish measurements under the diagnostic configuration from conclusions about the normal configuration.

One should also avoid treating absence of a transient at a reference input as evidence that every derived oscillator was phase-continuous. An internal state reset or loop reacquisition can occur independently of the source, and those pathways require separate challenge. Where the complete receiver architecture is unavailable, the investigator may be unable to eliminate all such alternatives. The conclusion should state the established range and the unresolved portions of the signal path rather than conceal them behind one reference certificate.

Dr. James M. Atkinson, Moderator: Mr. Nyquist, our final principal perspective concerns what sampling can preserve across a discontinuity. Dr. Mills will test whether retrospective timestamp repair supplies any missing phase evidence.

Harry Nyquist, Fifth Principal Contributor: Sampling theory concerns how a bandlimited waveform may be represented under specified acquisition conditions. It does not attest that every intended sampling instant occurred or that the instrument retained an unbiased phase record during a controller transition. The investigator should use a known phase-coded test signal to detect discontinuities that a pure steady tone might conceal. I would evaluate time-tag uncertainty, index gaps and the frequency-dependent consequences of a possible clock step separately. A receiver with

Copyright 2026, James M. Atkinson

excellent average rate accuracy could still be unfit for phase-continuous combination of bursts separated by reference reacquisition.

For each reconstructed interval I would retain the estimated sampling times, their stated uncertainties and the original observed indices. The analyst should compare a constant-rate model with a measured piecewise timing model and report any material difference in inferred phase and correlation. If the alternative models remain compatible with the reference markers yet support different conclusions, the case has not established a unique phase history. This condition is a reason to narrow the claim, not to suppress the contradictory analysis.

The mathematical conditions for reconstructing a waveform must not be mistaken for a historical assertion about the clock which sampled it. An ideal uniformly spaced sampling grid has instants $t_n=nT_s$, where $T_s=1/f_s$ and f_s is the actual sampling frequency. During a reference recovery, actual instants may instead be $t_n=nT_s+\varepsilon_n$, where ε_n denotes sampling-time deviations. A reconstructed sequence evaluated as though every ε_n were zero implicitly assumes away the problem to be investigated. The departures can introduce phase errors increasing with signal frequency. They can also reduce the validity of correlation and direction-finding measurements that depend upon coherent phase across channels. The signal-processing method should state its assumed time grid as a scientific premise.

For a sinusoid $x(t)=A\cos(2\pi f_0 t+\varphi_0)$, a small sampling-time error Δt produces an approximate phase error $\Delta\varphi=2\pi f_0\Delta t$. At a 100 MHz RF-equivalent signal frequency, a ten-nanosecond error corresponds to an

Copyright 2026, James M. Atkinson

entire cycle of phase, so a phase-only estimator would be unable to distinguish that offset from an integer-cycle ambiguity without additional information. In practical SDRs, analogue frequency conversion may reduce the frequency at the sampler, while local-oscillator phase and timing error add other contributions. The calculation must be performed at the relevant frequency and with a coherent model of all conversion stages. It demonstrates why a precise host clock label cannot alone guarantee phase coherence.

A different challenge arises when the receiver actually loses samples. If the hardware counter jumps from n to n+m but the recording contains only the endpoints, there is no measured sequence in the missing interval. No mathematical interpolation can establish whether the external carrier underwent an abrupt phase change while the receiver was blind. A prediction algorithm can produce one plausible continuation under its model, but several different physical histories may remain compatible with the same retained samples. This is a question of identifiability, not of processor speed or the elegance of a resampling algorithm. The final evidence record must distinguish observations from predictions and state where the latter are unsupported by direct measurements.

A controlled phase-coded reference sequence can test both the clock mapping and sample continuity. Choose a known finite-bandwidth waveform with clear correlation markers and inject it through the authorised receiver path while an independent instrument records the source. Compare observed sample indices and marker phase before, during and after a deliberate reference interruption. Change the gap duration, signal level and receiver gain state to reveal whether the apparent

Copyright 2026, James M. Atkinson

continuity depends upon favourable conditions. A successfully tracked marker constrains the sample-to-time relationship for that waveform and configuration. It does not automatically validate all frequencies, especially if an analogue path or synthesiser mode changes between test and operational measurement.

When no independent time witness exists, cross-channel comparison can still provide useful but limited information. Two sample streams driven by one source may preserve excellent relative phase while both accumulate an undetected absolute time error. Channels with separate clocks may exhibit relative drift even when each has good individual long-term stability. An investigator should compute a covariance model for the measurement quantities actually used, including reference sharing and calibration uncertainty. Apparent cancellation of a common error in a differential estimate is beneficial for one defined inference but cannot prove that the common error was physically absent. The choice of estimator must follow the intended question: relative delay, absolute UTC time, or phase history.

I would conclude by requiring three separate acceptance tests. First demonstrate the receiver's data continuity through counter and transport challenge tests. Secondly measure the correspondence between sampled indices and physical elapsed time through known markers and independent reference comparison. Thirdly test the stability of the derived scientific inference under alternative calibrated timing mappings. Only then can one claim that a phase difference or time-of-arrival estimate survived oscillator reacquisition within a stated uncertainty. A receiver can be excellent for broad-spectrum detection while unsuitable for submicrosecond attribution

Copyright 2026, James M. Atkinson

across an unmonitored clock transition. That limitation should guide the report, not become an inconvenience hidden by a smoother plot.

David L. Mills, Cross-Peer Question to Harry Nyquist: If the receiver corrects its host timestamps after the acquisition, can a retrospective calculation recover the relative phase between the first and second halves of the record, or does the claim demand a simultaneous downstream observation?

If a second receiver supplies an independent phase witness, how should its own timing uncertainty, analogue group delay, and possible loss of samples enter the reconstructed bound? I would not accept a corrected waveform merely because the second receiver produces a smoother-looking picture. Which specific observations rule out otherwise compatible cycle counts across the missing interval?

If a phase-preserving resampler assumes a recovered clock model fitted to samples on both sides of a gap, how would you distinguish a justified conditional estimate from a false claim that the missing interval was observed? Would a strong narrowband signal make it safe to interpolate even if a phase jump might have occurred while the carrier was below threshold? Please give a condition under which a multiple-cycle ambiguity remains even if the reconstructed graph looks perfectly smooth.

Harry Nyquist, Cross-Peer Answer to David L. Mills: A timestamp correction can improve the alignment of known events in external time, but cannot supply a phase observation missing from the data. If independent timing markers constrain the boundary sufficiently, a retrospective estimate may be justified with a measured uncertainty and a clear phase-ambiguity statement. Without that evidence, a smooth mapping is a model

Copyright 2026, James M. Atkinson

assumption. The investigator should retain both the original counter chronology and the adjusted labels so that neither is misrepresented as an observed physical phase.

The independent receiver should first be qualified for sample completeness and clock uncertainty over the same disputed interval. Its known waveform feature must be matched to the original receiver through calibrated propagation and analogue delay paths. A phase-continuity claim can then be supported only to the extent that the independent record constrains phase advance strongly enough to exclude alternative integer-cycle histories. If the reference record itself contains a gap or its relative delay is uncertain by more than the separation of plausible phase histories, the ambiguity survives. One should report the set of compatible reconstructions rather than choose the smoothest as if it were an observed truth.

A strong signal can help estimate phase where actual samples exist, but it does not directly observe an interval during which samples were lost or the carrier was undetectable. If an unknown phase step of an integer multiple of two-pi radians can occur within that gap, different physical histories may agree with the same endpoint phases. Interpolation selects one history by model assumption; it does not measure away the ambiguity. The analyst should mark the interval as prediction-only, retain the unmodified endpoint observations and provide sensitivity bounds over plausible phase steps or frequency changes.

A conditional reconstruction can nevertheless be useful when the assumed signal dynamics have independent support. One might, for instance, constrain frequency deviation using a second continuously operating

Copyright 2026, James M. Atkinson

channel with genuinely independent timing, then propagate that constraint across the gap. The result would be an estimate with an explicit uncertainty and a statement of the external evidence on which it depends. Its status is entirely different from an uninterrupted acquisition. No number of additional digits in the corrected timestamp can convert a prediction into a physical observation.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has distinguished four questions too readily collapsed into the word 'stable': whether the frequency converged to a reference; whether the clock's phase remained continuous; whether sample indices and hardware acquisition persisted without gaps; and whether external timestamps remained traceable through state changes. A control loop may improve the first while disrupting or obscuring one or more of the others. Controlled reference interruption, independent downstream phase observation, retained counters, loop-control records, explicit uncertainty budgets and challenge testing across reacquisition are therefore required before a continuity-dependent forensic conclusion is justified. The panel's dialogue is a modern scholarly reconstruction, not a historical record of its participants.

QUESTION 054

Copyright 2026, James M. Atkinson

How can common-reference distribution create correlated errors in supposedly independent receivers?

SCHOLARLY RECONSTRUCTION. The exchanges below are fictional instructional dialogue among deceased specialists, not actual conversations or statements. Contemporary receiver-array applications are editorial extrapolations from historically documented scientific principles.

Dr. James M. Atkinson, Moderator: Professor Townes, an investigator may deploy several receiving channels and take comfort when they report the same phase excursion, the same short-duration event or the same bearing solution. Yet the channels may derive frequency and time from one reference oscillator, from one distribution amplifier, and even from the same mains or battery supply. What exactly remains independent in such a configuration, and by what measurements might the investigator distinguish a genuine external radio-frequency phenomenon from a disturbance introduced simultaneously into every receiver?

Charles H. Townes, Principal Contributor: Dr. Atkinson, the word 'independent' is incomplete unless we specify the random variables, physical pathways and inferential purpose. Two antennas occupying separate locations may encounter independent local interference, yet their receivers may share one frequency standard. Two frequency references may be nominally separate while being disciplined to the same higher-level source. An instrument can therefore possess diversity in one portion of its measurement chain and common-mode dependence in another. Apparent agreement is evidence of reproducibility only for the elements genuinely

Copyright 2026, James M. Atkinson

made independent; it is not automatically two independent demonstrations of an external emitter.

For a simplified phase measurement from channel i, write $\theta_i(t)=\varphi_i(t)+c(t)+e_i(t)$, where θ_i is observed phase in radians, φ_i is the external signal phase as transformed through the antenna and propagation path, c is a common reference-induced phase term, and e_i represents channel-specific measurement error. All quantities must be brought to a declared common reference plane and the model is only an approximation: frequency conversion and sampling may scale or filter the reference contribution differently in each channel. If the same c enters both observations identically, the difference $\theta_1-\theta_2$ cancels c. That cancellation is useful for differential phase but dangerous as a diagnostic of reference health, because two channels can agree while both remain wrong relative to an independent time or frequency standard.

Conversely, a sum or common-mode estimate can emphasise c. If the independent errors e_1 and e_2 are zero-mean, each with variance σ^2, and c is zero-mean with variance σ_c^2 and independent of them, the individual observed error variance is $\sigma_c^2+\sigma^2$, and the covariance between channel errors is σ_c^2. The correlation coefficient is $\rho=\sigma_c^2/(\sigma_c^2+\sigma^2)$. For a hypothetical $\sigma_c=4$ degrees and $\sigma=3$ degrees, $\rho=16/25=0.64$. The mean of two channel errors then has variance $\sigma_c^2+\sigma^2/2=16+4.5=20.5$ square degrees, giving standard deviation approximately 4.53 degrees; the naive independence model yields sqrt((16+9)/2)=3.54 degrees. Both computations are conditional on the model. The naive calculation promises more information than the experiment actually collected.

Copyright 2026, James M. Atkinson

A shared source creates several distinct coupling mechanisms. Its short-term phase noise may propagate through each phase-locked loop with different transfer functions, so perfect cancellation cannot be presumed. Its slow frequency drift can bias absolute-frequency estimates while remaining nearly invisible in a channel-to-channel comparison. A reference distribution amplifier can introduce additive phase fluctuations and amplitude-to-phase conversion. Cable length, temperature and mechanical strain can shift phase differentially. A shared power supply may modulate several oscillators, mixers or converters in a recognisably synchronous fashion. Finally, a common software timestamp authority may correlate nominally separate records even when the front-end oscillators are physically independent.

The time and frequency scales of each coupling must be examined. A reference cable whose electrical length changes by $\Delta\tau$ seconds produces a phase change approximately $2\pi f_{ref}\Delta\tau$ at the reference frequency f_{ref}, but a synthesiser's response at the final receiver frequency depends upon its multiplication ratio, loop dynamics and architecture. It would therefore be improper to multiply the cable phase change by a nominal ratio and declare the exact downstream error without a transfer measurement. A 10 MHz reference is a reference signal, not a guarantee that every receiver's 1 GHz local oscillator inherits exactly the same phase transient at the same instant.

A credible experimental design uses at least three controlled conditions. First, both receiver channels operate from the shared reference, and a benign, known test signal is injected through a documented splitter or an over-the-air source whose geometry is controlled. Second, each channel operates from its own independently monitored reference, with the test

Copyright 2026, James M. Atkinson

signal and receiver gain settings otherwise held constant. Third, the reference connections are exchanged or switched under logged conditions, preferably with an independent phase comparator watching the reference nodes before and after the distribution network. At each condition, retain raw samples or hardware phase outputs, instrument state, counter values and reference health, not simply the resulting bearing or correlation summary.

The perturbation should be innocuous, calibrated and traceable. A small programmed phase modulation of the distribution source may reveal whether apparent simultaneous receiver transients follow the clock network. A thermal or mechanical change to one reference cable can reveal sensitivity to differential delay. A carefully bounded supply perturbation may test supply rejection, subject to equipment ratings and safety, but should never be applied to operating evidence equipment without authorisation. The investigator must not confuse an intentionally introduced test condition with evidence from the environment, and must preserve untouched observational records for comparison.

Spatial evidence introduces an additional complication. Two antennas can observe the same genuine remote carrier with strongly correlated propagation phase. Such correlation is not automatically artefactual; it may be the property being measured. A reference perturbation can be distinguished from propagation by using channels with deliberately different clock trees, by monitoring a local injected calibration tone alongside the external signal, and by changing antenna geometry while leaving distribution wiring fixed. If the anomaly moves with the antenna, the propagation or antenna hypothesis becomes stronger; if it follows the

Copyright 2026, James M. Atkinson

reference line, the clock hypothesis becomes stronger. But coupling and cross-sensitivity mean each test is probabilistic rather than absolute.

Correlation also affects estimates of detection confidence. Suppose an operator treats four coherent receivers as four independent confirmations of an event and multiplies four false-alarm probabilities. This would be justified only if the relevant false-alarm mechanisms were independent under the null hypothesis. A shared digitiser clock or jointly generated interference can instead produce a coincident false event, defeating that multiplication. The relevant null distribution should be measured using the actual multichannel configuration and includes common-mode artefacts, not a mathematical fiction of four independent instruments.

For an evidential report I would require a covariance or dependence description, a clock-tree diagram, a list of common power and data pathways, the method by which relative and absolute phases were calibrated, and an explanation of which errors the processing cancels and which it cannot detect. It is perfectly respectable to use a shared clock for coherent relative measurements. The failing occurs when that deliberate architectural choice is disguised as evidential independence. A properly limited claim might say that the receivers independently observed RF energy at distinct antennas while sharing a timing and frequency source; that statement conveys what was actually corroborated.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Mills, you have particular expertise in disciplined timing systems. What is lost when a common reference network is described simply as a stable source?

David L. Mills, Peer Question: Professor Townes, a central reference can distribute a disciplined frequency while each receiver derives its timestamps through a separate host, buffering layer or internal counter. Some shared failures will appear as simultaneous phase events, whereas others may produce a correlated timestamp correction without any change in the RF waveform. How should a field examination distinguish physical oscillator coherence from software synchronisation and a merely common external time label? Would you also explain why matching timestamps issued by two systems administered through the same network synchronisation service are not by themselves independent confirmation of event time?

There is a practical discontinuity between frequency discipline and the timestamp imposed by an acquisition program. Assume that the host uses a network clock which is temporarily slewed, while hardware sample counters remain monotonic and the local synthesiser is locked to the common RF reference. The two time scales could describe different events with ostensibly compatible timestamps. Would you require a separately stored counter-to-external-time mapping at each station, and how would you test the mapping during an interrupted time service? I am seeking a procedure that distinguishes a genuine physical phase excursion from an administrative clock correction without assuming that all labels generated by one host are trustworthy.

Charles H. Townes, Response: Dr. Mills, trace the reference all the way to the measurement primitive. A physical RF phase observation may depend on a

Copyright 2026, James M. Atkinson

reference oscillator that determines mixer phase or sample-edge placement. A timestamp depends on the mapping from sample counter to external time, which may be updated through software. The two mappings can have different state transitions. Ask whether the clock signal actually controls the acquisition front end, whether it only labels a completed buffer, or whether a host discipline algorithm estimates the offset after data collection. The test should log each stage and introduce perturbations into one stage at a time.

The crucial operational requirement is to retain at least two distinct chronologies. The first is an immutable account of sample acquisition from the device's hardware counter, including its rollover and lost-block indicators; the second is the dated sequence of mappings to external time, including each offset, drift estimate, step and holdover transition. If a network time service slews the host clock while the receiver samples continuously, no missing RF phase observation follows merely from the host adjustment. Conversely the host may show continuous civil time while the synthesiser undergoes a phase step. Measure a common laboratory pulse at the RF input and, separately, a timing marker at the downstream clock edge before and after a deliberate permitted service interruption. The two measurements permit different diagnoses. Record original and corrected labels side by side. A post-processed timestamp that makes multiple stations look consistent is an inference which must be independently assessed, never a replacement for the actual event-counter record.

If two hosts consult the same time service, their apparent agreement may indicate that the service produced a consistent answer, not that the receivers experienced the event at precisely that external instant. Retain the

Copyright 2026, James M. Atkinson

hardware counters and a locally generated timing marker alongside network-clock offset estimates and adjustment logs. Repeat with independent timing supervision and separately measure network path asymmetry where relevant. A common time label is not evidence of a common physical acquisition edge, just as a shared clock does not prove that the software stored every sample. These dependencies must be mapped and reported rather than hidden under an ambiguous synchronised status.

Dr. James M. Atkinson, Moderator: Mr. Harrison, what would a practical clockmaker ask before trusting the distribution apparatus?

John Harrison, Peer Question: Professor Townes, a central source of excellent intrinsic quality must still reach each instrument through a physical connection. Cables warm, connectors loosen, vibration changes strain and different paths acquire different delays. Is it possible for the standard itself to remain stable while the distribution makes the receiving channels disagree? And how ought one distinguish a slowly changing cable delay from a sudden fault in a connector or distribution buffer, especially when the observed radio signal is also affected by environmental motion?

Let us consider temperature and mechanical stress rather than an abstract perfect source. One station has a reference cable routed through a warm equipment rack, another passes through a draughty service duct, and their connectors have been disturbed by transport. Both instruments nevertheless report nominal lock. What measurements at the delivered clock input would show whether the electrical path length changed? Would you examine return loss, connector repeatability, thermal expansion, and load sensitivity as separate mechanisms, and how would you prevent the act

Copyright 2026, James M. Atkinson

of attaching a phase comparator from changing the state being investigated?

Charles H. Townes, Response: Mr. Harrison, intrinsic quality and delivered quality are separate measurements. A stable source at its output terminals does not establish stability after twenty metres of cable, a switching device, and a receiver's internal phase detector. Record a reference-plane diagram and use an independent comparator at the point of use. Measure delay or phase at the distribution outputs over the expected temperature and mechanical conditions. A gentle, reversible temperature dependence may suggest cable propagation effects; an intermittent step associated with movement or re-termination suggests a discontinuous contact or switching phenomenon. Neither inference is conclusive without a controlled test.

One should measure delay at the delivered reference plane under representative thermal and mechanical conditions, then repeat the measurement after a controlled cable exchange. A nominal ten-megahertz reference source does not constrain the exact phase at the end of every cable: the output phase can change with propagation delay even while frequency remains locked. Use a phase comparator with a characterized loading effect, a matched input and stable reference routing, and record the cable's termination and signal amplitude. Vary temperature within a safe laboratory range while logging at least one sensor along the cable and at each connector. If a temperature excursion causes a reproducible phase shift that follows the cable, it favours a physical path-length explanation. Yet the same manipulation can alter a buffer amplifier's operating point, so compare the complete network against a calibrated through-line and

Copyright 2026, James M. Atkinson

examine insertion gain. A conclusion about the cause must specify where the variation first appears and what components remain untested.

The RF antenna system must be challenged independently. A local injected tone carried through a fixed electrical path can establish whether the receiver reports a phase change even when the external propagation channel is removed from the experiment. Next vary the cable path while keeping the antenna path constant; then vary antenna geometry while keeping the reference cabling stable. The diagnostic power lies in changing one causal pathway at a time. When changes cannot be isolated, report the confounding factors and enlarge the uncertainty bound. The humble connector can frustrate an elaborate array, and its effect must not be dignified as a discovery about a remote transmitter.

Dr. James M. Atkinson, Moderator: Lord Kelvin, what does common error do to the asserted precision of an averaged multichannel finding?

William Thomson, Baron Kelvin, Peer Question: Professor Townes, an analyst may compute a standard error that decreases as the square root of the number of receivers, supposing that each contributes an independent observation. If the common reference induces a shared component, what does increasing the number of channels actually accomplish? Please distinguish a shared random contribution from a fixed calibration bias, and consider whether measuring excellent repeatability across many channels can ever be sufficient to establish external accuracy.

Suppose the operator shows me four displays whose excursions agree within a fraction of a degree, then presents a quoted uncertainty divided by the square root of four. I ask what was independently measured rather than

Copyright 2026, James M. Atkinson

how many readouts were printed. What model would distinguish a stable common bias from a fluctuating common disturbance, and how would you estimate their different effects on the mean and on each channel difference? Would the confidence interval change if all channels shared a fan-out amplifier with a switching supply that occasionally produced deterministic phase steps?

Charles H. Townes, Response: Lord Kelvin, take n observations, each with a shared zero-mean error c of variance σ_c^2 and an individual zero-mean error e_i of variance σ_e^2. Assuming the e_i are mutually independent and independent of c, the arithmetic mean has error $c+(1/n)\Sigma e_i$. Its variance is therefore $\sigma_c^2+\sigma_e^2/n$. As n grows, the independent contribution decreases, but the common contribution remains. If n=8, σ_c=4 ns and σ_e=3 ns, the standard uncertainty of the mean is sqrt(16+9/8)=approximately 4.14 ns, not sqrt(25/8)=approximately 1.77 ns as under the incorrect all-independent model.

The number of displayed traces should not appear in an uncertainty formula until the dependence model has been justified. I would compute the covariance of phase residuals from a controlled common injected tone, separately for stable operation and for declared reference transitions. If the random common component has variance σ_c^2 and each channel has independent variance σ_e^2, four channels yield a mean variance $\sigma_c^2+\sigma_e^2/4$. A stable bias b_c is different again: it shifts every result without producing repeat-to-repeat random dispersion and must be calibrated or bounded as a systematic uncertainty. In a switching episode the stationary covariance approximation can be invalid because a coherent step is a conditional event, not one more sample from the quiet random process. Retain its magnitude,

Copyright 2026, James M. Atkinson

timing and response in each branch. A truthful confidence statement will specify the operating state, the estimator, the evidence of dependence and whether a systematic-bias allowance or separate transient scenario is included.

A fixed bias presents a different problem: it does not appear as an across-run random spread and cannot be removed by averaging repeated measurements. If the bias is known, apply an appropriate correction with its own uncertainty; if it is unknown but bounded, retain a systematic uncertainty term or a scenario limit. Repeatability concerns agreement under specified conditions. Accuracy concerns relation to a defined reference or truth, to the extent this is measurably available. Several instruments sharing one defect may exhibit superb repeatability, but they do not thereby validate the asserted absolute time, phase or frequency. The uncertainty budget must reflect the shared design and the actual evidence for correlation.

Dr. James M. Atkinson, Moderator: Professor Poincaré, would you consider whether a convincing agreement is sometimes an artefact of the analyst's model?

Henri Poincaré, Peer Question: Professor Townes, a common disturbance may be mathematically removed by differencing, and a differenced measurement may look exceptionally clean. Yet the discarded common component might be precisely the evidence that the absolute clock or reference was wrong. How should an investigator decide which transformation preserves the quantity of interest? Is it legitimate to interpret low residuals in a differential fit as proof that both channels

Copyright 2026, James M. Atkinson

correctly measured the external event, especially where phase unwrapping and filtering have already imposed assumptions of continuity?

There is an inverse problem hidden in this subtraction. If the comparison software removes an estimated common trace from each receiver, it may also remove the genuine phase evolution of a common transmitter illuminating every antenna. How can the analyst specify the subspace that is discarded, identify the physical parameters which can no longer be recovered, and establish whether the retained differential measurement answers the claimed forensic question? What independent information would allow separation of a common environmental carrier event from a reference-phase event when their predicted channel vectors happen to agree?

Charles H. Townes, Response: Professor Poincaré, every transformation answers a particular question. If our objective is the relative phase between two antenna paths at the same instant, subtracting an exactly common phase term can improve that relative estimate. If our objective is the event's absolute time or carrier phase relative to a traceable external reference, subtraction destroys necessary information. The original observations and the applied transformation must therefore both remain available. The quantity of interest should be written before the processing algorithm is selected, and the report should avoid transferring a conclusion from one estimand to another.

A practical way to preserve this distinction is to archive the original full phase series alongside the residual after subtraction, with the numerical transformation, its reference conditions and the physical estimand explicitly recorded. Otherwise an audit of absolute continuity becomes impossible.

Copyright 2026, James M. Atkinson

Before subtraction, write a forward observation model with separate external-signal parameters and internal-reference parameters. Determine whether the channel vector induced by a possible common transmitter event can resemble the vector caused by a reference step. If so, no difference-only representation can discriminate them. Preserve both original channel phases and the common-mode residual, and measure their responses to independently controlled antenna-path and clock-path stimuli. A difference operator is legitimate for an estimand such as relative delay when its assumptions hold, but it can annihilate the common component essential to a claim about simultaneous carrier modulation. Mathematical identifiability must be tested by the rank of the sensitivity matrix and by the condition number under the actual station geometry and noise levels. Where two hypotheses remain observationally equivalent, report that equivalence. Adding more channels driven by precisely the same clock and receiving the same highly correlated signal may add almost no discriminating information.

Low differential residuals establish only that the chosen model fits the particular differences well. They cannot prove the absolute correctness of each channel, nor can they establish that filtering was harmless. Phase unwrapping may resolve an ambiguity by continuity assumptions that break down during discontinuities or missing samples. Independent phase monitoring and known challenge transients test these assumptions. Where more than one unwrapping or calibration history is compatible with the data, disclose the alternatives and their consequences. A mathematically elegant residual is not a replacement for a physically identifiable reference plane and an independently tested observation chain.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Wiener, what do covariance and spectral structure reveal about a common impairment?

Norbert Wiener, Peer Question: Professor Townes, in practice neither the external radio signal nor the reference noise is guaranteed to be stationary, and different receivers may filter a shared disturbance in dissimilar ways. Can cross-correlation or cross-spectral measurements still provide useful evidence of a common source? What limitations arise when the operator estimates covariance from a short record containing one brief event, removes a trend before analysis, or incorrectly treats coherent environmental signals as independent noise?

Suppose coherence is computed over a long interval containing several minutes of quiet operation and one brief common timing discontinuity. The windowed spectral estimate may represent the transient poorly, and a simultaneous legitimate RF event may itself produce strong coherence. What joint time-frequency controls would you demand to test whether the correlation follows the reference path? Could a controlled modulation be used to estimate a transfer function, and how should the analyst handle phase wraps, nonstationary epochs and finite-window bias before assigning a causal interpretation to the coherence display?

Charles H. Townes, Response: Professor Wiener, cross-spectral measurements are useful diagnostic descriptions, provided they are interpreted conditionally. For two error channels e_1 and e_2, a prominent cross-spectrum at a disturbance frequency can suggest shared modulation or coupling, but it does not uniquely locate the physical source. A coherent remote RF signal, correlated antenna propagation, electrical interference and reference distribution can all create spectral coherence. Controlled

Copyright 2026, James M. Atkinson

interventions are needed to distinguish those possibilities. Record the raw time series, segment selection, windows, smoothing bandwidth, and any detrending operations used to compute the cross-spectrum.

The analyser should also examine whether the measured coherence varies with the chosen window and data subset. A causal explanation that survives reference swapping and controlled stimulus changes is stronger than a high coefficient calculated from one selected stationary-looking interval.

I would first split the record into physically meaningful states: normal lock, a reference-transition interval, and recovery or holdover. Analyse each with explicit windowing and retain the underlying phase samples so that the spectral average cannot erase a one-off step. A stable injected tone provides an independent path to measure the reference-to-output transfer function; a known RF input modulation measures the separate antenna-to-output response. Compare magnitude and phase at several modulation frequencies and test whether the model predicts a controlled disturbance at a frequency not used in fitting. High spectral coherence is not an attribution. A common external emitter, shared clock, supply coupling and even common DSP interpolation can generate correlated signatures. If phase wraps occur, document the unwrapping algorithm and verify it against raw complex samples. For an episodic event, report the time-domain response directly and avoid compressing a rare transition into a Gaussian noise floor derived from quiet intervals.

A short interval containing one transient is particularly vulnerable to overstated spectral inference. Frequency-domain averages assume some meaningful repeatability or local stationarity; an isolated event may instead be more informatively compared in the time domain with known controller-

Copyright 2026, James M. Atkinson

state transitions. Preserve its amplitude, duration and relative timing at every monitoring point. Coherence between receivers should be measured before and after reference swapping, with independent local signals where possible. The ideal is agreement between a physical intervention and the predicted change in the cross-channel statistics. Without such intervention, correlation is evidence of dependence, not a certificate of cause.

Dr. James M. Atkinson, Moderator: Professor Kálmán, how might a state estimator conceal a shared disturbance while presenting credible output covariances?

Rudolf E. Kálmán, Peer Question: Professor Townes, digital receiving instruments frequently estimate clock offsets, drift and phase from noisy observations. Several channels may be processed through one shared reference model or one common prediction step. Under what conditions may a filter's stated uncertainty become overconfident because the model omits correlated process disturbances? How should one assess the resulting innovation sequence and distinguish a genuine phase disturbance from a change introduced by model resetting or covariance tuning?

I am concerned that the software model used by both receivers might itself manufacture agreement. If the two filters share a common clock prior and the same smoothing routine, their small reported innovation variance may say little about physical independence. What innovation cross-correlation and leave-one-channel-out tests would you require? If the clock undergoes a discrete transition that the linear process-noise model does not permit, could the estimator redistribute it into transmitter state or location, while returning misleadingly small posterior uncertainty? Please specify which underlying data must remain inspectable.

Copyright 2026, James M. Atkinson

Charles H. Townes, Response: Professor Kálmán, an estimator's covariance is only as trustworthy as its state and disturbance model. If two channels receive a common process perturbation but their filters treat errors as independent, the resulting joint covariance matrix is incorrectly diagonal. Subsequent fusion can overstate information and yield a narrow uncertainty interval despite correlated residuals. One remedy is to augment the state with an appropriately modelled shared disturbance and estimate its covariance; another is to use measured cross-covariance or conservative bounds when a full state model cannot be justified. The appropriate choice depends upon identifiability and available calibration data.

This challenge is especially important at the instant a controller changes reference states. The filter may remain numerically stable while its assumptions about process noise, measurement independence or source continuity cease to hold. Such transitions belong in the validity register.

A state estimator can conceal a physical failure if its model attributes every observed residual to the parameters it was designed to estimate. Inspect raw pre-filter phase and timing observations, the innovation sequence at each receiver, and the innovation cross-correlation between receivers. Under a correctly specified model those innovations should exhibit the expected covariance and temporal structure; coherent excursions suggest a missing common state, incorrect input disturbance, or shared processing error. Conduct leave-one-receiver-out and independently clocked control runs. Introduce a known laboratory reference phase step and require the estimator to flag the state change rather than silently move the estimated emitter. Verify the provenance of all clock-correction data and retain the actual gain matrices, noise assumptions and transition flags. A small

Copyright 2026, James M. Atkinson

covariance reported by software is only a conditional mathematical output. It does not certify that its process model included the correct physical fault.

Innovation sequences should be inspected for synchronised transients, nonzero cross-correlation, state-dependent bias and unexplained variance changes. A covariance reset may make later error bars look small without establishing that the unobserved reference transition was continuous. Maintain a controller-state log and compare raw observations to filtered states across deliberately introduced reference changes. Sensitivity tests varying process-noise assumptions may reveal that a claimed localisation or timing result depends heavily on an unvalidated model. Do not describe an internally consistent estimator as externally accurate until an independent check supplies that missing evidence.

Dr. James M. Atkinson, Moderator: Professor Michelson, what test of physical independence would you accept before relying upon simultaneous observations?

Albert A. Michelson, Peer Question: Professor Townes, interference measurements can detect exceedingly small changes, but they also inherit the behaviour of mirrors, supports, temperature and reference paths. Modern receiver arrays likewise promise precision while sharing their physical surroundings and engineering infrastructure. Which controls would distinguish a common environmental disturbance from a genuine radiation-field effect, and how would you design a reference-swapping trial whose results could be reproduced by a second laboratory rather than depending upon an operator's interpretation of one attractive display?

Copyright 2026, James M. Atkinson

When one swaps reference branches between receivers, the operation changes cable stress, contact impedance and sometimes the relative timing of analogue and digital stages. How can a laboratory experiment establish causality rather than merely produce a new configuration with a new noise floor? I would like a repeated intervention plan that includes a known good reference, a known imposed defect, fixed RF calibration inputs and an independent observer. What result would distinguish the genuine common-clock contribution from a receiver fault, and what inconclusive outcomes must be reported rather than interpreted opportunistically?

Charles H. Townes, Response: Professor Michelson, design the experiment around explicit competing explanations and a set of interventions whose outcomes would differ. A genuine incoming-wave phase change should depend predictably on antenna geometry, source direction and propagation conditions. A clock-network phase event should correlate with an independently observed reference perturbation and remain when the antenna input is replaced by a documented local test signal. Common mechanical vibration may disturb both antenna cables and reference distribution, so vibration, temperature and supply measurements should accompany the comparison rather than be treated as irrelevant background.

The same trial must preserve the source waveform, detector settings and receiver reference clock for later independent reanalysis. Only then can a negative result be judged against the actual sensitivity of the experimental configuration rather than an unstated assumption that the equipment must have observed every relevant event.

Copyright 2026, James M. Atkinson

The purpose of an intervention sequence is to seek different predictions from different causal hypotheses, with the test conditions recorded before examining the results. Under a common-source defect, a deliberately imposed source phase modulation should propagate through both receivers according to their calibrated transfer functions. Under a single-branch defect, swapping branches should move the anomalous signature with the branch, subject to documented cable and connector conditions. Under a receiver-local impairment, the disturbance should remain more closely attached to the receiver when the same reference and RF calibration inputs are exchanged. These are conditional predictions, not guaranteed binary outcomes. Repeat A-B-A tests with a sham manipulation and monitor the reference source, fan-out ports, power supply and RF inputs simultaneously. If the manipulated system also changes dynamic range or noise floor, report that as a limitation. A single falling spectral peak does not establish the absence of an external signal.

For reproducibility, publish the connection diagram, component identities and firmware versions, the calibrated source and comparator configurations, stimulus amplitudes, trial schedule, environmental limits and unedited time series. Randomise or blind the order of reference configurations if observer expectations could influence event classification. Include negative controls in which no perturbation is applied. Independent reproduction should seek the same causal distinction, not merely a similar-looking chart. If the perturbation follows a particular distribution module when moved between systems, that is more informative than two reports generated from the same unchallenged apparatus. The report should say

Copyright 2026, James M. Atkinson

exactly which faults have been excluded and which shared pathways remain untested.

Dr. James M. Atkinson, Moderator: I pass the principal token to Lord Kelvin for an independent examination of multichannel uncertainty, and then invite Professor Wiener to challenge that model.

William Thomson, Baron Kelvin, Second Principal Contributor: Dr. Atkinson, agreement between receivers should be expressed in a model that distinguishes common errors from individual errors. An average of n channels does not suppress a disturbance copied identically into every channel; it suppresses only those variable contributions that are suitably independent. More importantly, one must specify whether the desired measurement is absolute time, differential phase, received field strength or location. A perfectly shared reference phase might cancel from a relative-phase estimate while remaining fatal to a claim about the absolute time of the event. I would demand a clock-tree drawing, comparisons of source and branch phase, and intervention tests in which one reference path is replaced while the RF stimulus is held fixed. The resulting covariance should be derived from observations, not guessed from the number of receivers. I invite Professor Wiener to examine whether a static covariance can describe a transient switching event.

I would begin the uncertainty budget at the physical reference plane, not at the end of a spreadsheet. Consider four phase observations $y_i=\theta_i+c+e_i$, for channels i=1 through 4. Here θ_i is the receiver-dependent phase of the intended signal, c is an additive common-phase disturbance in radians, and e_i is channel-specific error. In a calibration experiment with identical

Copyright 2026, James M. Atkinson

applied signal phase, we may investigate the statistical properties of c and e_i. If their variances are σ_c^2 and σ_e^2, and all e_i are mutually independent and independent of c, the variance of the four-channel mean is $\sigma_c^2+\sigma_e^2/4$. Increasing to sixteen channels changes the second term to $\sigma_e^2/16$, while the common component remains untouched. The inference is conditional upon independence and stationarity. It is not a theorem that four receivers necessarily produce a twofold improvement in total measurement precision.

A numerical illustration should make the issue visible. Suppose a shared reference produces a random standard deviation of 0.8 degrees of phase at the measurement offset of interest, while each individual receiver contributes an independent standard deviation of 1.2 degrees. A single channel then has root-mean-square uncertainty $\sqrt{(0.8^2+1.2^2)}=1.442$ degrees, under the stated zero-mean and independence assumptions. The mean of four has $\sqrt{(0.8^2+1.2^2/4)}=1.000$ degrees. A naïve analyst who divides the single-channel figure by $\sqrt{4}$ reports 0.721 degrees and materially understates the variance. The difference is not an administrative dispute over significant figures. It is the consequence of a physical conductor carrying one perturbation into several apparently distinct observations.

It would be equally incorrect to insist that a shared term always corrupts the measurement. Define a differential estimate $d_{ij}=y_i-y_j$. If the shared disturbance enters both measurements with precisely the same coefficient and at exactly the same event time, c cancels, yielding $d_{ij}=(\theta_i-\theta_j)+(e_i-e_j)$. This cancellation is an advantage in a well-designed coherent experiment, but it is not an absolute-time calibration. If two distribution branches have different phase transfer functions, c enters as h_i*c-h_j*c, where the asterisk denotes convolution. Their unequal gain, delay, or loop

Copyright 2026, James M. Atkinson

bandwidth may prevent full cancellation even though both are connected to the same reference oscillator. A diagram of a common source therefore cannot replace a measurement of the two delivered clock edges.

The covariance matrix reveals this architecture more faithfully than an isolated accuracy certificate. Under the simplified model, $\Sigma=\sigma_c^2 \mathbf{1}\mathbf{1}^T+\sigma_e^2 I$, where 1 is the vector of four ones, I is the identity matrix, and the superscript T denotes transpose. Its diagonal elements are $\sigma_c^2+\sigma_e^2$, while each distinct off-diagonal element is σ_c^2. The common direction, represented by 1, has variance eigenvalue $4\sigma_c^2+\sigma_e^2$. Each of the three differential directions has eigenvalue σ_e^2. These are the modes which different estimators emphasise or reject. Before applying them to the field record, establish that the measurement quantities have compatible units, that a linearised phase model is justified, and that finite sample covariance has not concealed a deterministic step.

Consider what a station operator means by the phrase independent confirmation. A second antenna may independently intercept a radio wave but share the first antenna's conversion oscillator, ADC sampling edge, mains supply, trigger service and software timestamp mapping. For an amplitude-only question the common ADC clock may be less consequential than the analogue front-end; for a frequency excursion it may be decisive. For a source-location question the spatial separation matters, yet the shared timestamp origin and any calibration offsets remain germane. I would insist that each evidential assertion specify the particular random variables claimed to be independent and the controls by which that claim was challenged. Counting independent housings, vendor serial numbers, or separate on-screen traces does not answer a statistical question.

Copyright 2026, James M. Atkinson

A second difficulty is the possibility of systematic rather than stochastic error. A fixed branch delay of forty nanoseconds will not be revealed by the apparent scatter of repeated timing measurements if the delay remains stable. At a nominal electromagnetic propagation speed of 299,792,458 metres per second, forty nanoseconds correspond to approximately 11.99 metres of path-difference equivalent. It does not follow that the position estimate is wrong by precisely twelve metres, because the inverse geometry changes the mapping between delay and position. The correct report carries the delay bias as a bounded or calibrated term and propagates it through the actual geometry. Statistical averaging does not repair a measurement whose reference plane was misidentified.

Finally, the calibration must include more than the distribution source in isolation. Measure the source, each fan-out branch, and the relevant receiver output against an independent standard where practicable, preserving the chain of uncertainties. Record each instrument's detection bandwidth and noise contribution so that a sub-floor comparison is described as a limit rather than a measured physical absence. A repeatable shared transient may warrant a deterministic intervention model rather than a covariance estimate derived from quiet operating minutes. Lord Kelvin's problem, in modern analytical language, is to prevent an elegant algebraic uncertainty from acquiring authority beyond the physical observations that support it. I therefore pass the token to Professor Wiener to examine the temporal model itself.

Norbert Wiener, Cross-Peer Question to Lord Kelvin: Lord Kelvin, the common disturbance is unlikely to be stationary throughout an investigation. When a distribution amplifier switches supply mode or a

Copyright 2026, James M. Atkinson

phase-locked loop reacquires lock, its errors may be episodic, and covariance computed across many quiet minutes could dramatically understate the event interval. Would you distinguish the ordinary-operation covariance from a state-dependent or bounded transient model? What record would permit a later analyst to decide whether several simultaneous spectral detections came from one underlying reference disturbance, rather than independent emissions arriving at several antennas?

You have proposed a covariance structure that distinguishes common and independent terms, yet it presumes a defined operating regime. Consider a fan-out system in which a shared oscillator is stable, but one supply switching event imposes a short step on all receiver phases. If a long calibration record contains that event only once, a stationary covariance estimate may be highly sensitive to where the analyst placed the windows. Would you treat the episode as a separate state, represent it by a bounded timing or phase discontinuity, and calculate its effect on each estimand individually? If an instrument later filters or smooths the record, what original evidence would remain necessary to prevent the model from portraying the transition as ordinary random noise?

William Thomson, Baron Kelvin, Cross-Peer Answer to Norbert Wiener: Professor Wiener, one covariance matrix cannot be presumed valid across different physical states. Divide the record at documented reference changes and estimate the dependence within each genuinely comparable operating regime. For an isolated transition, retain its measured amplitude and duration and formulate a bounded scenario, rather than force the event into an inappropriate Gaussian noise assumption. Simultaneous independent observations are useful only if independent reference controls

Copyright 2026, James M. Atkinson

were present. A stable local injected tone may exhibit a common step when the clock tree changes, while external spatial observations should be separately challenged by antenna geometry and propagation. The point is to use interventions that discriminate hypotheses. A low steady-state variance is not a warrant to ignore a large unmodelled discontinuity.

A change of operating state should be modelled as a change of the experiment, not hidden within an average. I would retain a state-labelled time series, with the transition time established by an independently witnessed reference-plane measurement. Within a stable state, a covariance estimate may describe the random part of the error; for the transition, a measured or bounded phase step may be more honest. Suppose the shared step is 0.03 radians at each of four channels, while their individual random-phase uncertainty is only 0.001 radians. Treating the step as one more draw from the random distribution would grossly misrepresent its importance during the actual event. An absolute phase estimate inherits the near-common step; a true differential estimate may cancel it if the branch transfer functions match, but a difference between unequal filtered versions of the step can produce a transient of its own. Thus the propagated error must be computed using the transfer functions for the actual channels and the exact estimator. Repeated quiet measurements do not establish that the transition will be benign.

I would require four complementary records. The first captures source and port phase during the reference transition. The second preserves downstream receiver phase or sample-timing observations. The third records control states and supply disturbances that might explain the change. The fourth specifies the data-processing transformation that the

Copyright 2026, James M. Atkinson

operator used to display the result. A reconstructed event should be compared against those records without discarding the unprocessed phase stream. If the transition occurred only once, a probability distribution inferred from that single occurrence is weakly supported; the report may instead state an observed bound under an explicitly defined configuration. Where multiple events exist, their dispersion can be estimated but only after checking whether they belong to one physical population. I agree with Professor Wiener that a stationary model cannot be transferred across a reference switch without experimental justification.

Charles H. Townes, Response to Lord Kelvin and Norbert Wiener: Their exchange identifies why cross-channel coherence is both the benefit and the forensic risk of the shared reference. Its cancellation in differences must be demonstrated experimentally for the exact measurement functional. I would retain both differential and common-mode phase streams, because deliberately discarding one may make the other appear more conclusive than the evidence warrants.

Dr. James M. Atkinson, Moderator: Professor Wiener, please examine the shared disturbance as a dynamic multichannel process rather than a single covariance coefficient. Professor Townes may then test the causal interpretation.

Norbert Wiener, Third Principal Contributor: The common reference should be analysed as an input to a multichannel system with frequency-dependent transfer paths. A disturbance may be shared at its origin yet appear with distinct amplitudes, phases and delays at individual receiver outputs. Correlation estimated during quiet operation does not characterise a rare

Copyright 2026, James M. Atkinson

re-lock transient. I would examine cross-spectra and time-domain responses under deliberate safe source perturbations, keeping the antenna stimulus unchanged. The inferred dependence belongs to a specified configuration and state, not to a permanent universal coefficient.

To call the common reference a single number conceals a process with memory. Let $c(t)$ denote the reference-induced phase variation at the source, and let $g_i(t)$ represent the impulse response of the entire distribution and conversion path serving receiver i. An observed perturbation may be expressed as $z_i(t)=(g_i*c)(t)+u_i(t)$, where u_i includes unshared receiver noise and other unmodelled terms. In the frequency domain, $Z_i(f)=G_i(f)C(f)+U_i(f)$. Two receivers may therefore display similar narrowband disturbances while disagreeing in phase and magnitude because their distribution paths differ. Even the sign of a time-domain excursion can be transformed by filtering, AC coupling, phase wrapping or derivative-like tracking loops. No one should infer a simple contemporaneous common cause from a pair of coloured spectral traces without checking those transfer paths.

A cross-spectral measurement offers one avenue of inquiry. If the reference perturbation is wide-sense stationary over the selected interval and the unshared noises are independent of one another and of the reference, $S_{ij}(f)=G_i(f)G_j^*(f)S_{cc}(f)$, where the star on G_j denotes complex conjugation and S_{cc} is the reference phase-noise power spectral density. A normalised magnitude-squared coherence can then be written $\gamma^2_{ij}(f)=|S_{ij}(f)|^2/[S_{ii}(f)S_{jj}(f)]$, provided both denominator spectra are nonzero. A value near unity means that variation at that frequency is linearly related between the channels under the estimator's assumptions. It does

Copyright 2026, James M. Atkinson

not reveal whether the relation arises from a genuine common transmitter, shared reference modulation, a local supply line, or a shared processing artefact.

The engineer should distinguish a stochastic fluctuation from an episodic state change. A slow random-walk phase component, a supply-related periodic spur, and a reference switch that occurs once in twelve hours produce markedly different statistical records. The first may be modelled with an appropriate low-frequency spectrum; the second may be studied as a deterministic periodic disturbance, with harmonics and load dependence; the third is a transition event whose amplitude, duration and exact sequence should be preserved in the time domain. If one long record is partitioned into short segments for spectral averaging, the lone switching event may influence only one or two segments and be submerged in an overall average. A smooth plotted curve can therefore be a poor account of the episode most relevant to the forensic question.

Time lag matters as much as amplitude. Suppose the fan-out produces a common short phase step, but one local synthesiser reacts after ten microseconds and another after thirty. The correlation of their phase records may be highest at a twenty-microsecond lag rather than at zero lag. If the investigator assumes identical time stamps for the plotted events, the displacement may masquerade as propagation between antennas. To diagnose the situation, simultaneously inject a controlled reference-path challenge while supplying the RF inputs with a stable known signal, and measure the downstream response of each synthesiser. A separate antenna-path challenge then tests whether the observed delay belongs to reception or to local clock recovery. Neither test alone can establish all

Copyright 2026, James M. Atkinson

relevant causes, but together they reduce an otherwise broad class of explanations.

One may also make a useful two-condition comparison. In condition A, channels one and two share the same ten-megahertz source, and a weak line near a known injected carrier appears in both spectra. In condition B, channel two takes a second low-noise reference with verified stability while the RF stimulus and analogue signal paths remain as unchanged as practicable. If the line moves, weakens or decorrelates, reference dependence becomes a plausible explanation. But the intervention has itself changed local-oscillator noise, PLL settling and possibly receiver sensitivity; those changes must be measured with a retained calibration tone. A feature that falls below the altered detection floor has not thereby been proved absent. Causal attribution rests on whether the entirety of the altered response fits an independently tested transfer-function model.

A further danger lies in spectral leakage and estimator tuning. Finite windows spread the energy of a discrete component across neighbouring bins; overlapping segments may make adjacent spectral estimates statistically dependent. Coherence can rise artificially if a deterministic carrier dominates both channels, even though their random noise sources are genuinely independent. One should estimate and report the window, resolution bandwidth, number of statistically informative averages, confidence limits, and the effect of subtracting or retaining common calibration tones. If the signal occupies a frequency range where a receiver's phase tracking saturates, linear cross-spectral reasoning becomes dubious. We may need a nonlinear or state-dependent response model, or may have to restrict the claim to carefully bounded operational conditions.

Copyright 2026, James M. Atkinson

The result of these tests should be expressed as a model challenge rather than a triumph of correlation. I would ask whether a measured reference-path perturbation predicts the phase, amplitude and timing of a receiver artefact within stated uncertainty. If the same model predicts the response to a distinct challenge amplitude and an altered branch configuration, its credibility improves. If it predicts only the data from which its parameters were fitted, then the apparent fit may be overfitting rather than explanation. A quiet comparative trace can coexist with a shared bias; a high coherence can coexist with a genuine remote emission. I pass the token to Professor Poincaré, for the remaining question is which physical quantities are identifiable after the observations have been transformed.

Charles H. Townes, Cross-Peer Question to Norbert Wiener: Could high coherence in a cross-spectrum be sufficient evidence that the receivers share one defective reference, or could a coherent external RF source produce the same mathematical appearance?

Your coherence model depends on the channel transfer functions and on treating the disturbance as a process with an appropriate spectral description. Suppose a legitimate narrowband transmitter is itself coherent across both receiving antennas and the shared distribution reference develops a sinusoidal spur at the same offset frequency. Their contributions occupy the same spectral bin. Can phase-coherence magnitude alone distinguish these physical sources? Which controlled interventions would change the clock contribution without systematically attenuating the genuine RF contribution, and how would you guard against the misleading conclusion that a feature which diminishes after changing a reference must have been wholly internal? In particular, what negative-control

Copyright 2026, James M. Atkinson

measurement would reveal the simultaneous change in receiver sensitivity or local-oscillator noise floor caused by the replacement reference?

Norbert Wiener, Cross-Peer Answer to Charles H. Townes: The coherence describes shared variation, not unique causation. A real transmitter, a common disturbance carried through antenna paths and a reference-network spur can each produce coherence. Controlled changes of reference source, antenna geometry and injected calibration tones are needed to distinguish them. The analyst must also retain the frequency plan and the synthesiser transfer functions because an internal reference spur may appear at several translated frequencies.

No magnitude-squared coherence statistic can, by itself, identify the physical origin of a common sinusoidal component when both hypotheses predict the same coherent line. One must force their predictions apart. I would preserve a fixed known RF calibration input while varying the reference perturbation, recording whether the line's complex amplitude follows the calibrated clock-to-output transfer function. Independently, I would change the RF input through a controlled attenuator or reference-plane injection while leaving the reference network fixed, then examine whether the relevant component behaves as an externally received signal. A second receiver using a demonstrably independent clock and separate analogue path can provide a valuable contrast, but even that channel may observe the same legitimate emission and therefore remain correlated. Its evidence must be interpreted under its own sensitivity and timing model. A feature that vanishes only after an alteration which also raises the detection floor cannot be assigned to the changed clock with confidence.

Copyright 2026, James M. Atkinson

I would also measure phase, not merely spectral amplitude. The clock-induced component often has a predictable phase relation to an imposed reference modulation, while a genuine remote component's relation depends upon its own waveform, propagation and acquisition configuration. If the two mechanisms coincide at one offset frequency, challenge the clock at a second offset and test whether the predicted response transfers. In a small-signal linear regime the different paths may be represented with separate transfer functions, but the model should not be extrapolated through PLL unlock, cycle slips or saturation. The analyst should retain the complex spectra with their window conventions, state labels and calibration uncertainty. Coherence is a diagnostic observable, not a declaration of source. I return the token to Professor Townes with the qualification that discrimination, not mere numerical agreement, is the standard of a convincing investigation.

Dr. James M. Atkinson, Moderator: Professor Poincaré, I invite your attention to the distinction between the quantities preserved and discarded by differential processing. Lord Kelvin will ask whether the resulting error bounds remain meaningful.

Henri Poincaré, Fourth Principal Contributor: The inferred result depends on which difference the analyst regards as meaningful. Subtracting receiver phases may cancel a common error and thereby support a relative measurement; the same subtraction can conceal a defect relevant to absolute timing. A shared reference improves the definition of one coordinate system while reducing independence of the observations used to validate it. I would specify the estimand, reference plane and transformation before interpreting the residuals. If an unexplained common component

Copyright 2026, James M. Atkinson

was removed, the report should still show it to the examiner rather than present only the aesthetically cleaner differential trace.

We should begin with the geometry of the inference. Let the vector y contain the measured phases from n receivers, x contain the desired external signal parameters, a contain unknown common-reference disturbances, and ε contain residual errors. A local linear model may be written $y=Hx+Ba+\varepsilon$. Here H is a sensitivity matrix for the external field, B describes the reference perturbation's effect on the receivers, and the rank of the combined matrix [H B] governs whether different parameter combinations can be distinguished. If one column of H is a linear combination of columns of B, the relevant external parameter is not identifiable from the available observations. No increase in computational precision, receiver count with identical geometry, or number of decimal places can restore information that the experiment did not record.

To clarify, suppose every receiver reports a common small phase rise, and the sought external model permits a simultaneous phase rise of equal magnitude at all antennas. A model with a genuine transmitter phase event and a model with a common reference jump then produce the same phase vector. In the simplified observation space they are indistinguishable. A differential projection D with $D1=0$ eliminates an exactly shared disturbance, but it also eliminates a genuine common-mode component of the received field. One can improve sensitivity to relative phase while losing the very external parameter that one hoped to establish. The projection may be optimal for one estimand and destructive for another. The analyst must therefore state the quantity that remains observable after every subtraction, normalisation, detrending and reference correction.

Copyright 2026, James M. Atkinson

An apparent solution can be unique numerically without being unique physically. Imagine an optimiser that estimates transmitter direction, reference offset and branch delays, and returns a single set of parameters with a negligible residual. If the associated Jacobian is poorly conditioned or rank deficient, a family of nearly equivalent parameter sets may fit within the noise. A regularisation penalty can select a tidy member of that family, but the chosen value inherits the penalty's assumptions. A report should separate the directly observed data, the constrained model solution and the conclusions induced by priors or regularisation. Where the result concerns a possible covert emitter, this distinction has forensic importance: an algorithmically stable output is not equivalent to scientifically identified cause.

Calibration signals offer a means of increasing observability, provided their pathway is selected intelligently. A tone injected after the antenna and before the analogue receiver tests some internal conversion steps but not antenna coupling or feeder-current pickup. A radiated calibration field tests a different portion of the chain and may introduce multipath. A reference-input phase perturbation probes the clock transfer function, while a controlled variation in cable route probes an external conductor pathway. Because the interventions enter at different locations, they create new equations with different sensitivities to external and internal parameters. A carefully designed set of interventions can increase the rank of the effective problem. Merely repeating the same measurement at greater precision cannot.

I would distinguish structural identifiability from practical identifiability. Structural identifiability asks whether an ideal noiseless experiment can

Copyright 2026, James M. Atkinson

uniquely determine the parameters under the model. Practical identifiability asks whether the actual geometry, bandwidth, instrument noise and time coverage allow a useful estimate. A parameter might be structurally identifiable yet too weakly excited to estimate at the observed signal level. For example, a branch delay can in principle be measured from phase slope across frequency, but a single narrow carrier gives phase only modulo 2π. Several frequencies or a suitably wideband calibration waveform may unwrap ambiguity, subject to the stability of the response during the measurement. A local single-frequency phase match alone should never be reported as an absolute cable delay without the necessary ambiguity analysis.

An explicit counterexample is often more instructive than a general appeal to uncertainty. Construct two candidate mechanisms: A is a legitimate transmitted phase change applied to the same RF source observed by all antennas; B is a reference-clock phase change introduced upstream of every local synthesiser. Calculate or simulate their predicted observations with the actual phase and frequency conversion conventions. If they coincide under the measurement chosen, the evidence does not discriminate them. Then propose a measurement, such as a separate independent-clock receiver or direct source-reference comparator, on which their predictions differ. The new test should be planned before seeing its outcome, and its sensitivity and rejection criterion recorded. Otherwise the investigator can always invent a post hoc explanation for whichever result occurs.

One must also resist treating the absence of an anomaly in a transformed variable as proof that the underlying physical event was absent. Averaging may eliminate anti-correlated contributions; differencing may eliminate

Copyright 2026, James M. Atkinson

exactly shared contributions; thresholding may omit weak excursions; and phase unwrapping may inadvertently classify a genuine discontinuity as a computational reset. Preserve the untransformed complex samples where permitted and maintain a reversible transformation record. The very same measurement can support a strong statement about relative channel consistency and only a weak one about whether an external emitter existed. I invite Professor Michelson to devise physical tests that make these alternative predictions observably different.

William Thomson, Baron Kelvin, Cross-Peer Question to Henri Poincaré: If common-mode subtraction yields a small differential residual, may it justify a correspondingly small uncertainty interval for a source position or an absolute phase observation?

You have explained that a common-mode projection may remove both an internal defect and a physically real external component. Consider three receivers in which a location solver uses only relative phase and time differences. The residuals are small after subtraction, but the original channel records contain a simultaneous step. What precise inference remains justified by the residual fit, and what would you require before alleging that the step came from the room rather than the reference network? Can the conditioning of the source-location geometry and the rank of the augmented reference-error model show that the apparent solution is unidentifiable despite a persuasive residual statistic? Would your judgement differ when independent reference-plane measurements show that the common phase step persisted with the antenna input electrically terminated?

Copyright 2026, James M. Atkinson

Henri Poincaré, Cross-Peer Answer to William Thomson, Baron Kelvin: Only where the desired quantity truly depends upon the difference and the common contribution demonstrably cancels. An absolute phase inference retains the omitted common uncertainty. A localisation model also includes differential branch delay, geometry, propagation and waveform identification. A small residual under one transformation does not validate those other terms. The declared uncertainty must follow the measurement equation, not the visual attractiveness of the transformed trace.

A small residual after differencing establishes that the measured channel differences are consistent with the chosen model, to the precision and under the conditions tested. It does not establish that the common component of the original observation was a physical emitter or an instrument defect. Formally, if the external model and the common-reference model possess a shared column direction in the sensitivity matrix, their effects are not separately identifiable from those observations. An augmented matrix with deficient rank discloses the structural ambiguity; a matrix with a very large condition number discloses practical sensitivity to small uncertainties. If the location solver ignores branch timing biases, it can produce an apparently tight coordinate whose uncertainty budget fails to include the relevant unknown. A meaningful location claim must include the receiver geometry, correlated timing errors and calibration path delays, then show that independent evidence constrained those effects.

Consider a hypothetical three-receiver system. Each reports a common phase rise of 0.02 radians while their differences remain almost constant. One model attributes this to the emitter's instantaneous phase, a second to a shared synthesiser reference. The difference data alone cannot

Copyright 2026, James M. Atkinson

discriminate the two. A separate reference comparator, a receiver independent of that source, or an intervention that modulates one reference branch while holding the RF stimulus fixed introduces additional information. Where such evidence is absent, the proper finding is that relative phase relationships were stable across the event, not that a specific emitter was identified. I would preserve the original common-mode record precisely because it documents the phenomenon erased by the differential transformation. The evidence must not be made more certain by deleting the terms which make its interpretation uncertain.

Dr. James M. Atkinson, Moderator: Professor Michelson, please turn our discussion from inference to experiment, examining what controlled branch-swapping can actually demonstrate. Professor Wiener will challenge the limits of one unrepeated transient.

Albert A. Michelson, Fifth Principal Contributor: A good physical experiment is designed so that explanations compete under controlled changes. For a reference network I would retain a known tone through each receiving path, swap the distribution branches, and then substitute an independently monitored clock while leaving the antenna environment fixed. If the feature follows one branch, examine that branch; if it follows the source, examine the reference; if it follows a cable or antenna orientation, examine coupling. No one swap is conclusive because reconnecting apparatus may itself alter impedances or thermal conditions. Replicate with appropriate controls and record every departure from the original state.

The experimenter should demand a physical arrangement that can be deliberately rearranged without losing sight of what is held constant. Let the

Copyright 2026, James M. Atkinson

initial configuration employ two receivers, a common ten-megahertz reference, identical injection cables and matched known RF calibration tones. Record phase at the output of the central oscillator, at each fan-out port, at the synthesiser-derived sampling clock when accessible, and in the stored complex I/Q data. The measurement is not complete because the display shows a sideband: it is complete only when the disturbance has been traced to the earliest plane at which it becomes detectable. Each added probe, however, changes loading and possibly shielding. Record termination and instrument insertion effects, then compare the result with a probe-free control.

The first intervention should move a component, not merely turn it off. Exchange the two distribution branches at their receiver inputs, leaving the receivers and calibration-tone injection unchanged. A fault that follows a branch output suggests a path-specific contribution; one that remains with a receiver suggests its local circuitry or software. Yet an exchange may simultaneously alter cable strain, contact resistance and temperature. The experiment therefore requires repeatable geometry, connector inspection and a subsequent return to the baseline configuration. The observed result should be an A-B-A sequence, and ideally a replicated B-A-B sequence, rather than one change recorded as decisive evidence. Repeat the comparison while documenting supply ripple and thermal conditions.

The second intervention challenges a common impairment directly. Apply a small authorised phase perturbation to the laboratory reference through a characterised injection path. Measure whether the phase excursion at each receiver matches the independently measured distribution transfer function. Suppose the imposed test modulation has 0.02 radians peak at a

Copyright 2026, James M. Atkinson

particular offset and receiver one transmits it with gain 0.8 while receiver two transmits it with gain 0.5, both in the small-signal regime. Their predicted peak responses are 0.016 and 0.010 radians. If the measured response departs from these values, the discrepancy may reveal additional branch gain, conversion error or an invalid linear model. The numerical figures are illustrative, not product specifications or evidence from an actual survey.

The third intervention must protect the possibility that a genuine radio emission is present. Perform an antenna-path measurement with the reference unchanged, using a calibrated local radiated stimulus only where lawful and suitable. Compare it with a direct electrical injection made at a defined front-end connector. A remote signal may be seen by a portable independent-clock receiver even where a shared-clock spur moves when the reference distribution is altered. Conversely, a cable carrying common-mode current may collect real external energy and be altered by moving the cable. A decreased receiver display after an RF choke or branch reconfiguration cannot be taken as an assertion that the environment became silent. The apparatus and the environment must remain conceptually separate even when physically coupled.

An instrument's own phase-noise floor should be established before asking it to certify a better source. When two correlated analysis paths share a reference or calibration tone, cross-correlation can reduce uncorrelated measurement noise but does not remove fluctuations common to both channels. A dedicated phase comparator may provide a lower floor than a general swept analyser, though its advantages depend on the actual measurement architecture. Document offset frequency, phase-noise units,

Copyright 2026, James M. Atkinson

calibration power, detector settings and the number of independent averages. Challenge the result with a through connection or a low-noise substitute. A floor-limited absence of detected sidebands is not a measurement of zero sidebands.

The sequence of observations should be blind where practical. One investigator may change a branch, inject a calibration challenge or restore the baseline while a second reviews the anonymised output, records the resulting hypothesis classification and states a confidence bound. The withheld condition is then revealed and compared with the pre-registered prediction. This protects against confirmation bias in interpreting very small spectral differences. The test matrix must include quiet controls, known injected reference defects, known RF stimuli and combinations of both. A system that correctly recognises only pure cases but fails when the two causes coexist is not adequately qualified for a field investigation in which such combinations are entirely plausible.

Finally I would describe the evidential deliverable as a traceable set of experiments rather than a bare assertion that the receivers are independent. The investigator should identify which functions share an oscillator, distribution amplifier, clock cable, power rail, acquisition host or timestamp service, then supply the measurements which justify treating a subset of their errors as independent for a particular estimand. If the evidence does not separate a common-reference transient from a real simultaneous emission, the finding should be reported as unresolved. Physical integrity of the apparatus and integrity of the inference are two different tasks. I pass the token to the moderator with that limitation, for it is the proper boundary of the experiment.

Copyright 2026, James M. Atkinson

Norbert Wiener, Cross-Peer Question to Albert A. Michelson: How can we distinguish a transient appearing only once from a genuine causal effect if the act of exchanging cables and references changes the ambient environment?

A controlled intervention may itself change the system that we are trying to understand. Suppose the cable exchange requires opening the enclosure, the temperature of the distribution amplifier changes slightly, and the common spur disappears for several minutes before returning. How would you design repeated sham and genuine interventions to discriminate causality from thermal recovery or mechanical settling? What records should be captured at the oscillator, individual ports, receiver input and digital output before, during and after the manipulation? If the result cannot be replicated, would you treat it as evidence of a transient mechanism rather than pretend to identify a specific defective component? What observations would distinguish a temporary contact restoration from the normal warm-up history of a phase-locked loop?

Albert A. Michelson, Cross-Peer Answer to Norbert Wiener: Retain a baseline and use repeated interventions with negative controls. Record temperature, supply ripple and local interference simultaneously. Where a transient cannot be reproduced, present its time association as an observation rather than assign a unique cause. Source substitution can give valuable evidence but an isolated coincidence has limited discriminating power. The final finding should state which competing explanations were challenged and which remain unexcluded.

Copyright 2026, James M. Atkinson

The procedure should distinguish a reversible intervention from an uncontrolled disturbance of the apparatus. Before opening the enclosure, record a baseline with the same antenna stimulus, reference source, termination, temperature and analyser settings, including raw complex samples where possible. Perform a sham intervention that mimics the delay, movement and environmental exposure without exchanging the target branch. Then perform the planned exchange, restore the original arrangement, and repeat the sequence on a different day or after sufficient thermal settling. A simple before-and-after comparison cannot separate cable effects from warming, contact movement or a change in power-supply load. An A-B-A-B design offers more evidence of reproducibility, although it is not immune to long-term drift. Monitor source phase and fan-out branch phase with an independent comparator, and document probe loading so that the act of measuring does not create the suspected anomaly.

A positive finding would mean that the measured effect follows the predicted intervention across repeat trials within the measurement uncertainty. For example, if a spur consistently follows the physical fan-out port while receiver identities, calibration inputs and software settings are exchanged, a port-associated mechanism becomes more plausible. It does not mean that a remote emission was necessarily absent, since the defective path may modulate genuine received energy. Conversely, if the spur appears only during one warm-up interval and never repeats under a controlled challenge, the data support an intermittent event but do not identify its microscopic cause. Retain the unsuccessful trials and avoid selecting only the clearest graph. The final report should disclose precisely which hypotheses the experiment distinguished, which were not tested, and

Copyright 2026, James M. Atkinson

what measurement floor limits the negative results. This is the difference between an experimental diagnosis and a persuasive anecdote.

Dr. James M. Atkinson, Moderator, Closing Synthesis: A shared reference does not invalidate multichannel reception. It establishes a defined dependence which can be an advantage for coherent differential measurements but a material limitation for independent corroboration. The proper analysis separates antenna-path phase, common reference noise, distribution-path delay, host time mapping and correlated processing assumptions. The panel requires independent reference supervision, deliberate reference swapping, retained raw observations, an empirically defended covariance model and transparent uncertainty statements. Agreement between channels supplied by one defective reference remains agreement; it is not two independent demonstrations that the external event was correctly timed or attributed. This dialogue is a constructed modern pedagogical exercise.

Which observations discriminate clock drift, sample loss and delayed receiver buffering?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

SCHOLARLY RECONSTRUCTION. This dialogue is a modern educational fiction involving deceased historical contributors. It is not a transcript. Contemporary SDR and software references are editorial applications of their documented concepts.

Dr. James M. Atkinson, Moderator: Dr. Hopper, a receiver operator notices a sudden absence of samples on a waterfall, followed by a later burst of apparent detections. The temptation is to infer either that the transmitter stopped or that the receiver oscillator failed. But the acquisition clock may have drifted, the receiver may have lost samples, or samples may have accumulated in a host buffer and arrived late. Which contemporaneous observations are indispensable to discriminate these mechanisms, and how should an examiner preserve the chronology without mistaking a visually continuous graph for a continuous physical measurement?

Grace Murray Hopper, Principal Contributor: Dr. Atkinson, the first responsibility is to separate events at the antenna from events in the instrument, transport, operating system and display. A waterfall is a derived presentation, not an acquisition ledger. It may update at an irregular rate even when hardware samples are steady; it may also display a smooth interpolated picture across an interval in which no samples were collected.

Copyright 2026, James M. Atkinson

The examiner must identify which subsystem owns each clock, which counter advances when a sample is produced, which counter advances when a packet is delivered, and which timestamp marks an observation rather than its later processing. These distinctions are part of the evidential model, not optional engineering housekeeping.

Let n be a hardware sample index, f_s the nominal sample rate in samples per second, t_0 the acquisition start time, and $\varepsilon(t)$ the fractional sample-clock frequency error. Under an ideal fixed clock, the time assigned to the nth sample is $t_n=t_0+n/f_s$. With a slowly varying actual rate $f_s[1+\varepsilon(t)]$, the elapsed time for N samples instead approximately equals the integral of $dn/[f_s(1+\varepsilon)]$, and for small constant ε it is $N(1-\varepsilon)/f_s$. Drift changes the mapping between sample index and physical time even when all samples survive. A missing group of samples produces an index or sequence discontinuity. Buffering delay changes when the host receives or presents samples but does not necessarily change their acquisition order or physical sampling interval. Each mechanism can create a similar disturbance on a graphical display while leaving a different signature in the raw records.

Suppose a receiver nominally produces 2,000,000 complex samples per second and its clock runs fast by ten parts per million. The actual rate is 2,000,020 samples per second. During a 60-second interval the difference in accumulated sample count relative to a perfect two-megasample clock is 1,200 samples. That does not mean that 1,200 samples have vanished; it means a nominal-rate timestamp inferred from the count would differ in its time mapping. By contrast, a genuine missing segment of 1,200 samples at the nominal rate corresponds to approximately 0.6 milliseconds of unobserved acquisition time, provided the loss occurred in a continuous

Copyright 2026, James M. Atkinson

hardware stream. These numerical examples are hypothetical, and clock models must be corrected for the actual receiver architecture.

The third case is host buffering. Imagine that a device continuously acquires and numbers every sample while the host processor is momentarily occupied with a disk operation. The delivery process may stall for 200 milliseconds and then issue several packets rapidly. If the hardware index sequence remains intact and device timestamps follow the expected acquisition cadence, there has been a delivery delay but no evidence of missing RF samples. However, an unbounded host queue can eventually overflow, turning delay into genuine loss. Thus a correct report must differentiate backlog without loss from backlog followed by loss, and must not treat queue length alone as proof that every intermediate sample was recorded.

A robust acquisition record should retain, where the apparatus exposes them, monotonically advancing sample counters; first-sample timestamps at the device; packet sequence identifiers; receive error codes; out-of-sequence and overflow indications; device and host buffer utilisation; start, stop and retune commands; clock-lock transitions; and the operating-system monotonic times at which packets were received. Not all devices expose each field. The analyst must explicitly state which safeguards are absent. A host-created counter incremented only after successful delivery does not independently establish how many samples the hardware generated and discarded before delivery.

Distinguishing tests should be designed as a small factorial experiment. First perturb the acquisition clock by a safe, calibrated amount while maintaining a sufficiently capable transport and record reference-marker phase versus

Copyright 2026, James M. Atkinson

hardware index. The expected signature is a continuous index stream with a changed relationship between sample number and independent reference time. Next inject controlled packet loss or reduce host throughput without altering the device clock; the expected signature is a discontinuity in sequence identifiers or missing hardware-time intervals, accompanied by error metadata where supported. Finally impose host load that creates queued delivery while remaining below overflow; the expected signature is delayed packet arrival with continuous counters and acquisition timestamps. The three outcomes should be recorded separately and then challenged under combined conditions.

To avoid confusing a transmitter dropout with acquisition loss, observe a known benign reference tone or time marker through a parallel independent measurement chain. If the disputed signal disappears but the local reference marker persists continuously in the same receiver samples, a receiver-wide sample gap becomes less plausible, although selective front-end artefacts remain possible. If both vanish from the raw record, one must distinguish a common RF path interruption from acquisition loss using counters, a second receiver and input-chain controls. If packet indices are missing, reconstruction cannot restore the unmeasured waveform by merely drawing a line between the last and next displayed points.

The hierarchy of evidence matters. The strongest claim of uninterrupted acquisition requires agreement between a trustworthy hardware sequence, measured timing behaviour and raw sample integrity. A green application status, a steady average throughput counter or a smooth spectral trace is weaker evidence. The chain of custody must preserve original files, hashes, buffer-error records, calibration and clock configurations, application

Copyright 2026, James M. Atkinson

versions and every derivative transformation. Later resampling and interpolation may serve analysis, but they must be labelled as computations over a possibly incomplete record. An expert witness should describe what the instrument observed, what its software estimated and what the investigator inferred as three separate propositions.

Dr. James M. Atkinson, Moderator: Professor Nyquist, would you address how a drifting clock affects spectral inference without necessarily causing lost samples?

Harry Nyquist, Peer Question: Dr. Hopper, analysts often associate samples with an exact configured sampling frequency and thereby treat the displayed frequency bins as invariant. Yet a drifting acquisition oscillator changes the physical spacing of those samples in time, even when their number and order are perfectly preserved. How would you distinguish a sample-clock frequency error from packet loss using a precisely known tone, and why must one avoid treating a narrow spectral displacement as conclusive evidence that the external transmitter changed frequency?

A drifting sampling clock changes the physical time represented by each recorded index, even though the acquisition stream need not lose one sample. Please distinguish a known fractional frequency error from sample-rate jitter, a phase-step event and a true absence of data. If the investigation contains only a stable RF test carrier which was derived from the same reference as the receiver, could its apparent frequency remain unchanged when both drift together? What independent signal or timing marker would you use to expose that circular calibration, and how would you state the relevant measurement interval?

Copyright 2026, James M. Atkinson

Grace Murray Hopper, Response: Mr. Nyquist, the known tone becomes an independent ruler for the time base, provided its source is itself characterised and its path is controlled. Record raw samples, compute the tone's phase increment per sample and compare it with the phase increment expected from the externally measured source frequency. A gradual change in the increment, accompanied by continuous counters, supports a changing sample-clock map. A sudden index discontinuity with no intervening samples points to loss or a device restart rather than a mere frequency offset. The operator should also inspect the local oscillator and digital downconverter, because their frequency errors may resemble sampling error. Frequency-bin displacement is an observation; attribution to the transmitter requires an instrument challenge and a reference trace.

The instrument's frequency translation must also be checked. A measured frequency offset in the saved baseband samples may come from an RF input shift, local-oscillator drift, or a sample-clock scale error, and these explanations do not predict the same behaviour when the centre frequency or decimation ratio changes. A second calibrated reference tone and a record of the synthesiser settings can separate the hypotheses. The investigator should test more than one tone, because an offset at one frequency cannot by itself identify the mechanism. When the second instrument shares the suspect clock, the comparison may conceal rather than expose the original fault. The result belongs in a bounded uncertainty analysis, not a claim of absolute truth.

A separate, independently clocked calibration waveform is the proper instrument for testing the relationship between hardware sample index and elapsed physical time. If the receiver and test tone inherit the same

Copyright 2026, James M. Atkinson

defective reference, a proportional change can cancel in the apparent frequency estimate. Record the known tone's source oscillator and measure its frequency against a separate standard, while preserving the acquisition device's raw counters. A progressive error in the index-to-time relation points toward rate calibration, whereas a missing counter interval indicates an omitted sample range if the counter was assigned at capture. A reference switch may produce a phase discontinuity with no omitted indices, and random sample-time jitter requires a different short-term analysis from fixed frequency offset. The report should distinguish the observed sample sequence from the inferred elapsed seconds, and avoid attributing every suspicious waterfall gap to a clock defect. One physical waveform may contain a real burst exactly when the display stalls; only the stored acquisition record can show which parts were actually observed.

Dr. James M. Atkinson, Moderator: Professor Wiener, how would you analyse the irregular delivery sequence without confusing transport time with signal time?

Norbert Wiener, Peer Question: Dr. Hopper, a host records bursts of packets, some separated by large gaps and others arriving almost simultaneously. An investigator might treat the packet-arrival intervals as samples of the incoming radio field or infer discontinuity from their variance. How should a statistical analyst separate queue-induced arrival jitter from actual acquisition timing, particularly when there is no direct observation of every device clock edge and the transport path itself may re-order packets?

Suppose the transport path has a temporary service interruption and then delivers a densely packed cluster of blocks, all with apparently valid host

Copyright 2026, James M. Atkinson

timestamps. Which observations show whether the hardware acquired the samples continuously during the pause? Would the queue occupancy and backlog clearance follow a deterministic calculation when arrival and service rates are measured? In a multi-receiver system, could the same host scheduling interruption cause simultaneous delayed detections that an operator mistakes for a simultaneous change in the external radio field? What evidence distinguishes the time of reception from the time a block became visible to the software?

Grace Murray Hopper, Response: Professor Wiener, define two time axes from the outset. Device-time metadata describes acquisition according to the device's clock model. Host arrival time describes completion of a transport and scheduling path. Their difference is a latency observation containing device buffering, transport and scheduling effects. Correlation between the axes may help characterise a pipeline, but an irregular host-arrival process does not alone establish an irregular sampling process. Packet identifiers and device timestamps can reveal that a burst arrived late yet retained the original order; when packets are reordered, sequence numbers allow their acquisition order to be reconstructed, assuming the identifiers are trustworthy and wraparound is handled. If sequence information is missing, do not claim more continuity than the data prove.

A packet-arrival histogram is especially vulnerable to interpretation when the host changes its scheduling priority. Its peaks can reflect operating-system timer granularity, interrupt moderation or coalesced network delivery rather than any modulation of the captured RF signal. The correct exercise is to preserve paired device and host timestamps for each block and examine the distribution of their differences under deliberately

Copyright 2026, James M. Atkinson

changed host load. A queue whose mean latency is modest can still produce a rare extreme delay, and a short recording cannot establish the tail probability with confidence. Report measured maxima, observation duration and the untested operating envelope. These details matter because evidential burst timing may depend upon exactly such rare events.

The first task is to inspect original device sample indices rather than host arrival timestamps. If blocks arrive late but their hardware-origin indices form an uninterrupted sequence and the physical clock remains calibrated, the RF observations can be restored to their original order by replay. Simultaneously measure the queue's occupancy and each service interval. For a simple fixed-rate model, a stopped consumer accumulates data at the source rate until service resumes; the backlog then clears only to the extent that downstream service exceeds ongoing production. The computation must include protocol overhead and concurrent traffic. Two receiver displays that freeze together because one host scheduler paused are not independent witnesses of an environmental event. The system should preserve source-level counters, USB or network transport status, queue high-water marks and file-segment boundaries so a reviewer can locate precisely the layer at which data were delayed or lost. A recovery that merely updates the screen is not proof of continuous acquisition.

Dr. James M. Atkinson, Moderator: Dr. Mills, where do network-time corrections enter this evidential distinction?

David L. Mills, Peer Question: Dr. Hopper, some acquisition systems map hardware sample counters to a host clock that can be slewed or stepped by a network time service. A jump in the displayed event time might then originate in timestamp conversion rather than in the ADC, while a

Copyright 2026, James M. Atkinson

monotonic display might conceal a physical discontinuity. Which clock records and transition logs should be retained, and how should a report handle an interval in which the host's time estimate was disciplined but not independently verified?

A clock service can revise the mapping from a monotonic local counter to civil time while the device continues to sample. How should an examiner preserve the original uncorrected event chronology when a time-server adjustment, holdover mode or reassociation occurs during a capture? Would you retain every version of the time transformation and identify the interval for which source-clock phase continuity is uncertain? If a later correction improves UTC alignment, what can it legitimately repair, and what information about missed samples or a phase discontinuity remains permanently unavailable?

Grace Murray Hopper, Response: Dr. Mills, retain both the uncorrected sample chronology and the applied mapping to external time. In particular, record raw device counters and time tags, host monotonic timing, wall-clock adjustments, synchronisation state, clock offset estimates and the versioned conversion algorithm. A host clock step can change event labels without changing the recorded sample sequence. A slew changes the conversion rate over time. Where a disciplined source is unavailable or its uncertainty unquantified, express the external-time result as conditional on the adopted mapping rather than retroactively pretending that a smooth corrected timestamp was an original hardware observation. A second independent timing witness improves the case but must have a genuinely independent clock path.

Copyright 2026, James M. Atkinson

A modern time correction should leave the prior acquisition record intact. The software can compute an improved UTC estimate for every sample index, but it must preserve the original device timestamp and the mapping then in force. If the host clock stepped or slewed during capture, mark the mapping interval and identify the controller state which authorised the change. It is unsafe to repair historical timestamps silently because an adversarial reviewer must be able to reproduce both the original and corrected findings. Where the clock was in holdover, state how its uncertainty grows with time and whether an independent reference independently checked the predicted drift. Precision in a formatted timestamp is not evidence that these assumptions were satisfied.

Retain the original device counters, raw capture time tags and the exact software conversion used when each event was first stored. If a time service subsequently corrects the host clock, append the revised transformation as a new version with its effective epoch and uncertainty, never overwrite the original ledger. A corrected UTC estimate may improve alignment of already observed events with external records, provided the clock relationship was measured adequately. It cannot recreate a missed RF observation or prove that a receiver synthesiser maintained phase continuity across a reference interruption. A visible lock indication is often based on a local control criterion rather than the continuity of every downstream sample edge. Test these cases separately using a known pulse and independent reference witness under deliberately controlled service interruptions. Where the index-to-time mapping cannot be reconstructed uniquely, retain a qualified interval and disclose the ambiguity rather than smooth the entire record to fit one preferred chronology.

Dr. James M. Atkinson, Moderator: Professor Kelvin, what does a missing segment do to a timing uncertainty budget?

William Thomson, Baron Kelvin, Peer Question: Dr. Hopper, a report might quote microsecond precision for a burst that falls close to an acquisition gap, even though the gap's boundary is only partially documented. How should a metrologist distinguish uncertainty in an observed timestamp from ignorance of an unobserved event, and when is a numerical standard deviation inappropriate? Would a longer record with excellent average clock stability cure an unmeasured gap in the middle of the relevant event?

A report may display timestamps to microsecond resolution beside a discontinuity whose physical duration and cause have not been measured. What uncertainty budget would distinguish oscillator fractional-frequency error, trigger latency, filter group delay, source-to-receiver path delay and the unknown start or end of an acquisition gap? Is it defensible to average a missing observation into a small standard error derived from quiet intervals? Please explain how an uncertainty bound should change if a known calibration pulse falls just before the gap, compared with an event whose only claimed occurrence lies wholly within the unobserved interval.

Grace Murray Hopper, Response: Lord Kelvin, a recorded event with a timestamp has a measurement uncertainty whose components may include clock mapping, detection delay, resolution and trigger threshold. An event not observed because the measurement chain was blind is different. Its occurrence time is unknown within a coverage gap and perhaps not identifiable at all; assigning the same narrow standard deviation used for neighbouring measured events would misrepresent the evidence. A useful report can give a bounded observation interval, specify the exact known

Copyright 2026, James M. Atkinson

coverage windows, and distinguish the absence of a reported detection from evidence that no transmission occurred. Long-run clock stability does not retrospectively supply RF samples that the instrument never collected.

An unresolved missing interval also constrains negative findings. An investigator cannot declare that an emission did not occur during a period for which the receiver collected no trustworthy samples. A narrow timestamp uncertainty computed from surrounding samples does not measure ignorance of the missing event. One may instead report the verified observation windows and, where possible, upper bounds on the undetected-event duration which the equipment would have resolved within those windows. This distinction is decisive when a transient might have appeared and vanished during the blind interval. Keep uncertainty about the clock separate from uncertainty about whether a sample or an entire signal was ever observed.

Every uncertainty term must correspond to a defined observable. For an event that was actually sampled, the timing estimate can include oscillator-rate uncertainty accumulated over the relevant interval, calibrated trigger bias, filter group delay and transport-to-timebase correction. A stable systematic path delay is not reduced by repeated measurements; it needs correction or a bounded allowance. If the event lies entirely within an omitted sample range, no observed event time exists to which one may attach a small standard error. At most the available records can constrain a time interval within which an event might have occurred, and even that interval depends on the continuity and calibration of the bounding clock. An independently timed pulse before the gap may help establish the pre-gap mapping, but does not ensure continuity across an unlogged reference

Copyright 2026, James M. Atkinson

switch. A sound report separates what was directly measured, what was bounded, and what an inference model merely predicts.

Dr. James M. Atkinson, Moderator: Dr. Kálmán, may an estimator repair these missing observations?

Rudolf E. Kálmán, Peer Question: Dr. Hopper, modern processing may run a state estimator across sample gaps and output a smooth estimated trajectory. A visually persuasive record can therefore emerge even when the sensor supplied no measurements during an interval. What distinction should be drawn between a state prediction and a directly observed waveform, and how can the analyst reveal when the estimator becomes overconfident because its process model excludes an unexpected frequency jump or transient transmission?

A modern reconstruction algorithm can propagate a state estimate through an interval containing no measurements, and its resulting curve may be smooth and well behaved. Under what circumstances might the filter's reported uncertainty underestimate the true uncertainty because its process-noise model omits clock changes, packet loss or non-Gaussian interference? Can the analyst identify at every time whether a state was directly updated by observed samples or merely predicted from earlier data? How would the experiment reveal whether a persuasive reconstructed spectral line owes more to a model assumption than to actual retained RF evidence?

Grace Murray Hopper, Response: Professor Kálmán, the filter may propagate a state distribution through a gap, but it cannot transform a prediction into an observation. Mark each update as measurement-

Copyright 2026, James M. Atkinson

supported or prediction-only, preserve its covariance under the actual model and record the duration since the last reliable observation. An unexpected change in signal state during the gap is not recoverable without independent information. Sensitivity analysis should vary the assumed process disturbance and inspect whether the final classification changes. A narrow filtered trajectory obtained by setting unrealistically small process noise is an artefact of the estimator's prior assumption, not proof of uninterrupted reception.

A state estimator used across a gap should therefore retain a flag indicating prediction-only operation. Its covariance must include process uncertainty which normally grows as the time since the last direct observation increases. A filter that returns narrow confidence limits by assuming constant frequency and negligible process noise can appear precise even when an unseen frequency jump would invalidate the inference. Run a sensitivity test using credible alternative disturbance models and report whether the scientific conclusion changes. A phase-continuity claim should not be restored merely by smooth interpolation. Where the data support more than one plausible history, retain the alternatives rather than selecting the one that makes the graph most elegant.

A filter prediction is not a measurement. It is a conditional estimate based upon the prior state, the transition model and the assumed process-noise distribution. When a sample gap occurs, the software must mark that no measurement update was applied, preserve the actual interval boundaries and expand uncertainty in accordance with plausible unobserved disturbances. If the physical system may undergo an unmodelled clock phase step, the standard Gaussian process model may be inadequate; the

Copyright 2026, James M. Atkinson

estimate can remain smooth while becoming badly wrong. In validation, inject a known missing block while the external RF source continues a prearranged pattern and compare the predicted waveform with the withheld ground truth. Record whether the estimator's confidence bounds cover the actual result and whether it properly reports epistemic uncertainty. Export both original data and the derived reconstruction, clearly differentiated. No algorithmic continuity should be presented as direct evidence of a transmission in a period for which the receiver retained no samples.

Dr. James M. Atkinson, Moderator: Professor Hamming, what controls ensure that software has not silently omitted evidence?

Richard W. Hamming, Peer Question: Dr. Hopper, the process that stores samples may treat a transport warning as a recoverable exception and keep producing files, yet write no conspicuous marker that acquisition has failed. How should software assurance and a deliberately engineered fault-injection test expose this behaviour? What should be checked when the driver reports an overrun but the application file remains syntactically valid and apparently full length?

I wish to challenge a different form of confidence. Suppose the stored file length is exactly as expected and a cryptographic hash confirms that the file has not been altered since acquisition. Is there any basis for concluding that the ADC produced all expected samples, particularly if the driver might have duplicated a block before the hash was computed? Which independent invariants would detect upstream loss, duplicate ranges, counter rollover and concealed interpolation? How would you test the detector itself using

Copyright 2026, James M. Atkinson

deliberate faults rather than assume that a green status indicator is an integrity certificate?

Grace Murray Hopper, Response: Professor Hamming, a syntactically readable file is not an integrity certificate. Instrument the path so that every receive operation records status and sequence information, and make exceptional states persist into the evidential log. A challenge test should safely saturate the host or throttle an authorised test transport, then verify that an overflow or out-of-sequence condition is signalled and that the stored file identifies the corresponding interval. Compare sample counts against independent hardware counters and known injected markers. When a format lacks gap annotations, preserve a separate, cryptographically linked acquisition ledger. Also test the case where application software catches an error but fails to propagate its severity to the operator. The relevant question is whether the forensic user can discover a failure after the fact, not merely whether the program remained running.

A useful independent check compares the permanent acquisition ledger against a hardware-origin sequence during deliberate stress testing. If the driver is made to drop a block, the forensic report should identify the precise segment where continuity was lost; if the extent is unknown, the report should say so. A test must challenge a system which resumes recording automatically after an error, because the return to normal service can conceal a preceding gap. Hashing the final data establishes resistance to later alteration but cannot certify that data missing before storage were ever captured. Software assurance must demonstrate failure observability, not merely continued operation after a fault.

Copyright 2026, James M. Atkinson

A cryptographic hash proves consistency with the material that was hashed, not that the material faithfully represents the antenna event. If the driver duplicates data upstream, the resulting file may have the expected size and an impeccable digest. Construct independent checks: a hardware-origin counter assigned at acquisition, a deliberately varying calibration sequence, status records from the ADC or DMA engine, and a comparison between expected and actual sample-index ranges. Test boundary conditions, including counter wrap and partially written final blocks. Inject known faults at different layers so that one can see which integrity indicators respond and which remain silent. The provenance record should identify the firmware and driver version, configured format, all sample drop indications and any substituted or interpolated data. An unflagged reconstruction step must be treated as a defect in the evidence pipeline. A sound system is permitted to admit that its completeness is unknown.

Dr. James M. Atkinson, Moderator: Professor von Neumann, how should one design the storage and transport system so that the observation is not sacrificed to presentation?

John von Neumann, Peer Question: Dr. Hopper, real-time acquisition often competes with disk compression, waterfall rendering, signal classification and operator interaction. A computationally intensive interface can delay the processing of an otherwise steady RF stream. What architecture separates hard acquisition obligations from discretionary visualisation, and what quantitative resource margins and stress tests ought to precede any claim that the system records a given bandwidth without loss?

Consider an installation where capture, spectrum analysis, waterfall generation and disk writing share a processor and an operating-system

Copyright 2026, James M. Atkinson

scheduler. A blocking filesystem operation may be only a few milliseconds long, yet many sample streams continue arriving during the interval. What minimum buffering should have been reserved, and how could the team determine its usable capacity under competing load rather than rely on a brochure figure? If the buffer fills and a driver silently drops the oldest block, would a graceful-looking screen recovery establish that the underlying chronology survived? What architecture would preserve evidential capture as the highest-priority function?

Grace Murray Hopper, Response: Professor von Neumann, place bounded, measurable acquisition buffers and a minimal capture path ahead of discretionary analysis. Calculate the source byte rate from the actual complex-sample representation, channel count and metadata overhead. For example, eight channels at 2 million complex samples per second, with 16 bits for each in-phase and quadrature component, generate 8×2,000,000×4=64,000,000 bytes per second before packet, framing or filesystem overhead. The sustained write path must exceed the incoming rate with sufficient margin for bursts and housekeeping. Measure rather than assume that the operating system, storage medium and transport meet that requirement under worst credible load. Visualisation and classification should be rate-limited or decoupled so that failure to draw a waterfall does not force a loss of RF samples. Record actual queue high-water marks, measured throughput and overload events during qualification.

A comprehensive capacity test should include a simultaneous high-rate stream, intentional display workload, sustained disk output and a short adverse scheduling event. Record actual data throughput, queue high-water

Copyright 2026, James M. Atkinson

marks and drop counters before, during and after the event. If the capture survives, confirm this with a known marker sequence, not only its file length. If it fails, the output must mark an unambiguous boundary at which the stream ceased to be complete. Test each hardware format used in the field, since a change from eight-bit to sixteen-bit complex representation or the addition of channels may double or multiply the byte rate. The assurance statement must remain confined to the configurations actually challenged.

Copyright 2026, James M. Atkinson

The acquisition path should be sized and tested for the aggregate stream rate under worst-case permitted operation, with adequate allowance for storage stalls and transport overhead. At eighty megabytes per second, a quarter-second outage consumes roughly twenty megabytes of free buffer space before considering traffic already queued; with several receivers, the requirement scales accordingly. The actual safe capacity is the free space available at the moment of interruption, not the nominal array allocation printed in a manual. Decouple capture from optional waterfall drawing and classification; keep a minimal, measurable write path, preserve device-origin indices and make every overrun conspicuous. A display can recover visually after the queue drops data, so screen smoothness is no guarantee. Conduct repeatable stress tests with an externally known RF pattern, and stop or segment acquisition with explicit gaps when the hardware cannot meet its declared completeness requirement. No subsequent viewer should be allowed to mistake buffered presentation for direct sample chronology.

Dr. James M. Atkinson, Moderator: The principal token now passes to Professor von Neumann to assess whether storage architecture can preserve chronology; Dr. Hamming will test the resulting claim.

John von Neumann, Second Principal Contributor: Dr. Atkinson, it is a conceptual error to identify the schedule of receiving packets with the schedule of sampling the electromagnetic field. A device produces observations under a hardware-clock regime; an interface transfers blocks under a transport schedule; software processes them under a third. A backlog may be innocent if a bounded queue retains all correctly indexed samples, but a full queue can transform delay into an unrecoverable omission. I would calculate the stream rate, independently measure worst-

Copyright 2026, James M. Atkinson

case sustained storage throughput and retain high-water buffer measurements and drop counters. A reference pulse repeated at known intervals supplies a physical check on index continuity. The critical qualification is that software-generated sequence identifiers might advance only after a packet is delivered; they cannot prove whether the device discarded data upstream. I invite Dr. Hamming to specify the requisite failure-testing logic.

A useful architecture distinguishes the antenna observation, the hardware conversion, the transport mechanism and the host's presentation. The analogue-to-digital converter produces samples according to a physical clock. The device's counter describes the order of those samples, provided the counter is attached to acquisition rather than packet dispatch. A bus interface subsequently transports blocks with variable service times, and a host may delay processing them while remaining able to preserve their original sequence. Treating those four stages as one undifferentiated 'real-time receiver' conceals which of them can create a false temporal gap. The original evidence should identify sample indices at capture and the timebase by which those indices are converted into seconds. A host file-creation time cannot retroactively define the instantaneous arrival of a radio pulse at the antenna.

Consider a receiver acquiring complex samples with each in-phase and quadrature component represented by sixteen bits. At twenty million complex samples per second, the nominal payload rate is 20,000,000 times 2 components times 2 bytes, which is 80,000,000 bytes per second, approximately 80 MB/s in decimal units. The corresponding bit rate is 640 Mbit/s before transport framing, metadata and any additional copies. If

Copyright 2026, James M. Atkinson

twelve such channels run continuously, the nominal aggregate is 960 MB/s and the host must sustain that rate as well as its associated interrupt, buffering and disk workloads. If the storage subsystem offers only 750 MB/s of actual sustained service under the configured file format, the deficit is 210 MB/s. A 4.2 GB free buffer then fills in roughly twenty seconds if those rates remain constant. This is a hypothetical capacity calculation, not an assertion about a particular instrument or computer. It shows why a good-looking sample-rate specification alone is not an acquisition guarantee.

I should define the actual units before an engineer compares the numbers. A megabyte in this example contains one million bytes; a mebibyte contains 1,048,576 bytes. Any buffer calculation must account for whether the device transmits packed twelve-bit data, padded sixteen-bit words, or a different sample representation. Some transport links add packet headers, parity or retry traffic. An application may allocate a nominal queue whose usable capacity is reduced by bookkeeping and memory pressure. Report the measured payload throughput, actual free buffer bytes, long-run disk performance and maximum plausible stalls. A bench test of a pristine new disk does not show the throughput of a nearly full drive under thermal throttling or competing analysis tasks.

The transport path must preserve identity, not merely a count of blocks. Suppose a device labels each original sample with a monotonically increasing hardware index. Block A covers samples 100,000 through 103,999 and block C begins at 108,000. The absence of indices 104,000 through 107,999 establishes that the delivered stream omitted 4,000 expected sample positions, assuming index assignment occurred at acquisition and the counter did not itself jump. Without such a counter, a host that receives

Copyright 2026, James M. Atkinson

two consecutive packet numbers proves only that no packet number was missing within the host-side numbering system. An upstream overrun could already have erased an interval before the first packet was constructed. By contrast, a delayed block with correct sample indices does not constitute missing acquisition merely because the wall-clock interval between its arrival and its neighbour was unusually long.

A duplicated block creates a different deceptive symptom. If the software appends the same 4,000 complex samples twice and then numbers the duplicated copy as fresh data, the file has the expected length and can even look spectrally continuous for a narrow steady carrier. It is false continuity. A preserved device-origin sequence or independently injected nonrepeating test pattern can detect the duplication. The test pattern should be generated externally from the receiver system and time tagged independently, with enough variation to expose a repeated or omitted segment. A pure sinusoid by itself is inadequate because successive windows can resemble each other after an integer number of cycles. The validation apparatus must therefore be chosen to discriminate the defects actually under test.

One should establish a hierarchy of duties when load becomes intolerable. The minimal acquisition path stores original samples, device status, capture counters and integrity metadata first. Optional waterfall rendering, classification, compression, printout and operator interaction are consumers of that record rather than prerequisites for its existence. If the system cannot sustain the source rate indefinitely, it must report the limit and execute a controlled stopping or segmentation policy with explicit gaps, instead of continuing to produce reassuring traces. Queue lengths and high-

Copyright 2026, James M. Atkinson

water marks should be logged at the physical interface, driver, application and storage stages, with independent timestamps where possible. Merely recording a mean CPU utilisation obscures a short scheduler pause that might exhaust a finite buffer.

A final qualification concerns simultaneous receivers. Twelve independent streams can become dependent through one overloaded USB controller, storage pool, clock mapping or host scheduler. Their apparent shared loss of a spectral event might therefore be an acquisition failure, not evidence that the source stopped transmitting. Run a stress test in which the input generator continues a known, independently timed pattern while processor load, disk latency and transport contention are varied within safe limits. Determine whether the first observed defect occurs in hardware capture counters, interface packet sequence, application queue or written file. The answer specifies where evidence was lost and whether any downstream reconstruction is legitimate. I pass the principal token to Dr. Hamming because an architecture may be well designed on paper yet still conceal implementation faults.

Richard W. Hamming, Cross-Peer Question to John von Neumann: Professor von Neumann, suppose a file contains the expected number of bytes and its host-side timestamps advance monotonically, yet the acquisition driver silently discarded a block and duplicated a later block to maintain a constant file length. The output appears well formed. Which independent invariants would distinguish this from genuine uninterrupted acquisition? How should the test treat a host display that reconstructs missing spectral tiles by interpolation, especially when the only readily visible symptom of the original fault was a momentary backlog?

Copyright 2026, James M. Atkinson

Suppose a heavily loaded host stores the expected number of bytes, but a driver error duplicates one block after a genuine overrun so that the aggregate length remains unchanged. Which original acquisition counter or external stimulus would reveal that a segment was replaced? I also want to know whether the proposed bounded buffer design guarantees evidential completeness when a disk is intermittently unresponsive. How do we derive the necessary reserve from source rate and worst-case service interruption, then demonstrate in a stress test that those assumptions hold? If the hardware does not expose a trustworthy capture counter, what limitation must appear in the final interpretation of a short RF event?

John von Neumann, Cross-Peer Answer to Richard W. Hamming: Dr. Hamming, a byte count measures file length, not sample provenance. The driver should preserve hardware-derived sample counters or equivalent device timestamp observations and log every overrun, reorder and restart. A seeded laboratory stream with a known non-repeating timing pattern exposes duplication that constant-frequency energy alone may not. Independently capture the injected markers and compare their decoded chronology with the final file, including continuity at all buffer boundaries. Mark inferred or interpolated material so that it cannot be mistaken for observed samples. If the instrument lacks suitable hardware provenance, the report must narrow the claim: the stored file is internally consistent, but source acquisition continuity was not independently proven.

The byte count is the least satisfactory completeness witness precisely because a duplicate block can compensate for a missing one. We require an index recorded by the acquisition hardware before any transport or buffering failure can intervene. If blocks have authenticated first-sample

Copyright 2026, James M. Atkinson

indices and valid lengths, their concatenation can be checked for overlap, gaps and correct rollover. If the device exposes no such counter, supplement testing with an externally generated time-varying calibration pattern, but do not pretend that this supplies perfect retrospective certainty for arbitrary field captures. Calculate the reserve required for a worst-case stall using buffer headroom B, source rate R_s and during-stall service rate R_d. The simple bound $B \geq (R_s - R_d)T$ applies for a stall of duration T when R_s exceeds R_d, provided the initial occupancy and all other ingress are accounted for. If the actual free headroom is smaller, overflow is expected under the model.

The proof obligation extends beyond arithmetic. Establish source rates in the actual packed format, measure service performance under fragmentation, thermal load and concurrent operations, and deliberately create stalls near the expected limit. Verify the device counters before and after each test and record which subsystem declared overflow. Where a queue fills despite design margins, it is the system's defined behaviour that matters: explicit segmentation, alarm and preservation of unaffected intervals are acceptable; silent substitution is not. A stable displayed rate or a perfect file hash cannot rescue a span never captured. When there is no trustworthy hardware index, state the limits of any inference about millisecond-scale absence of signal. That qualification is more scientifically useful than a reassuring nominal sample count.

Grace Murray Hopper, Response to Professor von Neumann and Dr. Hamming: Their challenge makes the difference between software correctness and evidential completeness explicit. I would preserve errors as first-class data, not merely console messages. Host-scheduling delays need

Copyright 2026, James M. Atkinson

not be RF gaps, but a silent omission cannot be erased from the chain of custody by keeping the user interface alive.

Dr. James M. Atkinson, Moderator: Dr. Hamming, the acquisition ledger must be more than a well-formed file. Please address how a deliberate continuity fault should be exposed, with Dr. Hopper invited to question the policy for resuming capture.

Richard W. Hamming, Third Principal Contributor: A data file is not an evidential record merely because it has a valid header and an expected byte count. The acquisition system must be challenged with a known pattern that exposes dropped, reordered or duplicated content. The test should exercise the driver, transport and storage under deliberately stressed conditions while preserving original exception records. A waterfall display may interpolate a dropped block and look continuous, whereas a hardware-linked counter or embedded marker shows a gap. I would require tests proving that every exceptional acquisition state becomes an indelible entry in the investigative ledger.

It is not sufficient to declare an integrity check; one must define precisely what property it proves. A checksum calculated over a completed file can detect later alteration of that file but cannot establish that the contents were correctly sampled. A perfect cryptographic digest of a corrupted acquisition is still a perfect digest of the corruption. The software therefore requires invariants attached to the acquisition process itself. At a minimum, a genuine sample-origin counter must advance as specified, every block must declare its first index and valid length, and no index range may be silently duplicated, skipped or reordered. If a device lacks such counters, that

Copyright 2026, James M. Atkinson

limitation must appear in the evidential qualification rather than be repaired with plausible host-generated labels.

The state machine should treat counter rollover, reference reacquisition, dropped transport blocks and late-arriving valid blocks as distinct events. Rollover can be predictable modulo a documented counter width. A missing range is not predictable merely because the next received block happened to contain the expected number of bytes. Reference reacquisition may cause a phase discontinuity while every sample index remains present. A host backlog may produce irregular packet delivery while both sample order and physical sample times remain valid. If all these conditions are represented by a single 'stream interruption' bit, a later reader will be unable to determine whether a suspected RF signal genuinely vanished or the machine simply failed to observe it. An event log must therefore retain causal granularity.

A deliberate fault-injection campaign reveals whether those distinctions are implemented. Insert a software-instrumented packet drop after acquisition and determine whether the file records the missing original indices. Insert a duplicate packet and check that the recipient rejects or explicitly qualifies the repeated range. Impose a storage stall long enough to fill the declared application queue, then measure which layer first reports overrun. Restore a clock source after a safe laboratory outage and check for an explicit timing-epoch change. Each intervention has a known truth table: whether physical samples existed, whether they were transferred, whether they were stored and whether their timebase remained calibrated. The recorded output should be compared against that truth table before a production system is trusted.

Copyright 2026, James M. Atkinson

A powerful test stimulus is one which cannot be mistaken for a stationary period. For example, modulate a laboratory carrier with a long pseudorandom binary sequence whose origin, chip rate and epoch are independently known. Correlate the stored complex samples against the expected sequence, allowing for the characterised receiver transfer function. A duplicated block often produces an anomalous repeat in the recovered code phase; a dropped block produces a discontinuity; sample-rate error appears as progressive drift of correlation delay. Such a test requires a sufficiently long sequence to avoid accidental ambiguity and must use a separate source clock if it is intended as an independent witness. It is a system qualification experiment, not a reconstruction of missing field evidence.

One should also test the detector's presentation layer. A waterfall often displays short-time Fourier transform tiles rather than unmodified samples. It may hold the preceding tile during a processing pause, interpolate missing tiles or update the screen from a ring buffer that drops the oldest entry. These choices can be acceptable for operator situational awareness if clearly labelled, but they must not be confused with the underlying evidential capture. I would generate a visible fault marker across test tiles and require a reviewer to identify it from the exported plot and raw data independently. If the screen appears normal while the file reports a gap, the display is not a sufficient evidence record. The discrepancy must be reflected in the software's status indication.

Finally, automated checkers must themselves be verified. A quality-control function which scans only the metadata supplied by a potentially defective driver cannot independently prove the driver correct. Exercise boundary

Copyright 2026, James M. Atkinson

conditions such as first block, last block, counter wrap and simultaneous queue overflow. Preserve fault-injection logs in a protected test register, and re-run acceptance tests after firmware or driver revisions. For live operation, a monitor may be able to announce that sample completeness is unknown rather than categorically lost; that state is useful and should not be suppressed. A conscientious system sometimes produces an inconclusive finding because the instrumentation lacks an independent witness. That is a success of quality assurance, not a failure to produce a confident display.

The chain of custody must link each acquired segment to its source device, configuration, timebase epoch and immutable original file, with subsequent transformations recorded as separate products. In a retrospective analysis, the researcher should be able to replay the segmentation and recover the same detector outputs from the same samples. Where a small observed pulse lies adjacent to a missing range, an estimator cannot supply a fact about the unobserved pulse. I would allow a model-based prediction clearly labelled as prediction, with conditional uncertainty, but reject any software which joins the waveform across the gap and presents the result as if it had been measured. I pass the token to Professor Wiener for the mathematical distinction between delay and loss.

Grace Murray Hopper, Cross-Peer Question to Richard W. Hamming: Should an application still be permitted to continue logging after an overrun, or would that make subsequent observations intrinsically unreliable?

I also wish to know whether the proposed fault record is intrinsically generated by the acquisition device or is inferred from a software counter

Copyright 2026, James M. Atkinson

that could itself have been reset or renumbered. That difference bears directly upon the strength of any assertion that the record is complete.

Would you permit a receiver to continue operating after it has detected one upstream sample overrun, or should the complete evidential session be rejected? In particular, I should like a rule for delimiting verified intervals before and after a loss without allowing the software to interpolate an unobserved segment. How would you represent the discontinuity in a file format, and which tests would prove that later processing did not quietly close the gap? If a post-processed waterfall hides missing tiles, what status or provenance data would oblige a reviewer to see the altered presentation? Please distinguish a recoverable continued operation from an impermissible claim of unbroken acquisition.

Richard W. Hamming, Cross-Peer Answer to Grace Murray Hopper: Continuation is legitimate if the application makes the state boundary conspicuous and can determine which samples remain trustworthy. It must mark missing ranges and preserve all surviving original data. A hard stop may be appropriate where the mission requires an uninterrupted phase record, but it should not be imposed blindly for every exploratory signal search. The important issue is a truthful representation of measurement coverage rather than the appearance of uninterrupted operation. A defensible application should also expose the operational decision that follows an error: whether it quarantines a suspect interval, invalidates a continuity-dependent measurement, or retains the unaffected portions with a limitation. The logger ought to commit the error record before any recovery action that changes ring-buffer offsets, preventing the subsequent

Copyright 2026, James M. Atkinson

recovery state from overwriting evidence of the original fault. This is a testable software property, not a matter of operator preference.

Continued operation is permissible if the software maintains a transparent boundary between verified and unverified intervals. After a reported overrun, record the last known good device index, the first subsequent trustworthy index and the status of the physical sampling clock at recovery. The gap should remain explicit in the data representation and in every derivative display. A downstream file can contain distinct segments with provenance records describing their original sample-index ranges, rather than conceal the omission by inserting zeros or interpolated estimates into a single apparently uniform sequence. If an analyst wants to construct a model-based estimate of the missing interval, that is a separate derived product with a clearly marked uncertainty and its own transformation record. The original absence must remain visible.

The quality gate should include deliberate faults after every firmware, driver or processing change. Remove a block, duplicate a block, reorder two packets and force a counter wrap. Then verify that the integrity indicators detect the intended fault without falsely classifying a benign delivery delay as missing acquisition. Reprocess the captured record through the waterfall and event-classification pipeline to see whether the derivative products retain the gap marker. If the only accessible evidence consists of host-side sequence labels created after a transport failure, the completeness of earlier stages may remain unverified. A responsible system can preserve post-fault observations as a new segment, provided the transition and all unexamined intervals are disclosed. Evidence is not invalidated simply by a known boundary; it is invalidated when that boundary is hidden.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Wiener, may I pass you the question of whether packet latency has any necessary relationship to RF sample chronology? Professor von Neumann will explore the queue-capacity premise.

Norbert Wiener, Fourth Principal Contributor: Queueing changes the distribution of packet arrival times, not necessarily the distribution of sampling instants. A delayed batch can have highly irregular host timestamps while carrying a perfectly ordered acquisition sequence. Yet an overloaded queue can also become a loss mechanism, so latency and continuity must be measured separately. I would compare device-side counter increments with host reception intervals under several controlled service loads, and estimate the transition from harmless backlog to irreversible dropped data. Statistical smoothing of arrival times is not evidence that the missing samples survived.

Transport delay and missing observation are different random variables. Let $A(t)$ denote the cumulative quantity of valid samples delivered to a queue by time t, and let $S(t)$ denote the cumulative samples served or written. The queue occupancy is $Q(t)=Q(0)+A(t)-S(t)$ while it remains within available capacity and while losses are separately recorded. The physical acquisition process may be continuing at a uniform sample rate even when the service process pauses or arrives in bursts. The queue can grow during an interruption without any sample being lost, provided sufficient storage remains and the device can continue delivering data under the chosen backpressure behaviour. Loss occurs if a finite buffer is exceeded or if the device or transport discards data for another reason. A host pause observed on a monitor cannot alone tell which case occurred.

Copyright 2026, James M. Atkinson

A simple deterministic bound helps. Suppose an SDR produces 80 MB/s of data and the effective storage service halts entirely for 0.25 seconds. At least 20 MB of additional buffering is required to absorb that pause, aside from already queued bytes and transport overhead. A buffer with 64 MB free capacity can survive this pause under those assumptions. If the service afterwards resumes at exactly 80 MB/s, however, no backlog is drained; the queue remains twenty megabytes fuller. To return to its original occupancy, the service rate must temporarily exceed the acquisition rate. If it can sustain 120 MB/s, the excess drainage is 40 MB/s and the twenty-megabyte backlog requires another half-second to clear, assuming no other bottleneck intervenes. These figures are hypothetical and should be compared with actual measured capacities.

In probabilistic operation, mean service rate is insufficient. A disk may average 100 MB/s while occasionally pausing for several hundred milliseconds; a bus may retry packets in clusters; an operating system may suspend a process under memory pressure. Queue stability over long periods is influenced by the average offered load, but the probability of short buffer overflow depends on the distribution and dependence of arrivals and service interruptions. Where events are strongly bursty, averages can be reassuring yet dangerously unrepresentative. Record service-time histograms, tail delays and buffer high-water marks, then challenge the system with reproductions of the longest expected stalls. A modest average occupancy does not preclude a rare capacity failure at the instant of the signal of interest.

The relation known as Little's law, $L=\lambda W$, connects long-run mean number of items in a stable system, the mean arrival rate λ and mean time W spent in

Copyright 2026, James M. Atkinson

the system, under its conditions. It does not say that every packet has a delay of L/λ or that a finite queue can survive an arbitrary pause. Nor does it establish physical acquisition time. A block can be received half a second after the samples were taken while preserving an accurately indexed device chronology. It is precisely because queue residence time can change independently of antenna events that the host arrival timestamp must not be substituted for the capture timestamp. The two time coordinates should be stored and compared as distinct measurements.

If the host shows a burst of delayed detections, the analyst should reconstruct the causal sequence. First compare the hardware sample indices corresponding to each RF feature. Next examine transport receive times and queue occupancy during the event. Then compare the file write order and the displayed event time. If the indices remain continuous and an independently captured known pulse retains its proper temporal separation, the delayed display is plausibly a processing backlog. If an index range is absent, the hypothesis of mere delay is inadequate. If the indices are present but timing calibration changes, the system may have preserved observations while losing a valid relationship between indices and physical seconds. No single measure, whether throughput or lock status, resolves all three.

An overloaded receiver may also generate misleading correlation between channels. If several instrument streams share one host queue, a common scheduling pause can create simultaneous gaps in their host arrival histories. Their real sample histories might remain continuous, or a bottleneck may drop blocks from all of them. The observation that channel A and channel B ceased updating at the same moment is therefore not

Copyright 2026, James M. Atkinson

independent evidence of a radio source switching off. An independent monitoring path should log device-status counters directly and, where practicable, record a calibration waveform through a separate acquisition architecture. These controls distinguish the temporal structure of the environment from the temporal structure of the machine.

I would conclude the queue analysis with a falsifiable prediction. If the event was caused only by delayed buffering, the eventually stored original samples should retain their expected count and ordering, and a replay should reconstruct the correct chronology from acquisition counters. If the event was an irrecoverable overrun, a gap, flagged discontinuity or inconsistency should remain when the saved stream is checked against an independent known pattern. If the event was sample-clock drift, the relation between hardware indices and external time should vary systematically even with no missing indices. These cases can coexist, so the classification procedure must permit more than one cause. I pass the token to Professor Essen to explain what the time measurement can and cannot independently establish.

John von Neumann, Cross-Peer Question to Norbert Wiener: If a queue normally holds half a second of samples, what must be measured before one claims that a two-hundred-millisecond host pause cannot result in loss?

You model arrival and service rates, yet the operator has recorded only a mean queue occupancy and a mean storage throughput. Both numbers look acceptable, although an occasional storage stall may be sufficiently long to cause overflow. How would you characterise the tail of service delay and the queue high-water marks in a manner relevant to a finite buffer?

Copyright 2026, James M. Atkinson

Suppose a burst of packets is received after the host has been paused, and all original sample indices remain present. What evidence establishes that a delayed presentation should not be described as a radio burst arriving late? Would your classification change if the device index map itself were derived from host packet dispatch instead of ADC acquisition?

Norbert Wiener, Cross-Peer Answer to John von Neumann: The average occupancy is insufficient. Identify the actual buffer capacity, peak arrival rate, downstream service capacity and competing memory allocations. A transient pause may be harmless if enough unused capacity exists, but prior backlog and simultaneous bursts can change the result. Device-side overrun and sequence records should be retained. Test credible worst cases under the real sample format and number of channels rather than extrapolate from a single unloaded throughput benchmark.

Average occupancy and service throughput do not characterise the largest excursion of a finite queue. The relevant data include the arrival process, the distribution of service interruptions, high-water marks and the free capacity at the moment each interruption begins. For a deterministic test, a source at R_s bytes per second with zero service for T seconds adds R_sT bytes to the queue. A storage subsystem with a higher long-run service rate can nevertheless overflow if a single pause consumes more free capacity than remains. I would therefore test a family of controlled stalls while the receiver records an independently known input pattern and compare the observed queue history with the predicted bounds. When the actual process is stochastic, estimate tail probabilities with properly documented confidence and remain alert to correlations between source bursts and service slowdowns.

Copyright 2026, James M. Atkinson

A delayed cluster of packets is not proof that the radio signal arrived in a cluster. If acquisition-origin indices are continuous and the relevant clock maintained calibration, reconstruct the signal chronology from those indices rather than from packet delivery times. A one-second host backlog may contain a perfectly regular one-second RF record. If the apparent device index was allocated only when a packet entered the host, however, a lost upstream sample block could be invisible to that index; the premise of completeness would be untested. The distinction lies in where each counter was created and which failure path can alter it. I therefore recommend a trace that includes device counters, interface status, queue occupancy, file timestamps and the provenance of every conversion. Only then may the analyst decide whether the irregularity was in the electromagnetic environment or in the transport architecture.

Dr. James M. Atkinson, Moderator: Professor Essen, please add the independent metrological perspective missing from software-ledger checks. Dr. Hamming will then question whether an apparently continuous test tone is an adequate witness.

Louis Essen, Fifth Principal Contributor: An independent timing reference contributes something that internal software checks cannot: evidence of elapsed physical time. A hardware counter may remain continuous while its oscillator drifts, so its chronology must be compared with a stable external marker. Likewise, an externally accurate host time service does not imply the acquisition hardware used that same clock. A robust verification separates sample count, sampling interval and transport delay. I would retain both the calibration events and the reference uncertainty at the times of interest.

Copyright 2026, James M. Atkinson

The fundamental metrological distinction is between the presence of an observation and the time assigned to it. An uninterrupted sequence of complex samples proves no more about calibrated elapsed time than an evenly spaced set of pencil marks proves about the accuracy of a ruler. A sampling oscillator has a nominal frequency and an actual evolving frequency. If the actual rate differs from the nominal rate, an assignment $t_n=n/f_{nom}$ acquires error even when every sample index n is present. Conversely, a perfect source clock cannot recover an observation which was lost in transit or never captured. These defects must be measured independently and must not be conflated merely because all produce disturbances in a waterfall representation.

Let the nominal complex-sample frequency be f_0 in samples per second, and let the actual rate be $f=f_0(1+\varepsilon)$, with ε a small dimensionless fractional error over a bounded observation interval. After N samples, the nominal elapsed time is $T_{nom}=N/f_0$, whereas the actual time is $T_{actual}=N/[f_0(1+\varepsilon)]$. Their difference is approximately $-\varepsilon T_{nom}$ for $|\varepsilon|$ much less than one. If f_0 is 10,000,000 samples per second, ε is +2 parts per million, and the nominal acquisition interval is 100 seconds, the physical interval is approximately 99.999800 seconds. The nominal mapping is in error by about 200 microseconds. Every sample can be present, yet a cross-station timing inference using the nominal clock would be wrong. The figures are illustrative and assume constant ε for the calculation.

A missing block differs in its signature. Suppose the true hardware acquisition index advances by 10,000 positions beyond the last stored record before capture resumes. At ten million nominal samples per second, that nominal gap represents one millisecond of unrecorded sample

Copyright 2026, James M. Atkinson

positions. The time equivalent should be corrected for the actual rate and any clock-state transition. The investigator cannot claim that a one-millisecond radio signal was silent, because the observation of that interval is absent. By comparison, if a block is merely delayed in transport and later stored with contiguous original indices, there is no missing sample interval even though the operator may have seen a one-millisecond pause or a much longer screen freeze. The external time standard helps label the interval but cannot substitute for the original index ledger.

A known frequency tone offers a useful check of sampling-rate error. If an independently characterised RF signal of frequency f_t is sampled at actual rate f but interpreted using f_0, its apparent spectral frequency may be shifted in proportion to f_0/f, subject to the receiver's conversion frequency and filtering convention. This method must be used carefully: if the tone and receiver share the same reference, both may drift together and the apparent error may cancel, defeating the supposed independent check. The reference tone should therefore be derived from a source whose stability and provenance are independently established. Cross-check against hardware time markers or a phase comparator rather than relying upon one ambiguous spectral feature.

Frequency stability statistics describe particular scales of averaging, not an assurance that all intervals are continuous. Allan deviation can characterise fractional-frequency fluctuations over chosen averaging times but does not detect every missing packet or guarantee that a phase record was uninterrupted across an unlogged switch. A synthesiser can recover nominal lock while introducing a phase step. A clock algorithm can slew timestamps without changing the physical sampling sequence. Thus a complete audit

Copyright 2026, James M. Atkinson

preserves instantaneous counter events, oscillator-control states, local phase comparisons, and all versions of the map to the external time scale. A one-hour Allan deviation number should not be substituted for a test of a five-millisecond event.

Hardware calibration must encompass the relevant path. A one-pulse-per-second timing marker at the source may arrive at a receiver after cable and logic delay; a fixed delay can create an accurate-looking but biased timestamp. Record source-plane and receiver-plane observations with common and independent witnesses, identify the trigger threshold and any signal-dependent detection latency, and repeat calibration with representative temperature and load conditions. The uncertainty statement should distinguish repeatable systematic path delay, random phase variation and unknown state transitions. In forensic use, precision of a printed timestamp cannot exceed the physical evidence of the timing chain. It is better to state a bounded interval than to manufacture a precise instant which the apparatus did not observe.

The closing experiment should combine a long independently timed pseudo-random calibration sequence with occasional deliberate safe acquisition-load changes and a separately documented reference-frequency perturbation. When load changes but the sample index-to-time mapping remains calibrated, a delayed display without missing indices indicates buffering. When an overrun is injected, the hardware index record should identify the missing range; when a small clock offset is imposed, the phase or delay of the known sequence should drift predictably while the indices remain contiguous. An instrument which can distinguish these three laboratory truth conditions has earned greater confidence than one which

Copyright 2026, James M. Atkinson

simply produces smooth spectra. I return the token to the moderator with the recommendation that every finding identify its observation plane, chronology, calibration and limits.

Richard W. Hamming, Cross-Peer Question to Louis Essen: Could a continuous test tone alone prove that no samples were duplicated or omitted, particularly if duplicated blocks happen to preserve similar amplitude and frequency? I would also ask how one could design a deterministic challenge sequence that exposes repetition after a buffer wrap, distinguishes a duplicated packet from an oscillator-frequency excursion, and retains an independent chronology when the receiver and the challenge source otherwise share timing infrastructure. The answer needs to address identifiability, not merely signal visibility.

A laboratory check uses an apparently pure calibration tone and a nominally accurate oscillator. If a block is lost but the tone is periodic, the reconstructed complex signal may appear coherent across the missing interval. Could such a test falsely certify completeness, and what nonrepeating or independently timed waveform would be a better challenge? Would you require a downstream hardware time witness in addition to phase comparison at the external reference connector? Finally, how should the final metrological statement distinguish source-frequency accuracy from phase continuity and from the completeness of the stored acquisition, each of which appears to the operator as part of the same 'synchronised' receiver?

Louis Essen, Cross-Peer Answer to Richard W. Hamming: A pure tone may be too repetitive to expose every omission. Use a time-varying known test

Copyright 2026, James M. Atkinson

pattern, pulse sequence or suitable phase-coded stimulus and compare the original record with the independent reference. The challenge must exercise the same file path, buffer limits and processing used in field acquisition. The resulting conclusion should be bounded to the fault classes the known pattern can reveal. The sequence generator must not rely upon the same drifting or interrupted reference under test, since a common failure could leave its test pattern and receiver equally wrong. Test distinctive block boundaries, deliberately introduce separately identified loss and duplication, and compare reconstructed ordinal positions rather than only a spectral average. Record any ambiguity where different failures could reproduce the same observed pattern.

A periodic pure tone is not a sufficient completeness witness because an omitted or repeated segment may join at nearly the same phase after a whole number of periods. A more discriminating test uses an independently timed sequence with nonrepeating or suitably long-period phase and amplitude structure, together with markers whose positions are measured outside the receiver under examination. A pseudorandom code or designed pulse sequence can distinguish a skipped interval from a rate error when its ambiguity properties and signal-to-noise ratio are known. Compare recovered marker positions against sample indices and against a separate calibrated timebase. Do not derive the generator and the receiver from the same questionable reference when seeking an independent check of their relative drift; a common defect could cancel in the comparison. The testing arrangement should itself have a documented calibration and uncertainty.

I would separately report frequency accuracy, time offset, short-term phase behaviour and the completeness of the observed sample sequence. A clock

Copyright 2026, James M. Atkinson

with small long-term fractional-frequency error can nevertheless undergo a brief phase step; a system with an uninterrupted sample counter can still have an inaccurate mapping to external time; and a system with a magnificent external reference can still lose samples through buffer overflow. Measure at the receiver's actual sampling edge when possible, not merely at the external oscillator connector. Known cable and logic delays require correction or uncertainty allowance. If the experiment establishes only that the external reference remained stable, that finding must not be extended to an unmeasured synthesiser or acquisition driver. I return the token to Dr. Hamming with the distinction between a calibrated clock and a complete record firmly preserved.

Dr. James M. Atkinson, Moderator, Closing Synthesis: Clock drift, sample loss and delayed buffering are different defects with potentially similar graphical appearances. Clock drift alters the relationship between sample index and physical time; loss removes observations and should appear in trustworthy counters, device timestamps or error metadata; and buffering delays delivery without necessarily changing the underlying acquisition. The panel therefore requires independent timing stimuli, raw sample and sequence records, driver-status logs, host arrival timestamps, controlled stress tests and explicit preservation of gaps. The forensic distinction is between what was physically sampled, what reached storage and what a later display or estimator made visible. None of these categories should be silently substituted for another.

QUESTION 055. VERIFIED TECHNICAL SOURCES AND LIMITATIONS

W. J. Riley and D. A. Howe, Handbook of Frequency Stability Analysis, NIST Special Publication 1065 (2008),

Copyright 2026, James M. Atkinson

https://www.nist.gov/publications/handbook-frequency-stability-analysis . NIST identifies phase and frequency analysis, data preparation, statistical methods and reporting as relevant elements of a stability assessment.

Ettus Research, USRP Hardware Driver and Device Manual, General Application Notes, https://uhd.readthedocs.io/en/latest/page_general.html . Receiver overflow is associated with a host failing to consume device samples sufficiently rapidly, and outcomes depend upon the device, transport and streaming mode.

Ettus Research, USRP Hardware Driver and Device Manual, rx_metadata_t reference, https://files.ettus.com/manual/structuhd_1_1rx__metadata__t.html . Documents receive metadata including time information, overflow errors and out-of-sequence indications. These are examples of product-specific metadata, not assertions that every SDR exposes the same fields.

Editorial limitations: All numerical examples are hypothetical. This constructed historical dialogue is not an actual transcript. Instrument-specific error semantics, packet ordering and the evidential adequacy of a particular capture must be tested with the deployed hardware and software. Individual word targets and the whole-book duplicate-text audit remain outstanding.

QUESTION 056

Copyright 2026, James M. Atkinson

What can network time synchronisation establish about an RF acquisition chronology?

SCHOLARLY RECONSTRUCTION. The following fictional instructional dialogue brings deceased historical specialists into a modern discussion. No statement below is an actual historical quotation; applications to network timing and contemporary SDR instruments are editorial extrapolations.

Dr. James M. Atkinson, Moderator: Dr. Mills, an RF monitoring console might display timestamps ostensibly synchronised to a national time standard, yet the underlying samples may have passed through an analogue signal path, an independent ADC clock, a device buffer, a transport interface and a host processing queue. What can a network synchronisation record establish about the original electromagnetic event, and where does the inference from computer time to the instant of physical acquisition become unwarranted?

David L. Mills, Principal Contributor: Dr. Atkinson, network time synchronisation is a means of estimating and correcting differences between clocks. It is not a direct sensor of when electromagnetic energy reaches an antenna. That distinction should govern every subsequent inference. A remote time server may help establish the host operating system's time relative to a recognised timescale. It does not automatically calibrate antenna propagation delay, analogue group delay, frequency-conversion latency, ADC aperture timing, USB queueing or the interval between an acquisition command and the first physical sample. An examiner must describe these transformations explicitly rather than treat a displayed timestamp as an observation made at the antenna terminals.

Copyright 2026, James M. Atkinson

Consider the four timestamps of a conventional request-response exchange. Let t1 denote the client's transmit timestamp, t2 the server's receipt, t3 the server's transmit timestamp and t4 the client's receipt. Assuming the timestamps have been interpreted consistently in the respective clock domains, the familiar offset estimate is $\theta=[(t2-t1)+(t3-t4)]/2$, while estimated round-trip delay is $\delta=(t4-t1)-(t3-t2)$. These equations are documented in RFC 5905. Their significance is conditional: symmetric outbound and return network delays make the offset estimate comparatively well behaved, but unequal path delays can cause an offset bias. Neither equation contains a measurement of the RF receiver's antenna-to-digital-sample delay.

For an illustrative asymmetric path, assume the server's clock is otherwise ideal and the client's true offset is zero. A forward network delay of 1 millisecond and a return delay of 3 milliseconds produce $\theta=(1-3)/2$ milliseconds, or minus 1 millisecond, under the usual sign convention. The four-timestamp estimate therefore appears to indicate a clock offset even though the assumed clocks coincide. This is not proof that any particular system will show precisely this error, because actual clock-discipline algorithms combine repeated measurements and use filtering, selection and other safeguards. The example demonstrates a limitation of single-exchange identifiability. A low numerical scatter in repeated measurements cannot establish that a constant path asymmetry has vanished.

The instrument chronology requires a different chain of evidence. First establish how the sample-producing hardware defines time: by a free-running ADC counter, a sampled pulse-per-second marker, a synchronised device clock, or a host-issued command. Then document the relation

Copyright 2026, James M. Atkinson

between this hardware timebase and host time. Let n denote sample index, f_s the actual sampling rate and t_a the actual time corresponding to the first retained sample at a declared electrical reference plane. For an ideal uniform stream, $t(n)=t_a+n/f_s$. If the acquisition hardware clock drifts, or if samples are dropped, a nominal constant-rate relation can become inadequate. Separately, if a host labels a packet at its arrival, the label is $t_{host}=t_a+\tau_{analogue}+\tau_{device}+\tau_{transport}+\tau_{host}$, where each τ refers to a declared latency component and the decomposition is illustrative. None of those terms can simply be set to zero by enabling a network-time client.

A disciplined operating system may maintain a monotonic clock and an externally referenced wall clock with distinct purposes. Slewing a wall clock changes the mapping between a time label and a physical interval. Stepping it may create an apparent discontinuity in recorded event times. A carefully designed acquisition system should preserve its monotonic hardware counter, clock-adjustment state and timestamp conversion alongside the externally presented clock label. Records should distinguish measurement time, device packaging time, network receipt time, processing time and final display time. A single column named 'timestamp' is a poor foundation for a forensic conclusion unless its origin and error bounds are unambiguous.

A useful experiment captures a known, lawful laboratory timing marker along the complete receiver chain while independently measuring the marker at a calibrated upstream reference plane. Record simultaneous device sample counters, device-provided timestamps, host monotonic and wall clocks, time-synchronisation logs and network-delay measurements. Then introduce a controlled asymmetry into the network time path while keeping the RF marker and acquisition wiring unchanged. If displayed host

Copyright 2026, James M. Atkinson

event times change but the hardware sample-index relation to the independent marker does not, the evidence points toward timestamp mapping rather than a change in the sampled event. Repeat the converse experiment by altering a documented analogue delay or the device sampling clock while leaving the network synchronisation unchanged.

A two-way network timing system also inherits a network topology. Server hierarchy, reference selection, authentication, operating-system timestamp placement, and routing can all influence the meaning of a reported offset. A server's claimed upstream relationship to a standard must be supported by a traceability or configuration record if that relationship is material to the case. Authentication may help establish message provenance but does not by itself improve propagation-delay symmetry or make a receiver's sampling clock accurate. Moreover, two hosts consulting the same timing hierarchy may share a systematic error, so their agreement cannot automatically be counted as independent corroboration.

What, then, can the network record support? It may provide evidence about the host's estimated clock offset, delay and synchronisation state within a specified period, subject to the protocol model and observed network conditions. When a properly instrumented calibration bridges host and hardware clocks, it may support a traceable estimate of sample acquisition time with an uncertainty statement. Without that bridge, the network service describes computer time, not directly the antenna event. For an adverse forensic interpretation, this is not a semantic distinction but the boundary between a defensible timestamp and a derived figure whose precision is unearned.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Poincaré, does the four-timestamp exchange uniquely identify clock offset when path delays are unknown?

Henri Poincaré, Peer Question: Dr. Mills, simultaneity and clock convention acquire operational meaning through the signals and procedures by which clocks are compared. If the forward and reverse propagation times are unknown separately, might different combinations of clock offset and delay asymmetry explain the same four recorded times? How would you demonstrate this ambiguity without making the unwarranted leap that synchronisation is impossible, and what supplementary evidence could narrow the family of compatible explanations?

For a legally consequential RF chronology, I ask that the time-transfer convention be written in a way an independent examiner could challenge. Suppose a route is asymmetric by an unknown constant amount while the client's clock is stable, and another experiment produces the same four timestamps by changing the clock offset. What observation would distinguish these cases? Please specify the reference plane at which you would obtain that observation, and state whether adding servers through the same provider network truly creates a new constraint. Otherwise the displayed offset may be an apparently precise solution to an equation having several physically admissible answers.

David L. Mills, Response: Professor Poincaré, the observations determine a round-trip interval and an offset estimator under stated assumptions, not the two one-way delays individually. Write the outward delay as d_f and the return delay as d_r. If the server and client clock offset is Δ, the measured estimator contains $\Delta+(d_f-d_r)/2$, with signs depending on which clock is

Copyright 2026, James M. Atkinson

defined as positive. An unmeasured change in $d_f - d_r$ can therefore imitate a change in Δ. Multiple exchanges, minimum-delay filtering and path characterisation improve practical inference, but they do not logically measure an unknown constant asymmetry in isolation. Independent clock comparison, calibrated symmetric paths, or direct physical timing links can help constrain it. The report should disclose which assumption makes the desired timing estimate identifiable.

One can begin by keeping the relevant variables visible. Write the measured offset as the clock difference plus one half of the path-delay asymmetry, with the sign convention specified. Additional packets on the same asymmetric route can refine an estimate of changing jitter while leaving a constant asymmetry unidentified. What changes the inference is an intervention or observation whose dependence on the unknown delays differs from the original exchange. An independently calibrated local pulse, a physical comparison against a third clock, or a carefully characterised bidirectional link supplies such information. The reference plane must be stated, since a calibrated signal at a network interface does not establish the analogue receiver's internal latency. A second server adds useful independent evidence only to the extent that its transport and reference dependencies differ; two addresses may share the same timing source and network infrastructure. I would retain a diagram showing upstream services, forward and reverse paths, timestamp placement, and each expected delay uncertainty. I would then compare all clock-offset hypotheses compatible with the records rather than choosing the one that gives the neatest UTC labels. If a bounded asymmetry of ±0.8 ms remains, for example, the event-time claim cannot responsibly advertise an absolute

Copyright 2026, James M. Atkinson

uncertainty of 0.02 ms merely because the filtered offsets vary by that amount. A laboratory may develop a stronger result by replacing the unknown path with a measured local reference. But until it does, it must describe the bound honestly. This is the difference between using an operational time service and certifying the instant of a physical RF event.

Dr. James M. Atkinson, Moderator: Professor Wiener, what does repeated statistical agreement prove about a timing service?

Norbert Wiener, Peer Question: Dr. Mills, an investigator may obtain thousands of closely clustered offset values and report a very small standard deviation as though it were the absolute timing uncertainty. Yet a deterministic delay asymmetry could persist through the entire series. How should measurement statistics separate short-run fluctuation from fixed model error, and what dangers arise when filtering selects only apparently favourable low-delay samples from a changing network environment?

A further issue concerns the independence of repeated samples. The clock algorithm may select those exchanges with the smallest observed round-trip delay, but successive exchanges on one route can inherit the same bottleneck, physical asymmetry, server load or timestamp implementation. If hundreds of retained observations look similar, how should a researcher decide whether their uncertainty reflects genuinely fresh information? I ask especially about hidden dependence after outlier selection and about the difference between statistical confidence in the filtered estimator and confidence that it estimates the correct physical quantity.

David L. Mills, Response: Professor Wiener, precision within the selected observations is not equivalent to accuracy against an external standard.

Copyright 2026, James M. Atkinson

Repeated low-scatter estimates can coexist with a persistent systematic error, and the selection rule can materially affect the distribution reported. Preserve all candidate exchange timestamps, not only the accepted offsets, together with network path changes, chosen peers, filter parameters and rejected observations. Evaluate the residual variation conditionally on routing and load, and include an uncertainty or bias qualification for unmeasured asymmetry. A clean statistical plot is evidence of repeatable behaviour under the selected conditions, not an automatic certificate of traceability to the RF sample instant.

The samples are informative about different things. A low-dispersion series can indicate that the estimator's observable is stable under the present conditions, yet that observable may contain a persistent asymmetry. Repeated packet exchanges should be examined as a time series containing shared route and server states, not counted as independent trials merely because the clock software printed new numbers. I would retain all candidate offset and round-trip-delay pairs, including the values rejected by the filter, together with peer changes and time-of-day or routing context. A conditional analysis might show that a congestion episode increases both delay and variance; excluding that episode can improve operational synchronisation but changes the population being described. If a persistent return-path bias survives in the selected low-delay subset, there is no statistical means to identify it from those same exchanges alone. Its influence needs an independent test or a conservative bound. Nor should uncertainty shrink as the inverse square root of the raw sample count when correlations make effective sample count smaller. Autocorrelation, common server disturbances and change points must enter the assessment. An

Copyright 2026, James M. Atkinson

attractive mean is not a calibration certificate. For RF evidence the estimator should additionally be tested against a hardware timing reference near the receiver acquisition chain. The resulting report can distinguish three conclusions: the host clock's short-term consistency, its conditional time-transfer accuracy, and the entirely separate accuracy of mapping a physical sample index to an external timescale. Each has its own source of uncertainty and cannot simply inherit the strongest number from the other two.

Dr. James M. Atkinson, Moderator: Professor Kálmán, how should a receiver behave when its host clock is corrected during ongoing capture?

Rudolf E. Kálmán, Peer Question: Dr. Mills, a state estimator may smooth offset and frequency measurements before issuing host-clock corrections. During a server change or transient packet delay, the estimator may change its state without a corresponding event in the hardware acquisition stream. How can an investigator distinguish measured clock evidence from the filter's prediction, and why should a very narrow estimator covariance be treated cautiously when an unmodelled shared network disturbance is present?

The usual filter reports a predicted clock state and a covariance that depend upon an assumed dynamical model. Suppose an alternate upstream time server is chosen abruptly, a network route changes, or the host oscillator is commanded to slew while acquisition continues. Can the filter become overconfident during that transition because its state-space model assumed smooth frequency wander? How should the measurement record distinguish the pre-transition estimate, raw packet observations, control actions and revised conversion of hardware sample indices? It would be

Copyright 2026, James M. Atkinson

insufficient to present a post-transition covariance ellipse without exposing the state reset that created it.

David L. Mills, Response: Professor Kálmán, maintain the observation and state-estimate streams separately. A correction issued by the discipline loop is a control action based on measurements and model assumptions; it is not an RF observation. The hardware sample counter should remain the primary order record, while a versioned conversion relates counter positions to external time. A clock-source change, reset or unexpected network asymmetry warrants an explicit boundary in that conversion. Correlated measurement errors can render an assumed diagonal covariance model overconfident. Test residuals, retain the raw exchanges and compare the resulting mapping with a separately monitored timing reference. If the hardware-to-host relation was never measured during a gap, mark the external event-time estimate as model-dependent rather than claim continuity from estimator output alone.

A discipline loop is a controlled estimator, and its error statement rests on a specified process model. If that model treats oscillator drift as smooth while an upstream server switches, the innovation sequence may contain a disturbance too abrupt for the assumed process noise. The filter can respond by a state jump, a temporary slew or an increased uncertainty interval depending on its implementation. The stored state covariance immediately after a reset describes the revised model, not necessarily the unmeasured error immediately before the transition. An acquisition report should preserve the raw four-timestamp tuples, clock-selection and system-state changes, and both old and revised counter-to-UTC mappings. It should never silently rewrite the timestamp that was first attached to a sample. A

Copyright 2026, James M. Atkinson

useful test introduces a known path-delay change while an independently monitored device clock continues to produce a periodic test marker. If the software labels shift while marker intervals in the device sample domain remain stable, the disturbance belongs to the mapping. If the device counter and physical marker also change, investigate the hardware clock. When the evidence cannot discriminate those cases, enlarge the uncertainty statement or quarantine the interval. Model checking should examine cross-correlations, innovation outliers, state-dependent residuals and the effect of alternative process-noise assumptions. A narrow filter covariance obtained from an overly certain model is not proof of narrow measurement uncertainty. The resulting record should explain every clock-state boundary relevant to the claimed event order.

Dr. James M. Atkinson, Moderator: Dr. Hopper, how should software retain the original chronology when several timestamps compete?

Grace Murray Hopper, Peer Question: Dr. Mills, a logging application can quietly overwrite a packet's arrival timestamp with a later corrected timestamp, and a database can sort records by a wall clock that has stepped backwards. Both decisions can make the chronology appear inconsistent or conceal what the operator initially observed. What minimal provenance fields and transaction rules would allow a later examiner to reconstruct acquisition order while distinguishing genuinely absent samples from an altered timestamp mapping?

Consider a computer program that preserves only its latest corrected UTC time, discarding original device counters, earlier wall-clock labels and the raw synchronisation transactions. It may produce a beautifully ordered event list after the analyst changes the correction model. What audit trail

Copyright 2026, James M. Atkinson

would prove which events were physically captured and which times were computed after capture? Please address the possibility that processing threads reorder blocks, a failed transport duplicates records, and a host's wall clock steps backwards. Which identities must remain immutable to make a later courtroom or laboratory replay genuinely possible?

David L. Mills, Response: Dr. Hopper, preserve immutable source records: acquisition-device identity, stream and packet sequence numbers, hardware sample indices, device timestamps, raw host monotonic arrival time, contemporaneous wall-clock label, clock-discipline state and the method used to produce corrected UTC estimates. Do not overwrite a raw timestamp with the result of later calibration. Store the transformation separately, with its version, assumptions and uncertainty. Sort by a reliable acquisition sequence when reconstructing sample order, then annotate how that order maps to external time. Hash the original acquisition data and the associated event ledger, documenting any missing identifiers or counter resets. Such controls distinguish what was stored and when from what an improved clock model later inferred.

The acquisition device should produce an identity that remains valid when every wall-clock label is recalculated. A hardware sample index or unambiguous monotonic sequence is preferable when supported, coupled with the receiver identifier, channel, configuration epoch and raw device timestamp. Retain host monotonic arrival time and the original wall-clock time separately. The network synchronisation subsystem should preserve the selected server, source of calibration, raw exchanges, offset estimate, applied adjustment and any reference changes, permitting reconstruction of the time conversion applicable when the file was written. A later corrected

Copyright 2026, James M. Atkinson

UTC estimate belongs in a new field or derived table with its transformation version and uncertainty; it should not overwrite the original. The pipeline also needs explicit exception records: dropped and duplicated packet identifiers, queue overflow, counter wrap, device restart, retune and filter-latency changes. If parallel workers produce records out of order, use the device sequence to restore acquisition order, documenting any unresolvable gap. Hash or otherwise integrity-protect the raw records and retain provenance sufficient to reproduce a calculation rather than merely replay a picture of the waveform. For a challenge test I would induce an authorised host-clock step while a stable marker and counter stream continue, and separately induce a controlled transport loss. A correct logger should preserve the different signatures. What the programme can prove after this test is not that its receiver is always correct, but that the configured faults remain visible to a later examiner and cannot be mistaken for a real change in the radio environment.

Dr. James M. Atkinson, Moderator: Professor Michelson, could a carefully repeated laboratory calibration validate the complete timing chain?

Albert A. Michelson, Peer Question: Dr. Mills, the host reports accurate time to within a small estimated interval, but the RF input passes through filters and cables of unknown group delay. Can an end-to-end challenge reveal the true acquisition latency without relying upon the network estimate alone? How should a laboratory ensure that the calibration target is the same reference plane and event definition used by the field report?

I should like the calibration described at the actual RF measurement plane. A time protocol can characterise a computer clock, but a received pulse may experience cable delay, analogue filtering, frequency conversion and

Copyright 2026, James M. Atkinson

feature-dependent trigger latency before it is logged. How would the laboratory design an end-to-end challenge that distinguishes those contributions without relying on the same computer clock to judge itself? If the input amplitude changes and the timestamp shifts, what test establishes whether the physical event changed or the event detector moved its threshold crossing?

David L. Mills, Response: Professor Michelson, inject a sharply defined but bandwidth-appropriate, non-damaging timing event at a known physical reference plane. Observe it with an independent calibrated timing instrument while the SDR records the corresponding feature, raw samples and hardware counters. Repeat to characterise trigger jitter, algorithmic detection latency, front-end group delay and the hardware-to-host time mapping. A filter's delay can depend upon frequency and settings; a detection algorithm's timestamp can depend upon threshold and signal-to-noise ratio. The calibration should therefore match the relevant bandwidth, gain, firmware and processing configuration. Report both a correction and its residual uncertainty, and distinguish a laboratory result from a deployment claim unless continuity of configuration is established.

An end-to-end calibration must begin at a declared physical reference plane, such as the RF connector with a properly characterised calibration path or an antenna measurement point. Introduce a waveform with a defined feature and observe its generation time independently of the receiving host. The recorder should capture raw samples and hardware counters while the host simultaneously logs its network-time discipline. Compare the physical marker with the sample index of the detected feature, then repeat through variations of frequency, bandwidth, level, filtering and environmental state.

Copyright 2026, James M. Atkinson

Those variations expose group delay, threshold walk and trigger jitter that a single fixed-point calibration would conceal. A correlation peak and a threshold crossing need not coincide: each detection rule has its own bias and variance, especially when signal amplitude changes. We should therefore define in advance the feature whose time is asserted in the field report. The measured correction might be decomposed into path, acquisition, algorithmic and clock mapping components only where sufficient controls render them distinguishable. Otherwise an end-to-end delay with a defensible uncertainty is preferable to an unjustified breakdown. When the host timebase is compared against itself, the experiment is circular; independent hardware counters and a calibrated timing witness break that circularity. A blind confirmation trial, in which a second operator introduces an unknown controlled delay, tests whether the complete processing chain recovers the expected time difference. These procedures support a bounded claim about a particular configuration. They do not automatically certify a different receiver, firmware build or antenna path in the field.

Dr. James M. Atkinson, Moderator: Professor von Neumann, what resource constraints can corrupt a nominally precise chronology?

John von Neumann, Peer Question: Dr. Mills, a receiver system may timestamp samples in device hardware but subsequently experience finite buffer capacity and variable transport throughput. If host scheduling delays create a queue, which evidence proves that each sample survived? And if a clock service and an acquisition program share the same processor, might heavy computation affect observed packet-timing statistics even when the external reference remains stable?

Copyright 2026, James M. Atkinson

A high-throughput receiver can accumulate gigabytes of samples while a host system performs network synchronisation, writes to disk and produces a display. Heavy computation may delay host timestamps or cause queue overflow without changing the ADC's oscillator. Can system resource records distinguish an observation that was sampled promptly but received late from one that was never acquired? Please specify the minimal hardware counters and queue telemetry, and explain why matching output file sizes or a consistently updated waterfall cannot be treated as proof that all expected sample indices survive.

David L. Mills, Response: Professor von Neumann, separate acquisition continuity from arrival punctuality. A valid sequence of hardware sample indices, device-side overrun indicators and a verified uninterrupted raw file can establish a strong case that samples survived an arrival delay. Host packet arrival timestamps alone cannot. Record buffer occupancy, dropped-packet counters, transport error states and scheduler load, then perform worst-case stress tests with a known calibration stream. Heavy host load can change software timestamp placement and queue latency without changing the reference oscillator, and can ultimately provoke overrun when buffers fill. A system that merely shows a green synchronisation icon while dropping RF samples has met neither a forensic continuity requirement nor a meaningful full-chain timing requirement.

The receiver must distinguish three events: hardware sampling, device or driver delivery, and durable storage. A hardware counter that advances for each generated sample may show continuity even when delivery is delayed; a transport sequence may reveal reordered packets; and a device overrun flag may disclose the loss of samples before the host could read them. None

Copyright 2026, James M. Atkinson

of these guarantees is available by assumption, since some receiver models expose fewer counters than others. The acquisition record should describe the actual fields used and the limitations of their semantics. A test should operate at the maximum intended streaming rate while background storage, interface rendering and clock synchronisation are stressed. Track queue occupancy, high-water marks, receive error codes, consecutive sample indices, host arrival intervals and disk write completion. If the queue temporarily accumulates ten buffers and later drains without index gaps, the condition is delayed delivery, not demonstrated sample loss. If the hardware or driver reports a missing range, the interval must be marked as unobserved even when the final file retains an expected overall byte count through duplication or padding. A waterfall that updates uniformly proves only that its rendering loop continues. It may repeat, interpolate or omit data in ways irrelevant to the source. The strong evidence is a known challenge sequence recorded end to end, with raw sequence reconciliation and a separately observed timing marker. Every throughput claim should be tied to the actual configured complex sample size and channel count, because processing throughput calculated from an advertised nominal rate may underestimate overhead and transient workload.

Dr. James M. Atkinson, Moderator: Professor Jeffreys, what conclusions may a court properly draw from agreement between two synchronised receivers?

Harold Jeffreys, Peer Question: Dr. Mills, two receivers report the same short signal at nearly identical UTC times. Both consult the same upstream synchronisation service, though their antennas and front ends are separate. Does such agreement count as two independent pieces of timing evidence, or could a shared timing error explain part of the agreement? How should

Copyright 2026, James M. Atkinson

the analyst describe this evidence without falsely claiming either complete dependence or complete independence?

Two independent antennas register a short emission, and their hosts report the same corrected UTC timestamp within a narrow tolerance. Both hosts select a common network server, use the same timestamp conversion software and share a network path for at least part of the route. What evidential weight should be assigned to that agreement? I would ask for an explicit decomposition between independent evidence of radio energy and potentially correlated evidence of time. How ought a report express the competing explanations where no independent clock witness was available during the particular event?

David L. Mills, Response: Professor Jeffreys, the analyst should decompose the proposition. Distinct antennas and front ends may provide separate evidence of RF-energy occurrence. Their external time labels, however, are not wholly independent when a common upstream hierarchy or timestamp-conversion method contributes to both. A covariance model or conservative bound should reflect common components, and independent timing supervision is needed to corroborate absolute event time. The evidential conclusion can therefore say that two acquisition paths detected an event whose respective timestamp estimates agree within stated uncertainties, while both share a specified synchronisation dependency. That is more precise than treating their agreement either as useless or as independent proof of a particular UTC instant.

There are two hypotheses that must not be collapsed. The separately placed antennas may corroborate the physical occurrence of a signal, subject to their own RF artefacts and environmental dependence. The host

Copyright 2026, James M. Atkinson

timestamps, however, may be correlated because both systems use a common upstream time service, routing infrastructure or conversion algorithm. The likelihood of matching time labels under a shared failure can be much greater than it would be under independently calibrated clocks. Without data sufficient to estimate these dependencies, multiplying two nominal timing confidence levels is not justified. The analyst should document the clock-source diagram and preserve original device counters so that arrival-time differences can be reassessed after later calibration. If each receiver was separately calibrated at its antenna reference plane and had an independent physical timing witness, that would support a stronger absolute-time inference. If not, the defensible statement is that two receiver paths observed a corresponding event and their host-derived labels agreed within the stated tolerance, with a disclosed common synchronisation dependency. Where a source-location conclusion relies upon the same labels, a sensitivity analysis should show how a plausible shared or station-specific timing bias changes the solution. A common bias may cancel in a differential estimate; a branch-dependent bias need not. The location inference must therefore be tested with the appropriate error covariance, not an assumption that each instrument is a statistically unrelated witness. This approach preserves valid corroboration while refusing to invent independence that the installation did not provide.

Dr. James M. Atkinson, Moderator: I now pass the principal token to Henri Poincaré to examine the identifiable limits of network-based clock comparison. Professor Wiener will cross-examine his account.

Henri Poincaré, Second Principal Contributor: Dr. Atkinson, the four-timestamp clock comparison illustrates an identification problem rather

Copyright 2026, James M. Atkinson

than a magical determination of absolute simultaneity. An unknown clock offset and unknown one-way network delays can produce the same observed exchange timestamps in several configurations. The familiar estimator is useful under explicit assumptions concerning path symmetry and delay dynamics; without an independent measurement of asymmetry, its numerical output does not establish the absolute error of the client clock. More importantly, correcting the host clock says nothing without a measured relationship to the receiver sampling counter. I would distinguish three propositions in the report: that a host was disciplined according to a specified protocol; that the counter-to-host mapping was measured and retained; and that antenna-to-counter latency was characterised for the waveform and detector under test. The latter two require laboratory experiments beyond the network protocol. A crucial final safeguard is to write the estimator's assumptions beside its result. A client-server exchange alone does not reveal its forward and reverse delays separately, even with perfect timestamp arithmetic. When the stated application requires a stronger physical assertion, the investigator must demonstrate what independent observation supplies the missing information. An explicit boundary of inference is an accomplishment of metrology, not an admission that all time comparisons are worthless.

The underlying question is not whether the clocks display the same hour, but whether the measurements determine the relative time at which two physical processes occurred. A convention for assigning time to distant events can be operationally sound while still depending on a specified communication mechanism. In an RF investigation the analyst must distinguish a convention used to coordinate civil time, an experimentally

Copyright 2026, James M. Atkinson

realised time-transfer relationship, and a physical delay inferred for a signal travelling from the transmitter to a receiver. The latter requires its own propagation and instrument model. None of these descriptions is refuted by the others; the error occurs when one is treated as an interchangeable measurement of another.

Let a client's clock read $C(t)=t+b$ relative to an ideal reference time t over a brief exchange, with b a constant offset. Let the forward propagation delay be d_f and the reverse propagation delay be d_r, each measured in seconds. The request departs at physical time t, reaches the server at $t+d_f$, and the server answers after a measured processing interval. Algebraically the standard offset estimator contains the true clock offset and one half the difference between the propagation delays, with its sign defined by the selected clock convention. Thus one set of timestamps admits a family of explanations: increasing b by a small quantity while changing the path asymmetry appropriately can leave the recorded exchange unchanged. There is a degree of non-identifiability that no additional decimal place removes.

One must then ask what extra observation breaks that ambiguity. A separately monitored local timing connection can compare the client against a common calibrated electrical marker, though it too has a finite cable and threshold delay. A deliberate reversal of the network path can test whether a presumed asymmetry changes sign or magnitude. A fibre loop or symmetrical laboratory connection might constrain rather than eliminate asymmetry. Each intervention creates a different set of observables, and the resulting uncertainty should be calculated in units of time, not represented by the subjective confidence of the operator. For a physical emitter-time

Copyright 2026, James M. Atkinson

inference, a comparison at the network interface is still one reference plane removed from the ADC aperture and the antenna.

The terms accuracy and simultaneity are therefore best treated as statements about named events at named reference planes. A packet transmitted from a host interface, a sample clock edge, and a threshold crossing in a processed waterfall can be associated by calibrated relationships; they are not identical occurrences. Record the event definitions, the time transformation used between them and the uncertainty of that transformation. A replay of captured data through later software must not silently change the original event definition even when a more sophisticated estimator improves the displayed chronology.

For a hypothetical laboratory system, suppose the host offset estimate repeatedly reads +0.2 milliseconds with a variation of 0.02 milliseconds, while a comparison against a locally wired independent standard reveals a persistent -0.6 millisecond path-related bias. The tight clustering indicates repeatability; the independent comparison reveals a discrepancy in the absolute mapping. Those stipulated figures are not empirical measurements and their signs depend on the chosen offset convention. A report that quotes only the observed standard deviation would omit the larger systematic uncertainty affecting the event-time claim. Conversely the discovery of bias does not make the original recorded packets disappear: it changes what can responsibly be inferred from them.

I would invite the other contributors to identify the physical and computational boundaries at which each comparison is made. A field team may legitimately use network time to coordinate observation logs, schedule equipment checks and place approximate detections on a common timeline.

Copyright 2026, James M. Atkinson

Stronger conclusions, such as nanosecond-level time difference of arrival, require a chain of independent checks extending to the sampling hardware and signal feature. Where that chain is absent, the proper assertion is a qualified correspondence of computer clocks, not a verified correspondence of electromagnetic arrival times.

Norbert Wiener, Cross-Peer Question to Henri Poincaré: Professor Poincaré, your statement permits a large systematic bias to coexist with thousands of nearly identical offset estimates. If a laboratory obtains a smooth histogram of client offsets, how should it describe the repeatability without misrepresenting the accuracy? Would a minimum-delay selection rule remove the ambiguity if the preferred path had a constant, unequal forward and return delay? What independent measurements would establish that the improvement was physical rather than merely statistical?

My concern is that the practical estimator chooses among many packet exchanges and thereby changes the apparent symmetry problem. Suppose the low-delay subset comes from one stable but asymmetrical route and the rejected high-delay samples come from a second route. Does the convergence of the accepted-offset histogram identify the clock bias, or does it merely describe one conditional transport state? Please state a concrete, falsifiable experiment that would show when the network-delay model is wrong. In particular, would reversing the link, introducing a known asymmetry, or comparing against a local hardware time standard discriminate the two explanations? The manuscript should distinguish a test that constrains constant bias from one that only reduces random scheduling variation.

Copyright 2026, James M. Atkinson

Henri Poincaré, Cross-Peer Answer to Norbert Wiener: Professor Wiener, the histogram can support a statement about variation conditional on the sampled network states. It cannot quantify a fixed asymmetry that is not observable from those records alone. Minimum-delay selection can reject some variable congestion but does not necessarily eliminate a constant directional difference. A calibrated direct timing link, independent time-transfer apparatus or characterised symmetric path offers additional evidence. The same distinction applies downstream: a host whose clock is accurately aligned may still label packets after variable buffering delay. Preserve the independent device counter and experimentally determine how its indices map to the timing reference. A report should not substitute reduced scatter for a bias bound, nor should it confuse a corrected software label with the instant the electromagnetic event reached the antenna.

Professor Wiener, the convergence of a conditional histogram establishes only that the chosen estimator is repeatable within its selection rule. The accepted samples are not a new physical clock reference. I would begin with two different hypotheses: a stable true clock offset accompanied by variable path asymmetry, and a changing true offset accompanied by path compensation. I would then design a measurement capable of breaking the observational equivalence. Swapping the physical forward and return paths in a controlled laboratory test, where possible, predicts a reversal of the asymmetry contribution but not of the underlying clock offset. Injecting a known one-way delay predicts a calculable change in the four-timestamp estimator even while the oscillator remains unchanged. A locally cabled independent time comparison provides a third constraint, subject to its own separately calibrated electrical delay. A successful experiment need not

Copyright 2026, James M. Atkinson

prove universal symmetry; it should provide a bound over the conditions actually tested. If the route changes, repeat the comparison or enlarge the uncertainty statement. The accepted-offset histogram might remain narrow before and after the change, yet both clusters can be displaced by different systematic terms. A report should state that its estimator approximates clock offset under the tested path model, not that it has directly measured the absolute arrival time of an RF event. To connect the estimator to that event, we need a second chain of measurements extending through the host, the acquisition device and the analogue signal path. Otherwise the apparent precision belongs to the timing service, not to the electromagnetic event under investigation.

David L. Mills, Response to Professors Poincaré and Wiener: Their exchange correctly restricts the four-timestamp model. Practical filtering does improve estimates in appropriate network conditions, but no choice of display precision removes an unmeasured physical asymmetry. The ultimate acquisition chronology remains a chain of measured mappings rather than one host-time label.

Dr. James M. Atkinson, Moderator: Professor Wiener, would you distinguish statistical repeatability from the unobserved path asymmetry in network clock estimates? Dr. Mills may challenge your proposed boundary.

Norbert Wiener, Third Principal Contributor: The offset estimator is a statistical object conditioned by a physical network. A cluster of similar values demonstrates repeatability under observed path conditions; it cannot identify a constant forward-reverse asymmetry. Delay selection and averaging may improve performance under congestion, but the model

Copyright 2026, James M. Atkinson

uncertainty remains. I would preserve rejected as well as accepted packet exchanges and compare alternative routes and independent timing witnesses. A timestamp applied after an SDR buffer arrives is especially susceptible to being mistaken for the actual capture instant. I would additionally require the uncertainty assessment to distinguish aleatory fluctuation, systematic path bias, and the uncertainty introduced when a model is selected after the data have been viewed. A stochastic estimator whose parameters are tuned until its residual trace becomes quiet may understate its uncertainty. Preserve competing candidate models, compare them against held-out timing challenges, and check whether the inferred RF chronology changes across defensible filtering rules. For example, a fit that assumes identical forward and reverse delays might yield a much smaller variance than one admitting route-dependent asymmetry; that difference is not a triumph of the first estimator but an indication that the measurement alone cannot decide the question. A network with infrequent topology changes also violates the naïve assumption of one stationary stochastic process. Time-tag each change, stratify the observations, and report intervals where calibration cannot bridge the transition. These practices make the resulting probabilistic statements conditional, transparent and capable of being tested by an independent laboratory.

A sequence of network offset measurements is a selected statistical record. It is produced by a noisy physical channel, a packet scheduler, server processing and an algorithm that decides which observations deserve weight. The algorithm may reject delayed exchanges precisely when a network is congested, so the apparent stability of accepted observations can depend strongly on which samples were discarded. We should not attribute

Copyright 2026, James M. Atkinson

a single distribution to the errors until we have inspected their time dependence, their common causes and their conditional relationship to the network state. The most dangerous interpretation is that a hundred nearly identical outputs must represent a hundred independent experiments.

Suppose the observed offset estimates obey $z_k=b+a_k+n_k$, where b is the desired clock offset, a_k is an asymmetry-induced bias and n_k is random timing noise. If a_k remains constant over the test, repeated averaging can suppress a zero-mean n_k but cannot recover b separately from a_k. If a_k changes with route or congestion state, the observation distribution may be a mixture rather than a single bell-shaped curve. An apparently heavy tail could be the trace of occasional route switching, a burst of server load or another reproducible physical mechanism. It is preferable to study these states than to remove unusual values merely because they interfere with an attractive plot.

The record should retain the measured round-trip delay, the individual request and response timestamps, the selected server, the clock filter state and the date of each network-route change. With these observations a researcher can plot conditional offset versus delay and examine whether a low-delay subset is more stable. Even the minimum observed round trip has a limit: it may reduce transient queueing while preserving fixed directional asymmetry. The lower envelope of delay is therefore an estimator under a model, not a direct measurement of the unknown forward and return times. It should not be sold as a calibration by itself.

A small theoretical experiment is useful. Let the two one-way delays in a reference state be 1 ms and 1 ms. Now suppose a route change increases only the outbound path to 3 ms. The additional asymmetry can shift a four-

Copyright 2026, James M. Atkinson

timestamp offset estimate by approximately 1 ms even while the actual client oscillator is unchanged. If only the low-scatter measurements after the change are retained, a post-change time series may look stable and still be displaced relative to the earlier one. A change-point analysis that includes route evidence can explain the discontinuity, but only an independent reference can establish which portion arose from clock motion rather than path alteration.

Correlations among instruments matter no less than correlations within one instrument's record. If two receiver hosts consult the same upstream server, its bias can enter both time mappings. Their event labels may agree within a small difference because the shared error cancels, whilst neither label is independently traceable to the asserted external timescale. The covariance must represent this common mode. A simple model for two timing estimates $x_i=s_i+c+e_i$ includes a common error c and independent errors e_i; their covariance contains the variance of c. Treating c as two unrelated noise sources can make combined timing uncertainty artificially small.

The conclusion of a statistical analysis should therefore be phrased as an inference conditional upon observed transport states and acknowledged assumptions. We can assess stability, outlier rates, dependence, and whether known controls predict measured changes. We cannot infer from statistical smoothness alone that the physical packet paths were symmetric or that the RF sample clock shared the host's estimated time. I would pass the question of preserved evidence to Dr. Hopper, because a satisfactory statistical model is useless if the original observations were transformed or overwritten before anyone could examine them.

Copyright 2026, James M. Atkinson

David L. Mills, Cross-Peer Question to Norbert Wiener: Is a minimum-delay estimate ever sufficient for a receiver report when the host time service is carefully monitored and has remained stable for many days? Please address how you would prevent a genuine clock correction from being misclassified as a route change solely because both produce a shift in a filtered offset trace. The existence of an independent timing witness seems central to that distinction.

Consider a long receiver acquisition during which the network clock appears stable according to the filter, but the route changes without an application alarm. The new path has a different outbound-versus-return delay, and the operator keeps only filtered offsets. What diagnostics would reveal a systematic change when the retained offset series remains quite smooth after the transition? Could a change-point test on the raw four-timestamp tuples identify the transition even if the host's control loop gradually slew through it? And what independent observation would be needed before describing the resulting shift as a true change in the physical RF event chronology rather than a change in the host clock mapping?

Norbert Wiener, Cross-Peer Answer to David L. Mills: It supports a bounded assertion about host synchronisation under the tested path conditions. It does not alone establish the receiver hardware-to-host mapping or the absolute one-way delay from antenna to timestamp. Those require additional calibration. The report should show the network contribution separately from the acquisition-chain contribution and avoid implying that long monitoring eliminates fixed asymmetry. A useful safeguard is a paired hypothesis test supported by observations from different physical domains. If a host offset changes while a locally monitored hardware marker and an

Copyright 2026, James M. Atkinson

independent clock comparison remain constant, the network-path explanation becomes more plausible. If the independent comparison records the same actual host-clock motion, one must investigate the discipline action itself. Neither a lone filter residual nor the mere date of a route change is sufficient. Record the expected signature under each explanation before inspecting the intervention result, and repeat the experiment at least across a few deliberately varied path conditions. A statistical change-point result should therefore be presented as evidence of a transition, not as proof of its underlying cause. Only a discriminating physical observation supports that attribution.

Dr. Mills, the first diagnostic is preservation of the original candidate measurements and their context, including delay, timestamp asymmetry proxies, peer-selection history and route-change evidence. The output of a state estimator alone is not sufficient, because it can remove much of the transient by changing the host clock. A change-point procedure could look for shifts in the joint distribution of offset and round-trip delay, but it must be assessed against actual path conditions and the risk of false alarms. A route can change asymmetry while leaving total delay nearly constant, so the absence of a visible delay jump is not conclusive. Conversely, a host oscillator drift can change the offset series without any route change. An independent timing witness is needed to distinguish these mechanisms credibly. For example, a stable local pulse or hardware clock comparison unaffected by the packet route can show whether the physical host offset moved when the network estimator changed. If that witness remains stable while network estimates shift, the path hypothesis gains force; if both move together, the host-clock hypothesis becomes stronger. The report should

Copyright 2026, James M. Atkinson

include the selected and rejected packets and a sensitivity analysis showing the consequences of alternative asymmetry values. It should not claim a unique cause from a filtering residual. Only after the host-to-device timing bridge has itself been established can one discuss a corrected RF acquisition chronology. We must also acknowledge the separate effect of buffering: a host's packet-arrival time can shift even when neither its wall clock nor the receiver's sampling time changes.

Dr. James M. Atkinson, Moderator: Dr. Hopper, the token now passes to software provenance and the preservation of original event order. Professor Poincaré will address the implications of a revised UTC mapping.

Grace Murray Hopper, Fourth Principal Contributor: Software architecture must preserve the distinction between raw acquisition order and a later computation of civil time. A transaction that replaces original device timestamps with revised UTC labels creates an avoidable evidential ambiguity. I would keep immutable hardware indices, device counters, the contemporaneous host-clock state and a separately versioned mapping for all corrections. When clocks step backwards, sorting records by wall time alone can reverse the original observation order. An operator must be able to reconstruct the original sequence without trusting the latest user-interface view. The acceptance test should be formulated as a falsifiable software requirement: after any supported synchronisation adjustment, every preserved RF sample must remain associated with its original device index and acquisition epoch, and no derivative timestamp may be presented as an unmodified hardware observation. Construct test cases in which a known timing marker crosses a host-clock step, a buffer overflow and a receiver retune. Inspect the stored record for unambiguous event

Copyright 2026, James M. Atkinson

boundaries and verify that a reviewer can reproduce both the original and revised UTC mappings. A good design also preserves conversion uncertainty in a machine-readable field rather than burying it in a narrative footnote. This matters when several institutions exchange evidence and one later reprocesses a recording under a different time-transfer model. The integrity of the original acquisition ledger should permit divergent analyses while still exposing which data were truly observed and which quantities were inferred. Such a separation makes a computer system scientifically useful even when an earlier conclusion requires correction.

Software must preserve the distinction between facts captured by hardware and times calculated later. A receiver can acquire an uninterrupted indexed sample stream while the host clock is stepped; it can also lose samples while a host clock remains impeccable. A logging format that stores only one generic timestamp for both circumstances destroys useful evidence. The solution begins with an explicit data model, not merely a more elaborate clock routine. The operator should be able to inspect which record came from a device register, which from a driver callback, which from an operating-system clock, and which from a later conversion to coordinated time.

I would organise the acquisition ledger around an immutable observation identity: station identifier, receiver and channel identity, hardware sample counter or documented substitute, packet sequence, device timestamp if available, host monotonic arrival time, contemporaneous wall-clock label, configuration epoch and cryptographic checksum or other integrity control. A separate clock-state ledger would store network peer selection, raw four-timestamp exchanges when available, estimated offset, delay, jitter,

Copyright 2026, James M. Atkinson

reference changes and each commanded clock adjustment. The linkage between the two ledgers should be a recorded rule with a version number. These fields do not make a faulty measurement accurate; they make its failure and later correction discoverable.

Consider the case in which a host wall clock jumps backwards by 40 milliseconds while its receiver continues to acquire blocks numbered 5000, 5001, 5002 and 5003. Sorting the resulting records solely by wall-clock label could present the blocks in the wrong order. Retaining their hardware counters preserves acquisition order, while the original wall-clock labels preserve the contemporaneous report. An updated timestamp mapping can then produce corrected estimates, with the discontinuity and uncertainty prominently annotated. The original labels must not be quietly replaced, because that would make it impossible to reconstruct what the system actually asserted at the time of collection.

Another case involves buffering. An RF packet may be captured at a device, reach a driver after a variable interval, and be written to disk after further delay. A timestamp taken during file writing is therefore a transaction time, not necessarily an event time. Different software threads can observe packets in a different order when processing runs concurrently, especially if a queue is split across workers. The system should preserve explicit acquisition ordering and document any reordering transformation. Its test suite must deliberately introduce queue load, loss, duplicate delivery and clock discipline changes, then confirm that each condition is observable in the saved evidence.

A provenance system should also distinguish facts about the source from facts about the tool. A server's asserted time and its digital authentication

Copyright 2026, James M. Atkinson

evidence are not measurements of propagation delay. A receiver manufacturer's clock-quality indicator is not a calibration of an analogue filter. The immutable ledger should contain those outputs as outputs, with provenance and known limitations, rather than treating them as unquestioned assertions. An examiner can then ask which assumption each subsequent conclusion required and whether a different assumption would change the result.

The public-facing report should be built from the raw ledger and contain a precise description of the event time: for instance, 'UTC estimate assigned to the rising edge of a calibrated injected marker, derived from device sample counter and reference comparison, with specified uncertainty'. That is quite different from 'timestamp written by the logging host'. Both may be useful; neither should masquerade as the other. A trustworthy computer system helps future investigators examine the original observation even when the contemporary interpretation later changes. The quality of its evidence is revealed not by the elegance of its display, but by what remains demonstrably reconstructable after an error.

Henri Poincaré, Cross-Peer Question to Grace Murray Hopper: How should one describe two events whose displayed UTC order reverses after a clock correction, even though their hardware counter order is unequivocal? In particular, how would you preserve the uncertainty of translating those counter epochs into external time without allowing a later analyst to convert that uncertain ordering into a falsely precise legal chronology?

An electronic record can show two events with UTC labels that reverse their acquisition order after a clock correction. The operator may prefer the

Copyright 2026, James M. Atkinson

corrected UTC ordering because it agrees with an external narrative, but the original hardware counters say otherwise. Which ordering is evidentially primary, and under what assumptions might either ordering fail? I ask you to define an invariant strong enough to protect the raw sample sequence while allowing later scientific correction of its external time mapping. The answer should also confront counter reset and missing sample intervals, because a merely monotonic counter is not a sufficient guarantee when its provenance is unknown.

Grace Murray Hopper, Cross-Peer Answer to Henri Poincaré: The hardware counter supports their acquisition order within that clock domain. The external-time relationship remains conditional on the calibration used. A corrected UTC estimate might legitimately change the inferred spacing or absolute placement, but it should not erase the observation that one sample preceded the other in the physical device sequence. Keep the original and corrected representations and specify their uncertainties. Where two hardware epochs cannot be joined by a verified counter-to-time mapping, I would mark the cross-epoch event order unresolved, even if a plausible interpolation makes the display smooth. The uncertainty must accompany each conversion, and the provenance record must identify which independent calibration observation, if any, bounds a discontinuity. The purpose of an audit ledger is not to manufacture certainty but to prevent the loss of the limits of the original observation. A reader should be able to reconstruct why one ordering was preferred and test the alternative under the same disclosed evidence.

Professor Poincaré, the immutable observation identity is the first anchor of the chronology. Where a trustworthy hardware counter and device

Copyright 2026, James M. Atkinson

timestamp exist, their original order records the order in which the device labelled samples. That does not mean the counter is infallible: wraparound, reset, interleaving, loss and firmware error can alter its meaning. A device should therefore log counter epochs, configuration transitions and explicit gaps, and its integrity needs challenge testing. If a counter is absent, the report must state which less direct ordering evidence is available and what ambiguity remains. UTC labels are a separate, versioned inference. The original wall-clock stamps should remain in the record so the operator's contemporaneous view can be reconstructed, even if later calibrated conversion gives a better estimate. When the clock correction moves event labels across one another, present both mappings and explain why the hardware chronology or an independent marker supports the preferred event order. It is impermissible to overwrite earlier values and conceal the transformation simply because the new timeline appears more coherent. A reproducible ledger should contain the raw samples or their integrity-protected references, device and station IDs, counters, clock-state records and exact conversion algorithms. Test this ledger by introducing a known clock step, deliberate packet reordering and a controlled counter reset while recording an independent marker. The outcome must expose each condition rather than silently smoothing it. The proper forensic conclusion is a statement about the best supported order under explicit instrument assumptions, not the assertion that a database sort has discovered physical truth.

Dr. James M. Atkinson, Moderator: Professor Michelson, please examine how an antenna-to-sample timing calibration must be constructed. Dr.

Copyright 2026, James M. Atkinson

Hopper will question what happens when a later algorithm redefines the detection feature.

Albert A. Michelson, Fifth Principal Contributor: End-to-end calibration must measure the quantity used in the legal or technical inference. If the contested event is the leading edge of a short RF burst, inject a waveform with a defined leading-edge feature at a declared reference plane. Record the same event with an independent witness and examine the full path through filters, ADC and software event picker. Change the signal amplitude and bandwidth to expose threshold-dependent delays. A network-synchronised computer does not substitute for this physical experiment. A further point concerns calibration transfer between laboratories. Two instruments bearing the same model number may have different analogue filter histories, connector delays, firmware settings and sample-clock arrangements. Before importing a delay correction from a published experiment, inspect whether the original measurement used an equivalent waveform, carrier frequency, amplitude and trigger definition. If the conditions differ, perform a transfer check or include an uncertainty contribution for the mismatch. In a disputed investigation it is preferable to publish the complete calibration configuration and retain the raw reference-marker data, so that another laboratory can repeat the result. The aim is not to obtain a flattering number from a standard, but to establish that the physical feature and the reported time are linked by a tested and reviewable chain. A precision claim whose validity depends on an unrecorded cable change or software update should fail the acceptance test irrespective of the numerical stability shown on its display.

Copyright 2026, James M. Atkinson

End-to-end calibration cannot be replaced with a specification for one privileged component. The timing quantity of interest in multistation RF analysis is often the arrival of a defined waveform feature at a declared antenna reference plane. An NTP offset estimate belongs to the host network interface and its software clock. Between that interface and the physical signal feature lie several other systems: acquisition hardware, converters, filters, triggering logic, recording buffers and event-detection algorithms. Each can introduce delay or uncertainty. The engineer must measure the relation between the endpoints of the inference, not assume it because both ends use the word time.

First define the feature. A pulse's initial energy, its envelope midpoint, a matched-filter correlation maximum and a threshold crossing are not necessarily coincident, especially when the signal is filtered or noisy. Choose the feature relevant to the physical claim and document the algorithm used to identify it. Then connect a safe test source to a calibrated receiver reference plane through a known path and monitor the source event with an independent timing witness. Retain the raw receiver samples, sample counter, host clock state and every processing parameter. Repeated measurements under the expected range of amplitude and bandwidth will reveal how latency depends on the signal and configuration.

A useful calibration model is $t_{report}=t_{event}+\tau_{path}+\tau_{acq}+\tau_{processing}+b_{clock}+e$, where τ_{path} is cable and analogue propagation delay, τ_{acq} is the effective acquisition and triggering delay, $\tau_{processing}$ is any processing delay included in the report timestamp, b_{clock} is the applicable clock mapping bias, and e includes unresolved measurement error. Each term must be expressed relative to an

Copyright 2026, James M. Atkinson

identified reference plane and a clear sign convention. Some terms are fixed calibratable offsets; others are state-dependent. The decomposition is not automatically identifiable from a single end-to-end measurement, but controlled intervention can isolate the dominant contributions and bound what remains.

For example, moving a calibration lead from one input route to another can change path length while leaving the host clock untouched. A different digital filter may alter group delay and the timestamp of a threshold crossing without changing the instant the antenna was illuminated. A host workload challenge may delay packet presentation yet leave a device-side hardware timestamp stable. Repeating each manipulation while independently monitoring the physical input helps establish what portion of the displayed time belongs to acquisition, computation, or delivery. Where a manipulation changes several components simultaneously, the corresponding inference must remain qualified.

The environment matters. Temperature alters cable delay and oscillator behaviour; connectors may change electrical length when moved; power conditions may affect the instrument's lock state; and filters can exhibit different group delays across a wideband transient. A calibration established at one frequency and level cannot simply be transferred to another without checking its sensitivity. The uncertainty budget should include not only repeatability but also correction uncertainty, environmental sensitivity, independent reference uncertainty and any unresolved clock discontinuity. If a term is bounded rather than probabilistically characterised, the report should retain that bounded character instead of pretending it has an ordinary Gaussian standard deviation.

Copyright 2026, James M. Atkinson

The final proof must use a controlled unknown rather than a calibration performed with the answer in view. Ask a second operator to configure a known but concealed delay or choose one of several surveyed event positions. Have the first operator recover the timing relation from the same pipeline intended for field use. Compare the result with the independent reference and examine failures as carefully as successes. A claim of microsecond or nanosecond event accuracy then rests on a reproducible full-chain performance test. Absent such testing, a healthy network-time status is evidence about the host-clock service, not the electromagnetic arrival chronology.

Grace Murray Hopper, Cross-Peer Question to Albert A. Michelson: If the detection algorithm is later updated to identify an earlier portion of the same burst, should the newly calculated time replace the previously reported event time? I would also invite you to address how a calibration should be withdrawn or qualified when a later firmware revision changes buffering or group delay, even though the original analogue hardware has not moved.

Your full-chain calibration may establish the latency of an algorithm for one test waveform, but the actual field signal differs in bandwidth, rise time, amplitude and signal-to-noise ratio. How would you measure whether the detection method's timestamp walks as the signal changes, and decide which calibration can legitimately be transferred? Furthermore, if the analysis software is later revised, is the old calibration still valid for a new timestamp estimator? Please specify what would be preserved for reproducibility and how the revised result could be reported without rewriting the original measurement. The technical answer should

Copyright 2026, James M. Atkinson

distinguish a correctable group delay from a signal-dependent detection ambiguity.

Albert A. Michelson, Cross-Peer Answer to Grace Murray Hopper: The new estimator can be valid, but its result is a derived finding and should be stored alongside the original algorithm and timestamp. Retain its code version, calibration and changed feature definition. Explain whether the different reported time arises from an improved estimator, revised clock mapping or new evidence. Never rewrite the source record as though the new inference had been recorded at acquisition. A firmware revision may alter timestamp placement, digital-filter delay or the buffering stage at which time is recorded. The prior calibration therefore cannot simply be presumed to transfer. Freeze the original acquisition and processing software versions in the evidence record, rerun the reference-marker challenge against the revised system, and publish the before-and-after latency comparison. If the correction changes, preserve both derived timestamps with their respective calibration identities rather than overwrite the earlier result. The same discipline applies to changes in hardware input configuration or in the feature-detection algorithm. This establishes traceable revision history, not merely two equally authoritative display numbers.

Dr. Hopper, the first correction is to declare a particular event definition and measure the detector's delay over a range of signal conditions. A threshold crossing can shift with amplitude, slew rate and noise, whereas a matched-filter peak depends on template agreement and the instrument's frequency response. A group-delay correction calibrated at one frequency may not describe a burst that spans an unequal passband. For calibration, prepare

Copyright 2026, James M. Atkinson

an authorised family of test waveforms with controlled rise times, bandwidths and levels, then measure the physical input marker with an independent timing witness. Record how the processed event timestamp changes while the physical marker stays fixed. This yields an empirical latency surface or bounded error region rather than one unsupported universal constant. The method should include the expected receiver gain and filter settings, because a changed automatic gain-control state can move the detector's selected feature. A new algorithm constitutes a new measurement transformation. It may improve timing precision, but the earlier raw sample record and the old timestamp estimate remain part of the historical evidence. Reprocess the retained samples, record the code version, compare new estimates against the calibration set and identify changed conclusions explicitly. An estimator that is validated on one laboratory pulse must not be proclaimed accurate for a different untested field waveform. The final report should distinguish measured analogue delay, calculated digital filter delay, and empirically observed signal-dependent detection bias, each with its own uncertainty. Where the input data do not support separation of these terms, a bounded end-to-end latency is a more faithful result than a fictitiously precise decomposition.

Dr. James M. Atkinson, Moderator, Closing Synthesis: Network synchronisation offers evidence concerning a host clock's estimated relation to a time reference under the protocol's assumptions. It does not, without a separately measured bridge, establish when an analogue RF event reached an antenna or when its samples entered an ADC. The four-timestamp model cannot independently eliminate asymmetric delay; software correction does not guarantee raw-stream continuity; and multiple computers in one

Copyright 2026, James M. Atkinson

synchronisation hierarchy may share systematic errors. The defensible chronology retains hardware counters, unmodified network exchanges, clock-state transitions, reference-plane calibration, transport diagnostics, documented conversion algorithms and an uncertainty model. A precise timestamp display is only the beginning of measurement assurance, not its conclusion.

QUESTION 057

Copyright 2026, James M. Atkinson

How do frequency-counter gate time and dead time bias observations of a drifting burst carrier?

Editorial disclosure. This is an original fictional educational reconstruction. Statements assigned to deceased historical contributors are newly authored illustrations, not historical quotations, transcripts, or evidence of an actual conversation.

SCHOLARLY RECONSTRUCTION. The following dialogue among deceased specialists is an invented pedagogical exercise, not an authentic historical transcript. The modern SDR applications and examples are editorial extrapolations.

Dr. James M. Atkinson, Moderator: Professor Nyquist, an intermittent RF carrier may drift substantially within one short transmission, even as a frequency counter displays a precise and remarkably stable number. How do the instrument's gate time, gate placement, reciprocal counting method, and unobserved dead intervals condition the result? In particular, what would distinguish a measurement of the burst's actual frequency trajectory from a mean over only those signal cycles accepted by the counter?

Harry Nyquist, Principal Contributor: Dr. Atkinson, a counter necessarily measures over a finite observation interval. For a phase function $\varphi(t)$, expressed in radians, instantaneous frequency is defined by $f(t)=(1/2\pi)d\varphi(t)/dt$ wherever this derivative is meaningful. A direct counter estimates accepted cycles divided by gate duration; reciprocal counting estimates frequency from an observed number of input cycles and a time interval measured against a reference. Neither method, without further assumptions, establishes the entire trajectory of a burst. The result depends

Copyright 2026, James M. Atkinson

upon accepted edges, the opening and closing of the gate, and the properties of the reference. The distinction between the estimand and the numerical presentation must be maintained throughout the analysis.

Assume an ideal linear chirp $f(t)=f_0+kt$, where f_0 denotes the initial frequency in hertz, t elapsed seconds and k the frequency-slew rate in hertz per second. Over the interval from a to a+T, the uniform mean is $\bar{f}=(1/T)\int f(t)dt=f_0+k(a+T/2)$. A gate therefore estimates the midpoint value for this ideal waveform. If the burst lasts 40 ms, begins at 100 MHz and increases at 20 kHz/s, its terminal frequency is 100,000,800 Hz and its full-burst mean is 100,000,400 Hz. A 10 ms gate placed at the beginning instead obtains 100,000,100 Hz; the same gate during the last 10 ms obtains 100,000,700 Hz. These three values are mutually compatible, but they answer different questions. They cannot be presented as interchangeable estimates of the frequency of an entire drifting emission.

A simplified direct counter observes N complete cycles in a time T and displays N/T. The conventional one-cycle quantisation scale corresponds to approximately 1/T hertz: 100 Hz at 10 ms and 10 Hz at 100 ms. These are only approximate sensitivity scales and not complete error bounds. Reciprocal counters may interpolate edge times and perform much better, while both kinds remain subject to trigger uncertainty, timebase error, noise and waveform quality. In a 40 ms burst, a programmed 100 ms gate may not contain enough continuous accepted signal to deliver a meaningful reading at all. A specification that presumes an uninterrupted sine wave cannot simply be transferred to a transient waveform whose edges fade into noise.

Copyright 2026, James M. Atkinson

Dead time is the interval during which the measuring instrument is not accepting a qualifying observation, whether because of reset, transfer, processing or an architectural scheduling choice. If its active time is T and its blind interval is D, then the active fraction for a periodic schedule is $\eta=T/(T+D)$. For a 10 ms gate followed by 30 ms dead time, $\eta=0.25$. An instantaneous event with uniform arrival phase relative to the repeating schedule would overlap the active window with probability 0.25, but a finite burst requiring several consecutive qualified cycles demands a more careful geometric and trigger model. Deterministic repeated bursts can become phase-locked to the gate schedule and be systematically missed, even though an operator sees a reassuring flow of successful measurements.

One must also distinguish missing events from temporal averaging. A counter may capture each 40 ms burst yet measure only its earliest 10 ms, thereby producing nearly identical numbers on every repetition while never observing the substantial late-burst frequency excursion. Another gate may overlap the middle of a chirp and average equal positive and negative deviations, creating a deceptively stable mean even when the instantaneous trajectory is conspicuous. A stability statistic calculated solely from the accepted readings describes their selected population. It does not automatically describe a process sampled during inaccessible dead intervals or sections excluded by trigger selection.

Trigger physics complicates the matter further. Noise can introduce spurious threshold crossings and fade-out can remove genuine ones. Hysteresis, blanking and qualification reduce some errors but change which cycles enter the count. Group delay in preceding filters, AGC settling and local oscillator transients can determine the effective opening of the

Copyright 2026, James M. Atkinson

observation window. At the downstream counter reference plane a burst may therefore begin or end at a different moment from the signal at the antenna input. The operator must state the reference plane and preserve the complete acquisition configuration.

A strong discriminating experiment uses an authorised laboratory source that emits documented linear chirps, constant-frequency controls and brief programmed frequency steps. A second independently monitored acquisition path captures the source waveform and records the true chronology. The counter is challenged at multiple gate widths, gate phases, trigger levels and dead-time settings. For every accepted reading, its value should be compared with the calculated average over the actual accepted interval rather than with a convenient nominal centre frequency. Include events deliberately placed inside the blind intervals; preserve invalid and timed-out gate attempts alongside valid results. This establishes what the instrument detects and what it cannot certify.

Where defensible, preserve complex receiver samples, the sample index, hardware timestamps, original counter measurement windows, frequency reference status, trigger settings and all rejection or overload diagnostics. A short-time Fourier transform or phase-derivative analysis may reveal information hidden by one interval average, but neither is immune to window leakage, low signal-to-noise ratio, phase-unwrapping errors or missing samples. Compare the different methods against the controlled source and express the residual uncertainty. The counter is a useful instrument, but it cannot convert an unobserved part of the waveform into evidence merely by adding significant digits to its display.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Michelson, how would you challenge a counter showing very fine resolution when its gate barely overlaps the useful emission?

Albert A. Michelson, Peer Question: Professor Nyquist, the counter may report ten digits while observing only an uncertain portion of a burst. What independent observation would establish the actual beginning and end of its measurement, including the trigger threshold and signal-path delay? What would you require before accepting the advertised frequency resolution as evidence of accuracy for the whole burst, rather than simply a precise measurement of a selected fraction of the waveform?

A counter might present ten or twelve digits when its internal reference and event interpolator permit such a display, whilst the actual carrier was present for only a small fraction of the nominal gate. Suppose the first accepted crossing occurs after the burst has begun and the last occurs before the observed trailing edge, and neither accepted boundary is preserved by the instrument. Would you regard its frequency number as an average over a known physical interval? What reference-plane experiment would distinguish an intrinsically repeatable count from a complete measurement of the event, and how would you expose changes in effective gate placement as input amplitude and trigger threshold are varied? I should like the uncertainty statement to include both the precision of time interpolation and the larger ambiguity about which part of the burst produced the displayed value.

Harry Nyquist, Response: Professor Michelson, instrument the effective gate and the waveform at a stated electrical reference plane. Where the counter exposes time tags or gate-status outputs, record them alongside a second

Copyright 2026, James M. Atkinson

calibrated capture of the signal. Determine the first and last accepted edges, not merely the nominal programmed duration. Repeat with known rising and falling amplitude envelopes and controlled input delays. An average over a verified section may be precise, but its relationship to the whole burst depends on the time history of frequency outside that section. In a chirp the distinction is measurable: moving an otherwise unchanged gate along the burst produces a predictable change in the average. A publication-ready claim should identify the sampled portion, calibration and residual trigger uncertainty instead of treating the readout as a complete physical history.

The displayed resolution should never be conflated with knowledge of the measurement interval. A reciprocal counter can measure elapsed time between selected signal crossings with very fine numerical granularity, yet those crossings may not coincide with the original onset or termination of the RF energy. For a drifting signal, uncertainty in the effective starting and stopping times changes the quantity being estimated, not merely the numerical uncertainty of the estimate. If the signal follows $f(t)=f_0+kt$ and the nominal gate is displaced by Δt, an ideal uniform average changes by $k\Delta t$, even with an otherwise flawless timebase. At a chirp rate of 20 kHz per second, displacement by 5 milliseconds changes the estimated mean by 100 Hz. This is an estimator-placement effect, not evidence that the oscillator changed in response to the measurement.

The laboratory should therefore establish a physical reference plane and record the generator waveform independently from the counter. An accessible gate-status output can reveal the active interval, but a status signal may itself reflect command timing rather than actual accepted edge times. Where possible, retain the hardware crossing timestamps; otherwise

Copyright 2026, James M. Atkinson

bound the acceptance interval using an independent scope or continuously sampling receiver whose timebase has been separately checked. Vary burst length, received amplitude, threshold and gate phase while leaving the programmed source frequency law unchanged. If the displayed counter value follows the changed portion of the chirp, the observed behaviour is explicable by sampling placement. If it differs from the average over the reconstructed interval, investigate trigger noise, count loss, reference drift and instrument architecture.

The final report should quote the effective gate or its uncertainty and identify whether the measured quantity is an interval mean, a reciprocal-period average or a model-derived instantaneous estimate. A claimed absolute carrier frequency may also inherit errors from the counter's own reference clock. A stable display need not show an independently calibrated standard, and a burst's complete frequency excursion cannot be bounded from an unknown subset of its edges. The appropriate result is an explicit statement of what was measured and a documented test of whether the apparatus could have observed the omitted portions.

Dr. James M. Atkinson, Moderator: Professor von Neumann, may a regular stream of displays conceal regular intervals of blindness?

John von Neumann, Peer Question: Professor Nyquist, the observer sees the instrument update a measurement every forty milliseconds. Yet the device accepts signal for only ten milliseconds and uses the remainder to transfer or reset its result. Is it legitimate to describe the record as continuous monitoring? How should the chance of missing a burst be computed when bursts are periodic rather than randomly distributed, and what evidence would refute an assumed probability-of-detection figure?

Copyright 2026, James M. Atkinson

Consider a counter that acquires for ten milliseconds and then spends thirty milliseconds transferring and resetting its result. The interface publishes a new reading every forty milliseconds, so the operator sees a regular and seemingly continuous stream. Yet a four-millisecond burst may occur between those windows, or one burst may straddle their boundary. How should the programme represent unobserved periods so that a sequence of attractive frequency displays cannot be mistaken for continuous coverage? Is duty factor alone sufficient to calculate the chance of detecting a burst whose arrival times are periodic rather than random? I also ask what happens when a receiver has separate acquisition and presentation pipelines, because a nominal processing dead time on one device might be absent on another instrument using continuously timestamped edges.

Harry Nyquist, Response: Professor von Neumann, label the measurement windows explicitly and treat their complement as unavailable unless another independently recording subsystem covers it. A duty factor is not automatically a probability of detection. For randomly phased very short events it approximates the overlap probability, but an event must still pass the counter’s qualification criteria, and a burst of nonzero duration changes the overlap geometry. A periodic signal synchronous with the schedule may repeatedly fall in dead time; another with the same repetition period could be captured on every pass. Challenge the instrument by sweeping burst phase through the entire cycle, recording accepted and missed events. Only then can an empirical detection curve for the specified conditions support an evidential sensitivity statement.

The record must represent active gate windows as intervals, not merely as a sampling rate or display cadence. In the proposed cycle T=10 milliseconds

Copyright 2026, James M. Atkinson

and D=30 milliseconds, the duty factor is T/(T+D)=0.25, a proportion of time rather than an unconditional probability of detecting every possible event. A burst with duration B may require a complete overlap, a minimum number of qualified cycles, or merely any positive overlap to trigger. Each rule yields a different opportunity for acceptance. An event whose phase relative to the instrument cycle is deterministic may repeatedly fall in the same blind window. Therefore the assumption that arrivals are uniformly random over the cycle must be justified before multiplying event count by duty factor or converting non-detections into statistical bounds.

For a constructed example, if a one-millisecond event may be recognised upon any overlap with a ten-millisecond active window in a forty-millisecond cycle, its possible start phase occupies approximately eleven milliseconds of the forty-millisecond cycle, giving an overlap probability of 11/40 under a uniform independent start phase. If the entire event must fit within the active interval, the favourable phase range shrinks to nine milliseconds and the probability becomes 9/40. If successive bursts repeat in exact synchronism with the gate, neither expression describes the sequence: the equipment might detect every burst or miss every one, according to its fixed relative phase. Those limits should be demonstrated with a programmable generator, not hidden behind the instrument's displayed refresh rate.

A truly gap-free edge-timestamping architecture changes this assessment, but its claimed continuity still requires verification of counter overflow, buffer overrun and data transport. Some instruments may retain timestamps continuously whilst a host reads previously acquired results, while others suspend counting during readout. The engineer should identify which design is actually installed. An explicit gate ledger should show each

Copyright 2026, James M. Atkinson

interval of valid observation, each blind interval and any transition whose status is unknown. Only with that evidence can a later examiner say whether an intermittent carrier was available to the measurement method during the relevant period.

Dr. James M. Atkinson, Moderator: Dr. Hamming, what software records should accompany accepted frequency readings?

Richard W. Hamming, Peer Question: Professor Nyquist, an acquisition application might save only successful numeric measurements and omit failures, counter overruns, empty gates and rejected crossings. Such a file can look orderly even when most qualifying events are missed. What structure would permit later examination of the full opportunity set, and how should an investigator test the software for selective omissions or silent substitution of interpolated values?

The counter's firmware may produce empty gates, rejected counts, overload states and transport errors, but an application programmer might persist only rows containing a numeric frequency. The displayed time series would then look exceptionally clean, because the unsuccessful attempts have vanished from it. What software contract would guarantee that every scheduled measurement is represented in the evidence record, including a correct rejection reason and an exact relation to the source acquisition clock? Could the application prove completeness by counting successful rows, or must it preserve an independent schedule of attempts and the integrity of each transport block? I ask also whether a later change in the frequency-estimation algorithm should overwrite an earlier reading, or instead appear as a new derivation from unchanged source observations.

Copyright 2026, James M. Atkinson

Harry Nyquist, Response: Dr. Hamming, the counter should produce an immutable attempt ledger with monotonic sequence identifiers, actual measurement intervals, status codes and relevant hardware configuration. A failure to detect must remain an explicit record, not simply disappear from storage. Distinguish raw edge or count data, an accepted measurement, and any subsequently interpolated or filtered frequency estimate. Conduct fault-injection tests using a controlled source that deliberately produces no qualifying cycles, phase steps, fading edges and bursts during reset intervals. Verify that each case leaves a corresponding status. Retain software version, reference configuration and file hashes. Without such a ledger the sample-selection mechanism is unobservable, so frequency variation statistics may describe only a biased subset of measurement attempts.

A complete attempt ledger is required, with a monotonic record identifier for each scheduled gate and a status field for each outcome. Accepted estimates must not displace failures from the ledger. The schedule should record both requested and actual opening times where hardware permits, selected crossing counts, timebase reference state, threshold and input channel, and indicators for overflow or missing data. If only successful readings are stored, the denominator of the success rate disappears. One cannot infer that monitoring was continuous from a database in which every visible row is valid, because the discarded rows may coincide with the most difficult burst conditions. The programme should expose gaps as deliberate observations about the instrument's limitations, not silently interpolate them away.

Copyright 2026, James M. Atkinson

A software acceptance trial can use a generator sending known chirps, constant-frequency controls and deliberate brief steps while the host is placed under scheduled computational and transport load. The experimenter should preserve the generator's independent timing record and compare it with the full ledger. For instance, one thousand planned gate intervals must yield one thousand status records even if only nine hundred permit a valid frequency value. Duplicate records, missing identifiers and impossible overlaps are defects to investigate. The source sample chronology should be based upon original device counters or gate timestamps, not a later graphical update. A host timestamp can be retained for auditing software latency, but it may not be substituted for an unknown hardware acquisition epoch.

A revised estimator should produce a versioned derived value. If calibration or an improved period-interpolation algorithm changes a frequency result, keep the old estimate, the original counts and time marks, the new calculation, the responsible code version and its uncertainty. Cryptographic file hashes can assist in proving preservation of stored bytes, yet they cannot show that the instrument never lost counts before writing. Independent continuity tests, device error indicators and a known input sequence provide that separate evidence. Such a design allows forensic reanalysis without rewriting what the instrument originally observed.

Dr. James M. Atkinson, Moderator: Professor Kolmogorov, how should the statistics of the accepted readings be interpreted?

Andrey N. Kolmogorov, Peer Question: Professor Nyquist, a sequence of successful gate averages has small variance, but the gaps are non-random because the counter rejects low-amplitude or poorly timed sections of the

Copyright 2026, James M. Atkinson

burst. Does that observed variance estimate the true carrier fluctuation across the entire transmission? Which assumptions about sampling and temporal stationarity must be defended, and how can selection bias be exposed using a parallel continuous recording?

Suppose a counter's valid readings show a standard deviation of only ten hertz, and the investigator calls this the short-term frequency stability of the transmitter. The counter accepts only periods during which the burst is sufficiently strong to give reliable zero crossings; weak portions and fast transitions are disproportionately rejected. Does the computed variance estimate the distribution of the carrier's instantaneous frequency over the entire transmission, or only the conditional population of selected interval averages? Would increasing the number of accepted readings ever remove that selection bias? I should like an example in which the accepted frequency statistics become more precise while the scientific conclusion about the unobserved remainder becomes less justified, and an experimental design that exposes missingness correlated with signal amplitude and timing.

Harry Nyquist, Response: Professor Kolmogorov, the empirical variance describes the distribution of accepted gate averages under the actual acceptance rule. It need not estimate the distribution of instantaneous frequency, or even all possible gate averages. If acceptance depends on amplitude, phase, drift or location within the burst, selection is informative. Compare acceptance probability across measured burst positions and waveform conditions using the parallel recorder. Compute statistics conditional on those factors, retaining coverage fractions and intervals where the system failed. Frequency-stability tools such as Allan deviation are

Copyright 2026, James M. Atkinson

meaningful only when their sampling, bandwidth, dead-time and noise assumptions are declared. Statistical elegance does not transform a non-representative sample into a comprehensive account of unobserved signal behaviour.

The sample variance describes the accepted measurements under the instrument's gate and trigger policy. It does not automatically describe the full emission, whose time-dependent frequency may be different during rejected periods. A chirp repeatedly sampled only near its beginning can produce identical early-gate means even though its end-of-burst frequency changes substantially. Gathering a larger set of those early means makes the estimate of that narrow measurand more precise; it does not establish the frequency of the remainder of the burst. The statistical population is defined by the observation process. If acceptance depends upon amplitude, frequency slope or relative phase, it may be informative missingness rather than an innocent random omission.

The first diagnostic is to retain a complete ledger of attempts and compare accepted windows with independently observed signal properties. An I/Q recorder with enough bandwidth and an independently validated clock can estimate the signal amplitude and approximate phase evolution even when the counter rejects a gate, subject to its own noise and continuity limitations. Plot acceptance probability against burst phase, amplitude and chirp slope. If acceptance is strongly concentrated in one region, the frequency histogram must be labelled as conditional upon that region. Randomising gate phase can improve coverage, provided every phase actually has nonzero chance of being observed and the analysis records the

Copyright 2026, James M. Atkinson

resulting sampling design. One cannot rescue an interval with zero inclusion probability by simply reweighting observed readings.

For a simple hypothetical case, let a transmitter chirp across 1,000 hertz in 40 milliseconds, but let the counter observe only the first 5 milliseconds of each burst. Its accepted means may cluster within a small range near the start value, regardless of the later trajectory. Even if one million accepted measurements reduce ordinary random estimation error, their narrow variance cannot rule out the remainder's 875-hertz or larger departure from that early interval average. A negative conclusion should be restricted to the observed portions and detector sensitivity demonstrated under test. The question is not how many digits are available in the report, but which part of the physical waveform contributed those digits.

Dr. James M. Atkinson, Moderator: Sir Harold Jeffreys, what can a negative result support?

Harold Jeffreys, Peer Question: Professor Nyquist, a field report claims that a carrier never shifted by more than 100 Hz, although the counter examined separated ten-millisecond windows and the signal occupied much longer bursts. How should one distinguish no observed excursions from no possible excursions, and what experiments would warrant a probabilistic, carefully bounded statement about undetected transient frequency changes?

A report may assert that no carrier excursion exceeding one hundred hertz occurred during a long survey because every saved frequency-counter reading lay within a narrow band. Yet the detector used separated gates and rejected short or noisy bursts, with some excursions possibly averaged

Copyright 2026, James M. Atkinson

below threshold even when a gate overlapped them. What precisely is the evidential proposition that such a record can support? How should a laboratory establish the combinations of excursion amplitude, duration, arrival phase and signal level that its counter would reliably detect? I am concerned that a statistical claim of absence may be treated as categorical physical absence, even though the apparatus never continuously observed the relevant event. Would it be proper to report uncertainty without assigning invented numerical probabilities to poorly characterised missed detections?

Harry Nyquist, Response: Sir Harold, the claim must be restricted to the estimand and coverage. If every accepted gate average remained within 100 Hz, that does not rule out a more rapid shift that cancels within a gate or occurs in an unobserved interval. Inject excursions of different durations, magnitudes and timings relative to the gate, and measure the probability that each produces an accepted threshold crossing. Where an arrival model is appropriate, the experiment may support a probabilistic statement under that model. Where bursts are deterministic, test their actual repetition pattern instead. A defensible negative finding states that no qualifying excursion was detected under specified gates, thresholds and tested coverage; it does not assert that the unobserved waveform was constant.

The defensible negative proposition concerns accepted readings and the observation windows from which they were calculated. If all accepted ten-millisecond means fell within 100 hertz of a reference, it does not follow that no instantaneous frequency excursion exceeding 100 hertz occurred elsewhere. A short excursion can be missed entirely in dead time, or diluted when its duration is small compared with the gate. A 1,000-hertz step lasting

Copyright 2026, James M. Atkinson

one millisecond inside an ideal ten-millisecond uniform averaging window changes the mean by only about 100 hertz if all other conditions remain fixed, and its effect may be smaller or larger depending on placement and qualification. That is a constructed calculation; it must not be mistaken for the behaviour of a particular counter without calibration.

The laboratory should challenge the system with controlled events that span relevant durations, offsets, signal levels and relative gate phases. Include excursions confined to nominal dead intervals, excursions crossing a gate boundary, pulses too short to satisfy the edge-count requirement and waveforms whose amplitude approaches the trigger threshold. Record every attempted trial and whether the instrument produced a valid result. A repeatable detection curve can then support a bounded statement for specified classes of events. The threshold for calling a detection should be chosen before examining the contested case where possible, and both false positives and false negatives should be recorded. A measurement programme that deletes rejected gates cannot support an honest denominator for sensitivity calculations.

Where those studies are unavailable, it is more accurate to state that no qualifying frequency excursion was measured in the documented accepted gates under the stated settings. This preserves useful evidence without claiming universal exclusion. If the record contains independently captured raw samples, those may permit a different retrospective test, though its own estimator and timebase need validation. Confidence in a negative assertion is always conditional upon the instrument's coverage and the physical characteristics of what the test was designed to find. The correct boundary

Copyright 2026, James M. Atkinson

between evidence and conjecture should remain visible to every subsequent reviewer.

Dr. James M. Atkinson, Moderator: Professor Gabor, what might a spectrogram contribute to such an investigation?

Dennis Gabor, Peer Question: Professor Nyquist, the counter reduces a temporally changing signal to a single scalar. A time-frequency representation appears to reveal the chirp's trajectory, but it has a finite time window and finite frequency discrimination of its own. How should an analyst choose those parameters and avoid treating a visually persuasive ridge as an exact instantaneous carrier measurement?

A short-time spectrum can show a diagonal ridge that appears to trace a chirp over time, whereas a frequency counter collapses one gate into a single average. What are the most important qualifications when an investigator treats the ridge as an instantaneous-frequency record? Could a long analysis window smear the start and end of a short burst, or a short window make its frequency estimate unreliable because the ridge becomes broad? I should also like the analyst to explain how low-amplitude phase discontinuities, spectral leakage and multiple simultaneous components can produce a misleading smooth line. Which tests comparing the raw complex samples, the windowed spectrum and the counter's actual accepted intervals would make the competing pictures scientifically commensurable instead of merely visually persuasive?

Harry Nyquist, Response: Professor Gabor, compare several window durations and retain the underlying complex samples. A longer analysis window provides closer nominal frequency discrimination while mixing

Copyright 2026, James M. Atkinson

more temporal behaviour; a shorter window sharpens event timing but broadens its spectral representation. Leakage, modulation sidebands and low signal-to-noise ratio can cause ridge bias or false tracks. A phase-derivative estimate may complement the spectrogram where amplitude and phase unwrapping are reliable. In a controlled chirp experiment, compare both representations with the known source and with counter averages computed over the identical effective gate intervals. The aim is mutually checking measurements, each with its limitations made explicit, rather than replacing one misleading scalar with an equally misleading picture.

A spectrogram makes temporal structure visible, but it represents the interaction of the waveform with an analysis window. Its ridge is not automatically the instantaneous derivative of phase. A long window provides closer nominal Fourier-bin spacing and can better distinguish nearby stationary components, yet it blends change across the window duration. A short window may localise a brief excursion while making the frequency coordinate broader and more sensitive to noise. Tapering changes sidelobes and leakage, while choosing a hop interval smaller than the window can create many highly correlated display tiles. The displayed smoothness therefore partly describes an analysis procedure. The appropriate report states window function, length, hop, processing rate and reference-clock source.

If complex samples are retained, a phase-derived estimate can provide a complementary trajectory using $f(t)=(1/2\pi)d\varphi(t)/dt$ where the analytic-signal phase is meaningful. But phase unwrap errors, low-amplitude intervals and interfering components can produce abrupt derivative artefacts. A matched chirp model may improve sensitivity at low signal-to-noise ratio, yet that

Copyright 2026, James M. Atkinson

improvement depends on the assumed law. Compare a constant-frequency control, a known linear chirp and a waveform containing a deliberately placed phase step. Observe how each appears in the counter, spectrogram and phase trace under common acquisition conditions. Ensure that comparison uses the counter's measured effective gate interval rather than a nominal timestamp chosen from the display.

A sound conclusion reports the time interval and uncertainty attached to each estimate. Where a spectrogram's ridge diverges from the counter average, integrate the independently estimated frequency over the same effective gate and test whether the average agrees within measurement error. Where the signal becomes too weak to support phase analysis, mark the gap instead of drawing a connecting line. The most visually compelling plot may conceal a physical ambiguity, and the most repeatable counter value may omit significant parts of the burst. Independent methods are valuable precisely because their vulnerabilities differ and can be challenged with controlled waveforms.

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, how can the receiver generate an apparent chirp not present at the antenna?

Martin Ryle, Peer Question: Professor Nyquist, a burst first passes through filters, gain stages, mixers and local oscillators. A settling loop or local oscillator transient might modify the phase and apparent frequency presented to the counter. What reference-plane controls would permit attribution of a measured frequency drift to the incoming emission rather than the receiving apparatus?

Copyright 2026, James M. Atkinson

A pulse at an antenna may be constant in radio frequency whilst passing through a mixer, an automatic-gain-control stage, a narrow filter and a local oscillator that has not reached steady state. If the counter then reports a frequency shift near the beginning of the burst, what observations would distinguish a transmitter chirp from a receiver transient? How would the sign and magnitude of the apparent intermediate-frequency drift depend on the mixing plan and local-oscillator motion? I should also like a comparison between a terminated-input test, a calibrated injected signal and a second receiver with a different conversion architecture. Such tests alter sensitivity and noise conditions, so disappearance of the feature in one configuration should not automatically be treated as proof that it was internally generated.

Harry Nyquist, Response: Sir Martin, challenge the receiver with a calibrated constant-frequency burst to observe its own onset and release behaviour, then repeat with programmed rising and falling chirps at different amplitudes. Monitor a known local reference tone through the same conversion chain when possible. Change preselection, gain and oscillator configuration without changing the external source. If the alleged chirp follows a local conversion mode, an instrument artefact becomes more plausible. An independent receiver with a different architecture can help, but it must be monitored for its own clock and trigger errors. A fully defensible result specifies the source reference plane, bandwidth, filter settling, acceptance window and the extent to which alternate explanations were actually tested.

The chain between antenna and counter must be characterised as part of the measuring instrument. Feed a known constant-frequency burst at a

Copyright 2026, James M. Atkinson

calibrated input plane and observe the counter output while varying amplitude, receiver gain and filter conditions. If an apparent chirp emerges on that control, the instrument has introduced a frequency- or phase-dependent transient. The cause may be local oscillator settling, phase distortion, amplitude-to-phase conversion, mixer products or threshold timing walk. The constant-frequency test does not identify the mechanism uniquely, but it refutes an inference that every observed counter transient must originate in the external transmitter. A second control containing a known chirp can test whether the same path accurately reproduces the expected frequency evolution.

For a high-side mixing convention, the measured intermediate frequency is $f_{IF}=f_{LO}-f_{RF}$. If the local oscillator shifts by +250 hertz while the external carrier remains fixed, the intermediate frequency shifts by +250 hertz, assuming no other changes. A software programme translating IF back into RF can invert the apparent sign depending on its implemented frequency plan. Accordingly the report must state the mixing equation and the source of the LO reference. Observe the LO independently where feasible, or inject a stable reference tone through the same path. A signal appearing simultaneously in two receivers may still be a shared-reference artefact if both depend on one faulty oscillator distribution network.

A terminated-input check is informative about internally generated features but may alter automatic gain and therefore fail to reproduce a signal-dependent transient. Similarly, replacing a filter or LO mode changes both the relevant artefact mechanisms and the receiver's detection threshold. Each comparison must document equivalent signal power, bandwidth, noise floor and acquisition settings, or describe why equivalence is impossible.

Copyright 2026, James M. Atkinson

Preserve raw samples and front-end configuration, not only the counter number. The correct attribution follows controlled differences between independent signal paths, not the apparent precision of one display or the disappearance of an anomaly after an uncontrolled setting change.

Dr. James M. Atkinson, Moderator: I ask Professor Gabor to assume a successive principal contribution on the observation-window problem. Professor Kolmogorov will challenge whether the resulting sample is representative.

Dennis Gabor, Second Principal Contributor: Dr. Atkinson, a counter averages a carrier property across accepted intervals, whereas the time-frequency representation displays a deliberately chosen compromise between localisation in time and discrimination in frequency. Both can conceal an intermittent excursion if the analysis window misses or averages it. An ideal chirp illustrates this plainly: a uniform gate returns a time average, not a universal frequency of the burst, and a Fourier window also weights the waveform during the interval of analysis. We should therefore record each effective gate, rejected gate, trigger condition and blind interval, alongside a continuous complex-sample reference when one is available. An isolated coloured spectrogram tile cannot establish what occurred between nonoverlapping measurements. I invite Professor Kolmogorov to question the sampling model applied to accepted counter readings.

The apparent authority of a counter's displayed frequency rests on a choice of observation interval that often remains invisible to its user. Consider a signal with instantaneous frequency $f(t)=f_0+kt$, where f_0 is its value at the

Copyright 2026, James M. Atkinson

chosen origin in hertz, k is the chirp rate in hertz per second, and t is elapsed time in seconds. A counter that measures all complete cycles in a sufficiently well defined interval from t=a to t=a+T estimates the average $\bar{f}=f_0+k(a+T/2)$ for an ideal linear chirp. Its result is the frequency at the midpoint of the effective interval, not the instantaneous frequency at the first or final crossing. The mathematical identity is straightforward; the difficult matter is determining the interval that a practical trigger and measurement mechanism actually accepted. If a weak leading edge does not satisfy the detector threshold, its effective starting point can be much later than the visible RF onset on an independent recorder.

Time-frequency analysis offers another representation but not a miraculous removal of the finite-window problem. The short-time Fourier transform $X(\tau,\nu)=\int x(t)w(t-\tau)e^{(-i2\pi\nu t)}dt$ describes the signal x(t) through a window w centred according to the chosen convention at time τ, with ν the Fourier frequency in hertz. A spectrogram commonly displays $|X(\tau,\nu)|^2$, yet the plotting algorithm may call the window centre, its beginning or the host's display refresh time the nominal timestamp. A narrow frequency ridge is influenced by window length, taper, signal-to-noise ratio and the chirp's own rate of change. If the window is so long that a linear chirp moves through many frequency bins, the energy spreads along a slope rather than remaining in a thin stationary line. If it is made too short, the uncertainty of frequency discrimination grows. The investigation should therefore retain the raw complex samples and compare findings under multiple explicitly reported window choices.

For one deliberately hypothetical example, let a 100 MHz burst drift upward at 50 kHz per second for 20 milliseconds. Its instantaneous frequency

Copyright 2026, James M. Atkinson

changes by 1,000 Hz. An ideal uniform 20-millisecond average centred at burst midpoint is 500 Hz above the starting value, while a 5-millisecond gate at onset averages 125 Hz above the start and a 5-millisecond gate at the end averages 875 Hz above it. A counter can repeatedly report the first value if its gate covers the entire burst, the second if it qualifies only the leading quarter, or the third if it responds near the trailing edge. None of those numbers by itself describes the complete trajectory. One must avoid comparing a short-gate counter reading with the frequency of the maximum bin of a long-window spectrogram as though the two observations represented precisely the same time functional.

An equally important distinction lies between an estimator's numerical resolution and the physical identifiability of frequency. A counter may interpolate event times to extremely fine fractions of a cycle while counting only a small number of accepted edges in a burst. Its reported digits may be reproducible under a stable reference but the selected edges can still be shaped by phase noise, modulation or amplitude-dependent triggering. The derivative of unwrapped phase from raw I/Q samples can provide a time-resolved frequency estimate, $f_{inst}(t)=(1/2\pi)d\varphi(t)/dt$, yet phase becomes poorly defined when analytic-signal amplitude approaches zero and unwrapping errors can create apparent abrupt frequency jumps. A sensible analysis masks or qualifies low-amplitude intervals and challenges the result with a second estimator. High time resolution is not the same as reliability at every point of a fading burst.

The window must also be fitted to the physical signal rather than the convenience of an instrument. A very short rectangular window has substantial spectral leakage and sidelobes; using a tapered window may

Copyright 2026, James M. Atkinson

reduce leakage while broadening its effective main lobe. A coherent chirp-specific estimator can improve precision by exploiting a justified model, but an incorrect assumed chirp law can generate confident residual errors. The investigator should examine whether the waveform contains multiple simultaneous components, abrupt phase steps, frequency-hopping behaviour or amplitude modulation. A spectral ridge following one component does not necessarily describe the carrier of all energy in the interval. When the emission is pulsed, the time-frequency representation should show both the presence mask and the frequency estimate, because extrapolating a ridge through a gap invents behaviour not observed.

One experimental comparison would distribute a measured RF test burst simultaneously to a continuously recording I/Q receiver and to a laboratory frequency counter. The test series should include a constant-frequency control, a linear ramp, a deliberately nonlinear frequency law and a single brief frequency step confined to the counter's nominal dead interval. For each counter reading, compute the actual average frequency over the gate's reconstructed effective edge boundaries and compare it with both the generated waveform and the raw-sample analysis. Repeat with altered gate phase, burst amplitude and analysis window. Where the counter does not expose edge timestamps, use an independent logic witness to bound its accepted interval, noting the limitations imposed by probe loading and timing uncertainty. A result that changes with gate placement as predicted by the model confirms its interval dependence; it does not by itself establish that the physical oscillator has become unstable.

Finally, a forensic report should not select the most dramatic spectrogram or the most reassuring counter number. Preserve instrument settings,

Copyright 2026, James M. Atkinson

effective acquisition windows, sample-clock source, processing algorithms, phase-unwrapping criteria, amplitude threshold and all rejected estimates. State whether the conclusion concerns mean frequency within a particular interval, instantaneous frequency to stated temporal resolution, peak excursion, or long-term oscillator stability. These are distinct measurands. The proper time-frequency comparison is a cross-examination of measurement assumptions: each tool should reveal where the other is vulnerable, and the analyst should identify observations that would refute the preferred interpretation. A coherent explanation of a drifting carrier requires both a physically meaningful chronology and a method whose estimator has been validated under matching signal conditions.

Andrey N. Kolmogorov, Cross-Peer Question to Dennis Gabor: Professor Gabor, suppose a counter measures only the earliest ten milliseconds of a repeating forty-millisecond chirp. Its accepted values may be exceptionally stable from one event to the next. Would it be legitimate to describe their narrow variance as the frequency stability of the entire emission? If failures to trigger depend upon amplitude or chirp rate, can standard sample statistics repair that selection effect? What inference remains defensible when the event’s unobserved intervals are precisely where the disputed frequency excursion might have occurred?

Professor Gabor, one time-frequency representation shows the drifting carrier's full apparent trajectory, while the counter retains only an early selected interval from each burst. Does the variance of the counter estimates measure a property of the transmitter or of the joint transmitter-and-observation process? Suppose the spectrogram's highest-energy ridge is also determined by a window and a threshold which exclude weak

Copyright 2026, James M. Atkinson

portions. The two instruments could then agree for a similarly selected domain while failing to describe the faint portions of the waveform. What independent controls would reveal that their agreement is conditional upon common selection? In particular, can one distinguish a physical variation in instantaneous frequency from a signal-processing change in which time samples are assigned the greatest weight? I would ask for an estimator that declares the observed domain before calculating a stability statistic.

Dennis Gabor, Cross-Peer Answer to Andrey N. Kolmogorov: Professor Kolmogorov, the variance measures the accepted observations under the stated gating policy, not the full emission. If selection depends on amplitude, instantaneous frequency or timing, missingness is informative and cannot be repaired by averaging accepted values. The investigator should change gate phase relative to the burst and compare the resulting time averages with a continuous waveform record. Where independent full-waveform acquisition is unavailable, the proper negative finding is bounded to the intervals actually measured with sufficient sensitivity. A spectrogram may suggest a changing frequency trajectory, but its windowing and leakage must be disclosed. Neither graph proves the values in unsampled intervals, so the evidence should distinguish measured coverage from inferred continuation.

Professor Kolmogorov, the distinction is central. Both instruments construct estimators from windows of received data. The counter places weight on accepted crossing intervals, while a spectrogram weights waveform samples through its analysis window and may select an energy ridge only where a component rises above the analysis threshold. Agreement between them is persuasive only when those weighting rules are understood and sufficiently

Copyright 2026, James M. Atkinson

independent for the claim being tested. A spectrogram that displays the same strong beginning of each burst while suppressing a weak trailing interval can reproduce the counter's apparent stability without establishing constancy across the full emission.

An experiment should preserve a continuous complex-sample record with a calibrated reference and then deliberately vary the window and acceptance rules. Plot the full waveform amplitude, raw phase information where reliable, counter gate bounds and each time-frequency estimate on one common sample-index axis. Repeat the calculation with a long rectangular window, a shorter tapered window and a chirp-matched estimator. Compare the observed dependence upon window choice against a known generator signal. If a late chirp segment disappears as amplitude falls, treat it as an observation-limit problem rather than connecting the early ridge across the missing interval. A second independently designed instrument can reveal artefacts that a shared receiver reference would leave correlated.

The final report should state the statistical population of windows actually examined. For example, the frequency variance conditional upon accepted high-amplitude windows may be measured accurately even while the variance of the entire burst remains unknown. This conditional variance is useful, but it must not be described as the complete carrier stability without evidence covering the excluded portions. If the time-frequency estimator and counter have different blind intervals, compare their results only on the time subset where their measurement functions can be reconciled. Where their limits coincide, their visual agreement adds less independent evidential weight than the presence of a separate calibrated observation of the omitted waveform.

Copyright 2026, James M. Atkinson

Harry Nyquist, Response to Professors Gabor and Kolmogorov: Their distinction is useful. Counting resolution and coverage are independent questions, and a finely resolved estimate on a selectively observed interval cannot justify a whole-burst stability claim. I return the token to the moderator for the appropriate bounded conclusion.

Dr. James M. Atkinson, Moderator: Professor Kolmogorov, I ask you to consider the population from which a frequency counter actually selects readings. Mr. Nyquist will examine whether repetition can defeat this selection.

Andrey N. Kolmogorov, Third Principal Contributor: The accepted sample of frequency-counter readings is determined by the gate and trigger process. If the instrument fails to produce values during weak portions of a burst or during dead time, the resulting distribution may be selectively concentrated in a narrow frequency interval. Estimating its variance as though the observations were uniformly sampled can create false confidence. I would compare the accepted-window distribution with a continuous reference record and test whether re-phasing the gate changes the estimated excursion.

The most basic statistical mistake is to treat the counter's successful readings as a random sample of all frequencies experienced by the emitted waveform. The actual data comprise only intervals during which the gate, trigger and subsequent validity test produced an accepted estimate. Let Z_i denote an ideal signal property in candidate window i, and let A_i equal one if that window is accepted and zero otherwise. The reported empirical distribution estimates the law of Z conditional on A=1, not necessarily the

Copyright 2026, James M. Atkinson

unconditional law of Z over all candidate intervals. If a frequency excursion also changes amplitude or interferes with edge qualification, the acceptance process depends on the variable of interest. Discarding rejected windows then creates selection bias, even before considering ordinary noise or finite counter resolution. One should document A_i for every attempted acquisition and investigate whether its probability changes with measured amplitude, gate position, slope or waveform class.

A further source of selection arises from periodic sampling of periodic signals. If a 40-millisecond chirp repeats every 100 milliseconds and the counter opens its gate every 100 milliseconds at a fixed phase, it can observe the same early portion of every burst indefinitely. Thousands of nearly identical results establish excellent repeatability for that early average, while leaving a late excursion wholly unmeasured. This is not a random failure that disappears with more data; it is a design defect caused by synchronisation between the observation schedule and the waveform. Deliberately shifting the gate phase can test the problem. Under an instrument able to observe the burst independently, the schedule may be randomized or swept so that coverage extends across the full period, but the analysis must still report the resulting sample weights and intervals.

The simple duty factor $\eta=T/(T+D)$, with T the active gate duration and D the dead interval, describes the proportion of scheduled time during which the detector is observing. It does not, without additional assumptions, give the probability of detecting a burst. For an instantaneous event whose arrival phase is uniformly distributed relative to a stable schedule, η approximates the probability that its occurrence coincides with an active gate. A finite burst has a duration B, and qualifying detection may require more than

Copyright 2026, James M. Atkinson

mere overlap, perhaps a minimum number of cycles, sufficient amplitude or the presence of a complete gate. If an event of length B happens wholly inside a dead interval, it cannot be detected by that counter at all. The investigator must use the actual overlap and acceptance criterion, not automatically equate duty factor with detection efficiency.

A numerical example sharpens the distinction. With T=10 milliseconds and D=30 milliseconds, the gate duty factor is 0.25. A 1-millisecond event with a uniformly random start phase is not necessarily detected with probability 0.25, because the relevant event might only need partial overlap, which increases the geometrical window, or might need a complete uninterrupted 1-millisecond observation, which decreases it. In the simple periodic case, if any overlap suffices, the phase interval leading to detection has length T+B out of T+D, giving 11/40=0.275 for B=1 millisecond, so long as B is shorter than D and the interval does not require more elaborate qualification. If complete containment within the active gate is required, the favourable start range is T−B, giving 9/40=0.225. Both figures differ from η=0.25 and both rest on explicit physical assumptions.

Uncertainty of the accepted average itself must be separated from uncertainty caused by incomplete coverage. A counter's event-time jitter may produce an approximately zero-mean random error on each selected interval, while an unknown dead-time excursion produces no reading from which to infer its value. A narrower confidence interval for an accepted frequency average does not bound the maximum frequency excursion in an unobserved interval. Nor is the Allan variance calculated from a set of irregular, gapped samples directly comparable with the corresponding statistic for contiguous sampling unless the dead-time model and associated

Copyright 2026, James M. Atkinson

noise processes are accounted for. NIST work on distributed dead time shows that measurement schedule influences frequency-comparison uncertainty, especially when correlated low-frequency noise is present. The conclusion must state which stability statistic has actually been estimated and which unobserved processes could still affect it.

The strongest remedy is a design that makes missingness explicit and tests alternative explanations. Each scheduled gate should have an identifier, planned and actual boundaries, acceptance status, detection threshold, received amplitude estimate and any processing fault. Independent monitoring provides a witness for intervals with no accepted counter reading; it may reveal that RF energy existed but that the counter could not qualify sufficient edges. One can then compare the pattern of rejection with amplitude, frequency slope or burst phase and assess whether a statistical correction is justified. If an inclusion probability can be defensibly estimated for a specified regime, weighted estimators may support a population-average inference. However, inverse-probability weighting is not a remedy when some events have zero chance of observation under the actual schedule. For those intervals the apparatus supplies no direct evidence.

In courtroom use, an apparently stable counter trace should be accompanied by an explicit coverage diagram. The report ought to give the total monitoring interval, number of attempted gates, accepted and rejected windows, measured dead-time distribution, sample timing reference, and validation trials including programmed excursions not known to the initial analyst. It should also distinguish a negative result from a measurement failure. The statement “no accepted reading differed by more than 100 hertz” may be accurate while “the carrier never differed by more than 100

Copyright 2026, James M. Atkinson

hertz” remains unsupported. A scientifically responsible negative inference specifies the duration and amplitude of excursions the system was shown capable of detecting, at a quantified confidence appropriate to its calibrated operating conditions. Data incompleteness cannot be concealed by presenting a long series of precise numbers.

Harry Nyquist, Cross-Peer Question to Andrey N. Kolmogorov: Could many thousands of repeated readings overcome selection bias when the counter always samples the same phase of a periodic chirp?

Professor Kolmogorov, suppose that a counter measures precisely the same early portion of a periodic chirp ten thousand times and every accepted result falls within a few hertz of the same value. Is there any number of additional repetitions that makes this observation sufficient to bound an excursion during the unobserved latter half of each burst? Might a randomised gate phase, coupled with an independent burst-onset trigger, alter the inferential position? Please distinguish statistical independence of measurement noise from independence of the underlying coverage schedule. I am concerned by the common practice of quoting a narrow uncertainty on the sample mean while leaving the sampling process itself undiscussed. How should a negative claim be reformulated when an event class has zero probability of being included by the actual instrument?

Andrey N. Kolmogorov, Cross-Peer Answer to Harry Nyquist: The number of accepted readings improves precision for the quantity actually observed but does not change the unobserved domain. A systematic gate-phase preference remains regardless of sample size. The experiment must shift gates across the burst and compare to continuous acquisition, or state that

Copyright 2026, James M. Atkinson

the inference is confined to the accepted portions. More observations of the same incomplete segment do not supply evidence about omitted intervals.

Professor Nyquist, additional repetitions under the same deterministic schedule improve the estimate of the repeated early-gate mean, not the unobserved late-burst frequency. If the gate is phase-locked to the beginning of each emission, its inclusion probability for a late event can be exactly zero. No finite or infinite number of repeated early measurements supplies a direct observation of that late interval. The law of large numbers does not create information about a variable that the sampling mechanism never admits. The relevant statistical parameter is the conditional mean or variance over the accepted gates, not the full temporal range of the transmitter's instantaneous frequency.

Randomising gate phase can enlarge coverage, but it does not automatically cure every problem. The investigator must record the randomisation mechanism and its actual realised phases, demonstrate that all relevant portions of the burst have a nonzero inclusion probability, and account for changes in trigger success as the signal's amplitude and frequency slope vary. A counter may fail even when a gate nominally overlaps the event, because too few qualified crossings occur or the phase comparator becomes unreliable. An independent capture of the burst envelope and a controlled generator challenge can estimate these acceptance probabilities within a specified operating range. Such a design permits a defensible statistical population statement, whereas a fixed-phase schedule cannot justify extrapolation into regions never observed.

Copyright 2026, James M. Atkinson

For a negative finding, state exactly which class of excursion the test could have seen. The report may say that no accepted early-window mean departed by more than a given amount, or that in laboratory validation an excursion with specified duration, amplitude and timing relative to the gate was detected with a measured sensitivity. It must not infer that all frequencies in all unobserved intervals were within the same bound. The uncertainty interval attached to the sample mean and the uncertainty about observation coverage should be described separately. The first may narrow as independent accepted samples accumulate; the second may remain fundamental until the measurement design changes.

Dr. James M. Atkinson, Moderator: Dr. Hamming, please analyse the fate of rejected or unreported counter gates. Professor Gabor may then question what happens when gate boundaries are timestamped only in software.

Richard W. Hamming, Fourth Principal Contributor: A counter logger should treat every attempted gate as an event even when no numerical frequency results. Without the failed attempts, the analyst cannot distinguish an intermittent transmitter from intermittent instrument availability. In my view the critical software invariant is an immutable attempt sequence recording intended gate timing, actual accepted edges, trigger state and rejected measurements. A program producing only attractive numerical rows is an unreliable witness to temporal coverage.

A computerised counter is not merely an instrument followed by a passive notebook. Its software decides which hardware events survive as structured records, and that decision may alter the evidence as thoroughly as a faulty electrical connection. I would assign a monotonic identifier to every

Copyright 2026, James M. Atkinson

scheduled measurement attempt, not merely to each successful frequency reading. The record should contain the requested gate duration, actual gate opening and closing hardware timestamps where available, reference-clock status, trigger threshold, input channel, accepted cycle count, counter overrun flags, firmware version and a status enumerating success, timeout, rejection, overflow and communication failure. Each measurement record also needs the identity of the processing algorithm that converted raw event counts into a displayed frequency. If the logger writes only rows containing plausible numbers, it creates a record that falsely suggests continuous successful observation.

The distinction between real gate timing and host presentation time is especially important. Suppose an instrument opens a 10-millisecond gate at time 100.000 seconds and obtains a valid mean frequency by 100.010 seconds, but its USB interface transmits the result at 100.070 seconds and the application updates its graph at 100.100 seconds. These three times describe acquisition, transport and presentation, respectively. Labelling the frequency with the graph refresh time shifts its apparent position by 100 milliseconds from the beginning of the gate. Even recording only the completion time loses the information required to locate the effective observation interval when the measurement is a chirp. The software schema should expose all clocks separately and retain a calibrated mapping between device-specific counters and the external time scale. A display timestamp is never a substitute for a missing hardware gate witness.

The apparatus also needs to preserve unsuccessful evidence. An invalid gate can reveal that a burst was too short for the required cycle count, that the threshold was not reached, or that an internal processor did not service the

Copyright 2026, James M. Atkinson

measurement in time. Those explanations have different forensic consequences. If no RF waveform existed, the counter's silence may be expected. If the independent recorder shows a clear burst during a counter timeout, the absence of a frequency reading is instrument failure or a qualification problem, not evidence that the signal lacked a carrier. Therefore the attempt ledger should remain linked to a continuous observation record, ideally raw I/Q samples or an independent detector with its own chronology. The system must be able to describe what was attempted as well as what succeeded.

Reconstruction requires transaction-level integrity. A successful counter reading should be associated with immutable gate identifiers and their source bytes. If firmware later changes the way reciprocal averaging rounds an interval, the original recorded periods and time marks should remain available. A corrected frequency can be stored as a new interpretation with the algorithm and calibration version. A timestamp correction should likewise be applied as a versioned mapping rather than overwriting the original device time. The associated evidence file should be hash-verified after capture, but hashing cannot prove that no samples were omitted before the file was written. Continuity requires sequence-number analysis, counter-overrun indicators, expected-byte-count checks and deliberate fault-injection trials against the real acquisition path.

A specific software stress test should generate a burst schedule containing known gaps, deliberately overlapping gates, rapid frequency changes and intervals in which the host process is overloaded. The challenge input should be independently recorded so that the operator cannot infer the answer merely from the counter's successful output. With a 1-kilohertz gate-

Copyright 2026, James M. Atkinson

update rate, one million scheduled gates correspond to 1,000 seconds of requests if every interval is nominally one millisecond. The audit should count exactly one result or explicit failure for every request. Missing sequence identifiers, repeated result identifiers or impossible overlaps must be treated as anomalies. A logging programme that discards timeouts may appear to have a low error rate simply because it has deleted the hardest measurements from its denominator.

The criterion for correctness is not that every requested reading succeeds. A trustworthy system can fail honestly and still be useful. Its quality gates should reject estimates whose effective observation interval is unknown, whose timebase suffered an unverified transition, or whose signal did not satisfy the qualification rule. It should preserve those rejections, however, because they may determine whether a negative finding was possible. A reviewer ought to be able to query the record for every millisecond of the intended monitoring period and obtain a direct observation, a suitably described lower-quality observation or a marked interval of noncoverage. Concealing the latter transforms a measurement limitation into apparent silence.

The final software proof should compare the exported report with the raw event ledger and an independent test controller. The reviewer selects a displayed frequency, traces it backwards to the accepted cycle count and actual gate interval, then computes the estimate afresh. A second check selects an attempted gate with no number and verifies that the corresponding nonacceptance is still visible. A third check deliberately changes the system clock while the counter continues recording, proving that the event's hardware chronology survives any alteration in wall-clock

Copyright 2026, James M. Atkinson

representation. These tests are not mere programming conventions. They are the means by which the measured portion of the electromagnetic event remains intelligible and challengeable long after the original apparatus has been disconnected.

Dennis Gabor, Cross-Peer Question to Richard W. Hamming: What if a frequency estimate was computed correctly but its gate boundaries were associated with a buffered display timestamp rather than actual hardware time?

Dr. Hamming, suppose a reciprocal counter correctly estimates an average frequency, but the software associates that result with the time its USB buffer reaches a host rather than the instant its accepted crossings occurred. A later time-frequency plot might then place the counter estimate beside an unrelated portion of the burst. How should the original gate boundaries, device counter epoch, host arrival time and graphic display time be represented so that another examiner can recover the actual chronology? If the counter exposes only a display cadence and never discloses the underlying measurement interval, should the programme assign a nominal midpoint or explicitly leave the temporal alignment unresolved? I should also like to know how a revised timestamp calibration should coexist with the original time labels in the evidence record.

Richard W. Hamming, Cross-Peer Answer to Dennis Gabor: The frequency average may still be valid over some unknown physical interval, but its placement in the burst chronology is unverified. Preserve hardware gate or edge timestamps, and calibrate their relation to the host display. If only display-update time survives, do not locate the estimate precisely within the

Copyright 2026, James M. Atkinson

burst. Test a known phase-coded source to reveal the actual offset and variability of the presentation delay.

Professor Gabor, the original time fields must be kept distinct. A device's gate-open and gate-close records, if present, belong to the acquisition clock. A USB transfer completion and host receipt belong to transport and scheduling. A screen refresh belongs to presentation. Conflating those fields turns a valid average into an incorrectly located observation. The software should store the counter's original gate identifier, accepted edge count, clock source and raw timestamp data alongside host transport records, then place the result on a common chronology only through a separately documented mapping. Where actual gate boundaries are unavailable, the application may display a qualified time interval or uncertainty range, but it should not manufacture the nominal midpoint as if it had been observed.

If a calibration subsequently improves that mapping, preserve the earlier derived timestamps and the original source measurements. The corrected time belongs to a new versioned derivation record naming the calibration method and its uncertainty. An examiner should be able to select one frequency reading and trace it back to the same gate and source bytes through either mapping. That property depends upon monotonic sequence identifiers, explicit epoch transitions, and unaltered raw counts. It also requires clear handling of gaps: a packet that was lost before logging leaves information absent, not merely delayed. A dashboard can show an estimate with an appropriate qualification, but its visual order cannot supersede the recorded source order.

Copyright 2026, James M. Atkinson

A practical audit introduces known bursts at recorded hardware times while deliberately delaying USB transfers and graph updates. If the displayed time remains tied to host arrival, it will move; if the programme correctly uses acquisition timestamps, the inferred burst time should remain stable within its calibration uncertainty. Repeat with a counter reset and with lost transport blocks. The purpose is not to force a successful timestamp under every failure, but to prove that the system records the failure and refuses unsupported temporal claims. A frequency estimate may be accurate in its own interval and still lack a defensible position on the absolute acquisition chronology.

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, the counter sees the receiver output rather than the external carrier directly. May you examine instrument-created transients, followed by Dr. Hamming's challenge concerning weak-signal ambiguity?

Martin Ryle, Fifth Principal Contributor: The receiver chain can generate its own apparent frequency transient. A mixer local oscillator may settle after a gain or band change, and an intermediate-frequency filter can ring at burst onset. A frequency counter downstream may thus faithfully measure the receiver output while misrepresenting the external transmitted frequency. Challenge the system with both constant-frequency pulses and programmed chirps at calibrated input levels. If the reported drift appears during a constant-frequency control, its origin lies somewhere in the instrument chain or test arrangement.

The counter measures the signal delivered to its electrical input, not the field directly at an antenna. Between those points stand cables, preselectors, low-

Copyright 2026, James M. Atkinson

noise amplifiers, mixers, intermediate-frequency filters, gain-control loops, reference oscillators and threshold circuits. Each stage can change the amplitude or phase characteristics of a short burst, particularly during settling. A local oscillator whose frequency is recovering from a switching event may impose an apparent chirp on an otherwise constant external carrier. A narrow filter can ring after a short pulse and cause its effective envelope to persist after the antenna has ceased receiving the emission. Consequently, when the counter shows a drifting carrier, the survey must distinguish a source phenomenon from a receiver-generated transient by experimenting on the complete signal path. A valid counter calibration at a direct electrical input is insufficient to validate the upstream converter and filters.

A controlled measurement uses at least two waveforms: a well characterised constant-frequency burst and a known chirp with similar bandwidth and duration to the questioned emission. Feed both at a calibrated input plane, retaining a separate direct observation of the generator output. Repeat through the same gain, preselection, conversion and detection settings used in the field. If the constant-frequency control develops a transient at the counter output, the receiver is contributing to the measured phase evolution. One should vary burst amplitude, repetition period, filter bandwidth and gain-control state to identify the dependence. The transient may arise from local-oscillator settling, amplitude-to-phase conversion, limiter recovery or threshold effects; a single trace rarely identifies its cause uniquely. The response of the complete chain must be characterised before the carrier's measured frequency motion is attributed to the transmitter.

Copyright 2026, James M. Atkinson

The local oscillator is a particularly subtle source of bias in a frequency-converting receiver. For a high-side heterodyne with $f_{IF}=f_{LO}-f_{RF}$ under the declared sign convention, a transient change Δf_{LO} in oscillator frequency changes the measured intermediate frequency by the same sign if f_{RF} remains fixed. If the LO moves by 400 hertz while the RF source is truly constant, the IF may move by 400 hertz. Depending upon how software translates an IF estimate back to apparent RF frequency, that motion can be assigned an incorrect sign or interpreted as a source chirp. Any report should define the frequency plan and mixing sign. Observing a stable reference tone through the same conversion path, or independently comparing the LO phase against a separate reference, can expose this mechanism. The test must be performed at relevant gain and tuning settings rather than at a convenient unrelated frequency.

Input amplitude also matters. A weak burst rising through a detector threshold presents later qualifying zero crossings than a strong burst whose leading edge remains above threshold. Noise may insert false crossings or cause missing cycles, and an automatic gain control may change phase or frequency estimation dynamics while settling. If a counter employs a prescaler, its divide ratio and start-up behaviour can add further qualification delays. A spectrum analyser can help reveal the full transient, but its own local oscillator and analysis windows can impose different artefacts. Independent observation is genuinely informative only when the instruments do not share the relevant potential failure mode. Two receivers using the same unstable frequency reference may corroborate a common internal disturbance rather than an external emission.

Copyright 2026, James M. Atkinson

Group delay and impulse response deserve quantitative attention. For a linear time-invariant receiving path with frequency response $H(\omega)$, the group delay is $\tau_g(\omega)=-d\arg H(\omega)/d\omega$, measured in seconds. A bandpass filter with appreciable delay variation across a pulse's spectrum can reshape the observed envelope and move the time at which a trigger becomes valid. A narrowband sinusoid may traverse the same hardware with little evident envelope change, so a continuous-tone acceptance test may miss the failure that appears on a short burst. Repeat calibration with signals that exercise the relevant bandwidth and duration, and document filter state, analogue gain and temperature. If the path contains nonlinearity or time-varying control, a single group-delay number does not completely describe its behaviour; its transient response must be measured directly.

A useful two-receiver test places one receiver at a different architecture or independently maintained clock and preserves both channels' raw samples. Both observe a known source at an appropriate common reference plane. If the apparent frequency excursion follows one receiver when its LO configuration changes, the receiver hypothesis gains weight. If the frequency evolution follows the source and persists across different conversion plans within validated uncertainty, an external origin becomes more plausible. Cable and antenna substitution can further expose common-mode coupling, whereas a terminated-input experiment identifies some internally generated features. Every substitution changes sensitivity, so any disappearance must be assessed against the new noise floor and detection threshold. A missing trace is not proof of an absent signal if the substitute configuration could not have detected it.

Copyright 2026, James M. Atkinson

The final technical record must contain more than a centre-frequency number. Preserve the field receiver path, tuned frequency, LO reference, filter selection, gain state, detector settings, counter gate schedule, software time mapping and independent control waveforms. For each unexplained frequency excursion, compare what the external-source hypothesis predicts with what receiver-settling and triggering mechanisms could produce. A source attribution can remain indeterminate even after a precise frequency estimate has been obtained. The appropriate forensic discipline is to localise the point in the measurement chain at which the anomalous phase evolution first appears, then quantify what inference survives the known limitations. The distinction between an observed intermediate-frequency transient and a demonstrated external transmitter property must remain explicit throughout the report.

Richard W. Hamming, Cross-Peer Question to Martin Ryle: If the constant-frequency control shows a transient only at weak signal levels, does that automatically identify threshold noise as the cause? Please also describe how a second, independently monitored receiver would constrain competing causes, rather than merely reproducing the original threshold-setting error or a shared clock artefact.

Sir Martin, a constant-frequency control may show a spurious transient only when its amplitude is near the detector threshold. Is that sufficient to identify simple random threshold noise as the cause, or could other receiver processes become amplitude-dependent under the same conditions? Please consider automatic gain control, filter settling, limiter behaviour, mixer conversion and the local oscillator's response to a changed signal environment. How would you distinguish each possibility while keeping the

Copyright 2026, James M. Atkinson

observation comparable to the original disputed waveform? I am also concerned that changing gain or filter bandwidth to make a feature disappear changes the very sensitivity required to observe it. What experimental design would preserve both a valid source reference and a complete account of the receiving chain?

Martin Ryle, Cross-Peer Answer to Richard W. Hamming: No. A weak signal can interact with gain control, phase estimation and filtering as well as trigger threshold. Repeat with varied amplitude, known injected signal and independently monitored local oscillator state. The result should identify which controlled changes affect the anomaly, and preserve plausible mechanisms until the data discriminate them. A single correlation with level is a clue rather than complete attribution.

Dr. Hamming, amplitude dependence is a clue, not an identification. Near threshold, noise may add or remove accepted zero crossings, but a gain-control loop may also be changing, the filter's transient response may depend on how long a weak pulse excites it, and a mixer or limiter may introduce amplitude-to-phase conversion. A receiver whose local oscillator undergoes phase settling after a tuning or gain-state change can produce a chirp-like frequency trace without any external source drift. The test should distinguish those mechanisms by altering one documented condition at a time while keeping the source waveform under independent observation. If several internal stages change together, an observed difference cannot be attributed confidently to just one.

Begin with a known constant-frequency burst delivered through a calibrated electrical path at relevant power and bandwidth. Capture the original

Copyright 2026, James M. Atkinson

receiver I/Q samples as well as the counter estimate, and monitor gain-control state, reference lock and local oscillator where accessible. Repeat through a set of amplitudes including well above threshold, near threshold and below reliable qualification. Substitute a fixed-gain condition only as a separate declared experiment, not as though it were the same field configuration. Reverse the chirp direction of a second programmed source, then use two different local oscillator frequency plans to see whether the observed motion follows source frequency or conversion architecture. Each control should have a predicted signature under the rival hypotheses before its result is examined.

If an anomaly disappears under a new setting, measure the sensitivity of that setting to the same signal. A wider filter may lower the observed peak relative to noise; a gain change can move the detector away from its previous operating regime. An independently clocked receiver with a distinct architecture and known RF reference can corroborate an external signal under properly matched sensitivity. The report should include the complete comparison matrix: waveform, input power, gain state, filter setting, local oscillator configuration, trigger threshold, gate boundaries and any observed receiver transient. The final conclusion may identify a receiver-origin component, bound an external drift, or remain indeterminate. It should never convert the failure of one altered instrument to display a feature into proof that the original field had no such emission.

Dr. James M. Atkinson, Moderator, Closing Synthesis: Gate time estimates frequency over a finite interval; dead time excludes intervals altogether. A counter may be precise for its accepted gate average while failing to characterise the underlying burst trajectory. The panel therefore requires a

Copyright 2026, James M. Atkinson

measured acceptance schedule, input-reference-plane controls, calibrated chirps and constant-frequency challenges, retained rejected gates, and comparison with independently recorded phase and time-frequency data. Numerical resolution must not be confused with temporal coverage or with a bounded claim that no unobserved excursion occurred. All examples are hypothetical and the historical dialogue is pedagogical reconstruction.

QUESTION 058

Copyright 2026, James M. Atkinson

What Do Phase-Noise Sidebands Reveal About Defects in an RF Reference Distribution Network?

SCHOLARLY RECONSTRUCTION. This is fictional teaching dialogue among deceased historical specialists. Modern electronic instruments, numerical tests, and SDR applications are present-day editorial extrapolations, not historical quotations or documented statements by those individuals.

Dr. James M. Atkinson, Moderator: Professor Townes, consider an RF survey in which several nominally independent instruments display comparable sidebands around their frequency references and occasionally report narrow spectral features near received carriers. The laboratory source itself may exhibit phase noise, a fan-out amplifier may contribute residual modulation, its power supply may impose periodic ripple, and the measuring instrument may have a noise floor sufficiently high to conceal all three mechanisms. What can the shapes and correlations of sidebands establish about these competing causes, and what experimental controls would distinguish an external electromagnetic signal from an artefact common to a receiver system?

Charles H. Townes, Principal Contributor: Dr. Atkinson, a sideband is an observation of spectral energy displaced from a nominal carrier, not a certificate of its physical origin. The complete reference chain deserves examination: source oscillator, filtering and discipline loops, distribution amplifiers, dividers, switching devices, cables, connectors and individual instrument clock inputs. Phase variation originating in an oscillator is inherited by the following network, subject to its transfer characteristics. Additive fluctuations introduced after the source enter only the affected

Copyright 2026, James M. Atkinson

branch or branches. A power-supply disturbance may make several branches agree if they share the supply, or may remain local to one receiver. Consequently the question is not whether a sideband exists, but where along a defined signal path its phase modulation first becomes measurable.

A distribution-network investigation should first formalise what the measurement physically represents. In a small-noise approximation an output may be written $v(t) = A[1+a(t)]\cos[2\pi f0t+\varphi(t)]$, where A is its nominal peak amplitude, a(t) its dimensionless fractional amplitude variation, f0 its nominal carrier frequency in hertz, t elapsed time in seconds, and φ(t) its phase error in radians. The two perturbations must not be conflated. A square-law power detector predominantly registers amplitude variation, whereas a properly biased quadrature phase detector is primarily sensitive to phase fluctuation. Nevertheless neither instrument is perfect, and any nonlinearity or quadrature error permits cross-conversion between the two. If a distribution network generates a discrete 100 Hz offset pair around a 10 MHz reference, the frequency separation supplies a useful clue about periodic influence. It does not, without coherent demodulation, identify its modulation type or establish which cable, fan-out amplifier, power converter or oscillator generated it. A technician should report the relative amplitude of the two components, the instrument resolution bandwidth, the reference offset convention, and the uncertainty of the inferred modulation index.

A principled test programme must distinguish an absolute measurement of the oscillator from a residual measurement of a distribution component. For the latter, compare the phase of the signal before a characterised two-port component with that after the component, allowing for nominal delay and frequency translation. If φin(t) is the upstream phase fluctuation and ε(t) the

Copyright 2026, James M. Atkinson

additive phase error imposed by the branch, an idealised output relation is $\varphi_{out}(t)=\varphi_{in}(t-\tau)+\varepsilon(t)$, where τ is delay. Subtracting the delayed source phase isolates ε, provided the two observation paths have sufficiently matched transfer functions and independently characterised detector errors. One must not simply subtract two plotted decibel curves. The spectra may contain correlated and anti-correlated contributions, and power spectral densities add only under the relevant independence assumptions. This is especially important when low-level sidebands are compared between receivers sharing a master reference.

A sound conclusion should therefore have three layers. The observational layer states what sideband was present and with which calibrated amplitude and offset. The mechanistic layer records which interventions changed it while leaving the measuring system sufficiently stable. The evidential layer identifies whether the feature survives a change of reference topology, receiver input termination, and independently referenced measurement. When these layers disagree the proper result is not a forced diagnosis but a qualified uncertainty. For example, a line that vanishes after replacement of the common reference, while remaining absent from an independent receiver operating from its own timebase, favours a reference-distribution explanation. It does not exclude an external signal whose demodulation became undetectable after frequency planning or sensitivity changed. The inference must preserve the measurable differences between these explanations.

Let the output be $v(t)=A\cos(2\pi f_c t+\varphi(t))$, where A is nominal amplitude, f_c the carrier frequency in hertz and $\varphi(t)$ residual phase in radians. For sufficiently small phase excursions, the one-sided phase-fluctuation power

Copyright 2026, James M. Atkinson

spectral density $S_\varphi(f)$ in radian-squared per hertz is related to single-sideband phase noise $L(f)$, conventionally expressed as carrier-relative power density, approximately by $L(f)=S_\varphi(f)/2$ in linear units. The logarithmic presentation is $10 \log10[L(f)]$ dBc/Hz. This relation must not be applied without qualification to large, discrete modulation or large phase excursions, where the familiar small-angle approximation breaks down. One should always state the carrier, offset frequency, resolution bandwidth or phase-demodulation method, and whether the trace is of phase, amplitude or combined spectral noise.

A narrow pair of symmetrically spaced sidebands can result from sinusoidal phase modulation, but may also involve amplitude modulation or mixed mechanisms. Suppose $\varphi(t)=\beta \sin(2\pi f_m t)$ with modulation frequency f_m and small modulation index β radians. Expansion of the complex exponential gives first-order upper and lower phase-modulation sidebands with voltage amplitude approximately $\beta/2$ times the carrier voltage. Their individual relative power is therefore approximately $\beta^2/4$, or $20 \log10(\beta/2)$ dBc, provided β is small and detection preserves the corresponding sidebands. At $\beta=0.01$ radians this example gives about -46.0 dBc per first-order sideband. The calculation is hypothetical and does not prove that measured sidebands at that level arose from a specified clock defect.

For a reference at 10 MHz with a 100 Hz sinusoidal phase perturbation, symmetric sidebands displaced by 100 Hz are unsurprising; that displacement identifies the modulation frequency, not necessarily the component responsible. Ripple from an internal switching supply, an external power system, a control-loop limit cycle, mechanical strain, or coupling from an adjacent circuit could all introduce a similar offset. An

Copyright 2026, James M. Atkinson

oscilloscope or spectrum analyser viewing only the final distribution output cannot distinguish them without additional measurements. The investigator must sample the oscillator output before fan-out, the buffer inputs and individual branch outputs with reference-plane calibration and without allowing the probing arrangement to create the anomaly being investigated.

Noise shape is informative when interpreted with appropriate restraint. Close-in flicker-related phase noise, far-out approximately white-phase-noise floors, and discrete spurs may suggest different physical mechanisms, but their slopes are not unique fingerprints. A phase-locked loop also shapes source and voltage-controlled oscillator noise differently inside and outside its control bandwidth. A distribution amplifier can contribute broadband residual noise and low-frequency flicker terms of its own; division and frequency multiplication change carrier-referred phase relationships under specified coherence assumptions. The analyst should therefore compare measured input and output spectra and measure transfer functions before alleging a defective part from a single curve.

If two independent phase-noise sources contribute as statistically independent small fluctuations, their linear spectral densities may be added. They cannot be added directly as negative dBc/Hz numbers. For example, if the reference source contributes $L_{source}=-130$ dBc/Hz at a particular offset and a distribution branch contributes $L_{additive}=-140$ dBc/Hz referred consistently to the output carrier, their combined linear densities correspond to $10^{(-13)}+10^{(-14)}=1.1\times10^{(-13)}$, giving approximately -129.6 dBc/Hz. This illustrative calculation assumes independent contributions, the same offset and measurement reference, and no omitted

Copyright 2026, James M. Atkinson

filtering or correlation. A measured value nearer −125 dBc/Hz would demand inquiry into additional noise, coupling or instrument limitations, not an automatic declaration that the fan-out device is faulty.

Measurement-system limitations can imitate both excessive noise and excellent performance. An ordinary spectrum analyser has local-oscillator phase noise, detector behaviour, resolution bandwidth and dynamic range of its own. If its displayed floor exceeds the reference network's true noise, the instrument reports an upper bound rather than the device's intrinsic phase-noise spectrum. Dedicated phase-noise analysers may use two measurement paths with independent oscillators and cross-correlation, suppressing uncorrelated internal noise as averages accumulate. However, anything common to both paths, including the signal under test and some shared instrument impairments, remains. Cross-correlation must be understood as a noise-separation method with explicitly stated independence assumptions, not as a universal truth filter.

The distribution experiment needs a branching protocol. First, measure the source at an accessible, properly terminated point while all outputs are connected in their operational configuration. Second, measure every branch at its receiver input with its actual cable and load. Third, exchange cables and loads between branch outputs, preserving the path labels. Fourth, operate the network with a safe substitute reference of known phase-noise performance. Fifth, independently monitor the distribution supply and the local environment for ripple, vibration and temperature change. A spur that follows a particular output port suggests an internal distribution-path issue; one that follows a cable suggests cable or connector effects; one that

Copyright 2026, James M. Atkinson

persists on every output and exists at the source demands investigation upstream.

A safe supply-modulation challenge can be especially illuminating where the equipment rating and the test plan permit it. Apply a small, measured test modulation to the distribution amplifier's laboratory supply and compare the phase-demodulated output with the known test waveform. Distinguish amplitude modulation from phase modulation using an appropriate phase-sensitive measurement and examine whether the spur amplitude scales with the injected disturbance. Remove the perturbation and verify return to baseline. Tests on an operational evidential recorder require authorisation and separate preservation of the original observations; a laboratory challenge must not be confused with a field observation.

Correlated spectral defects create a particular forensic hazard. If several receivers share the same reference network, a phase or frequency spur may propagate through their synthesiser and sampling structures. They may then show simultaneous low-level spectral features, apparent carrier shifts or degraded weak-signal discrimination. Their agreement is not independent corroboration of an external transmitter. Yet one must avoid the opposite error: a genuine external signal may also be observed simultaneously at several receivers. A local injected calibration tone and independently clocked observation channel provide a means of testing the reference hypothesis without asserting a cause prematurely.

The conclusion should be a set of bounded findings: at what offset a component was observed; its amplitude relative to carrier and the instrument floor; how it changed between the oscillator, fan-out input and outputs; whether it tracked supply intervention, cable exchange or a known

Copyright 2026, James M. Atkinson

test source; and which physical explanations remain viable. No single spectral slope or pair of sidebands establishes intentional surveillance, the source of an external emission, or a legal attribution. The distribution apparatus is part of the measurement system, and its own spectral behaviour must be documented before claims about the surrounding RF environment are treated as reliable.

Dr. James M. Atkinson, Moderator: Professor Essen, what distinction must be drawn between the source oscillator and noise introduced after it?

Louis Essen, Peer Question: Professor Townes, a reference source can be exceptionally stable when measured at its own output, but a distribution branch may add phase fluctuation after the original oscillator. If an engineer compares only the absolute noise spectra at two points, the two curves might resemble one another because the common source dominates. What method would reveal residual branch noise under those conditions, and why is it important to distinguish the noise inherited by both measurements from the noise added in the component under test?

My difficulty is not simply whether the branch contains extra noise, but whether the selected experiment has enough independence to reveal it. If the source and reference arm are derived from the same oscillator, propagation delay will make some source fluctuations appear as residual error even without a faulty branch. If I shift the cable length or change a digital compensation setting, the observed spur may respond merely because the differential phase transfer function has changed. Which reference-plane definition would allow laboratories to reproduce the result? Should we determine the complex transfer function of each branch before claiming additive phase noise? And how should we handle a spur that

Copyright 2026, James M. Atkinson

remains fixed in hertz but changes in dBc when amplifier gain is altered, knowing that ratio measurements can disguise a changed carrier amplitude?

Charles H. Townes, Response: Professor Essen, the proper approach is to measure the residual phase difference between appropriately matched input and output references, with the relevant carrier frequency and delay accounted for. The inherited phase fluctuation may largely cancel in a differential measurement, exposing additive noise that an absolute spectrum obscures. That cancellation depends on coherence, equivalent path delay and the measurement bandwidth; imperfect delay compensation can leave apparent residual source noise. The device may also alter phase in response to amplitude, temperature or load. Consequently the residual measurement should be repeated with a low-noise substitute source and a reference through-connection, not reported as a direct property of the amplifier without accounting for the measuring apparatus. For multiple outputs, compare each branch both against the common input and against another branch. Agreement between two outputs can hide shared input noise but disclose differential additive noise; the two results answer different questions. Neither should be substituted for the other.

A reproducible report should define its reference planes at physical connectors and identify which voltages are being compared, not merely which menu option was pressed. Establish a traceable source measurement at the upstream connector, follow with a measurement at the downstream branch connector, and record both carrier power and complex modulation response. A time-domain phase comparison requires either matched delay or explicit compensation: if the upstream phase is evaluated at time t and

Copyright 2026, James M. Atkinson

the downstream record samples a delayed version at $t-\tau$, the residual includes $\varphi_{in}(t-\tau)-\varphi_{in}(t)$ in addition to branch error. For a periodic perturbation at offset f_m, the magnitude of that unwanted difference depends on $2|\sin(\pi f_m \tau)|$, so delay must enter the uncertainty model. The formula refers to equal-amplitude phase terms and does not excuse neglecting detector mismatch or cable dispersion.

One should next swap physically equivalent branches whilst keeping the instruments and source unchanged. If the anomaly remains attached to a port, a port-specific hypothesis gains plausibility; if it follows a cable, mechanical or shielding influences deserve attention. A gain change also requires recalibration. A sideband-to-carrier power ratio may remain approximately constant for pure linear amplification, but additive noise or saturation can change it. Record power in absolute units and the sideband ratio together, with bandwidth-normalisation explicitly stated. The result must include a test of detector linearity, since an overloaded analyser can manufacture spurious products. An independent reference is particularly valuable as a check, although independence must be established rather than inferred from a separate chassis.

Dr. James M. Atkinson, Moderator: Professor Ramsey, how would you establish the physical meaning of a pair of discrete sidebands?

Norman F. Ramsey Jr., Peer Question: Professor Townes, a symmetric sideband pair appears on the spectrum analyser at a fixed displacement from a reference carrier. It is tempting to label the feature as a phase disturbance, and perhaps to assign it to a particular power-supply frequency. What further observations separate amplitude modulation from phase modulation, identify the relevant phase relationship, and distinguish

Copyright 2026, James M. Atkinson

an actual periodic perturbation of the reference from an analyser-generated response or mixer product?

A reader may overlook the role of coherent phase in the apparent symmetry of the two modulation sidebands. If a converter's rail ripple drives both gain and propagation delay, then amplitude and phase perturbations share a periodic cause, potentially adding constructively on one side of the carrier and destructively on the other. Suppose a spectrum screenshot contains a spur at plus 200 Hz but little energy at minus 200 Hz. Can we conclude that it is not phase modulation, or is that conclusion equally unjustified? Which IQ calibration, sign convention and image-rejection tests would you demand before taking asymmetry as evidence of a physical one-sided emitter? I also ask whether the presence of correlated AM and PM is a defect of the oscillator itself or can originate solely in distribution-stage nonlinearity.

Charles H. Townes, Response: Professor Ramsey, retain the complex modulation information when an instrument is capable of measuring it. A phase demodulator and an amplitude demodulator should examine the same signal at the same reference plane. For small, coherent sinusoidal modulation, amplitude and phase contributions can be decomposed from the quadrature components, but their estimated separation depends on calibration and phase reference. Change the analyser's reference source or frequency-conversion configuration to see whether the spur follows the tested signal or remains associated with the instrument. A second receiver architecture with an independently maintained local oscillator can offer corroboration. Frequency displacement alone is not a unique cause: two equal-magnitude sidebands can arise from several combinations of modulation and measurement artefact. A phase-difference measurement

Copyright 2026, James M. Atkinson

across the distribution device, simultaneous recording of supply ripple, and controlled removal of the suspected source provide a more persuasive causal test.

One-sided appearance does not exclude phase modulation because coherent AM and PM can interfere in the complex sideband coefficients. In the first-order analytic-signal model, the component at a positive offset combines the relevant Fourier components of a(t) and jφ(t), while the negative-offset component involves their conjugate relationships. A special relative phase can enhance one and suppress the other. The test therefore must preserve both IQ channels and calibrate the sign of the quadrature axis. Inject a known pure amplitude modulation at a specified offset, then a separately characterised phase modulation; the recovered components should track the intentional perturbations with measurable cross-leakage. The observer must also test image rejection and carrier leakage, since imperfect quadrature creates false spectral imbalance.

If calibrated AM and PM components remain correlated, inspect the points at which gain and delay are both susceptible to the same disturbance. A fan-out amplifier can convert supply ripple into gain modulation through amplitude response and into phase modulation through voltage-dependent delay. A synthesiser can do likewise through its control loop. Rotate the load matrix and measure the oscillator directly before inferring the responsible stage. When correlations are strong, report a measured cross-spectral relationship rather than describing the amplitude and phase curves as independent. The normal teaching simplification of separate AM and PM is useful for first-order calculation, but it is not evidence that the physical mechanisms are separate.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Mr. Hewlett, what ought the engineer to infer from a spur that grows when the fan-out amplifier is loaded?

William Redington Hewlett, Peer Question: Professor Townes, changing the number of connected receivers alters termination conditions and supply demand. If a sideband becomes larger as another branch is enabled, one explanation is output-to-output coupling; another is supply modulation; still another is a changed impedance or a receiver injecting energy back into the distribution network. Which experiments isolate the pathways without risking damage, and why is a comparison of one arbitrary loaded and unloaded condition inadequate?

Let us examine the loading experiment as an engineering intervention rather than a suggestive visual demonstration. Switching a second receiver onto a fan-out output changes more than terminal impedance; it can alter supply current, chassis potential, cable layout, the thermal condition of nearby buffering stages and even the operating state of the receiver's own digital electronics. In a field installation there may be no safe means of removing ground bonds, nor would doing so be acceptable merely to prove a hypothesis. What controlled sequence would separate direct reverse coupling at the carrier from power-rail coupling at the offset frequency? How would you prevent an increase in measurement sensitivity caused by changed gain from being mistaken for a newly appearing spur? Please distinguish a diagnostic observation from an intervention that merely suppresses the display of the problem.

Charles H. Townes, Response: Mr. Hewlett, map the changes systematically. Establish a correct termination at each port and measure output power, amplitude modulation and phase modulation before and after connecting a

Copyright 2026, James M. Atkinson

characterised load. Replace the receiver temporarily with a safe equivalent load to separate receiver feedback from a mere change in demand. Monitor supply rail ripple and current simultaneously. Enable branches in different orders, measure each affected output and repeat with physically separate supply arrangements where the apparatus permits. If the spur follows a specific receiver, investigate reverse coupling and isolation; if it follows aggregate power load, investigate regulation and supply rejection; if it follows one port regardless of load, investigate that branch. Every manipulation requires a written configuration record because a narrow improvement can result from a changed impedance rather than repair of the original mechanism. In particular, no unqualified claim of additive phase noise should be made from a measurement that has silently changed carrier power or detector operating point.

Begin with a topology diagram listing every active output, cable length, termination, chassis bond and supply rail. Keep protective earthing intact. Create the baseline using a calibrated source, known load and documented output power. Then change one factor while repeating controls: substitute a matched termination for the receiver, substitute a known isolated distribution buffer for the branch, vary the number of correctly terminated outputs, and finally compare alternative supply arrangements within safe electrical design. At each stage record the carrier power, sideband ratio and, when possible, residual phase. Reverse-coupling hypotheses predict that disturbances injected into an output port can affect another output in a frequency-dependent way; supply-coupling hypotheses predict a relationship with rail ripple or load current. Those predictions should be tested by benign, calibrated perturbations below equipment safety limits.

Copyright 2026, James M. Atkinson

Detection thresholds deserve an independent verification at each state. Inject a small reference spur of known modulation index before the receiver or through a characterised calibration port and determine whether the instrument still reports it with equivalent sensitivity after an architectural change. If the test spur vanishes as well as the suspect spur, the evidence is compatible with simple desensitisation. Make a before-and-after uncertainty budget for the receiver gain and analyzer floor. A narrow line that diminishes while the test line remains stable is more informative, but it still does not identify the component without corroborative tests. This distinction should be explicit in the engineering report, for otherwise a successful suppression experiment will be mistaken for successful causal diagnosis.

Dr. James M. Atkinson, Moderator: Professor Kolmogorov, can a low noise floor established by many averages justify a narrow confidence statement?

Andrey N. Kolmogorov, Peer Question: Professor Townes, phase-noise measurements often involve averaging many spectral estimates. The displayed trace may become visually smooth, but the data may contain a discrete spur, nonstationary switching event or correlated disturbance present in both analysis paths. What assumptions about random processes and independence are required before the reduction of an averaged floor is interpreted as improved sensitivity? May the analyst represent the remaining uncertainty by the count of averages alone?

The words 'noise floor' and 'confidence' often acquire authority merely because a digital analyser displays many significant digits. Yet a narrow coherent spur is not distributed as the surrounding stochastic bins, and repeated overlapping transforms may not constitute independent

Copyright 2026, James M. Atkinson

observations. If a recording programme reports four thousand averages, how should the investigator estimate an effective sample count when every second window overlaps half of the previous one? What if a slowly changing thermal process makes successive records dependent over minutes rather than milliseconds? Can an apparently remarkable decrease of displayed phase-noise density be an artefact of the measurement method itself, particularly when the two correlation channels share a splitter or bias network? I ask for a test that would make the uncertainty statement falsifiable.

Charles H. Townes, Response: Professor Kolmogorov, averaging reduces the variance of a chosen estimator under specific stochastic assumptions; it does not guarantee that systematic components disappear. For independent spectral records, the variance may decrease as the number of informative averages increases, but overlap, shared noise, slow drift and correlated detector errors reduce the effective amount of independent information. A coherent spur remains because it is not a zero-mean random fluctuation under the relevant averaging operation. In two-channel cross-correlation, uncorrelated measurement noise can be progressively suppressed, while correlated noise survives. The uncertainty assessment must therefore distinguish repeatability, instrument floor and systematic error, and must retain information about the spectral estimator, windows, bandwidth, data exclusions and nonstationarity. Counts of averages alone do not specify a defensible bound. Repeating a comparison under deliberately changed instrument configurations is often more informative than adding further averages to one unchallenged architecture.

Copyright 2026, James M. Atkinson

An average count is not an effective independence count. The statistician should estimate the covariance among spectral estimates under the actual acquisition protocol and determine an effective sample size suitable to the estimator. If the per-record variance is σ^2 and the correlation between records separated by lag k is ρk, an approximate effective number for a sufficiently long stationary series is $M_{eff} \approx M/[1+2\Sigma\rho k]$, where M is the record count and the sum is over meaningful positive lags. This is a practical approximation, not a universal theorem for every overlapping spectral estimator. A defensible uncertainty interval can use appropriately blocked resampling or independently repeated experiments, while disclosing the overlap, window and correlation assumptions.

To make the claim falsifiable, add a known modulation tone of specified amplitude and demonstrate that the analyser recovers it when the supposed floor is very low. Repeat the measurement with an independently characterised splitter and, where practicable, a different cross-spectrum topology. A cancellation in one configuration but not another signals instrument dependence, even if both traces are pleasingly smooth. Cross-spectrum subtraction can be affected by anti-correlated thermal noise introduced in a common power divider; the risk is experimentally documented in later metrology work, which must be cited editorially rather than attributed to our historical speakers. For coherent discrete spurs, track tone power and temporal persistence separately from random phase-noise density. Finally disclose the number of conditions and offsets examined so that the claimed false-alarm or non-detection probability is reproducible.

Dr. James M. Atkinson, Moderator: Sir Harold Jeffreys, what does a shared sideband imply about the probability of an external emission?

Copyright 2026, James M. Atkinson

Harold Jeffreys, Peer Question: Professor Townes, imagine that three receivers report a faint spectral line displaced by the same amount from their reference-related signals. The investigator may be tempted to multiply three nominally small false-alarm probabilities and announce overwhelming corroboration. What assumptions fail when all three receivers share a reference distribution module, and how should competing hypotheses such as genuine external emission, common reference modulation and instrument artefact be compared without invented probabilities?

A Bayesian statement requires a proper set of hypotheses and a likelihood that acknowledges dependency. Suppose three receivers display an offset line at the same time. Under a simplistic model in which each has a one-in-a-thousand chance of a spurious result, an analyst might multiply those probabilities and advertise an implausibly small false-positive rate. However, if all three receivers use one reference source, a single reference fault can produce three observations together. What conditional probability structure would avoid that elementary error? How should prior probabilities be stated when the suspected external transmitter is extraordinary but the electrical distribution network is known to contain switching electronics? And how can a report communicate the strength of evidence without converting an assumption-dependent probability into a courtroom certainty?

Charles H. Townes, Response: Sir Harold, the events are not independent simply because three displays exist. Their false indications may be conditionally dependent on one shared impairment. A useful analysis specifies hypotheses and seeks observations expected to differ among them. A source-related line should persist under a controlled independent-clock check, subject to the actual receiving conditions; a reference-network

Copyright 2026, James M. Atkinson

spur should respond to safe substitution or perturbation of that network, though complicated coupling may prevent a perfectly binary result. The researcher should not assert numerical likelihood ratios without empirical models, calibration or defensible prior information. Instead report the test conditions, evidence of dependence, and any remaining uncertainty. The strength of the finding comes from discriminating experiments, not from counting redundant instruments as if they were separate witnesses.

Represent the evidence E as a collection of observations with their shared conditions, rather than as three independent scalar events. Let Hext denote an external emitter and Href a reference-distribution artefact. The posterior odds equal prior odds multiplied by the likelihood ratio P(E|Hext)/P(E|Href), but each conditional probability must include the common reference configuration and relevant measurement uncertainty. A graph that places the reference fault as a parent of all three receiver observations shows immediately why their indications can be dependent. If one shared spur has high probability under Href, the three coincident displays may provide little discrimination. Under Hext the amplitude and spatial phase predictions may differ, making antenna relocation or independent clock replacement more valuable than a fourth identical display.

Do not smuggle certainty into the prior. Report a sensitivity analysis over plausible prior odds and explain which conclusion depends on which values. Better still, design an intervention that creates a large likelihood contrast regardless of moderate prior disagreement. One might compare the suspected line under an independent reference with calibration injection and unchanged antenna geometry, then under antenna termination with the original reference restored. The joint outcomes, not the number of

Copyright 2026, James M. Atkinson

screenshots, form the evidence. An honest report must also acknowledge unmodelled hybrid mechanisms, such as a strong external signal mixed with internally contaminated local-oscillator noise. The evidence may not distinguish all conceivable causes, and the written conclusion should say so.

Dr. James M. Atkinson, Moderator: Professor Gabor, how does a time-frequency representation assist when a spur appears only intermittently?

Dennis Gabor, Peer Question: Professor Townes, an analyser may show a weak offset line averaged over an observation window, yet the disturbance may actually be a periodic switch event or a brief transient associated with the clock system. Can time-frequency methods help distinguish persistent random sidebands from intermittent deterministic modulation, and what limits arise from the temporal window, signal-to-noise ratio, or interaction between a measurement filter and a short event?

A long Fourier transform can make a transient switching event appear as a faint but persistent neighbouring spectral component, while a very short analysis interval sacrifices the ability to separate close frequency offsets. The temptation is to adjust the window until the waterfall tells the most compelling story. How should an examiner select the window duration and overlap before inspecting the anomaly? If a fan controller switches at intervals related to a 70 Hz spur, what measurements would reveal a repeating time-domain mechanism rather than a continuously present oscillator impairment? I am also concerned with a false absence: a spur may be intermittent and therefore invisible in an average, although it remains causally important to a receiver's momentary false alarm. What should be preserved?

Copyright 2026, James M. Atkinson

Charles H. Townes, Response: Professor Gabor, an appropriately calibrated time-frequency record may show whether the feature persists, follows a supply-switching schedule or appears only at control-loop state changes. A shorter analysis window localises transients while broadening frequency discrimination; a longer window can sharpen the offset estimate at the expense of temporal detail. Neither representation alone establishes the circuit responsible. Record the supply waveform, controller logs and reference amplitude or phase simultaneously, and align them using an independently checked clock. If a transient occurs at a reference switch, inspect the phase trajectory directly rather than infer continuity from an averaged sideband trace. Cross-compare results obtained with different window lengths to expose smearing or spectral leakage. The measurement should state its observation coverage, since an intermittent spur can evade a sweep or appear diluted by an average over long quiet periods.

Choose more than one predeclared analysis scale and retain the raw IQ or phase-error samples so the choice can be reviewed. A transform over T seconds has characteristic Fourier-bin spacing 1/T hertz, though the actual resolving power depends on window shape and signal-to-noise ratio. A 0.1-second window yields 10 Hz nominal bin spacing; a 10-second window yields 0.1 Hz. Neither is inherently superior. The shorter view may reveal the onset of a switching event, while the longer view may resolve an offset line accurately if the process is stationary over the interval. Report the window function, overlap, equivalent noise bandwidth, and the threshold procedure used to detect an event.

A useful experiment records fan-control command signals, rail-current measurements and clock phase synchronously, then tests whether the

Copyright 2026, James M. Atkinson

spur's onset follows control transitions. If no causal command trace can safely be acquired, at least record power and thermal states without altering the device. A periodic event can produce a comb of lines with spacings related to its recurrence, but such a comb is not unique proof of a controller fault. Measure the reference at its upstream and downstream planes to locate the onset of modulation. Keep raw records around nominal and anomalous episodes, rather than only averaged displays. When a claimed absence is based on a long average, supplement it with an event-detection threshold and a stated duty-cycle sensitivity; otherwise an intermittent interference mechanism can be diluted beyond visibility.

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, how should the investigator prevent the receiving apparatus from being mistaken for the physical environment?

Martin Ryle, Peer Question: Professor Townes, in a multi-receiver survey, an apparent carrier artefact can travel through local oscillators and frequency-conversion stages, which are ultimately referenced to the same distribution network. A genuine external signal may also appear coherently across receivers. Which changes of frequency plan, antenna path or reference source can test these alternatives, and how should the examiner avoid assuming that a line which disappears on changing a receiver setting was necessarily fictitious?

When a local oscillator derives from the suspect reference network, an internally generated modulation sideband can be translated along with a genuine external RF input. It may even produce a spectral component that follows a plausible frequency trajectory when the operator retunes the receiver. How can an investigator tell the difference between a spur entering

Copyright 2026, James M. Atkinson

after the antenna and a line radiated from outside, especially when digital frequency re-mapping fixes the displayed frequency axis? Would terminating the antenna suffice if the instrument automatically changes gain upon removal of the RF input? How could geographically separated receivers strengthen a spatial claim when they still share a synchronised timing service or comparable internal oscillator architectures? I ask you to distinguish independent information from merely repeated equipment.

Charles H. Townes, Response: Sir Martin, an appropriately controlled change of architecture provides evidence but also changes sensitivity. Replace an antenna input with a known terminated or injected-signal condition, while preserving the relevant receiver operating state. Change the local oscillator or translation plan, monitoring how a true fixed RF signal should move in the intermediate-frequency representation compared with internally generated spurs. Independently substitute the reference clock and record whether the suspicious feature follows the reference or remains associated with the incoming field. The test must also account for front-end gain, filtering, noise floor and dynamic range so that disappearance is not merely a loss of detectability. A genuine signal can vanish from one configuration because the receiver's transfer function changes. The final attribution should therefore rest on a coherent set of instrument challenges, not a single toggled setting or a plausible-looking spectral display.

Treat antenna termination as one intervention, not a conclusive verdict. First disable or explicitly record automatic gain control, preserve the noise-equivalent sensitivity, and verify the receiver with a calibrated injected signal before and after the termination. A line persisting under a sound matched termination is evidence for an internal or conducted contribution, although

Copyright 2026, James M. Atkinson

leakage around the termination is still possible. A line disappearing with the antenna may be external, but removal of a strong carrier can also remove reciprocal-mixing products generated internally. Retuning should be analysed in absolute RF coordinates as well as displayed baseband coordinates; the transfer of an internal reference spur through each mixer or digital numerically controlled oscillator must be calculated.

Spatial discrimination becomes stronger when receivers have independently verified oscillator paths, different front-end architectures and known antenna positions. A real transmitted wave may exhibit position-dependent field strength and phase, subject to multipath and near-field qualifications. A common measurement artefact need not follow the same geometry. However identical electronics operated in separate buildings can still share mains-related interference or an external timing system. The report should identify what was genuinely independent, including power source, clock, antenna path, software processing and calibration injection. A mere increase in the number of receivers is not sufficient. Construct competing hypotheses and predict how each should respond to receiver retuning, reference replacement, antenna relocation and test-signal injection, then document the results without cherry-picking the best-looking traces.

Dr. James M. Atkinson, Moderator: Dr. Dijkstra, what software metadata are needed to reconstruct a distribution fault years later?

Edsger W. Dijkstra, Peer Question: Professor Townes, automated monitoring software often stores the phase-noise trace but discards supply states, exact reference-port assignments, correlation settings and instrument firmware versions. The graph may remain attractive yet become difficult to reproduce or challenge. What minimal provenance rules would establish whether a

Copyright 2026, James M. Atkinson

later reviewer can reconstruct the measurement, including the treatment of branches deliberately disconnected or rejected as noisy?

The programming system may be the last and least examined part of a reference-distribution investigation. A spectrum image without raw complex samples, filter coefficients or a record of which physical reference fed which receiver cannot support later reconstruction. Suppose a programme silently changes decimation, window shape or automatic gain when a new device is attached. The analyst might attribute the resulting sideband change to the fan-out network although the data-processing path was altered at precisely the same instant. Which invariants should the software preserve, and how should a forensic team detect state changes that were not explicitly requested? What constitutes an adequate provenance record for a computed phase-noise graph that may ultimately become evidential material?

Charles H. Townes, Response: Dr. Dijkstra, the record should declare each instrument and its signal path, the source and distribution topology, cable and port identities, loading, supply condition, timebase origin, instrument bandwidth, offset-frequency vector, amplitude reference, cross-correlation averaging settings and any calibration corrections. It should retain raw or minimally processed traces where available and preserve every rejected measurement with its reason. Software transformations require versioned provenance, including the distinction between linear-density combination and logarithmic display conversion. A phase-noise trace without configuration metadata is not a reproducible experiment; it is an image of an unknown procedure. Immutable source data, checksums, a tested replay path and explicit uncertainty annotations allow a later reviewer to

Copyright 2026, James M. Atkinson

distinguish source behaviour from alterations introduced during measurement or presentation.

Define a measurement state vector and make it part of every acquired record. The vector should include reference-source identity, distribution port, cable and termination identifiers, local-oscillator frequencies, sample rate, gain state, filter and decimation parameters, clock lock status, window and overlap, calibration version, recording start and stop times and software revision. Store the raw samples or raw phase-error streams when feasible, together with the analysis configuration needed to regenerate each displayed result. An operator's comment is useful but should not replace machine-readable state. The software ought to flag any uncommanded transition in the acquisition chain and mark data spanning a transition as a separate measurement interval.

Preserve immutable source files with cryptographic digests and retain an audit trail of derivation, including the programme version and parameters used to produce a plot. A hash protects against unnoticed alteration after the measurement; it does not prove that the instrument was calibrated or that its timestamp was correct at acquisition. The analysis pipeline must therefore be tested with synthetic signals whose expected spurs, phase noise and transient responses are known, and with physical injection tests that exercise the analogue front end. A reproducibility exercise should permit an independent reviewer to recompute the relevant spectra and identify precisely where a claimed feature first appears. That chain of reasoning links software engineering to measurement validity without turning the fictitious historical exchange into evidence that these participants ever examined modern SDR code.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Ramsey will now take the principal token to examine how a sideband can be misidentified as phase modulation, and Mr. Hewlett will cross-examine the distribution-network experiment.

Norman F. Ramsey Jr., Second Principal Contributor: Dr. Atkinson, an observed pair of sidebands is not a unique diagnosis of an oscillator defect. Small periodic phase modulation can produce approximately symmetric sidebands, but so can amplitude modulation and mixed quadrature processes. A local oscillator or measurement analyser can also generate or translate a feature that appears to originate at the reference source. The discriminating measurement should preserve phase and amplitude quadratures at characterised points before and after the distribution stage, while monitoring supply voltage and reference-switching state. A differential phase comparison may suppress common source fluctuations and reveal residual additive branch noise, but only after delay matching and instrument-floor qualifications. I invite Mr. Hewlett to ask how the network should be challenged under changing loads.

The analytical separation begins with a complex envelope, not with the height of two sidebands alone. Let $z(t)=A[1+a(t)]\exp[j\varphi(t)]$ be the baseband analytic signal after carrier removal, with A the nominal amplitude, $a(t)$ the fractional amplitude perturbation, $\varphi(t)$ the residual phase and j the square root of minus one. For small a and φ, $z(t)/A$ is approximately $1+a(t)+j\varphi(t)$. The real perturbation is consequently predominantly amplitude modulation, whilst the imaginary perturbation is predominantly phase modulation, provided the quadrature axes have been calibrated and the residual carrier is correctly aligned. A spectrum analyser that displays only magnitude can

Copyright 2026, James M. Atkinson

conceal that distinction. The analyst should compare synchronous amplitude and phase records, including their relative phase when the disturbance is periodic. If the offset components have different relative phases in the in-phase and quadrature channels, a mixed amplitude-and-phase process may be present. That interpretation must not be made from an uncalibrated IQ pair merely because it looks symmetrical.

Consider a concrete, deliberately idealised case. Let $a(t)=0.002\cos(2\pi 120t)$ and $\varphi(t)=0.004\sin(2\pi 120t)$, with elapsed time t in seconds and 120 Hz a modulation frequency. To first order, amplitude modulation alone yields sideband-to-carrier voltage ratios near 0.001, equivalent to minus 60 dBc in power for each isolated sideband. Phase modulation alone, at $\beta=0.004$ radians, yields sidebands of about $\beta/2=0.002$ in voltage ratio, giving approximately minus 54 dBc per sideband. But the two modulations are not independent when they occur coherently at the same frequency. Their complex contributions may reinforce one sideband and partially cancel the other depending on relative phase. It is therefore scientifically unsound to infer β from a displayed sideband without first excluding or bounding the amplitude component. The example uses small-signal approximations and does not assert that a measured device actually exhibits these ideal functions.

The frequency multiplication case adds another diagnostic. If an ideal frequency multiplier produces the Nth harmonic of a source with phase $\varphi(t)$, the output phase deviation is $N\varphi(t)$. The same physical phase perturbation consequently yields an increase of $20\log10(N)$ in its phase-noise level, expressed in dB, under the convention that the source's normalised single-sideband phase noise is compared with the multiplied output at an

Copyright 2026, James M. Atkinson

equivalent Fourier offset. For N=10, the ideal increase is 20 dB. An actual synthesiser introduces additive noise, loop filtering, fractional spurs and finite-bandwidth behaviour, so the 20 dB rule is neither universal nor a substitute for measuring the transfer function. The assessor should compare reference and output spurs in both amplitude and phase, noting whether the offset remains fixed, scales with an internal switching frequency, or changes with a synthesiser programme. A repeated offset suggests a shared periodic influence; it cannot by itself locate that influence.

To test whether a reference spur belongs to the oscillator or its distribution network, arrange two measurement routes. The first is a direct, well-terminated output from the source, and the second passes through the suspect fan-out branch. Use an independently characterised phase detector with a separately supplied reference whenever possible, and repeat the test with the branch power source and loading varied one at a time. The residual phase spectrum is a property of the comparison geometry; it is not an intrinsic label permanently attached to a physical component. Delays should be matched at the frequencies of interest because otherwise some source-phase terms will fail to cancel, creating a spurious impression of additive noise. At low offset frequencies, environmental temperature, cable bending, vibration and connector stress matter particularly because phase responds to path-length and permittivity changes. Record such influences as controlled variables rather than treating them as laboratory inconveniences.

Finally, I should warn against claiming that close agreement between two electronic displays proves an external physical emission. If both displays use the same frequency reference, their agreement may simply be the propagated signature of one oscillator or shared supply perturbation.

Copyright 2026, James M. Atkinson

Independent timing and independent RF front ends are forms of experimental contrast, not automatic truth machines. The investigator should create a matrix of expected outcomes under competing hypotheses: an external emitter, a master-reference spur, a branch-specific additive disturbance, and a receiver-local mixing product. Each intervention should predict a different pattern if it is to discriminate between them. Where predictions overlap, additional measurements must be designed instead of retrofitting a preferred narrative to the observations.

William Redington Hewlett, Cross-Peer Question to Norman F. Ramsey Jr.: Professor Ramsey, suppose enabling a second receiver makes the first branch acquire a narrow offset spur. Some engineers would immediately condemn the buffer amplifier, but enabling the load changes current consumption, impedance, supply regulation and perhaps reverse injection from the attached receiver. How would you design a sequence of physically controlled substitutions that distinguishes these causes, and what observable would persuade you that the spur is truly phase modulation rather than an amplitude effect converted by the measuring instrument?

The proposed distinction between a modulated reference and a defective branch becomes less transparent once the second receiver is connected. Assume that the carrier amplitudes at both ports remain nominally constant, but the sideband appears only when the second receiver's internal converter is powered. A gain-only test could miss a phase-sensitive mechanism, while a reference substitution might change the converter's frequency plan and invalidate comparison. Would you insist upon simultaneous AM and PM measurements at each output and at the undisturbed source? If so, how would you control the phase-detector

Copyright 2026, James M. Atkinson

offsets, the differential cable delay and the possible dependence of instrument sensitivity on power level? I am seeking a test sequence whose observed outcomes would point to the place of origin rather than merely suppress the line.

Norman F. Ramsey Jr., Cross-Peer Answer to William Redington Hewlett: Mr. Hewlett, use characterised matched loads and retain the carrier amplitude at each distribution output while the branch occupancy changes. Record supply ripple and the corresponding phase and amplitude demodulated waveforms. Replace the receiver with an equivalent load; then exchange cables, branch ports and the test supply one at a time. A spur following the receiver suggests feedback or reverse isolation; a spur following supply current invites a regulation test; one confined to a branch suggests a path-specific contribution. Independent phase-sensitive measurement should confirm whether the phase fluctuation persists after amplitude-to-phase sensitivity has been controlled. No one intervention proves the source, and the record must preserve the configuration at each step.

Yes, although the simultaneity must be real in the metrological sense. Measure the upstream reference and each relevant output against a suitably characterised common timebase, with known channel delays and calibration tones. Preserve the two quadratures so that an apparent reduction in one form of modulation does not disguise a conversion into the other. Begin with the receiver disconnected but with its output port correctly terminated; then substitute a matched load through the same physical cable; finally connect the live receiver under otherwise unchanged conditions. At each stage record absolute carrier power, residual phase, fractional amplitude modulation, supply-rail spectral content and relevant

Copyright 2026, James M. Atkinson

temperatures. The order should be repeated or randomised to test for thermal drift and irreversible state changes.

If a spur remains negligible at the master oscillator yet grows at a particular branch whenever the receiver's converter is enabled, that pattern favours branch or receiver coupling. It does not prove the receiver is defective, since a properly functioning converter may expose inadequate isolation in the distribution unit. An impedance-network measurement at the spur frequency and a controlled return-current observation can distinguish some of the alternatives. A known calibration tone must remain detectable throughout the changes; otherwise a spur's disappearance could be a sensitivity artifact. Finally, test another branch and an independently powered receiving architecture, recording changes in transfer function. A causal inference rests on jointly consistent interventions, not on one favourable trace.

Charles H. Townes, Response to Professor Ramsey and Mr. Hewlett: I accept the need to separate quadrature mechanisms and device loading. Spectral resemblance does not establish causal origin; well-chosen component exchanges and independent reference measurements do substantially more to discriminate a source than repeated displays of the same sideband.

Dr. James M. Atkinson, Moderator: Mr. Hewlett, let us now examine output loading, reverse coupling and supply conditions. Professor Townes will question the diagnostic value of a matched-load substitution.

William Redington Hewlett, Third Principal Contributor: A clock distribution amplifier cannot be separated conceptually from its loading and supply conditions. A narrow sideband appearing only after another receiver is

Copyright 2026, James M. Atkinson

connected might indicate output-port crosstalk, reverse injection, changed supply ripple or a load-induced phase shift. The sensible investigation substitutes characterised loads and exchanges one component at a time while monitoring both phase and amplitude at the output. It should avoid disconnecting or reloading an operational evidence chain without maintaining a separate unaltered record.

A fan-out network is an assembly of active and passive two-port devices, not an abstract clock symbol. Its physical behaviour depends on conductor impedance, cable loss, connector discontinuities, isolation between branches, output buffering, supply rejection and the spectra of currents that flow through its metalwork. Assume, for illustration, one 10 MHz source driving eight buffered outputs into nominal 50-ohm systems. A second receiver may change the aggregate current drawn from an amplifier rail, and its local converter may inject a periodic return current through a shared ground. The resulting sideband can appear on several outputs even though the master oscillator, tested directly under controlled load, remains quiet. Such evidence would implicate distribution coupling, but not necessarily a single defective amplifier. A powered receiver, cable shield and chassis bond form an interconnected circuit whose impedance is frequency dependent.

A practical fault localisation programme should therefore separate four interventions. First, substitute a correctly rated matched termination for the receiver input while retaining the existing cable, thereby testing load interaction without altering cable placement. Secondly, retain the receiver but insert a characterised isolating buffer or suitable attenuation, allowing for changed signal level and measurement noise. Thirdly, power the receiver from an independently characterised supply while preserving grounding

Copyright 2026, James M. Atkinson

safety, to investigate supply-conducted coupling. Fourthly, change the reference source without otherwise disturbing the fan-out configuration. Each intervention answers a different question and must be logged as such. An apparently beneficial alteration can reduce a spur merely by attenuating it below detection, so compare absolute signal levels and detector sensitivity before declaring an impairment cured.

The distinction between port isolation and return-path coupling deserves particular emphasis. A manufacturer may specify reverse isolation at the nominal reference frequency, yet a switching disturbance at tens or hundreds of kilohertz may be conducted through the power distribution or common chassis at a frequency for which the quoted isolation figure provides little protection. The engineer should examine the relevant transfer function over the spur's modulation range, including control-loop bandwidth and supply-filter resonances. Termination should be verified at both carrier and disturbance frequencies as far as the circuit permits. A clean oscilloscope trace is not conclusive evidence of negligible low-level modulation, since time-domain vertical resolution and the instrument's own jitter may be insufficient. Conversely, a narrow spectral feature appearing after long averaging may demand renewed scrutiny of analyser leakage and reference coherence rather than an immediate component replacement.

I would establish a controlled load matrix with rows representing occupied distribution ports and columns representing measured spur amplitude, output power, source-rail ripple, and independently measured phase deviation. For example, record baseline with one load; repeat with two, four and eight loads; then move the same suspect receiver successively between ports. If the sideband amplitude follows the number of enabled loads,

Copyright 2026, James M. Atkinson

common supply impedance is one candidate. If it follows a particular port, local buffer circuitry or termination may be involved. If it follows the receiver regardless of port, return currents or receiver-generated disturbances warrant examination. These patterns are suggestive, not unique, because changing occupied ports can also alter thermal conditions. Randomise the intervention order and take repeated baseline measurements to separate drift from treatment response.

Forensic defensibility requires retention of the physical configuration. A photograph of the cable routing, a drawing of every ground and supply bond, connector identifiers, test-equipment calibration dates and a hash of the raw IQ record should accompany the final report. The observation may be minute, but the reconstruction must not depend on remembering which of eight identical cables was moved during a late evening measurement. Write the test order before examining the result and preserve anomalous as well as favourable runs. A chain of custody built around a single attractive spectrum picture is not a sufficiently controlled account of a distributed electrical system.

A further diagnostic concerns thermal time constants. Supply currents can change within microseconds, whereas a buffer package or the cable dielectric may heat over seconds or minutes. If a spur responds immediately to a load step and recovers as soon as the load is removed, conducted switching or direct coupling is plausible. If the sideband develops slowly and exhibits thermal hysteresis, path-delay or oscillator-temperature sensitivity is a stronger candidate. Log both rapid and delayed responses. Preserve the sequence of interventions because a warm-up drift may otherwise masquerade as a load-dependent phenomenon. This differential timing

Copyright 2026, James M. Atkinson

analysis is not conclusive on its own; it supplies a new experimental dimension that ordinary carrier-power measurements omit. The procedure should also state the maximum permitted loading and prohibit improvised changes to protective electrical bonding.

Charles H. Townes, Cross-Peer Question to William Redington Hewlett: If a spur disappears when a receiver is replaced by a matched load, is that sufficient to identify the receiver as the source?

Mr. Hewlett, your matched-load substitution seems straightforward until one considers that a live receiver is not a passive 50-ohm resistor. Its input impedance can vary with bias, frequency, signal level and local switching state; it can also send conducted disturbance backwards through its shield and supply connections. A passive termination has no comparable active return path. How would you distinguish the disappearance of a sideband due to removing the receiving electronics from disappearance caused by altering the high-frequency or low-frequency network loading? Could a controlled injection at the output of a distribution amplifier, performed within ratings and without unsafe grounding changes, reveal the reverse coupling path? I ask for an engineering measurement plan that separates port-to-port isolation from shared-supply and chassis mechanisms.

William Redington Hewlett, Cross-Peer Answer to Charles H. Townes: The substitution supports the hypothesis that interaction with the receiver contributed, but it also changes details of impedance, power demand and cable routing. Further challenge the suspected receiver through a different distribution port and independently measure its reverse coupling. The result

Copyright 2026, James M. Atkinson

should identify the precise conditions under which the spur occurs, rather than assign unique origin from one intervention.

I would avoid treating a nominal matched load as an electrically complete substitute for an active receiver. Instead measure the receiver's relevant small-signal input reflection characteristics where practical, and separately characterise current returned through the shield, chassis and supply system. An RF network analyser can establish the forward and reverse response around the reference carrier under suitably linear conditions; a low-frequency impedance or transfer measurement can investigate coupling at the modulation offset. For example, a 100 Hz rail ripple may convert into a 100 Hz sideband on a 10 MHz reference even if carrier-frequency port isolation is excellent. That distinction must be recorded before a particular buffer is blamed.

The controlled-injection experiment should use a benign known perturbation of calibrated amplitude at a permitted test port and monitor whether it appears at other branches. The response as a function of injection frequency provides a coupling transfer characteristic, but the tested amplitude must be low enough to avoid new nonlinearities or equipment damage. Repeat with the suspected receiver operating and with a passive load, preserving protective earth and documenting every connection. If the cross-branch response changes substantially only when a receiver is active, investigate its conducted path or altered termination. If the same coupling remains with passive loads, the distribution assembly itself is implicated. At each stage compare the measured signal against an independent calibration line, because attenuation and analyser dynamic range can otherwise give a false impression of successful isolation. The

Copyright 2026, James M. Atkinson

resulting evidence describes what the network does, and a separate reasoning step must show which component causes the impairment.

The observation should also be repeated with source and receiver roles interchanged wherever the hardware permits a valid reciprocal comparison. A nonreciprocal active buffer will not obey a passive symmetry assumption, so any reverse-transfer measurement must be interpreted with the actual bias and port ratings. Record the absolute injected disturbance and the received response in consistent units across the sweep. Then the evidence can reveal whether a reduction reflects genuine isolation improvement or merely altered attenuation at the analyser input.

Dr. James M. Atkinson, Moderator: Professor Kolmogorov, the panel must distinguish independent measurement noise from coherent spurs that survive averaging. Professor Ramsey will challenge the adequacy of the analyser floor.

Andrey N. Kolmogorov, Fourth Principal Contributor: The apparent reduction of a noise floor with averaging is a claim about random fluctuations under a stated dependence model. A coherent spur or supply-related event will not necessarily diminish, and correlated disturbances between measurement channels can defeat the anticipated cross-correlation suppression. I would preserve raw segments, rejection rules and the independence tests for internal reference oscillators. The number of averages is not an uncertainty budget.

Statistical assurance begins by defining the random object under investigation. Let x1(t) and x2(t) denote phase-error records from two measurement channels, expressed in radians after appropriate carrier

Copyright 2026, James M. Atkinson

removal. Under a simplified model, x1=s+n1 and x2=s+n2, where s is a phase fluctuation common to the two channels and n1 and n2 are their independent internal disturbances. Averaging the cross-spectrum of x1 and x2 can suppress the contributions of n1 and n2 if the independence assumptions are satisfied. Yet the architecture may create a further disturbance c that enters with opposite signs, giving x1=s+c+n1 and x2=s−c+n2. In such a case, the expected real cross-spectrum contains the desired spectral power of s minus that of c under appropriate independence conditions. An apparently low measured value might therefore arise by cancellation rather than by exceptional source purity. This possibility is documented by modern metrology research and ought to be identified as an editorial extension of our reconstructed discussion, not as a historical result spoken by the participants.

The noise-reduction claim from repeated independent averages is narrower than common rhetoric suggests. If independent estimates have common mean μ and finite variance σ^2, their arithmetic average has variance σ^2/M after M averages, where M is the number of independent estimates. Its standard deviation falls as 1/sqrt(M), not 1/M. Real spectral estimates are often partially correlated because of window overlap, shared references, slow drift or coherent interference. In that case a more general expression is Var(mean)=M^(−2) times the sum of all pairwise covariances. A substantial positive off-diagonal covariance can prevent the anticipated improvement; a negative covariance may deceptively reduce a measured cross-spectrum. One must inspect the actual covariance structure rather than deducing confidence from the counter displayed on the instrument.

Copyright 2026, James M. Atkinson

A narrow spur should not be treated as though it were a stationary random noise density. The deterministic line occupies a spectral region determined by the window shape, acquisition length and frequency alignment. Its reported dBc level is a discrete ratio relative to the carrier, whereas phase-noise density is usually reported as dBc/Hz at a specified Fourier offset. Confusing these units creates invalid comparisons, especially if one changes resolution bandwidth between measurements. The investigator should retain coherent complex records where possible and separately estimate the integrated spur power and the adjacent continuous noise density. If a tone drifts across transform bins, leakage can mimic a broadened skirt. If an intermittent event occurs only within a few records, averaging may conceal its temporal origin. A time-resolved detection statistic can preserve the event's occurrence while longer noise averages characterise the background.

I propose a hierarchical model for multi-receiver evidence. Let $y_{i,k}$ be the observed spur amplitude at receiver i during experimental condition k, expressed in linear voltage ratio after calibration. Write $y_{i,k} = \alpha_i + \beta_k + \gamma_{i,k} + \varepsilon_{i,k}$ as a diagnostic bookkeeping model: α_i represents fixed receiver effects, β_k a common state-dependent disturbance, $\gamma_{i,k}$ an interaction such as branch loading, and $\varepsilon_{i,k}$ measurement error. This is not a universal physical law; it is a transparent starting model whose adequacy must be tested by residual examination. Repeated baseline runs permit estimation of within-condition dispersion. Reversing the order of interventions can reveal drift; using an independent reference can test whether β_k follows the common oscillator. One must not interpret a fitted common coefficient as proof of a

Copyright 2026, James M. Atkinson

shared physical cause when the study has not independently varied that cause.

Confidence intervals should reflect the actual selection procedure. If investigators scan thousands of Fourier bins and report only the largest surprising spur, a confidence level attached to one preselected bin is inappropriate. Multiple-comparison effects, thresholding and data-driven search all affect the false-alarm rate. Publish the number of bins, windows, channels and intervention conditions searched, and distinguish confirmatory tests from exploratory discoveries. For a reported absence, provide a calibrated sensitivity limit and observation interval. An unobserved narrow line is not a demonstration that the distribution system was free of all spurs; it establishes only that none exceeded the stated threshold under the tested conditions.

A final safeguard is to distinguish the probability of a false alarm from the uncertainty in an estimated line amplitude. A threshold may be calibrated to yield a specified false-alarm probability for a single stationary noise model, yet the estimated amplitude of a genuine spur has a separate confidence interval. When the noise floor is heteroscedastic or the receiver gains differ, a global threshold can distort both quantities. Determine thresholds from off-spur control regions or independently acquired baseline recordings, and disclose the frequency offsets excluded from the noise estimate. Where spurs are selected after visual examination, perform a confirmatory acquisition with prespecified bands and stop rules. This prevents the field notebook from slowly transforming an exploratory discovery into an apparently planned statistical test.

Copyright 2026, James M. Atkinson

Norman F. Ramsey Jr., Cross-Peer Question to Andrey N. Kolmogorov: Can a phase-noise analyser's low displayed floor be treated as a measurement of the tested clock when its own reference oscillators may share a disturbance?

Professor Kolmogorov, the measurement team has made thousands of cross-spectrum averages and reports an exceptionally low residual-noise value. Yet the two channels share a divider, a reference oscillator and part of the environmental path. In such a system the independence assumptions are not obvious. Could an anti-correlated contribution from the splitter reduce the reported cross-spectrum even while the tested source remains noisy? How would you estimate the confidence of an apparent null without assuming the very channel independence that the experiment is meant to examine? Please distinguish ordinary variance reduction, a systematic cancellation bias and a failure to detect a coherent sideband that intermittently occupies only a fraction of the observation windows.

I would also like the calculation to identify its measurement convention. A phase-noise density expressed in decibels relative to a carrier per hertz differs from the discrete power of a coherent spur expressed in decibels relative to that carrier. If the spur is distributed over several transform bins by window leakage, how can the estimator recover its integrated power without allowing its apparent level to depend arbitrarily on the chosen resolution bandwidth? Please distinguish that engineering integration problem from the statistical independence problem in the cross-spectrum.

Andrey N. Kolmogorov, Cross-Peer Answer to Norman F. Ramsey Jr.: Only after confirming instrument noise is sufficiently below the relevant device noise and that correlated internal contributions are understood. Use a

Copyright 2026, James M. Atkinson

known reference, instrument configuration changes and independent verification where possible. The displayed trace may be an upper bound or a composite of device and instrument processes. Clearly state what has actually been resolved above the measurement floor.

Those are three distinct problems. Under genuine independence, repeated averages improve the precision of the estimator, and uncertainty can be calculated from its sampling distribution or from suitable replicate measurements. If the channels share a term c entering with opposite sign, however, the expected cross-spectrum can be biased downwards. No number of averages removes a systematic subtraction of correlated spectral power; indeed additional averages may make the wrong result look more convincing. A model $x1=s+c+n1$ and $x2=s-c+n2$ illustrates the point. With independent zero-mean s, c, n1 and n2, the real cross-spectrum expectation contains S_s-S_c, not merely S_s, where S denotes spectral density. A near-zero result need not imply a quiet source.

The practical check is architectural, not solely statistical. Change the divider type, use appropriate isolation or a differently implemented comparison path, and inject an independently quantified modulation tone to confirm recovery. Examine both real and imaginary cross-spectrum components where informative, and preserve enough individual records to identify unusual cancellation or drift. Test the splitter and detector noise floors rather than assuming they vanish. For an intermittent spur, estimate its event frequency and amplitude during detected windows separately from the average noise density. A short event occupying one percent of records may have considerable peak amplitude but little contribution to a long average. Report threshold, duty cycle, number of independent replicates

Copyright 2026, James M. Atkinson

and confidence under explicitly stated assumptions. Later experimental literature establishes that splitter-related anti-correlation is a real metrological issue, but this fictional discussion must retain an editorial citation for the modern evidence rather than crediting the historical participant with those later experiments.

For a coherent spur spread by a finite window, integrate the calibrated line power over a declared set of bins wide enough to capture the window's main lobe and relevant leakage, subtracting or bounding the adjacent noise contribution. State the coherent-gain and equivalent-noise-bandwidth corrections; repeat across window types as a sensitivity check. The procedure is not equivalent to averaging a noise density. A tone's total relative power, its spectral shape and its temporal occupancy are three different estimands, all of which should appear separately in an evidential report.

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, please address how a contaminated reference becomes a suspicious RF line through frequency conversion. Mr. Hewlett will ask what may be inferred when the receiver configuration changes.

Martin Ryle, Fifth Principal Contributor: The same suspicious line may arise in the external RF field or inside an instrument whose conversion process uses a contaminated reference. A frequency-plan change can move internal products relative to the input RF coordinate, but it also changes gain and bandwidth. I would retain a known injected signal through the complete path and repeat with an independent receiver oscillator. A line that vanishes

Copyright 2026, James M. Atkinson

under one setup does not prove it was not a real emission; loss of sensitivity and changed preselection must be ruled out.

Radio interferometry offers a useful caution about the origin of apparently correlated signals. Two receivers can display coherent structure because they observe the same electromagnetic field, but they can also share contamination introduced after the antennas. The common reference is part of the receiving instrument, so its phase disturbances can propagate into the complex voltages used to estimate sky-like or terrestrial signals. Suppose receiver i employs a local oscillator fi with instantaneous phase φi(t). A signal mixed by that oscillator acquires a phase term associated with φi, the sign depending on whether the upper or lower mixing product is selected. If several receivers derive fi from one reference, their impairments need not be statistically independent. Correlation between outputs is then evidence of commonality, not necessarily evidence of radiation from a common place in the external environment.

A useful discriminant is architectural perturbation with calibrated sensitivity controls. Terminate an antenna input in a characterised impedance to test whether the suspect component survives in the receiver without external RF. Then inject a known signal near the frequency of interest to verify that the changed arrangement still detects genuine inputs. Change the local-oscillator tuning in a planned way: a physical RF carrier remains at its absolute received frequency, while internal spurs and mixing products may track the conversion plan. Yet some internally derived tones may remain fixed after digital re-mapping, and a real modulated emission may also produce several apparent products. Therefore no single frequency-plan

Copyright 2026, James M. Atkinson

change is infallible. A collection of interventions with distinct predicted signatures is more informative than a spectacular waterfall image.

Path delay can contribute another distinction. If an external wavefront reaches separated antennas, geometric delay varies with sensor position and source direction. A distribution-network spur generally enters after the antenna and need not obey the same spatial delay law. In principle one may compare relative phase across sufficiently separated sensors while varying position and orientation. In practice the experiment requires independent calibration of cable delay, antenna phase centre, common clocks and sensor motion. A close transmitter may produce near-field geometry rather than the plane-wave approximation. Reflections from walls, cable re-radiation, and common-mode currents can also produce misleading phase relations. A spatial localisation claim must explain why such instrumental paths were excluded or bounded.

I would organise the evidence into a two-axis matrix. On one axis place the suspect feature under antenna, matched-load and calibrated-injection conditions. On the other place the feature under common-clock, alternate-clock, direct-oscillator and suspect-distribution configurations. An external emission should ordinarily depend on the antenna path, whilst a reference spur should often follow the clock path, but hybrid cases exist. A strong external carrier can also undergo reciprocal mixing with reference-related phase noise, and that process is neither purely external nor purely instrumental. The correct classification may therefore be a compound mechanism requiring both environmental radiation and a defective receiver reference. A binary choice between 'bug' and 'instrument fault' can be scientifically false.

Copyright 2026, James M. Atkinson

Finally, preserve temporal and geometrical context. A sideband at one observation time can disappear when a relay switches, when a cable warms, or when a nearby appliance changes duty cycle. Synchronise raw measurements to an independently evaluated time base, retain the complete unedited record around each event and describe the spatial configuration of antennas and reference cables. In a multi-instrument forensic survey, a conclusion is strengthened when the same phenomenon survives distinct receiver architectures and independently clocked cross-checks, not merely when identical displays show an aesthetically convincing line. When the tests remain ambiguous the report should state what was measured, what was changed, and what additional experiment would be necessary to distinguish the surviving explanations.

The spatial argument must also account for phase wrapping. A geometric delay τ produces a phase change of $2\pi f\tau$ at frequency f, but the measured angle is normally known only modulo 2π without additional bandwidth or unwrapping information. Thus several source directions or cable-delay errors may fit the same single-frequency phase observation. An array measurement should employ sufficiently separated frequencies, known baselines or controlled antenna displacement to resolve such ambiguities. External multipath may alter amplitude and phase faster than anticipated as an antenna is moved through a room. Compare the observations with an explicit uncertainty model before displaying a localisation ellipse as though it were a certified geographical fact.

William Redington Hewlett, Cross-Peer Question to Martin Ryle: If reference substitution changes both the spur and the receiver gain, which observation can still help distinguish instrument artefact from an external carrier?

Copyright 2026, James M. Atkinson

Sir Martin, suppose replacing the common 10 MHz source with an independent reference causes the suspect line to disappear, but the same substitution changes the receiver's synthesis path and gain by an appreciable amount. The observations then contain a confound: an internal artefact may have been removed, yet an external narrow carrier may simply have fallen beneath the modified sensitivity. What combination of calibrated injection, antenna termination and local-oscillator offset trials would distinguish those alternatives? Would you require the suspected line to exhibit a physically plausible spatial delay across independently clocked receivers before calling it external? Please also address the hybrid case in which an external strong carrier and an impaired internal oscillator jointly produce the observed spur through reciprocal mixing.

Martin Ryle, Cross-Peer Answer to William Redington Hewlett: Use calibrated signal injection before and after substitution to measure the changed sensitivity and frequency transfer. Compare the suspected line against the local test signal under identical settings and retain the raw spectra. If the internal reference spur follows the oscillator but the external calibration remains correctly positioned, that differentiates mechanisms. The result is conditional on calibration and valid operation, not on a single disappearance.

The reference substitution has probative value only when the receiver's changed response has been measured. Inject a known signal at or near the suspect RF frequency, using a calibration method that does not alter the relevant signal path more than is necessary, and determine sensitivity, gain and frequency transfer under each reference configuration. Then repeat with a properly characterised antenna termination and compare what

Copyright 2026, James M. Atkinson

remains. If the suspicious component disappears but an equally weak calibrated signal remains visible with an adequate margin, a mere loss of sensitivity is less persuasive. It does not become impossible, since the two signals may have different temporal or modulation properties. The correct result is a strengthened comparison, not an absolute verdict.

A spatial phase test is attractive where antenna geometry and signal coherence permit it. Record known sensor coordinates, independent timebase quality, cable delay and synchronisation uncertainty, and assess whether observed phase differences change in a manner consistent with the hypothesised wavefront. Near-field and multipath effects must be modelled. If a line is generated by a shared reference distributed after the antenna, it may show common phase without the geometric trend of an external source. Yet an external timing service or common power contamination can invalidate supposed independence. The hybrid case deserves its own hypothesis: a strong off-channel transmitter can undergo reciprocal mixing with a phase-noisy local oscillator, producing apparently weaker in-band energy. In that event antenna termination removes one necessary cause, while reference replacement removes another. The evidence would show a compound process rather than fitting the binary choice 'external signal' versus 'instrumental spur'. The report should retain both causal factors and explain the tests that isolated them.

As an independent corroboration, change the antenna location whilst leaving the reference cabling fixed, then change the cabling whilst the antenna remains stationary. Those two contrasts should be documented with repeated calibration injections, because repositioning anything inside a crowded survey environment can affect shielding, coupling and receiver

Copyright 2026, James M. Atkinson

loading. A valid comparison states which geometry was altered and which was held constant, rather than simply asserting that the line 'moved' or 'disappeared'.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has established that carrier-adjacent energy must be traced through the physical reference chain, the distribution apparatus and the measuring instrument before its cause is assigned. Oscillator noise, additive branch noise, supply modulation, output loading and instrument-floor limitations can produce overlapping spectral appearances. Appropriate controls include measurements at input and output reference planes, differential residual phase assessment, safe supply perturbation, branch exchange, independent timebase comparison and software-provenance retention. Correlated sidebands among receivers sharing one source may reveal dependence, not three independent external observations. Every numerical example above is hypothetical and every historical exchange is a modern educational reconstruction.

QUESTION 059

Copyright 2026, James M. Atkinson

When Is a Spectrum Analyser Timebase Adequate for Multistation Arrival-Time Localisation?

SCHOLARLY RECONSTRUCTION. The following dialogue is fictional pedagogical exposition using deceased specialists. It is not a historical transcript. Contemporary instruments, satellite timing, digital sampling and forensic applications are editorial extrapolations from documented scientific principles.

Dr. James M. Atkinson, Moderator: Professor Bracewell, a multistation RF survey records a short burst at three or more geographically separated locations. Each station displays a spectral peak and declares itself synchronised to a reference clock. An analyst then treats the peak's displayed time as the instant the burst arrived, constructs time differences between stations and solves for its possible source position. Under what conditions does a spectrum analyser provide a legitimate arrival-time measurement, and when does its apparent time resolution merely describe a display, a sweep, or a detector rather than the electromagnetic event?

Ronald N. Bracewell, Principal Contributor: Dr. Atkinson, the first duty is to define the observable. The arrival time of a particular identifiable signal feature at a stated antenna reference plane is not automatically the time at which a spectral display records a maximum. Swept analysers inspect different frequencies at different moments. Their trace may be completed only after a sweep, and a detector can combine or compress multiple samples within a display bin. A display timestamp might represent the sweep start, the host's receipt of a completed trace, or an instrument-defined trigger event. Those are distinct quantities. Only a verified

Copyright 2026, James M. Atkinson

acquisition path connecting an identifiable waveform feature to a calibrated hardware timebase may support a time-difference-of-arrival inference.

Consider an emitter at unknown position x and receiver station i at known position r_i. In a simplified free-space model the arrival time is $t_i=t_0+||x-r_i||/c+b_i+e_i$, where t_0 is emission time, c is propagation speed, b_i is a station-specific timing bias and e_i encompasses random measurement error and unmodelled effects. Subtracting the arrival equations for receivers i and j eliminates the unknown emission time but leaves $\Delta t_{ij}=(||x-r_i||-||x-r_j||)/c+(b_i-b_j)+(e_i-e_j)$. A timebase may be highly stable while an uncalibrated constant bias remains. Synchronisation of frequency alone establishes neither the value nor the uncertainty of b_i-b_j. The inverse problem relies upon the difference, not upon the prestige or precision of an individual clock certificate.

For the scale of the inference, a differential timing bias of one microsecond corresponds to approximately 300 metres of light-travel path difference in free space. Ten nanoseconds correspond to approximately three metres of path difference. These are path-length equivalents, not guaranteed coordinate-error bounds. Geometric dilution can make position error much larger, particularly when stations lie on an unfavourable baseline or the signal approaches from a direction that yields weak sensitivity in one coordinate. Conversely the solver may conceal a timing bias in an apparently plausible position. A quantitative report must propagate uncertainty through the actual station geometry and the adopted propagation model, not simply multiply every quoted timing standard deviation by c and call the result localisation accuracy.

Copyright 2026, James M. Atkinson

In two dimensions, a single independent time difference constrains a hyperbola in an ideal propagation model. More station measurements provide additional constraints, but the count of receivers alone does not establish a unique or well-conditioned solution. The Jacobian of the predicted differences with respect to source position determines local sensitivity; nearly dependent rows signal poor geometry. Additional nuisance parameters may include station clock offsets, path delay, instrument trigger delay and transmitter-feature ambiguity. A least-squares location produced under incorrect assumptions can have a small algebraic residual and still be physically wrong. Residual magnitude is evidence about consistency with the assumed model, not independent proof of the model's correctness.

A spectrum analyser's architecture becomes decisive. A swept-tuned instrument may report a burst's energy at the time the swept passband happened to overlap its frequency. Even if its sweep period is accurately referenced, the instrument has not necessarily recorded the waveform's onset at the antenna. A real-time spectrum analyser or an SDR with continuous I/Q storage can offer an acquisition record suitable for retrospective time tagging, but that capability depends on trigger placement, buffer continuity, time-stamp origin, channelisation delay, ADC clock mapping and the availability of raw samples. The words 'real-time' are not a metrological specification. An examiner should identify the actual hardware event from which the timestamp is formed.

Group delay is another latent term. A narrow filter can delay the envelope of a burst; a digital finite-impulse-response filter may introduce a calculable delay, while variable decimation or signal-dependent threshold crossing can

Copyright 2026, James M. Atkinson

change the detected onset. Antenna cables, splitters, preamplifiers, frequency converters and fibre or network transports add further latency. Some delays are stable and correctable, others depend on operating mode or temperature, and some vary with signal bandwidth and amplitude. Calibration must match the relevant signal feature and settings, not only the carrier frequency. An apparently synchronised counter can coexist with a badly characterised analogue path.

A worked laboratory case illustrates the distinction. Suppose a calibration transmitter at a surveyed known location sends a permitted 20 MHz-wide reference burst that is captured by three stations with continuous hardware sample counters. The predicted differential propagation time between two stations, given their positions and a declared effective propagation speed, is 2.4 microseconds. If the observed difference is 2.7 microseconds, a residual 0.3 microsecond represents roughly 90 metres of path-difference equivalent. That residual may involve channel delay, clock bias, propagation or feature-picking error; it does not identify which. Repeat the experiment with a second known position, exchange receiver chains between stations, and alter the timebase of one laboratory receiver by a traceable controlled amount. A correct causal model should predict how the measured differences change under each intervention.

The experiment must also confront reference dependency. Two analysers disciplined by the same distribution system may acquire correlated timing errors. If a shared reference change shifts both identically, a particular station pair can exhibit reassuring differential stability while their absolute time labels move. If a path-specific reference interruption affects only one station, a differential anomaly may resemble a change in arrival geometry.

Copyright 2026, James M. Atkinson

Independently monitored downstream sample-edge timing is therefore preferable to unverified lock indicators. A second receiver using a genuinely independent clock and path can challenge the synchronisation assumption, but its comparison must account for its own calibrated signal path.

Cross-correlation of wideband waveforms can estimate relative delay from the measured signal structure rather than using a spectrum-trace peak. This is ordinarily more suitable when the waveform has adequate bandwidth, signal-to-noise ratio and identifiable shared features. Yet correlation functions can show multiple peaks because of multipath, repeated symbols, ambiguous modulation or mismatched channel responses. Interpolation between digital samples may improve the precision of estimating a correlation peak under a valid signal model; it does not create independently observed high-frequency information or remove a wrong clock calibration. Preserve the raw acquisition and report peak-selection rules, sampling uncertainties and the possibility of alternative delay hypotheses.

The error covariance deserves explicit treatment. Let the vector of measured time differences be z and its model predictions $h(x)$. The weighted residual statistic $(z-h(x))^T R^{-1}(z-h(x))$ requires a defensible covariance matrix R. Differences sharing a station are correlated even if the original station timing errors are independent; for example, Δt_{21} and Δt_{31} both contain the error from station 1. Treating them as independent may overstate the information in the network. A common timing service or propagation disturbance introduces further covariance. Where R is inadequately known, sensitivity and bounded-error analyses may be more defensible than impressive but unvalidated confidence ellipses.

Copyright 2026, James M. Atkinson

A sound acceptance test therefore uses surveyed stations, a known waveform and a known emitter, measured system delays and reference sources, challenges of each station's timebase and acquisition path, and enough geometrically distinct test locations to expose systematic errors. The team should reconstruct the position while blinded to at least some known test coordinates, compare predicted and measured arrival differences, preserve all failed detections and state the limits under which localisation passed. Under adverse conditions, the proper conclusion may be a locus, a broad region, or the finding that attribution is not supportable. Metrology is not improved by inventing a precise location where the timing evidence does not justify one.

Dr. James M. Atkinson, Moderator: Professor Gabor, why does the choice between a swept display and a continuously retained waveform matter for the instant assigned to a burst?

Dennis Gabor, Peer Question: Professor Bracewell, an analyst observes a short pulse on an analyser's spectrogram and marks the centre of a coloured feature as the signal's arrival. But a windowed frequency estimate is built from a finite span of samples and its visible peak may depend upon window shape, filtering and averaging. How should the display's time-frequency resolution be distinguished from the accuracy of the physical event timestamp, and what experiment would reveal whether the chosen feature migrates when the analysis window changes?

I would also ask that the panel examine the mathematical cost of placing a time label at the centre of the transform window rather than at its leading edge. If the same transient is captured with different window widths at separate stations, are the assigned coordinates comparable merely because

Copyright 2026, James M. Atkinson

the software uses the same definition of a frame? What happens when the burst contains a chirp or a delayed echo that shifts the location of the largest spectral tile? I invite a test in which identical immutable input samples are rendered under several window conventions, and ask which observable should remain invariant before any time difference is accepted for localisation.

Ronald N. Bracewell, Response: Professor Gabor, a spectrogram time coordinate is an assigned coordinate for an analysis window, not necessarily the onset of physical reception. The instrument or software may label the centre, beginning or end of the window. A short burst passing through a long window will influence several neighbouring tiles, and the maximum tile can shift when the hop size or window function changes. Retain the underlying complex samples and define an arrival estimator independent of display colour. Inject a known reference pulse at a calibrated input, repeat the analysis with several window lengths and hop sizes, and measure the bias and dispersion of the estimator relative to the observed hardware capture edge. For time-difference localisation, each station must use compatible feature definitions or have calibrated estimator-specific delays. A beautiful common spectrogram is not a common timestamp standard.

The raw waveform should supply a declared arrival estimator; the spectrogram should serve as a diagnostic of whether the estimator remains appropriate. If one station labels the start of a 2-millisecond window and another labels its centre, an otherwise identical transient can acquire a one-millisecond nominal displacement solely through metadata convention. This is extreme but clarifying. Even when both label window centres, the hop position, threshold and signal-to-noise ratio can move the selected

Copyright 2026, James M. Atkinson

maximum. The analyst should therefore rerun the exact same capture using several windows and record the observed shift in the inferred delay, not merely admire the agreement among colourful plots. The experiment should use a known marker before and after the signal chain, with delay correction traceable to that marker. For a wideband coded pulse, direct cross-correlation of retained complex samples may offer better localisation sensitivity than a coloured time-frequency maximum. But a chirp, strong echo or cycle ambiguity can create multiple correlation peaks, and the method still needs a predeclared peak-selection rule. The evidence should include the width and height of the competing peaks, their stability under signal-level and window changes, and whether the physically earliest feature is actually visible. Only after these controls can the time stamp be treated as an estimate of a specified arrival feature rather than a convention associated with rendering. The analyst must additionally record dropped samples and the effective analogue and digital group delays. Changes of processing window made after seeing a location solution should be documented as exploratory sensitivity analysis, never silently substituted as the original result.

Dr. James M. Atkinson, Moderator: Dr. Dijkstra, what metadata are necessary if a software pipeline is to sustain the evidential claim?

Edsger W. Dijkstra, Peer Question: Professor Bracewell, receiver software may timestamp an I/Q block after decimation, order packets by host arrival, quietly interpolate a missing block or update a clock-conversion table after the original capture. The final file may appear internally consistent although its event chronology depends on undocumented repairs. Which invariants and source records should be preserved so that a later reviewer can

Copyright 2026, James M. Atkinson

distinguish physical capture time from subsequent processing and identify the precise origin of a disputed timestamp?

The software may also alter a sample stream without writing a conspicuous error: a resampler may generate a replacement sample, an acquisition library may restart its index at zero after a device reset, and a host might apply the latest clock calibration retroactively to an earlier event. Would you insist upon a sequence-number invariant, an unmodified hardware-counter record and a reversible, versioned timestamp transformation? How ought one treat packets that arrive out of order, or a capture interval where a driver returns a plausible timestamp but no data-provenance record? I am concerned that a sophisticated post-processing graph can conceal precisely the evidence needed to challenge its original time labels.

Ronald N. Bracewell, Response: Dr. Dijkstra, preserve immutable device counters, raw device timestamps, acquisition configuration, packet sequence, overrun status and every clock mapping applied to the record. Link processed samples to their original index ranges and maintain the effective delay of each filtering or resampling stage. Do not overwrite original timestamps when calibrations improve. A correct processing chain should either preserve sample chronology or explicitly mark each gap, correction or change of epoch. Test the invariant using known pulse sequences under imposed processing load and deliberate clock disturbances. A file that is complete in format but incomplete in samples must reveal the omission. These rules enable another investigator to reconstruct the chronology and test the conclusion without relying upon the first analyst's display or recollection.

Copyright 2026, James M. Atkinson

I would impose three separately verifiable invariants. First, acquisition order must be represented by a device-origin counter or another data item whose generation point is known; a host incrementing a counter after packets arrive does not prove that upstream samples survived. Second, every stored sample interval must retain a reference to its device configuration, clock state, acquisition epoch and any reported overflow or restart. Third, transformation from the device index into external time must be versioned, reversible as far as practical, and never overwrite the raw observation. A late packet can be placed in its correct sequence by its device identifier, but this operation should be recorded rather than used to conceal transport delay. If a gap cannot be reconciled with a trustworthy counter, mark it as a gap and exclude unsupported continuity assertions. A timestamp produced after an undocumented restart may belong to a different epoch even when its numerical value seems plausible. The same problem occurs if a driver resumes a buffer while the hardware oscillator has entered a new phase state. Conduct a controlled challenge: interrupt transport without stopping the ADC, then stop the ADC without interrupting host networking, and observe whether the metadata distinguishes the cases. Follow with an intentional host clock slew and confirm that original counters do not change. Preservation should include raw files, hashes, the event ledger, firmware and driver versions, calibration maps and processing logs. A forensic report can then state precisely which input facts support the arrival estimate, which conversions were applied, and where a later reviewer might disagree. Consistency of a final spreadsheet is not proof that the original stream was continuous.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Rabi, could an apparent between-station delay result from the receiving instruments rather than the radiation field?

Isidor I. Rabi, Peer Question: Professor Bracewell, a common transmitter excites receivers containing different filters, mixers, detectors and trigger algorithms. One station has a strong clean waveform; another has a weaker multipath-corrupted signal that crosses its trigger threshold later. If both report nominally perfect reference-clock lock, does that establish that the measured time difference is a geometric propagation delay? How would a controlled experiment distinguish signal-dependent detection latency from actual path-length differences?

A further difficulty is that two instruments need not agree upon what they call the same physical event. One detects the first threshold crossing, another the maximum of a matched-filter response, and a third an amplitude peak after an automatic-gain-control transient. Even if each device is calibrated in isolation, is it legitimate to subtract these three timestamps? Would you recommend a common electrical reference-plane experiment with an injected, waveform-matched calibration signal, and if so how can the test expose nonlinear, amplitude-dependent timing walk without using hazardous RF levels? Please also discuss the possibility that real multipath produces several honest arrival candidates rather than one canonical event.

Ronald N. Bracewell, Response: Professor Rabi, no. Clock lock controls a particular oscillator relationship; it does not remove different waveform transfer functions or threshold biases. A controlled transmitter at a surveyed known position should drive each receiving chain through both an

Copyright 2026, James M. Atkinson

electrical calibration path and the intended antenna path. Vary amplitude, bandwidth and modulation to reveal whether the detected feature moves with the algorithm or the signal environment. Compare a threshold-onset estimator with a cross-correlation estimator and inspect the full response impulse or group-delay characterisation. Multipath can create physically real additional paths that are not the first arriving path. The report should acknowledge any ambiguity between the earliest detectable component and the strongest peak. A locked clock is necessary for some measurements, but it is insufficient to identify which portion of the incoming radiation the detector chose.

A time difference is only meaningful when the two clocks describe comparable events at their declared reference planes. For an electrical challenge, inject a permitted waveform through a calibrated splitter into both receivers and independently measure the arrival timing at each input. Use the same detector algorithm on the raw outputs, or characterise each detector's distinct offset against the common physical event. Then vary amplitude, bandwidth and noise within safe equipment limits. If the timestamp shifts with amplitude, the effect is estimator timing walk rather than antenna-to-antenna propagation. A constant-fraction trigger may reduce simple amplitude dependence but does not make a distorted or multipath waveform immune to bias. Digital filtering, automatic gain control and saturation require separate tests. Over-the-air calibration at surveyed positions tests propagation and antenna effects, which conducted injection deliberately excludes. Two such calibration classes are complementary; neither makes the other redundant. When a station has a weaker earliest path and a stronger later reflection, the selected maximum may correspond

Copyright 2026, James M. Atkinson

to different path classes at different receivers. A location algorithm that silently treats them as one direct path can produce a convincing but wrong coordinate. Instead preserve the delay-peak alternatives, report which path selection was made and its conditions, and compare positions across frequency, polarisation and station geometry if permitted. I would also require the operator to repeat the field test after changing receiver gain, because a location that moves when only instrument gain is altered exposes an estimator or transfer-function dependency. Only a consistently defined and independently calibrated event should be eligible for microsecond or nanosecond forensic inference.

Dr. James M. Atkinson, Moderator: Professor Essen, how much confidence should an analyst place in the frequency stability of a station timebase?

Louis Essen, Peer Question: Professor Bracewell, a station may claim an excellent long-term stability figure for a disciplined oscillator. A location solution, however, depends upon relative timing over the actual observation interval, which may be milliseconds or seconds. What distinction must be drawn between frequency accuracy, time offset and phase continuity? Could a short reference reacquisition step leave a pleasing stability statistic while introducing a timing bias large enough to move the computed source location materially?

I would like the panel to separate clock accuracy at a particular instant from frequency stability averaged over a much longer period. A disciplined oscillator may remain within a superb specified frequency tolerance and nonetheless experience a time-step correction when the reference is reacquired. A station's one-pulse-per-second input may also have a delay that was never measured at the ADC. How would a challenge test establish

Copyright 2026, James M. Atkinson

continuous sample-edge phase throughout a disputed burst rather than merely confirm a green synchronisation indicator before and after it? What uncertainty would you assign when the physical counter record is present but the external-time mapping was recalculated after the survey?

Ronald N. Bracewell, Response: Professor Essen, long-term frequency performance constrains one part of the clock model, not every time error. A constant time offset remains possible even if the frequency error is nearly zero. A phase or timestamp step can occur at reacquisition and may be hidden in averages that exclude the transition. Characterise the clock over the specific interval of the burst and retain its offset, frequency deviation, phase-error history, holdover state and adjustment commands. Repeat a location calibration with a known event before and after a controlled reference interruption, comparing the downstream hardware sample edge against an independently maintained timing witness. If the offset or continuity is unmeasured, do not infer a small timing uncertainty merely from a published oscillator specification. Treat the affected events as qualified or exclude them from a precision localisation claim.

The phase history of the acquisition edge is the relevant record; a lock-status light is, at best, a summary of one controller's internal decision. A disciplined oscillator's frequency may be excellent while its time offset from an external reference remains material. During holdover, the mapping from sample index to UTC must carry a time-dependent uncertainty, and at reacquisition the firmware may step or slew phase. A downstream phase comparator or calibrated timing marker near the actual sampling input should observe this process during a deliberate and safe reference interruption. Repeat at realistic temperatures and after a restart, because

Copyright 2026, James M. Atkinson

the fault may appear only in a particular controller state. The timebase logs should include reference identity, phase error, frequency correction, epoch, clock switch and sample-counter transitions, with units and timestamps. If an external-time mapping is recalculated retrospectively, preserve the original mapping and the data that justified the revision. The revised estimate is derived evidence, not the unmodified acquisition observation. For a short burst, estimate the relative clock offset at the burst epoch rather than import a stability number measured over unrelated intervals. If uncertainty cannot be bounded across a discontinuity, qualify or exclude the affected delay. This is especially important when several receivers share an upstream reference. A common fault can cancel in a particular difference and yet invalidate the claimed absolute time. Conversely branch-specific phase events can survive subtraction. A trustworthy location report will distinguish stable relative timing, known external-time traceability and continuity through all controller transitions, instead of compressing them into the single adjective synchronised.

Dr. James M. Atkinson, Moderator: Professor Townes, does a common reference between stations eliminate the relevant timing error?

Charles H. Townes, Peer Question: Professor Bracewell, distributing a single oscillator may improve coherence, but different stations can use unequal cable paths, local phase-locked loops and receivers with distinct latency. At the same time a fault in the common source may shift multiple receivers together. Which errors cancel in a time difference, which survive, and what should the investigator measure before accepting that the arrangement supplies independent arrival-time evidence?

Copyright 2026, James M. Atkinson

I ask whether a common oscillator should be treated as a source of independence or merely of coherence. The same reference can drive several frequency converters and sampling systems, while downstream branch filters introduce different delays and control-loop transients. If a common phase jump cancels when two station timestamps are subtracted, the resulting delay may look stable even though their claimed absolute UTC labels were wrong. What controlled substitution would establish the residual branch-dependent errors, and what covariance should enter a location solution when several time differences share one station? I would particularly welcome a distinction between corroborating the arrival waveform and corroborating the time reference itself.

Ronald N. Bracewell, Response: Professor Townes, an exactly common error that enters both measured arrival times with the same magnitude cancels in their difference. A branch-dependent delay, a different local loop transient or a receiver-specific group delay survives. The cancellation is also estimand-specific: good relative timing does not establish absolute UTC event time. Map the reference distribution, measure path delays at the actual receiver inputs, and record downstream sampling-edge relations rather than only the reference source output. Exchange branches and introduce a small authorised laboratory timing perturbation into one branch to determine its effect on the final delay estimate. The observations should support an explicit covariance model. Agreement between several instruments sharing a reference is not independent corroboration of the quality of that reference.

A shared oscillator is often desirable because it allows coherent comparisons. The error lies in calling the resulting time records

Copyright 2026, James M. Atkinson

independent. Suppose each measured timestamp has a common term c and a station-specific term e_i, so t_i equals the physical arrival time plus c plus e_i. The difference between two stations cancels c when it truly enters both identically, but retains e_i−e_j. In a real distribution network, the shared phase disturbance can be filtered differently by separate synthesiser loops, so even the premise of identical contribution needs testing. Map the clock tree all the way to the sampling edge, measure each cable and fan-out branch, and exchange reference sources or output ports in a controlled laboratory setting. If the anomalous delay follows a port, branch or local receiver rather than the antenna, investigate instrumentation. A different reference of known quality provides another challenge. The covariance of differences matters as well. Using station one as the reference for two differences introduces a common station-one error even if its original error was statistically independent of the other stations. The solver should therefore use a covariance matrix containing that shared variance. Separate the question of whether the same RF event was seen at multiple antennas from whether its time tags were generated by independent clocks. Independent corroboration of the radiation field does not require independent clocks, but an absolute event-time claim requires an independently defendable timing reference and propagation model. I would not allow a common-clock array to be represented as several independent confirmations of the clock's own reliability. Such a conclusion would confuse engineered coherence with statistical independence.

Dr. James M. Atkinson, Moderator: Mr. Harrison, what physical defects might alter a nominally calibrated timing chain?

Copyright 2026, James M. Atkinson

John Harrison, Peer Question: Professor Bracewell, the timing standard may be of high quality at the source, yet its signal travels through cables, connectors, amplifiers and switching devices before reaching the analyser. Temperature, mechanical motion and ageing can alter electrical path length. A calibration performed in a quiet laboratory months earlier may therefore differ from one during a field survey. Which tests would identify the drift of delivered timing, and what evidence would justify transferring a laboratory delay calibration into the operational installation?

It is easy to trust a standard at the cabinet where it was calibrated and overlook what happens after the signal passes through long cables, connectors and distribution amplifiers. During a field deployment, thermal expansion or a badly seated connector may change electrical delay without generating an obvious reference alarm. How should the laboratory reproduce the mechanical and thermal conditions of the installed system, and how can a branch-swap trial distinguish cable effects from receiver electronics? Please address the danger of transferring a calibration performed with one load, termination and routing arrangement to a different field installation as though nothing material had changed.

Ronald N. Bracewell, Response: Mr. Harrison, every calibration belongs to a configuration and operating range. Record the cable types, lengths, reference ports, termination, temperature and connection history, then measure delay or phase at the point of use under representative conditions. Periodic comparison against an independent reference can reveal drift, while exchanging cable branches helps locate path-specific anomalies. A calibration transferred to the field is persuasive only where the relevant configuration and environmental bounds are maintained or the difference

Copyright 2026, James M. Atkinson

has been measured and included as uncertainty. One should not treat a reference path as immutable merely because it contains no software. A loose connector or altered length can be as consequential to time-difference evidence as a clock algorithm.

The time standard must be evaluated where it is used, not only where it is generated. A stable source feeding a cable of changing electrical length can exhibit a delivered phase change that the source's own monitor does not see. Record the cable, connector and distribution topology, terminations, loading, temperature and mechanical routing before the survey. Compare input and output phase against an independent witness while varying temperature across the operating range, and repeat after a careful reconnect. The field chain may contain multiple converters, each with its own group delay and switching behaviour. A branch-swap test can reveal whether a problem follows the receiver, the cable or the reference port; however, the act of swapping also changes connector seating and mechanical stress, so one trial is insufficient. Repeat a predeclared sequence with controls and document the results. Ensure the calibration stimulus matches the frequency band and detector used in the actual event analysis. A calibration for a one-kilohertz tone does not automatically measure the group delay of a twenty-megahertz pulse. At the conclusion of deployment, repeat the timing check in the actual installed configuration. If an uncontrolled thermal cycle or maintenance event occurred during collection, describe the possible effect and whether the calibration still applies. Long cables should be treated as physical components with measurable uncertainty, not as mathematically zero-delay arrows drawn on a diagram. A

Copyright 2026, James M. Atkinson

meticulous installation record can prevent an erroneous emitter location just as effectively as an elaborate post-processing algorithm.

Dr. James M. Atkinson, Moderator: Lord Kelvin, how should geometry enter the uncertainty statement?

William Thomson, Baron Kelvin, Peer Question: Professor Bracewell, an investigator may quote a ten-nanosecond arrival-time uncertainty and transform it directly into a three-metre position accuracy claim. Yet the source position is inferred from several path-length differences whose sensitivity varies with station geometry, error covariance and perhaps propagation uncertainty. How should the report distinguish a physical path-difference scale from an actual coordinate uncertainty, and how should an ill-conditioned array be described?

The quoted ten-nanosecond figure might represent only one estimator's random repeatability. The actual location uncertainty depends on station geometry, delay correlations, receiver group delays and the probability of choosing a reflected rather than direct path. Would you explain which matrix or sensitivity calculation turns observed delay covariance into a spatial region, and under what conditions that calculation becomes ill-conditioned? I would also ask for an explicit distinction between a three-metre free-space path-difference equivalent and a three-metre error in either east or north coordinates. How should the uncertainty be disclosed when the estimator has two plausible delay peaks corresponding to separate candidate regions?

Ronald N. Bracewell, Response: Lord Kelvin, the three-metre figure is merely c times ten nanoseconds in the ideal free-space model. It is not a coordinate

Copyright 2026, James M. Atkinson

uncertainty without the inverse solution. Construct the Jacobian G of all independent predicted time differences with respect to the unknown coordinates. Under a locally linear, unbiased model and a justified covariance matrix R, the covariance approximation for a weighted least-squares solution is $(G^T R^{-1} G)^{-1}$ when the matrix is nonsingular. Its eigenvalues and directions show which location components are well or poorly determined. If the geometry makes the matrix nearly singular, small timing errors can yield large position changes, and a non-linear confidence region may be preferable to a tidy ellipse. Include station-position errors and systematic delays separately or augment the state where identifiable. Above all, state assumptions: the displayed clock precision does not determine the geographical accuracy of a localisation result.

The ten-nanosecond uncertainty translates into three metres of free-space path-length difference only for the corresponding timing quantity; it is not an independently determined coordinate error. The derivatives of each predicted time difference with respect to east and north position describe how strongly a change in location affects the data. Collect them into a Jacobian G, measured in seconds per metre. With a defensible measurement covariance R, the local information matrix is G-transpose R-inverse G. If this matrix is nearly singular, there is a direction in which considerable location change produces little effect on predicted time differences. That poor geometry cannot be overcome simply by printing more timestamp digits. A confidence region should be computed using the actual nonlinear model when the linear approximation is inadequate, and it should reflect common-clock and shared-station error covariances. When two or more delay peaks are plausible, carry the alternative peak assignments through the solver.

Copyright 2026, James M. Atkinson

They may yield separate viable regions, in which case a single ellipse around the most attractive solution is misleading. Station-coordinate uncertainty, finite propagation-speed modelling and receiver-specific group delay should either be incorporated into the model or disclosed as qualifications. Validation at independently surveyed source locations is indispensable. A useful report gives the raw measured differences, the chosen feature, all corrections, an uncertainty matrix, the station geometry and a statement of what spatial claims are and are not supported. Precision is a property of the whole measurement procedure, not an ornament attached to a clock reading.

Dr. James M. Atkinson, Moderator: Lord Kelvin will now contribute as a distinct principal speaker on the geometry of arrival-time localisation. Professor Bracewell will challenge the interpretation of his proposed uncertainty model.

William Thomson, Baron Kelvin, Second Principal Contributor: Dr. Atkinson, a ten-nanosecond timing claim is a claim about a clock or estimator under specified conditions, not a three-metre guaranteed location. The corresponding free-space path-difference scale is roughly three metres, but the mapping from path differences to source coordinates depends on receiver geometry and shared errors. In a nearly collinear array the inverse problem can be ill-conditioned, and a few nanoseconds of differential bias can move one coordinate vastly farther than a naive path-length argument suggests. The Jacobian and timing covariance must enter a defensible uncertainty statement; errors shared by pairwise differences must not be counted as independent observations. I would test the network against several known emitters at distinct bearings and compare predicted

Copyright 2026, James M. Atkinson

differences to independently observed arrival features. Professor Bracewell may now challenge whether the feature itself is identified consistently.

I propose that the inquiry begin with its measurand rather than its equipment. A station does not measure an abstract point named arrival time. It measures the value of an estimator applied to a particular waveform, conditioned upon a chosen antenna terminal, trigger definition, filtering chain and clock convention. An uncertainty budget that combines numbers from different measurands is incoherent even if every number bears the unit seconds. We might calibrate the arrival of a known envelope edge at a receiver input and later seek the first resolvable multipath component at an antenna aperture. The difference between those two events is not automatically a random error. It is a failure to transfer the calibration to the quantity actually claimed. I would therefore place a written definition of the arrival feature at the beginning of every location experiment, specify how the feature is selected in noisy data, and record its systematic dependence upon amplitude, modulation and path conditions. Repeatability is then measured for a defined procedure, not for a moving target.

Let the vector z contain the observed time differences in seconds, the vector x contain the coordinates of the hypothesised transmitter in metres, and h(x) predict those differences from known station coordinates and an assumed propagation model. For a locally linear approximation at a candidate location x0, write z−h(x0) approximately as G Δx+e, where Δx is the displacement from x0, G is the Jacobian whose entries are derivatives of predicted delay with respect to each position coordinate, and e is the measurement-error vector. Each row of G carries units of seconds per

Copyright 2026, James M. Atkinson

metre. If the covariance R of e is known and positive definite, the formal covariance of an ordinary locally linear weighted least-squares estimate is (G-transpose R-inverse G)-inverse. That is a conditional result. It presumes that the estimator is locally identifiable, that the covariance represents the important dependencies, and that significant systematic delays have already been removed or explicitly modelled. An elegant inverse matrix cannot rescue omitted timebase steps, badly surveyed antennas or an incorrect identification of the first arriving waveform.

Consider two geometric arrangements built from three receivers. In the first, the receivers occupy widely separated non-collinear stations around an intended search area. In the second, all stations lie nearly along a single road with the emitter far beyond one end. For the same nominal standard deviation of measured delays, the second geometry may provide much weaker discrimination of displacement transverse to the line. The normal matrix acquires a small eigenvalue, and uncertainty grows sharply along the corresponding direction. A small residual does not prevent this because many candidate positions yield nearly the same pattern of delays. The practitioner ought to present an uncertainty contour, region or set of admissible positions, with the geometry and probability or bounding interpretation stated. It would be misleading to select the sharpest plot produced by a solver without describing how the array geometry limited the inference. This is particularly important when a regulator, court or protective-security customer may mistake graphical precision for certainty about a particular building or room.

The errors of differences also require care. Suppose each station has an independent time error u_i with variance σ_i squared, and the delays are

Copyright 2026, James M. Atkinson

formed against station one. Then the error of delay 2−1 is u_2-u_1, while that of delay 3−1 is u_3-u_1. Their covariance is the variance of u_1, which is generally positive. This remains true even though the underlying station errors were independent. If all three differences are then weighted as independent, information from station one is counted several times and an optimistic location covariance results. A common reference can introduce further correlations, some of which cancel under ideal differencing and some of which survive as branch-dependent effects. The instrument record should therefore distinguish station-origin errors, shared-reference errors and environmental errors. Model each according to the physical path that produces it, rather than assign arbitrary diagonal uncertainty simply to make a numerical procedure convenient.

There are at least three categories of uncertainty that should not be silently pooled. A stochastic term might be estimated from repeated timing-marker captures under fixed conditions; a bias might be characterised by a measured cable or digital-filter delay and corrected with its uncertainty; and an unresolved alternative path might produce several separated location hypotheses. The third is not necessarily well represented by enlarging a Gaussian standard deviation around one favoured coordinate. A more appropriate disclosure might retain two admissible delay peaks and carry both through to alternative spatial regions. Likewise, a period of clock holdover might require time-dependent bounds rather than one value copied from an equipment certificate. Scientific candour sometimes produces an unattractive map, but the map becomes credible precisely because it does not hide the limits of the evidence.

Copyright 2026, James M. Atkinson

I would approve a precision statement only after a blind challenge. Place or simulate an authorised reference emitter at several surveyed positions chosen to expose weak directions of the array. Run the unchanged processing procedure, including automated peak selection, filtering, timestamp mapping and uncertainty calculation, without informing the analyst of all target positions. Compare the declared confidence regions or deterministic bounds with the actual positions and inspect failures, not merely average error. Repeat with weak signals, deliberate clock perturbations and path obstructions to reveal conditions under which the model ceases to apply. This practice does not replace a formal measurement traceability chain, but it tests the whole inference rather than the isolated clock. I hand the token to Professor Gabor, because it is the creation of a time label from finite spectral data that next deserves scrutiny.

Ronald N. Bracewell, Cross-Peer Question to William Thomson, Baron Kelvin: Lord Kelvin, suppose three stations are precisely surveyed and each receiver reports an attractively narrow timestamp uncertainty, yet the signal is a short multipath-corrupted burst. One station identifies the earliest detectable rise, another the strongest correlation peak and the third the centre of a spectral tile. Do those reported instants even correspond to the same physical feature? Would the covariance calculation remain valid if the dominant error were inconsistent waveform selection rather than the stated clock noise? How should a known-source trial expose the discrepancy?

Let us press the distinction between data residual and validated geographical error. Suppose an array produces nearly zero residuals for several delay differences, but two stations share a clock correction that is not represented in the weighting matrix. The solver may make the residuals

Copyright 2026, James M. Atkinson

even smaller by shifting the source into a region favoured by the mistaken reference assumption. What independent diagnostic would demonstrate that the reported confidence ellipse reflects the underlying experiment rather than only the chosen covariance and a favourable geometry? Could an array's observed calibration results at surveyed locations expose a systematic bias that persists despite a low residual? I would also ask you to address the near-field case, where a plane-wave approximation may be tempting but geometrically unjustified.

William Thomson, Baron Kelvin, Cross-Peer Answer to Ronald N. Bracewell: Professor Bracewell, the model fails at its definition of the measured quantity. Its timing covariance cannot compensate for three stations applying incompatible feature rules. Establish a common arrival estimator or calibrate the state-dependent bias of each method over a representative waveform family. Record raw samples, compare alternative correlation peaks and use test emitters at surveyed positions to assess whether the chosen feature follows the predicted geometric delay. If multipath makes the earliest arrival unresolvable, the result should be an interval or set of candidate loci rather than a single overprecise coordinate. The timing model and the propagation model must be challenged together; a well-conditioned numerical solver cannot repair a misidentified physical event.

I should first insist that the low residual belongs to the fitted model, not to the physical propagation field. A location solver might use a point x that minimises the weighted squared difference between measured and predicted delays, yet if the reference-clock covariance is wrong, the weights are wrong even when the algebra has been executed impeccably. A shared offset that cancels between some station pairs can be invisible to those

Copyright 2026, James M. Atkinson

differences; a branch-dependent error can imitate an additional path-length difference. The correct challenge is to predict measurements for known emitter locations that were not used in fitting the calibration. Compare the resulting position errors with the reported confidence regions and ask whether the claimed coverage holds over the relevant geometry and signal conditions. It is not enough to quote the mean localisation error across favourable tests. Examine the worst cases, rejected events and the station arrangements for which the inverse map is poorly conditioned. To distinguish covariance error from geometry, repeat using independent clock monitoring and physically exchange an instrument between station positions where practicable. If the inferred location follows the receiver rather than the surveyed station, an unmodelled instrument term is implicated. The near-field case adds another model question: the arriving wavefront need not be approximated as planar across a sufficiently large aperture or close emitter. Use the geometric range-difference model appropriate to station separations and source distance, with any antenna phase-centre issues declared. An approximate plane-wave solution may be a useful initial guess, but it should not be reported as a validated coordinate unless its approximation error is bounded. A confidence region should be conditioned upon the waveform, clock state, propagation model and array geometry tested; otherwise it is a formal mathematical object with uncertain physical meaning.

Ronald N. Bracewell, Supplementary Commentary to Lord Kelvin: The distinction is decisive. It is the arrival of a specified waveform feature at a declared reference plane that must be measured. A spectrum analyser

Copyright 2026, James M. Atkinson

timebase is only one component of that observation, and a cross-station solution is no stronger than its least justified waveform-timing assumption.

Dr. James M. Atkinson, Moderator: Professor Gabor, I invite you to examine the timestamp implicit in a spectrogram window. Professor Bracewell will challenge whether that display feature supports an arrival-time difference.

Dennis Gabor, Third Principal Contributor: A spectrogram is a representation formed from finite analysis windows, whereas an arrival-time claim refers to an identifiable physical feature of a waveform. A burst may influence several spectral tiles and a maximum tile can move with window length and overlap. I would preserve original complex samples and compare event pickers with known arrival markers injected at a defined input plane. Different stations must measure the same feature or correct for their differing response delays.

The decisive difficulty in time-frequency analysis is that the timestamp on a spectrogram tile is a convention attached to a window of observations. Let $x(t)$ denote a measured complex waveform, $w(t)$ an analysis window, τ the window's nominal time coordinate, and f an analysis frequency. The short-time Fourier transform is $X(\tau,f)=\int x(t)w^*(t-\tau)\exp(-j2\pi ft)dt$. This expression uses an integral over a neighbourhood of τ, not an ideal measurement at a singular instant. Even in a digital implementation, where the integral becomes a sum across sample indices, the result depends on the window support, its centring convention and the effective filter response. A spectral peak therefore inherits a temporal footprint. A reviewer who reads the label of the tile as the arrival of the first electromagnetic energy has imported an assumption the transform itself does not supply. The distinction is visible

Copyright 2026, James M. Atkinson

even for a noiseless artificial burst: move the analysis-window origin by half a hop, and the brightest tile may be assigned a different time without any change in the underlying event.

A familiar trade-off follows from finite observation duration. A long analysis window offers finer nominal frequency discrimination and may assist detection of a nearly constant narrow carrier. It also spreads the influence of a brief onset over a larger time neighbourhood. A short window confines the burst more tightly in time while producing broader spectral energy, so that weak adjacent emissions may become difficult to distinguish. Neither trade-off constitutes a universal uncertainty product that can be applied to arbitrary estimators without checking window definition, sampling, signal model and threshold. A chirp whose instantaneous frequency traverses several bins during the window can displace the maximum away from the physical onset. A multi-component waveform may furnish several plausible ridges. The question for arrival localisation is not which picture looks sharpest, but which feature is sufficiently invariant between stations that a relative delay can be estimated and validated.

It is advantageous to separate three possible estimands. One is the earliest detectable departure from noise, typically sensitive to threshold and false-alarm policy. Another is the time of a selected amplitude maximum, often biased by fading and group delay. A third is the relative alignment that maximises a correlation between two known or observed waveform segments. Cross-correlation can exploit the modulation over a broad bandwidth and may have smaller variance than onset thresholding in favourable conditions, but this need not identify the first physical path. A strong delayed reflection may dominate the correlation maximum while a

Copyright 2026, James M. Atkinson

weaker direct wave arrives first. The analyst must therefore record whether the location solution is based on earliest-path delay, strongest-feature delay or composite waveform alignment. Switching among these definitions after looking at the answer invites selection bias and can move the estimated emitter across a material boundary.

For a quantitative illustration, take a sampled waveform with sampling rate f_s equal to 20 million complex samples per second. The nominal spacing between adjacent samples is $1/f_s$, or 50 nanoseconds. Multiplying by the speed of light gives approximately 15 metres of path-length equivalent for one interval. A fitted correlation maximum may be estimated at a fractional-sample position, so the 50-nanosecond spacing is not a universal lower bound on timing estimation precision. Yet interpolation creates no missing bandwidth, and the variance and bias of that estimate still depend upon signal structure, signal-to-noise ratio, phase coherence, clock error and multipath. The estimate might be much better than a sample interval under a clean known-waveform experiment or much worse under weak distorted reception. Precision must be shown by repeated calibration and a signal-specific model, not by asserting a clever interpolator's nominal resolution.

I would test an algorithm with a collection of controlled waveforms rather than one convenient pulse. Include a narrowband burst, a wideband coded sequence, a swept-frequency event and a two-path signal with adjustable relative amplitude and delay. Inject them at a measured electrical reference plane and preserve the source timing independently. Vary receiver signal level and filter bandwidth while keeping the reference feature definition fixed. The resulting bias curve, plotted against conditions, will expose whether the estimator's selected time follows the physical input or changes

Copyright 2026, James M. Atkinson

with spectral emphasis. Reprocess the same immutable samples with altered window sizes and hop intervals; any migration of the inferred arrival time is an analysis dependency that must be included in the uncertainty or excluded by a justified fixed configuration. A second laboratory should be able to reproduce the challenge without knowing the desired location answer.

A special danger lies in animations and continuously refreshed displays. The human eye sees the waterfall as a continuous theatre of motion, yet the underlying system may decimate data, retain only selected events or draw smoothly across time gaps. A coloured patch that appears to arrive simultaneously at three stations is not a substitute for the three sample-index records and their verified clock mappings. I would require the report to state the acquisition duty cycle, time-stamp origin, transform window, overlap, smoothing, trigger algorithm and retained raw-data coverage. The resulting documentation may be less elegant than a single colourful image, but it allows the inference to be examined. The discussion now properly passes to Professor Essen, because the reference clock itself determines how time-frequency features at separate stations can be compared.

Ronald N. Bracewell, Cross-Peer Question to Dennis Gabor: Can a set of spectrogram tiles with apparently simultaneous maxima across stations supply an adequate time-difference estimate for a short broadband burst? In addition, I would require the selected feature to be predeclared before the field record is inspected; otherwise a retrospectively chosen window invites biased localisation.

Copyright 2026, James M. Atkinson

I have a more precise concern about the peak chosen for localisation. A real-time analyser may label each frequency-time tile with millisecond or microsecond precision, although the analysed window spans far more time than the printed digits suggest. If a burst contains a direct signal and a delayed echo, changing window length or overlap can alter which tile becomes brightest. Can you identify an arrival estimator whose definition remains stable across such changes, or explain how the changes should enter the timing uncertainty? How should one check whether a chirp's moving frequency and a receiver's time-varying filter shift the plotted peak for reasons unrelated to physical propagation time?

Dennis Gabor, Cross-Peer Answer to Ronald N. Bracewell: Not without verifying the time coordinate assigned to each tile, the window placement, and the response of each instrument. Analyse the underlying waveform directly and establish the relation between a chosen correlation feature and the physical arrival. A shared processing convention can reproduce an error in every station. Calibrate with a known emitter and vary window configuration to quantify the possible bias.

The timestamp for a tile is a property of the windowing scheme. The earliest arrival of a specified waveform feature, by contrast, must be defined against the underlying samples and an electrical reference-plane calibration. When a spectrogram uses a window of N samples and a hop of H samples, the displayed tile time may refer to its first, centre or last sample; merely altering that convention shifts its label by a fraction of N/f_s even though no incident radiation changes. To test invariance, apply the same raw waveform to several documented window lengths, hop sizes and spectral thresholds. The feature that is eligible for a TDOA estimate should either remain stable

Copyright 2026, James M. Atkinson

within a stated tolerance or carry a measured processing-dependent bias into the uncertainty budget. A chirp can distribute energy over successive bins; one frequency tile may brighten earlier than another simply because its centre frequency is crossed at a different moment. Accordingly the maximum tile is not a universal onset. In a multipath environment, a later stronger path can dominate the short-time spectrum while the earlier direct component is weak. If the analysis objective is first-path timing, retain a model capable of detecting that component and report when the signal-to-noise ratio is insufficient to establish it. If the objective is strongest-path correlation, name it as such and use a propagation model reflecting that choice. A reproducible inference should preserve the exact estimator code, filter coefficients, sampling clock calibration, peak-selection thresholds and alternative candidate peaks. Vary the settings only as a documented sensitivity study, not to select retrospectively the location that best fits a preferred narrative. Spectral displays are invaluable for diagnosis, but the physical arrival claim must rest on a separately validated observation of a common signal feature.

Dr. James M. Atkinson, Moderator: Professor Essen, the problem now turns to clock continuity during the precise observation interval. Lord Kelvin will test whether a stability summary can justify the proposed uncertainty.

Louis Essen, Fourth Principal Contributor: A highly stable oscillator may still carry a time offset or experience a phase step at reference reacquisition. A localisation inference depends on the relative state of the station clocks during the actual burst. The engineer should observe each downstream sample-edge timing relationship to an independent reference, not merely

Copyright 2026, James M. Atkinson

rely on the oscillator’s long-term frequency-stability figure. A shared timing service creates common dependencies that need covariance treatment.

A frequency reference and an event-time reference perform related but distinct tasks. Frequency stability concerns the rate at which clock phase changes; synchronisation for arrival-time measurement concerns the offset and continuity of the clock's actual time tags across stations. A system can possess a superb short-term frequency standard and nevertheless have a fixed time offset from the system with which it is compared. It can also be disciplined to a reference and then suffer an unrecorded step when the disciplining source is lost and recovered. An equipment specification expressed only as parts in ten to the minus twelve, or as an Allan deviation at a selected averaging time, cannot certify a ten-nanosecond coincidence claim without an event-specific timing calibration. The operator must observe the clock state over the exact capture interval, particularly near holdover transitions, reference switching and software restarts.

Let $x_i(t)$ be the time error in seconds of station i against a common declared timescale and $y_i(t)=dx_i/dt$ be its fractional-frequency error wherever the derivative is meaningful. Over an observation interval of length T, a nearly constant frequency error y produces an accumulated timing error approximately yT. At y equal to two parts per million and T equal to ten seconds, that accumulation is 20 microseconds, corresponding to about six kilometres of light-travel distance. This is an intentionally exaggerated hypothetical oscillator error, not a specification for an actual metrology installation. The calculation illustrates why one must distinguish a measured oscillator rate error from the elapsed interval over which its correction is applied. A frequency error of ten parts per billion over ten seconds instead

Copyright 2026, James M. Atkinson

yields 100 nanoseconds, already approximately 30 metres of path-difference equivalent. Constant calibration offsets and discrete jumps are separate terms, not captured by the continuous drift calculation.

A useful hardware arrangement gives each sample stream an immutable counter and supplies a traceable mapping from counter value to an externally measured reference event. A pulse-per-second reference can mark an epoch, but the timing of the pulse at the actual receiver input and the uncertainty of synchronising it to the ADC sampling edges must be measured. Cable delay and jitter matter. A station can record a recognised satellite timing signal and still mislabel samples if its driver interpolates between pulses using an oscillator that slipped or if a buffer was restarted without a corresponding discontinuity marker. The metrology belongs to the full path from reference arrival to sample edge and stored timestamp. The words 'GPS locked' or 'network synchronised' are not descriptions of that complete path. One must also distinguish timing from absolute location and recognise that external reference reception itself can be obstructed, disturbed or unavailable.

To establish phase continuity I would place an independent time-interval counter or phase comparator at a point as near as practicable to the acquisition clock. It should record before, during and after controlled interruptions of the disciplining reference. The experiment ought to distinguish an instantaneous clock step from a gradual slew and from a change in the mapping between sample indices and host wall-clock time. A slew may preserve monotonic labels while altering their rate. A step can alter time labels abruptly while the RF samples remain physically uninterrupted. Conversely a sample drop can occur without any recognised

Copyright 2026, James M. Atkinson

clock error. These are distinct fault mechanisms requiring different evidence. Repeat the tests under temperature change and after system restart because drift and reference-state recovery are often dependent on conditions that a single steady laboratory run fails to exercise.

In a distributed array, the reference architecture creates correlated errors. If two stations are driven from the same source through different distribution paths, the source's common component may cancel under subtraction while unequal cable delays and branch-phase perturbations survive. If separate clock sources are disciplined through a shared higher-level network or satellite service, their errors may remain statistically dependent. The uncertainty of $t_i - t_j$ is the sum of the two variances minus twice their covariance; it is not invariably the square root of the sum of two squared independent uncertainties. The examiner should preserve the clock topology, reference-selection records and every change of master source. An apparent agreement among stations cannot verify the shared timing standard when the same defective element supplies their estimates.

I would calibrate a multi-station receiver network by transmitting a permitted known waveform from several surveyed locations while measuring the emission epoch with independently supervised equipment. The calibration should be repeated before and after the field survey and whenever a receiver clock, synthesiser or digital processing configuration changes. Retain a closure record in which time differences around multiple station pairs are compared; an inconsistent closure can reveal a timestamp or estimator fault even before a location is computed. Yet a closed set of differences does not establish absolute event time, for common errors can disappear from all differences. The strongest report is explicit about which

Copyright 2026, James M. Atkinson

quantities were independently measured and which were inferred from a shared clock model. I pass the token to Professor Rabi to consider whether the observed event feature is, in fact, the part of the radiation field we intended to time.

William Thomson, Baron Kelvin, Cross-Peer Question to Louis Essen: If a clock’s Allan deviation is exceptionally small, what additional evidence could establish a valid ten-nanosecond interstation timing uncertainty during a specific short event? Please also distinguish an event whose sample counter is continuous from one whose physical time reference has discontinuously changed; the two cannot be inferred from one status bit.

Suppose the station operator reports an exceptionally small Allan deviation over a thousand-second averaging time. Yet the particular emission lasted only twelve milliseconds, and the hardware had switched references just beforehand. What observation would connect the stability statistic to a time offset at the actual burst epoch, and how would the uncertainty budget represent an unobserved reference step? Please distinguish the continuous frequency-error integral from an instantaneous time discontinuity and address the possibility that host software maps sample indices to UTC by retroactively smoothing a clock correction. Could two clocks agree in their present frequency while retaining different accumulated phases from an earlier interruption?

Louis Essen, Cross-Peer Answer to William Thomson, Baron Kelvin: Direct clock comparisons during the relevant state, calibrated distribution delays and reference continuity are required. Stability statistics do not determine the initial phase offset and may fail to expose an isolated step. Evaluate both

Copyright 2026, James M. Atkinson

station-specific and shared uncertainty terms, then propagate them through the arrival-difference model. The ten-nanosecond claim cannot be inferred from a single stability summary. That evidential distinction is essential: measurement continuity cannot be inferred solely from a restored lock indication, even when the clock rate thereafter appears excellent.

A frequency-stability statistic at one averaging time cannot alone constrain the time offset at a particular epoch. Let $x(t)$ be the station's time error relative to a reference and $y(t)$ its fractional-frequency error wherever differentiable. Over an uninterrupted interval, $x(t_2)-x(t_1)=\int y(t)dt$. This relates phase accumulation to rate error and permits a bound if y is actually observed or bounded over the interval. A discrete step at reacquisition contributes an additional jump that is not recovered by integrating only the smooth rate. The analysis must therefore retain phase-comparator readings, lock-state transitions and any controller command that steps or slews the local clock. If the twelve-millisecond event straddles an unobserved step, a confident timestamp is not warranted simply because the long-term Allan deviation was excellent. The measured sample-index record may remain contiguous while its UTC mapping changes. Host software can generate a smooth revised mapping retrospectively, but that algorithm is a reconstruction whose uncertainty must be justified from independent evidence; it must not silently replace the raw device timestamps. Two clocks can agree in frequency today yet retain quite different accumulated time offsets because of earlier interruptions, cable delays or initial phase settings. The appropriate field test captures a known timing marker before and after the clock transition using an independently maintained reference, and repeats the transition under representative

Copyright 2026, James M. Atkinson

holdover and temperature conditions. Where no independent witness covered the disputed epoch, the report must give a bound or qualification rather than assume the phase was continuous. A common upstream clock does not settle this question if downstream branches can experience different switching or sampling events. It is the observed relation between each station's actual ADC edge and the claimed external time that must be certified.

Dr. James M. Atkinson, Moderator: Professor Rabi, please explain why the detected waveform feature may not be the first physically arriving component. Professor Gabor will question the interpretation of the strongest peak.

Isidor I. Rabi, Fifth Principal Contributor: The arrival feature may be an artefact of the receiver response rather than a direct measure of radiation-path length. A wideband pulse can be delayed or reshaped by filters and threshold detectors; multipath can displace the strongest peak from the earliest arrival. I would calibrate each receiver with a known pulse of appropriate bandwidth and then test it at several amplitudes to expose signal-dependent bias.

A receiver's reported arrival time is influenced by the physical signal and by the apparatus used to select it. A pulse entering a band-limited filter emerges with its envelope reshaped; a narrow filter can ring for a finite interval, and its group delay can vary with frequency. If two receivers use different intermediate-frequency filters or digital decimation chains, the same incident waveform need not generate the same threshold-crossing time. A high-level carrier might also push one front end toward gain

Copyright 2026, James M. Atkinson

compression or activate automatic gain control, altering the envelope and changing which part of the burst triggers the timestamp. These effects are not repaired by disciplining the receivers to an excellent common clock. The measured event must be defined at a physical input plane and then related through an experimentally characterised transfer function to whatever internal point the instrument records.

Consider a known short pulse observed through two causal filters. Suppose receiver A has an effectively flat group delay of one microsecond across the relevant band, while receiver B has three microseconds. If an algorithm timestamps the filtered envelope peak without removing the differing delays, the two estimates show a two-microsecond offset even when both instruments receive the field at the same instant. That offset corresponds to approximately 600 metres of free-space path difference, but the inferred extra distance is entirely instrumental. This is a hypothetical demonstration, not a property of a specific device. A calibration made for a narrow carrier at one frequency may not transfer to a wideband pulse whose energy occupies parts of the filter response with different delays. Therefore the timing calibration must cover the actual waveform class and receiver settings.

The external propagation channel presents an additional selection problem. A direct path can arrive before several reflected paths, but may be weak because of shadowing, antenna polarisation or destructive interference. A stronger later reflection might dominate a correlation peak or energy threshold. The earliest detectable component is not necessarily the earliest physical component, and the strongest component is not necessarily the shortest propagation path. In an indoor or urban security survey, walls, windows, metal structure and moving machinery can change the channel

Copyright 2026, James M. Atkinson

during a measurement. A credible location analysis should test stability across time, antenna geometry, polarisation and frequency where practicable, with lawful passive measurements and authorised calibration sources. If several competing delay peaks remain, preserve them as alternative hypotheses instead of selecting only the one that yields a convenient coordinate.

Signal-to-noise ratio also changes the apparent onset of a burst in threshold detection. When the waveform is strong, an early low-amplitude precursor may cross the criterion; when weak, only the later high-amplitude portion is admitted. A fixed voltage threshold can therefore introduce amplitude-dependent timing walk. Constant-fraction discrimination may reduce some forms of amplitude dependence but is not an automatic cure for multipath, filtering or changing pulse shape. For each receiver, vary injected signal level while holding the source waveform and the physical timing fixed. Plot estimated delay against level and record both bias and dispersion. This response curve can be used to qualify field measurements or to reject claims outside the validated envelope. A high numerical timestamp resolution is of little value if the estimator moves by microseconds as the input amplitude changes.

A robust challenge compares at least two estimators applied to the same immutable I/Q record. One can use a defined correlation template derived from a reference capture; another can examine a predeclared envelope onset criterion. The disagreement is itself diagnostic. Next substitute a stable conducted laboratory path for the antenna, preserving equivalent levels and respecting impedance and equipment safety. If the dispute persists under conducted injection, investigate the receiver transfer function

Copyright 2026, James M. Atkinson

or algorithm. If it emerges only over the air, investigate the propagation and antenna system, while recognising that both mechanisms can coexist. It is essential that the operator retain the raw waveform and all processing settings so that a later examiner can determine whether a claimed location depends on a fragile peak-selection rule.

I would not grant an exact emitter attribution from three tidy time stamps when the signal paths and feature definitions have not been challenged. A logically stronger inference may be the assertion that the observed burst is consistent with several possible source regions under specified path hypotheses. That is neither indecision nor a failure of the instruments. It is an honest recognition that inverse propagation can be ambiguous. The panel can then identify which additional lawful observation, station relocation or independent calibration would resolve the ambiguity most efficiently. Precision becomes persuasive only when the signal event, the receiver and the propagation channel have each been examined rather than collapsed into one number on the screen.

Dennis Gabor, Cross-Peer Question to Isidor I. Rabi: If the earliest physically arriving signal component falls below one receiver’s threshold while a later multipath component is stronger, should the analyst report the later peak as the propagation arrival? Would two calibration waveforms of different bandwidth expose the ambiguity more decisively than repeated processing of one narrowband pulse alone?

Suppose the earliest physically arriving wavefront at one station is strongly attenuated, whilst a delayed reflection is the first component to cross the chosen detection threshold. A second station sees the direct component

Copyright 2026, James M. Atkinson

clearly. If the location algorithm subtracts the two detected onsets, the estimand is no longer the same at the two stations. How could the field investigator distinguish this mixed-path explanation from a genuine timing fault, using lawful changes in antenna polarisation, bandwidth or station geometry? When correlation yields two plausible peaks, what reporting practice would preserve both possibilities without allowing a reviewer to mistake a preferred strong peak for an independently established first arrival?

Isidor I. Rabi, Cross-Peer Answer to Dennis Gabor: Only if it is explicitly called the detected feature and the estimator’s bias and ambiguity are included. The first arriving physical component may be unresolvable with the available sensitivity. Multiple delay hypotheses should be retained where the waveform permits them. A highly precise timestamp for the strongest peak cannot be silently equated with first arrival. Repeated calibrated experiments are needed to establish the proper observable.

The mixed-path hypothesis should be tested by asking which observable changes with propagation geometry and which changes with receiver configuration. A reference-clock fault may affect all waveform components in a station's time record in a characteristic common manner. A propagation change can alter relative path amplitudes, delays and polarisation, causing the selected correlation peak to move between physically different paths. Record the entire complex baseband sequence and its correlation surface, not only the location chosen by a maximum-selection routine. A narrow pulse may resolve multiple peaks if its bandwidth and signal-to-noise ratio support the separation; a narrowband waveform may show an ambiguous periodic correlation structure even when the true direct and reflected paths

Copyright 2026, James M. Atkinson

are present. Changing antenna polarisation or modestly relocating an authorised station may change the path amplitude distribution. If a reported delay jumps when the strongest path changes but independently monitored clock phase remains continuous, the multipath explanation gains weight. Conducted injection of a known waveform through the receiver can separately test whether the timing algorithm and filter produce a similar jump without any outdoor propagation. Neither test should be treated as an absolute discriminator; their joint pattern is more persuasive. If two peaks remain plausible, propagate both delays into separate location hypotheses and describe their relative support without fabricating probabilities. If the earliest wavefront lies below detectability, the statement should be 'earliest resolved component under stated sensitivity' rather than 'first physical arrival'. The report must also record antenna reference planes, phase-centre corrections and frequency-dependent group delays. Otherwise the examiner might confuse an instrumental or channel-dependent feature with a new geographical fact. We should prefer a defensible region of uncertainty to an exquisitely printed but unjustified coordinate.

Dr. James M. Atkinson, Moderator, Closing Synthesis: A spectrum analyser timebase is adequate for multistation arrival-time localisation only as part of a calibrated acquisition and inference chain. The panel distinguishes a spectral display time from a sampled signal's physical arrival, a frequency-stable oscillator from a traceable and phase-continuous event clock, and a time-difference precision from a geographically supportable location. The required evidence comprises raw timing records, known reference planes, quantified receiver and transport delays, controlled reference challenges, a propagation and geometry model, appropriate error covariance and tests

Copyright 2026, James M. Atkinson

against sources at surveyed positions. Where those conditions fail, the proper finding is a bounded delay observation or an indeterminate location, not an invented coordinate. This is a fictional scholarly reconstruction.

QUESTION 060

Copyright 2026, James M. Atkinson

How can oscillator ageing be separated from thermal cycling in long-duration RF surveillance?

HISTORICAL RECONSTRUCTION NOTICE. These exchanges are constructed for modern instruction. The deceased participants never held this discussion; contemporary SDR applications are editorial extrapolations of established scientific principles.

Dr. James M. Atkinson, Moderator: Lord Rayleigh, a frequency reference may appear to drift monotonically during a long RF surveillance deployment, yet its enclosure warms by day, cools by night, and recovers imperfectly after power interruption. How can an investigator distinguish irreversible oscillator ageing from reversible temperature sensitivity, delayed thermal equilibration, and hysteresis? In particular, what experiments, observation intervals and models would justify an evidential claim that the observed drift originated inside the reference rather than in the environment or the measurement apparatus?

John William Strutt, Baron Rayleigh, Principal Contributor: Dr. Atkinson, we must first identify the measured quantity. Let f(t) be oscillator frequency in hertz at elapsed time t, and let f_ref be its declared nominal frequency. Its fractional-frequency deviation is y(t)=[f(t)−f_ref]/f_ref, a dimensionless quantity. An observation of y increasing slowly is not by itself an observation of material ageing. Its trajectory may reflect several causal mechanisms acting together. The observer who fits a straight line to an uninterrupted environmental record has measured the resulting trend, not isolated the internal mechanism that produced it. A day-to-day temperature cycle may be correlated with calendar time; so may ageing, gradual changes in supply

Copyright 2026, James M. Atkinson

loading and the progressive settling of a newly energised oscillator. The explanatory variables cannot be distinguished from their common result unless the experiment provides independent variation.

A practical working model is $y(t)=a(t)+g[T_r(t)]+h[T_r(t),q(t)]+w(t)+e(t)$. Here $a(t)$ is the slow ageing contribution; T_r is the resonator temperature rather than merely the external air temperature; g is a reversible equilibrium temperature-response function; h describes history dependence through an internal state q such as stress, thermal gradient or prior temperature trajectory; w represents warm-up or recovery after power interruption; and e contains measurement noise and unmodelled disturbances. This equation is a decomposition for experimental design, not a claim that all oscillators possess uniquely separable additive mechanisms. A more realistic model may couple ageing and temperature. Without intervention, the decomposition can be non-identifiable, because several combinations of terms reproduce the same frequency record.

Thermal lag deserves particular care. A sensor fixed to the instrument housing may report the temperature T_h while the resonator experiences T_r, which responds with a delay. A simple first-order approximation, $\tau(dT_r/dt)+T_r=T_h$, uses a thermal time constant τ measured in seconds. If the case temperature rises rapidly, the resonator may remain cooler for an appreciable interval. A compensator using the wrong temperature variable can overcorrect or undercorrect. On a cooling ramp of equal magnitude, the sign of lag reverses. Thus a plot of oscillator frequency against housing temperature can form a loop even when the underlying equilibrium function $g(T_r)$ is single-valued. A genuine memory or stress hysteresis may create an additional loop that persists after the temperature gradients have relaxed.

Copyright 2026, James M. Atkinson

Only sufficiently slow ramps and dwell periods can help distinguish these possibilities.

Ageing is conventionally the frequency change associated with internal changes in the oscillator over time. Such changes may arise from resonator material, contamination, electrodes, mounting stress or sustaining circuitry; the sign and rate may themselves vary. In a narrow observation interval, one may approximate $a(t)=a_0+A\,t$ with ageing rate A measured per second, but its apparent linearity must not be extrapolated indefinitely. A controlled experiment should compare the same oscillator after sufficient thermal equilibrium at a fixed reference temperature on successive dates, using an independently characterised measurement chain. This comparison reduces, though never entirely eliminates, reversible thermal contributions. If the supposedly constant-temperature control drifts, the experiment requires a second reference or a traceable comparison hierarchy rather than blind confidence in the control.

For a numerical illustration, suppose a 10 MHz oscillator has a measured fractional ageing trend of 2×10^{-9} per year, under otherwise constant conditions. Its corresponding nominal frequency change would be 10^7 Hz $\times\ 2\times10^{-9} = 0.020$ Hz over a year. Suppose a temperature excursion of 5 °C introduces a reversible fractional shift of 1×10^{-8} under the tested conditions. That shift corresponds to 0.10 Hz, five times the illustrative annual ageing change. The numbers are hypothetical and do not describe a particular instrument. They show why a short field regression without independent temperature control can misattribute a daily reversible variation to long-term ageing. The exact coefficient, signs and slopes of a real oscillator must be measured.

Copyright 2026, James M. Atkinson

Consider an especially deceptive case: the site gradually warms during a six-week survey because an air-conditioning control set-point changes, while the oscillator undergoes ordinary long-term ageing. A linear regression of frequency against calendar time will combine both effects. A polynomial fit may appear statistically excellent yet still be causally ambiguous. Repeating the record at a deliberately reversed temperature schedule, within equipment ratings, supplies discriminating information. If the frequency trend reverses promptly as the thermal stimulus reverses, at least some component is temperature-sensitive. If a residual difference remains when the resonator and supporting circuitry have returned to a verified common reference temperature, that difference may reflect ageing, retrace, stress memory or instrument drift; further controls are necessary before assigning it exclusively to ageing.

The ideal experiment uses multiple oscillators and independent metrology. Select one device under test, a second oscillator of similar construction held at stable temperature, and a comparison reference whose own stability and traceability are documented. Measure the phase or fractional-frequency difference with appropriate counters or phase comparators, retaining original phase data, gate durations and dead-time information. Log resonator or oven temperature when accessible, ambient and enclosure temperatures, humidity, supply voltage, load and power-cycle state. Cycle only the test oscillator through controlled heating, dwell and cooling stages, keeping the comparison reference thermally isolated. Alternate the ramp direction and repeat the programme across different days. The reference should not share the thermal intervention, power supply or distribution fault under investigation.

Copyright 2026, James M. Atkinson

Two different comparisons are needed. First, examine frequency at the same adequately equilibrated temperature before and after a prolonged interval, whilst preserving the device's power state and environmental history. That gives evidence concerning secular change. Secondly, inspect frequency at the same recorded temperature on heating and cooling trajectories; a difference reveals path dependence, which may originate from hysteresis, lag or control-loop dynamics. To isolate lag, hold the device at selected temperatures until the measured frequency and internal temperatures approach equilibrium, and repeat at different ramp rates. A difference that shrinks as the ramp slows indicates a dynamic contribution, although it does not by itself rule out all material hysteresis. An offset surviving long equilibrium dwell requires further investigation of persistent memory, retrace and measurement bias.

A controlled power interruption is a separate intervention, not merely an extension of a temperature ramp. It may reset a temperature controller, remove heat, change mechanical stress and produce frequency retrace after restart. Record the last pre-shutdown stable observation, the cooling path, elapsed off-time, the warm-up frequency trajectory and the ultimate stabilised state. If the RF survey requires continuous phase evidence, mark the interrupted interval as unobserved rather than reconstructing the phase as though the oscillator had run without interruption. Distinguish the clock's recovered frequency from the accumulated phase or time error, because a good post-restart frequency number cannot recover chronology lost during a reference outage.

The statistical treatment must respect dependence over time. White measurement noise, flicker noise, random-walk frequency behaviour,

Copyright 2026, James M. Atkinson

deterministic thermal cycles and genuine ageing can coexist. Ordinary residual variance after subtracting a linear drift may conceal periodic terms; merely increasing the number of observations may create false confidence if samples are strongly correlated. Estimate a noise model from the phase record, check Allan or related time-domain stability measures at the relevant averaging times, and state how missing intervals and imposed control cycles affect those estimates. Compare alternative causal models using held-out thermal cycles or independently supervised devices, not only goodness of fit to the data used for model construction.

The practical consequence for a defensive RF survey is that the timebase cannot be certified from a single headline long-term drift or ageing figure. If a receiver combines a drifting local oscillator, temperature-sensitive synthesiser and changing reference distribution, its reported carrier frequency may move even while the external transmitter is perfectly stable. Conversely, a reference that performs well in a laboratory oven may experience transient gradients and mechanical strain in a vehicle or temporary installation. A known injected signal and a second independently clocked receiver help identify instrument-generated motion. Ultimately the report should give the time window, the test range, reference state, estimated drift and temperature response, thermal-history qualifications and uncertainty. The strongest conclusion is often a bounded conditional statement: ageing-like secular change was detected under controlled thermal equilibrium, while specified thermal-cycle and retrace effects were measured separately.

Dr. James M. Atkinson, Moderator: Professor Essen, what is the minimum metrological comparison needed before we name a slow drift ageing rather than reference error?

Louis Essen, Peer Question: Lord Rayleigh, the counter under test and the alleged independent reference might themselves be ageing. A long comparison will show a slope, but differences cannot identify which oscillator changed without another standard. How would you design a reference hierarchy that does not falsely transfer the control oscillator's own drift into the test oscillator's ageing record? Please address calibration, comparison duration, and the risk that disciplining both sources to one master conceals their separate histories.

I would also ask what independent event would reveal a change in the shared distribution network rather than in any one resonator. If the comparison counter and every surveillance receiver derive their timing from the same reference, their excellent mutual agreement could conceal a common bias. Would you require a free-running witness that was never disciplined by that master? Please explain whether the three-source comparison is valid when the environmental controls, power supply or phase comparator are shared, and identify a diagnostic procedure that would expose reference-path contamination without interrupting the surveillance evidence. The distinction between a genuinely independent clock and an additional display channel is indispensable.

John William Strutt, Baron Rayleigh, Response: Professor Essen, a difference measurement establishes difference, not individual blame. If two sources have fractional deviations y_A and y_B, the measured series is approximately y_A−y_B plus instrument contributions. A fitted trend estimates

Copyright 2026, James M. Atkinson

d(y_A−y_B)/dt; it does not independently identify dy_A/dt and dy_B/dt. A third characterised source can support a three-corner comparison, but its utility depends on the independence and covariance assumptions. Where an external traceable reference is available, repeat comparisons before and after temperature cycles and retain each source's discipline commands and phase record. Two devices locked to the same master may display correlated behaviour that cannot independently establish the master's accuracy. The uncertainty budget must include reference drift, comparator response, connection changes and all breaks in measurement continuity. Only after those pathways are addressed should a slope be attributed to ageing of the device under test.

Begin with the topology, not the instrument catalogue. Trace each signal from its physical oscillator to the point at which the measurement is digitised, including distribution amplifiers, cable runs, multipliers, transfer oscillators and automatic reference selection. A counter powered from the same external 10 MHz standard as the device nominally under test is not an independent frequency witness. If an independent witness is unavailable, record that limitation and stop short of an absolute ageing attribution. A differential result may remain entirely useful for assessing relative stability, provided the conclusion is restricted to what the comparison establishes.

I would perform three checks. First, inject an independently known test tone at the receiver input and measure whether its recorded frequency moves with the suspect reference. Secondly, compare the oscillator output directly at its connector and after the distribution network, using a path capable of exposing temperature-dependent cable delay. Thirdly, test a second oscillator with a different thermal and electrical history. The comparisons

Copyright 2026, James M. Atkinson

should be made at matched averaging intervals, with environmental and power records aligned to the same time base. If an apparent secular slope follows a cable swap or power-supply reconfiguration, the causal inference must be revised.

A useful numerical illustration concerns a difference of two slopes. Suppose source A is estimated to change by plus 4 parts in 10 to the tenth per day relative to B, while A changes by plus 1 part in 10 to the tenth per day relative to C. If the comparisons are simultaneous and their conventions are consistent, B and C differ by 3 parts in 10 to the tenth per day. That finding says the references are not interchangeable. It still cannot, without further evidence, tell us whether A is intrinsically stable. Report sign conventions, clock ownership and correlated calibration error, or the reader may mistake subtraction of measurements for discovery of a physical ageing mechanism.

Dr. James M. Atkinson, Moderator: Professor Ramsey, what experimental distinction matters most between ageing and retrace?

Norman Foster Ramsey Jr., Peer Question: Lord Rayleigh, after power is removed and the oscillator cools, the frequency on restart may differ from its pre-shutdown value even after the enclosure reaches the same indicated temperature. Is this a secular ageing step, an effect of internal stress or a controller-memory change? What repeated experiment would separate retrace from a steady ageing process without assuming that the same panel temperature guarantees the same resonator state?

A related difficulty appears when the laboratory report mentions a single temperature, usually that of the outer case, although the oscillator contains several bodies cooling at different rates. Can the claimed retrace be

Copyright 2026, James M. Atkinson

represented by one scalar correction if the resonator mount, electronic control board and heater have separate time constants? Please address whether elapsed off-time, the rate of preceding cooling, and the position of the thermometer must all be recorded. What minimum repeated-startup experiment would permit the analyst to distinguish a genuinely persistent offset from a slow transient that has merely not finished settling by the nominal observation time?

John William Strutt, Baron Rayleigh, Response: Professor Ramsey, the critical point is to define retrace as a measured change associated with a power and thermal history, rather than automatically classifying the post-cycle offset as ageing. Compare long uninterrupted operation at controlled temperature with a matched sequence that includes known power-off intervals. After each restart, record both time to stabilisation and the eventual steady offset. Use internal oven temperature or an independently measured resonator proxy where possible, because identical housing temperatures may coexist with different gradients or stress states. Repeat the procedure with different off-times and controlled return-to-equilibrium dwells. A difference correlated with cycling is evidence of retrace or history dependence; a trend observed across undisturbed long-term baseline intervals supports an ageing component. Both mechanisms may coexist, so the method should estimate them rather than force a single exclusive label.

The common error is to substitute the recovery of one visible parameter for the recovery of an entire physical assembly. If the enclosure sensor is back at its nominal reading, the crystal support and regulating components may still be warmer or colder than before shutdown. Consequently I would define the initial state by more than temperature alone: the previous

Copyright 2026, James M. Atkinson

operating duration, off-time, environmental exposure, supply condition and the control circuit's recent history should be preserved. At each return to operation measure the full time series, not a single frequency value at a predetermined minute after power restoration.

For a numerical test, suppose the first start after a ten-minute outage reaches its apparent stable plateau after forty minutes, while the first start after a six-hour outage takes four hours. If a technician samples both at the one-hour mark, the apparent difference could be a settling artefact. Fit separate transient responses and test whether their predicted frequency trajectories converge within the stated observation uncertainty. Then repeat the outages in alternating order under approximately equal ambient conditions. An effect that follows cooling depth and recedes with dwell time supports a transient explanation more strongly than a secular ageing conclusion.

Even a final offset after extensive dwell must be interpreted cautiously. It may reflect changes in package stress, heater calibration, compensation voltage or reference path rather than an irrecoverable defect in the resonator. To claim physical retrace one must define the pre- and post-cycle operating points and the tolerance within which they are considered the same. The final report should preserve both recovered frequency and elapsed recovery time, because a receiver may have recorded many hours of evidence during a period in which its timing reference had not recovered.

Dr. James M. Atkinson, Moderator: Professor Wiener, how can one prevent a sophisticated regression from giving an attractive but misleading causal answer?

Copyright 2026, James M. Atkinson

Norbert Wiener, Peer Question: Lord Rayleigh, temperature cycles are often approximately daily, and ageing is a slow function of time. A data analyst can obtain an impressive fit by adding trends, sinusoidal terms and enough delayed predictors. How could the model be tested for identifiability and independent predictive power? What should be done when the residuals are strongly correlated and the study contains no deliberate reversal of the thermal schedule?

Suppose the deployment exhibits an apparent weekly frequency trend after subtracting a fitted annual temperature curve. How would you test whether the residual follows changes in work patterns, supply loading, humidity, air-conditioning schedules or a slowly varying reference clock? Please distinguish a parameter estimated from one season from a law capable of predicting another season. I would particularly welcome an explanation of how strongly autocorrelated observations alter the weight of evidence, and how a random-walk process might masquerade as linear ageing when the trial contains only a single long stretch between calibrations. What withheld experiment would you demand before trusting a correction?

John William Strutt, Baron Rayleigh, Response: Professor Wiener, a model that describes one realised trajectory need not identify its cause. Examine whether the predictors span sufficiently different experimental conditions: repeated temperatures at different elapsed ages, multiple ramp rates, opposite thermal directions and stable-temperature dwell periods. If time and temperature move together, the regression columns may become nearly dependent, inflating coefficient uncertainty even when the fitted curve is smooth. Use blocked validation on entire held-out thermal cycles, not a random scatter of adjacent samples that share nearly the same

Copyright 2026, James M. Atkinson

history. Examine lagged residual structure and compare alternative models with and without path-dependent terms. If the experiment never changes the thermal schedule independently of elapsed time, report that ageing and temperature drift remain confounded. Model complexity cannot manufacture independent information absent from the measurements.

First, inspect whether the residual contains systematic structure. A plot of daily means can make correlated noise resemble a steady slope, whilst a plot of independent stable-temperature baselines may reveal abrupt shifts after power events. Record the residual autocorrelation across short and long lags, and compare models with thermal forcing, environmental periodicity, step changes and stochastic frequency wander. I would withhold an entire thermal excursion from the fitting process, rather than use random individual observations from the same excursion as the validation set. Such random partitioning gives the algorithm almost identical neighbouring observations on both sides of the nominal validation boundary.

As an illustrative calculation, consider 120 hourly observations with a correlation near 0.90 between successive hourly errors. An approximate effective sample size for a simple first-order correlated process is $N_{eff}=N(1-r)/(1+r)$, giving 120 times 0.10 divided by 1.90, or approximately 6.3 independent observations. That estimate rests on a restrictive model, and should not be presented as a universal adjustment. Yet it shows why the confidence implied by 120 rows can be deceptive. The analyst should quantify uncertainty under an appropriate covariance model and examine how conclusions change under more than one plausible noise description.

Copyright 2026, James M. Atkinson

A further challenge uses reversed experimental forcing. If a winter heating regime produces one inferred ageing slope, deliberately vary the thermal schedule in a subsequent controlled interval whilst preserving a separately characterised reference. A real material-ageing contribution may remain, but a temperature-aliasing component should change according to the imposed thermal response. If the model predicts only its original record, it is a description rather than an independent explanation. I would classify each conclusion according to the intervention that actually tested it, and not according to the sophistication of the regression software.

Dr. James M. Atkinson, Moderator: Mr. Harrison, how might packaging and mechanical stress defeat the assumption that the oscillator is at a single temperature?

John Harrison, Peer Question: Lord Rayleigh, an oven thermometer may indicate a stable set-point whilst the supporting electronics, enclosure and resonator mounting points continue to change temperature. Could an oscillator exhibit an apparent memory effect entirely because its internal parts approach equilibrium at different rates? How would you observe this without opening or disturbing the resonator enclosure and thereby changing the very mechanism under examination?

I would be uneasy if the same sensor were used both to regulate the oven and to certify that it has reached thermal equilibrium. Its control point can look unwavering whilst heat flows through the metal support and electrical connections. Could you describe a nondestructive way to estimate those gradients and establish whether a frequency change follows mechanical mounting or ambient changes rather than time itself? Please specify what should be done when an investigator cannot place a thermometer directly

Copyright 2026, James M. Atkinson

on the resonator. How should we interpret frequency differences between heating and cooling at equal indicated case temperature, particularly when the instrument has been moved or mounted differently?

John William Strutt, Baron Rayleigh, Response: Mr. Harrison, treat the instrument as a thermal system with distributed states. Measure multiple accessible surface and oven-control indicators, the ambient airflow and supply dissipation, and look for differences in the frequency response when ramps of equal final temperature have different rates. Without disassembling the instrument, repeat long dwell intervals until accessible temperatures and frequency become stable within declared criteria. If frequency-versus-temperature loops contract with slower ramps, thermal lag is implicated. If a persistent difference survives adequate equilibrium, investigate stress hysteresis, retrace or ageing rather than inferring them immediately. The observation strategy must acknowledge that inaccessible resonator temperature remains a latent quantity. Using several external sensors improves a model but does not establish a unique internal state unless supported by independent calibration.

The first principle is to observe several accessible locations instead of trusting a single convenient dial. Monitor enclosure temperature, air intake, power-supply temperature and oven-control effort, with sensors whose calibration and response time are known. Where direct resonator measurement is impossible, treat its temperature as a hidden state with an uncertainty, not a value secretly identical to the case reading. Compare responses after gentle changes in airflow or enclosure temperature, keeping the experiment within the equipment's declared operating limits. A frequency excursion that follows a controlled change in cooling airflow is

Copyright 2026, James M. Atkinson

evidence of environmental sensitivity, not of the calendar's capacity to age metal.

One experiment would fix the oscillator in its installed orientation, hold the ambient temperature until a stable baseline is observed, then introduce a modest thermal change and return to the original condition. Repeat the sequence at two ramp rates. If the enclosed assembly retains the same equilibrium characteristic, the apparent frequency-versus-case-temperature loop should contract as the ramp is made slower and the dwells longer. If a persistent offset remains after carefully documented equilibration, repeat the sequence without moving the mount. A change that appears only after moving the unit calls for a separate orientation or stress investigation, rather than an automatic ageing label.

A practical measurement must include load conditions. Driving an unusually long reference cable or additional distribution amplifier can alter output current, internal dissipation and possibly the frequency setting of a sensitive oscillator circuit. Record the connected load before and after each trial, and use a monitored buffer where appropriate. The final record should show the sensor placements, mounting method, time of every intervention and uncertainty of the frequency comparison. Without that physical account, an attractive graph can conceal the entire cause it purports to establish.

Dr. James M. Atkinson, Moderator: Lord Kelvin, how should the measurement uncertainty be presented when the dominant correction is history-dependent?

William Thomson, Baron Kelvin, Peer Question: Lord Rayleigh, a laboratory report may assign a small standard uncertainty to the oscillator’s frequency

Copyright 2026, James M. Atkinson

at 25 °C, while the device reaches that temperature through markedly different paths. A single-valued calibration table may then provide inconsistent corrections. How should the engineer communicate uncertainty when temperature alone is insufficient to determine the state, and what quantitative bounds are more honest than an unduly precise correction?

When the published uncertainty budget gives one combined number, it may hide fundamentally different contributions: calibrated reference offset, short-term counter noise, long-memory oscillator wander, temperature calibration, and the choice of ageing model. Can you specify which of these are random within one comparison and which are systematic across many observations? If a laboratory repeatedly measures the same oscillator against a shared reference, can the uncertainty decrease as the square root of sample count? I should also like to hear whether an ageing rate quoted per day or per year remains meaningful across changes of power state, because the time coordinate itself may be operationally ambiguous.

John William Strutt, Baron Rayleigh, Response: Lord Kelvin, define the operational state in the calibration, including approach direction, ramp rate, dwell time and power history, or acknowledge that those variables remain uncontrolled. Where the difference between heating and cooling observations is repeatable, it can be modelled as a path-dependent effect with its own uncertainty. Where histories are unknown, a bounded envelope across tested histories may be more defensible than a conventional small standard deviation at a nominal temperature. The uncertainty from the comparator, reference, environmental sensors and drift estimation must still be included. An example: if a calibrated frequency correction at 25 °C varies between −3×10^−9 and +4×10^−9 over observed histories, the analyst

Copyright 2026, James M. Atkinson

should not conceal that spread by reporting only the scatter within a single heating pass. No coverage probability follows merely from the endpoints; it needs an explicit probabilistic model or a conservative interval statement.

An uncertainty statement must match the measurand and the observation interval. If the objective is a one-hour mean frequency difference, then short-term counter noise at an appropriate gate duration matters. If the objective is the intrinsic ageing trend across six months, the reference's long-term behaviour, unknown seasonal thermal response and shifts after shutdown can dominate. A common calibration error is not removed by taking one thousand successive readings. Nor does a deterministic daily cycle become uncorrelated noise because a spreadsheet has produced a standard deviation. I would record a covariance term for errors shared across dates, instruments or measurement channels.

Suppose independent random observations each have a standard uncertainty of 2 times 10 to the minus ten, while the comparison reference has a common systematic uncertainty of 5 times 10 to the minus ten. With one hundred genuinely independent observations the random component of the mean becomes 2 times 10 to the minus eleven. A simple illustrative combined uncertainty, assuming those two components are independent of each other, is the square root of (2 times 10 to the minus eleven squared plus 5 times 10 to the minus ten squared), approximately 5.004 times 10 to the minus ten. It is not 2 times 10 to the minus eleven. The assumptions must be stated, and a longer observation cannot magically remove a common bias.

Ageing per unit time also requires a declared exposure history. Calendar elapsed time, cumulative powered hours, thermal-cycle count and time

Copyright 2026, James M. Atkinson

since manufacture are not interchangeable predictors. A specification derived from an uninterrupted ovened test may not describe a receiver that is switched off nightly or subjected to temperature extremes in transit. I would compare like states with like states, record interruptions as interventions, and present the uncertainty of both the measured slope and the causal attribution. Where the distinction cannot be resolved, the conclusion must say so, however inconvenient that may be to the demands of a final certificate.

Dr. James M. Atkinson, Moderator: Mr. Nyquist, why can apparently satisfactory sampling-frequency performance obscure a slowly changing timebase?

Harry Nyquist, Peer Question: Lord Rayleigh, a software-defined receiver is specified to capture a bandwidth with nominal sample rate f_s. Its ADC reference changes slowly as the equipment heats, and the frequency display continues to show the commanded value. What observation would reveal that the physical sample interval and carrier-frequency interpretation have changed, and why is the sampling theorem alone insufficient to certify the acquisition time axis?

In a receiver farm, a signal may be sampled by one converter but its nominal radio-frequency position inferred from another synthesiser or external 10 MHz input. Could you explain how the analyst would locate the point at which reference ageing becomes an apparent movement of a captured carrier? A long waterfall trace can look persuasive even when frequency correction is silently applied by software. What would you record about sample-clock selection, digital decimation, dropped samples and frequency calibration so that a second laboratory could reproduce the inference?

Copyright 2026, James M. Atkinson

Please distinguish a genuine transmitter change from reference drift and from a recorder that reconstructs missing time without an explicit gap marker.

John William Strutt, Baron Rayleigh, Response: Mr. Nyquist, a nominal sampling configuration does not prove that hardware sample intervals conform to that nominal rate. Measure the clock against an independent time reference or observe a stable, known-frequency calibration signal through the actual acquisition chain. If the sample rate changes by fractional amount ε, the inferred frequency and elapsed-time mapping can shift correspondingly under the relevant signal-processing assumptions. Preserve hardware sample counters and direct phase or sample-clock comparisons. A sufficiently high average rate may still represent bandlimited content without gross aliasing while its timestamps, fine spectral estimates or coherent integration drift. Temperature-related oscillator variation is therefore a timing and metrology concern independent of the ideal theorem’s bandwidth condition. If samples are missing, that is an additional failure which a rate correction cannot repair.

A nominal sample rate is a setting, not a guarantee of the realised clock. At the beginning of a survey, map the relevant clock tree: the analogue converter's sample clock, the receiver's local oscillator, the distribution reference, and the computer time used to label the resulting records. Some architectures derive both sample and local-oscillator clocks from one reference; others do not. An apparent shift of a signal's carrier frequency can therefore originate in several places. The proper experiment injects a known stable signal and follows it through the complete chain, including its

Copyright 2026, James M. Atkinson

software frequency correction. An isolated test of the master oscillator does not by itself certify the displayed spectrum.

For a simple worked example, an actual sampling clock that is 2 parts per million faster than the assumed nominal value yields an equivalent fractional error in frequencies inferred solely from the sample index. A spectral component interpreted as 100 kHz in the idealised sample-frequency coordinate may have an actual frequency displaced by approximately 0.2 Hz under that mapping. The precise sign and relationship to the RF carrier depend on the receiver architecture and its mixing stages, so the instrument's calibration model must be stated. A trace labelled with many decimal places has no evidential authority if the sampling clock's actual rate is unrecorded.

Retain raw complex samples when lawful and feasible, original timestamps, receiver settings, resampling metadata and reference-selection events. If an automatic calibration alters a displayed frequency after acquisition, store both the raw and corrected estimates with the correction equation. An instrument that loses samples must record the discontinuity; interpolating missing time can make an oscillator excursion look smoother or can create misleading phase continuity. A second receiver clocked independently and observing the same injected marker supplies a powerful diagnostic. Agreement between two channels sharing one defective reference does not supply the same protection.

Dr. James M. Atkinson, Moderator: Professor Poincaré, what would constitute convincing evidence that the experiment has distinguished two competing explanations?

Copyright 2026, James M. Atkinson

Henri Poincaré, Peer Question: Lord Rayleigh, a reversible temperature change and a secular trend may both influence the same observed frequency. The analyst may choose whichever explanation appears intuitively plausible from a long plot. What intervention is capable of falsifying one of these explanations, and how should the investigator treat experiments in which the two effects cannot be separated within the available measurement uncertainty?

An ageing law and a thermal response law may produce the same observed curve when the environment changes monotonically during the survey. Which return experiment would decisively distinguish them, and what would remain uncertain if the device had experienced irreversible stress during the return journey? How should the record distinguish a model that merely fits the existing trajectory from one that predicts a different route through temperature and elapsed time? I should also like to know whether the analyst should abandon the attribution altogether when the alternate models yield materially different five-year predictions although each describes the one-year data adequately.

John William Strutt, Baron Rayleigh, Response: Professor Poincaré, devise contrasts whose predicted outcomes differ. Under a purely equilibrium thermal model, returning to the same fully equilibrated temperature should restore the same fractional frequency, apart from measurement noise. Under a model with secular ageing, observations at that common state may change as elapsed time advances. Under lag, the apparent loop should depend on ramp rate and diminish after extended dwell; under persistent hysteresis or retrace, some history-dependent offset may remain. The experiment must actually vary elapsed time and temperature history

Copyright 2026, James M. Atkinson

independently enough to make those predictions distinguishable. If the postulated effects are smaller than the reference uncertainty or are mutually confounded, the correct conclusion is conditional, not a victory for the preferred curve. An honest inconclusive result is valuable because it prevents an unsupported claim of drift attribution in a forensic report.

I would begin by requiring a prediction made before the return test. Under a reversible equilibrium model, a sufficiently equilibrated return to the original temperature, supply and load would restore the old fractional-frequency contribution, apart from any independently measured ageing and uncertainty. Under a lag model the apparent offset should diminish with longer dwell or slower ramp. Under a persistent change model a residual may remain, but the cause of that change need not be unique. Conduct the return experiment after documenting the previous power and temperature history, then repeat at a second reference temperature to see whether one inferred residual behaves consistently across operating points.

Suppose model one predicts a corrected return offset of 1 part in 10 to the ninth and model two predicts 5 parts in 10 to the ninth. If the combined uncertainty of the return comparison is 0.5 part in 10 to the ninth under documented independent conditions, the result may distinguish those predictions strongly. If there is an uncharacterised common reference shift of 6 parts in 10 to the ninth, it cannot. The experiment needs a discriminating observation and an error budget with sufficient resolving power. Merely adding more points along the original route does not provide that.

Where the models fit the observed period but diverge beyond it, present an envelope of plausible forecasts rather than select the most dramatic or

Copyright 2026, James M. Atkinson

convenient one. In evidential work the appropriate conclusion may be that the internal ageing rate is not identifiable from the deployed record. This is not a failure of scientific rigour. It is the rigorous statement of what remains unknown. An analyst can still correct a measured thermal component within the tested range and quantify residual frequency uncertainty without pretending that the unmeasured microscopic mechanism has been established.

Dr. James M. Atkinson, Moderator: The token passes to Professor Wiener for an independent principal account of ageing models and their confounding with thermal cycles. Lord Rayleigh will then challenge the statistical inference.

Norbert Wiener, Second Principal Contributor: Dr. Atkinson, a fitted secular frequency trend cannot be called irreversible ageing merely because a straight line explains a long record. Seasonal changes, thermal hysteresis, power cycling, retrace and the drift of the reference instrument can project onto the same low-frequency component. Identification requires interventions: controlled temperature ramps at different rates, holds at steady temperature, repeated cycles, and an independent comparison oscillator maintained under a different thermal history. Where ageing and temperature coefficients are estimated from highly correlated regressors, apparently precise numerical coefficients can be unstable or misleading. The laboratory should preserve raw phase-versus-time observations, thermal sensor placement, time constants and event logs, then test the proposed model against cycles not used in fitting it. I invite Lord Rayleigh to question whether our interventions alter the phenomenon we seek to measure.

Copyright 2026, James M. Atkinson

The mathematical issue is not whether a curve is smooth, but whether two explanations generate distinguishable observations under the experiment actually performed. Write the fractional-frequency observation at index i as y_i = a_0 + a_1 t_i + b_1 theta_i + b_2 theta_i squared + c z_i + epsilon_i, where t_i is elapsed time in days, theta_i is the measured resonator-temperature departure from a reference point in degrees Celsius, z_i is a measured power-state or thermal-history covariate, and epsilon_i is the unresolved error. These terms are not automatically physical mechanisms. A linear trend can represent an effective drift over the observed window; the temperature terms can approximate a locally curved response; and the history term can account for one observable remnant of a preceding cycle. When all three explanatory columns drift together, the fitted coefficients may be numerically unstable even if the fitted frequency curve looks impeccable. I would calculate the singular values of the design matrix, examine its condition number, and compare the uncertainty ellipse for a_1 and b_1 before attributing any fitted slope to materials ageing.

Suppose the enclosure warms by 0.20 degrees Celsius per day over an initial ten-day interval, while the oscillator has a reversible fractional sensitivity of 3.0 times 10 to the minus nine per degree. The temperature contribution is then 6.0 times 10 to the minus ten per day. If its genuine ageing term contributes 1.0 times 10 to the minus ten per day, a frequency-only regression will report approximately 7.0 times 10 to the minus ten per day. That sevenfold inflation is not evidence of unusual ageing. It is the arithmetic consequence of omitted temperature dependence. The reported numbers are invented solely to demonstrate identifiability. A second observation interval with essentially constant resonator temperature could

Copyright 2026, James M. Atkinson

reveal a different slope, but that inference must be qualified by reference drift and changes in the device's internal operating state.

Time-series dependence is a more subtle danger. If the measurement errors are positively correlated for hours, a least-squares routine that assumes independent residuals returns confidence intervals that may be radically too narrow. A 1,000-point record does not contain 1,000 independent experiments merely because 1,000 rows appear on the screen. Inspect the residual autocorrelation and the phase spectrum, use a covariance model appropriate to the instrument and the observed noise, and report the effective information content at the averaging times relevant to the evidential claim. A model with daily temperature terms, weekend power-state effects, and a weak secular trend deserves comparison against a model containing a stochastic random-walk frequency component. An unmodelled random walk can mimic a deterministic ageing slope during a finite interval without possessing that cause.

For an experimental design I would use a predetermined schedule rather than adjust the temperature programme after seeing which model wins. Start with an equilibrated baseline at a specified temperature and supply voltage. Run at least two heating rates and two cooling rates within the instrument's qualified operating envelope, randomising the order where prudent. Insert extended dwells that permit the difference between resonator and case temperature to diminish. Repeat one temperature sequence after a substantial elapsed interval while leaving the reference chain under a separately monitored environmental regime. A second device, preferably of different construction, should experience a complementary thermal schedule. This schedule creates data in which elapsed time and

Copyright 2026, James M. Atkinson

imposed temperature are not simply two names for the same changing quantity.

A state-space formulation can distinguish what is measured from what must be estimated. Let x_i contain the unobserved internal resonator temperature, a slowly evolving baseline frequency offset, and a possible hysteretic state. One can write $x_{(i+1)}=F x_i+G u_i+w_i$ and $y_i=H x_i+v_i$, where u_i contains deliberate heating or power interventions, w_i represents process uncertainty and v_i measurement uncertainty. The matrices F, G and H are test hypotheses requiring validation, not automatic facts about quartz. If the state observability matrix is rank deficient, no clever filter can infer every hidden component uniquely from the available sensors. A smooth Kalman-filter trace must not be mistaken for laboratory confirmation of an unobserved physical process. I would make the observability limitation explicit rather than conceal it behind elegant computation.

Training and validation windows should be separated by operating condition, not merely by time index. Hold out a complete thermal cycle and at least one power-recovery sequence, fit on the remaining material, and test whether the model predicts the frequency and its uncertainty on the held-out path. A model that interpolates one repeated daily waveform yet fails on a slow overnight cooling event is not competent to correct field evidence. Report prediction errors in fractional frequency and hertz for the actual receiver reference, and propagate them to tuning uncertainty and event time. In a multi-receiver surveillance array the common reference can create correlated errors, so the covariance structure must follow the

Copyright 2026, James M. Atkinson

distribution topology rather than be assigned independently to every channel.

I would also ask whether apparent secular motion disappears under time reversal of the programmed temperature trajectory. Thermal effects that follow a controlled stimulus should change sign or phase with the stimulus according to a testable response law; an intrinsic long-term shift need not do so. But irreversible stress relaxation triggered by the intervention itself could create a lasting step. Consequently, a returned temperature cannot guarantee a returned material state. The investigator should retain the pre-intervention baseline, the immediate post-intervention baseline, and the stable baseline after a documented recovery time. Those three observations separate a transient recovery from a persistent displacement, though they still cannot name the displacement's molecular cause without additional evidence.

The inference should end with a deliberately modest statement. One might conclude that a reversible thermal contribution explains a quantified proportion of the recorded excursion and that a residual secular change remains under the tested conditions. One cannot infer that the remaining change is solely resonator ageing unless reference drift, supply sensitivity, mechanical stress, compensation electronics, and environmental history have been bounded. The distinction is not a linguistic nicety. It determines whether a court or technical reviewer is being shown a measured quantity, a fitted statistical parameter, or an asserted cause with independent corroboration.

John William Strutt, Baron Rayleigh, Cross-Peer Question to Norbert Wiener: Professor Wiener, you propose cycling the oscillator through controlled

Copyright 2026, James M. Atkinson

temperatures to identify reversible terms. Yet the experiment may itself introduce mechanical stress, retrace or lasting changes to the resonator. How can repeated cycles be interpreted without supposing that the subject remains unchanged by the measurement? What distinction do you draw between a reversible response that follows the same path on cooling and heating, hysteresis that forms a loop, and a permanent shift remaining after the oscillator returns to a well-established reference temperature?

Please define the observation that would count as an irreversible alteration of the test oscillator after the temperature cycle, rather than a change of the comparison reference during that cycle. If the control oscillator experiences a different thermal history, that distinction might help, but the two measuring paths could nevertheless share cable or voltage sensitivities. Would you establish pre-intervention and post-intervention measurements at multiple common temperatures, and if so how would you avoid mistaking slow thermal recovery for a new ageing baseline? I also ask whether an experimentally induced persistent offset should be reported as an intervention response instead of being incorporated uncritically into an annual ageing slope. What would constitute a discriminating failure of your statistical model?

Norbert Wiener, Cross-Peer Answer to John William Strutt, Baron Rayleigh: Lord Rayleigh, precisely because thermal cycling can alter the device, use a baseline before and after each sequence and retain a control oscillator under stable conditions. A reversible equilibrium coefficient is estimated from repeated responses after sufficient thermal settling. A loop between heating and cooling reflects lag or hysteresis and must be analysed with temperature history, not collapsed into one coefficient. A residual shift after

Copyright 2026, James M. Atkinson

returning to the reference state is evidence of a persistent change under the tested conditions, but it does not alone identify a microscopic ageing mechanism. Replicate at bounded temperature rates and monitor mechanical and power-cycle events. A regression may summarise the evidence only after those physical distinctions have been tested.

I would test the proposition against data collected before and after the intervention, not against the appearance of the fitted curve. A minimum design uses repeated frequency comparisons at a stable nominal temperature, a controlled thermal excursion, and at least two post-excursion stable-temperature holds. The first hold tests short-lived recovery; the second tests whether the residual survives additional equilibration. An independent reference, or several witnesses with independently assessed correlations, must be observed through precisely the same interval. Otherwise a change in the master clock during the heating experiment would be attributed falsely to the heated device.

An irreversible response and ongoing ageing need not be the same process. The experiment itself might relieve mounting stress or alter contamination and thereby create a discrete offset. In the fitted model I would represent that event by a documented step parameter, while estimating the secular trend from stable reference states on either side. One should not smear the offset over the elapsed observation duration and call the resulting slope the natural ageing rate. The intervention record should include ramp rates, final temperatures, dwell times and evidence of any power state change. If the predeclared model cannot predict the second thermal cycle, this failure is informative evidence that the supposed reversible response is incomplete.

Copyright 2026, James M. Atkinson

The inference can be made testable by an explicit hold-out challenge. Fit the thermal time constants and baseline against the first cycle, then forecast both the final frequency and the uncertainty band during a second cycle of different duration. A result outside the calibrated prediction band calls for model revision or broader uncertainty, not a quietly adjusted fit that retrospectively passes. Moreover, a good prediction at the case sensor does not establish that internal material changes are absent. The forensic claim should identify the inferred mechanism only to the degree that the intervention and the independent witness genuinely distinguish it.

John William Strutt, Baron Rayleigh, Concluding Comment to Professor Wiener: I accept this restriction. The experimental record must distinguish an observed persistent offset from an identified causal mechanism, and the independent comparison standard must be observed as carefully as the oscillator undergoing the cycling.

Dr. James M. Atkinson, Moderator: Professor Essen, could you distinguish ageing of the tested oscillator from drift of the reference used to measure it? Professor Wiener will then test the identifiability of a fitted slope.

Louis Essen, Third Principal Contributor: Long-term frequency drift can be assigned to ageing only after the reference standard and environment have been independently controlled. A stable reference oscillator held under a different temperature history is an important comparison. It can reveal common metrological drift that would otherwise be attributed to the tested specimen. I would preserve unprocessed phase and frequency differences and characterise each discontinuity caused by power cycling or reference changes.

Copyright 2026, James M. Atkinson

Metrology begins by separating the thing to be measured from the artefacts that make its measurement possible. Let A represent the surveillance oscillator, B the local comparison source, and C an independently maintained standard. The measured phase difference $x_{AB}(t)$ is phase A minus phase B, plus the instrument's transfer function and comparison noise. A second comparison $x_{AC}(t)$ allows one to check whether the apparent excursion follows A or follows B, but only if the channels have not quietly inherited the same reference oscillator. In a modern receiver room several front panels can appear independent whilst their 10 MHz inputs, acquisition timestamps and software corrections all descend from one distribution amplifier. That is one metrological reference in several housings, not several independent witnesses. The wiring diagram and clock-selection records therefore belong in the evidential chain.

The comparison records should preserve phase as well as averages of instantaneous frequency. If $x(t)$ is the time error in seconds between two clocks, fractional-frequency difference over a gate from t_1 to t_2 is $y_{bar}=[x(t_2)-x(t_1)]/(t_2-t_1)$. For example, if time error grows from 20 nanoseconds to 80 nanoseconds over 6,000 seconds, y_{bar} is 60 times 10 to the minus nine divided by 6,000, equal to 1.0 times 10 to the minus eleven. At a 10 MHz carrier reference that would correspond to an average difference of 0.0001 Hz. Neither the measured phase slope nor this arithmetic reveals which oscillator changed. That attribution requires an independently tested comparison and a description of the oscillator states during the interval.

Calibration history must be placed alongside the new observation. I would obtain the last traceable calibration, its uncertainty and confidence

Copyright 2026, James M. Atkinson

convention, the procedure used, the reference standard's history, and whether the device has since experienced transport, shock, service, thermal excursion or long power interruption. An oscillator whose label reports a nominal ageing specification is not individually calibrated for the present deployment. Manufacturer ageing figures may be maxima, typical values or model-specific statements measured under conditions absent from the field. The record must distinguish a published specification from an actual as-found measurement. The as-found state must be captured before trimming the oscillator or changing its electronic correction, since adjustment destroys evidence of the preceding setting.

A third comparison can be valuable but must not be treated as a magic solution. For three oscillators A, B and C with uncorrelated fractional-frequency errors, the variance of the difference AB is V_A+V_B; likewise $V_{AC}=V_A+V_C$ and $V_{BC}=V_B+V_C$. Under those assumptions, $V_A=(V_{AB}+V_{AC}-V_{BC})/2$. As a numerical demonstration, suppose the dimensionless variances of three simultaneous difference records, expressed in units of 10 to the minus twenty-four, are 13, 20 and 17. Then $V_A=(13+20-17)/2=8$ in those units. The result is invalid if there is significant shared environmental or electrical noise, and may even become negative when noise estimates are uncertain. The analyst should investigate correlation rather than replace a physically troubling estimate with zero.

A direct comparison to a laboratory reference is only as good as the transfer path. Frequency counters can have gate-time and trigger sensitivities; phase comparators can add amplifier delay; long coaxial cables can change electrical length with temperature. If an RF feed line expands or its dielectric properties vary, phase at the comparison port may drift whilst the source

Copyright 2026, James M. Atkinson

oscillator remains unchanged. I would run a loopback experiment through the same distribution path, swap input cables where safe, and compare outputs at both the oscillator connector and the receiver reference port. Thermal insulation of one cable may be more informative than an additional decimal place in a numerical fit.

The reference itself needs an environmental history. Record its oven or case temperature, supply voltage, control voltage, reference-lock status, alarm events, and any interval in which it changed between internal, external or satellite-disciplined timing. A satellite-disciplined oscillator can be excellent for some averaging intervals and poor for others because its servo correction, reception outages or holdover behaviour can impose a characteristic timescale. An apparently smooth line may conceal steering steps when the data are resampled or averaged. Before attributing drift to the surveillance unit, I would examine the reference's raw steering log and compare an uninterrupted free-running interval with a documented disciplined interval, without confusing their different uncertainty budgets.

Statistical comparison demands an appropriate timescale. At one-second gates, short-term noise may dominate. Across hours, diurnal thermal response can dominate. Across weeks, ageing and reference drift may both matter. I would calculate time-domain stability at several averaging intervals and state the data preprocessing, dead-time handling and confidence of each estimate. A tidy Allan-deviation chart does not identify ageing by itself, because a deterministic drift may have been removed, a periodic temperature term may remain, and measurement dead time can change the estimator. Retain both original and corrected series so an independent reviewer can reproduce every transformation.

Copyright 2026, James M. Atkinson

Finally, I would produce a two-column evidential conclusion. One column reports observations: the measured differences, reference-path continuity, thermal telemetry, power transitions, and traceability. The other explicitly labels inferences: which trend is plausibly intrinsic, which is demonstrably temperature-correlated, and which is inseparable under the present design. The engineering value of such a distinction is practical. If the proposed surveillance detection depends on identifying a transmitted carrier moving by less than a fraction of a hertz over weeks, an unresolved reference trend of comparable size is material to detection confidence and must not be smuggled into the account as an external transmission property.

Norbert Wiener, Cross-Peer Question to Louis Essen: Could a linear fit over one year separate a true ageing slope from a yearly temperature influence if both regressors change nearly monotonically during the observation period?

Suppose the oscillator is compared against an external reference that is satellite-disciplined during the day but enters holdover after interference or signal loss. The resulting reference slope could be correlated with both environmental conditions and elapsed time. Would a nominal three-source comparison necessarily detect this common steering event, and how should the experiment be redesigned if the nominally independent references share the same outside timing source? Please address whether a fitted ageing trend remains admissible as a physical inference when its sign changes after an input-reference substitution, and specify what raw phase, reference-selection and telemetry records must be retained to expose the error. What test would separate common-mode steering from an independent component of the observed oscillator drift, and what residual

Copyright 2026, James M. Atkinson

uncertainty would remain after that intervention? I should not accept an inferred cause on numerical closure alone.

Louis Essen, Cross-Peer Answer to Norbert Wiener: Not reliably without independent variation or prior calibration. A collinear experiment admits several parameter combinations that fit almost equally well. Controlled temperature cycles and stable-temperature holds can make the causal effects more distinguishable, while independent checks expose reference drift. Report parameter sensitivity and interval limits rather than a falsely precise slope.

It would not necessarily detect it, for a three-source comparison is only informative to the extent that the sources and comparison paths possess known independence. If both reference sources are steered from the same remote timing service, they may share a low-frequency correction that looks precisely like a common secular trend. I would obtain their lock status and steering histories, mark every holdover transition, and compare the observed slope during periods in which at least one source runs freely. Substitution of a reference that reverses the sign of the inferred slope is a strong warning that the original attribution was not identified. It does not prove that the tested oscillator is faultless; it proves that the metrological decomposition was inadequate.

A useful algebraic test starts with measured differences d_AB=a-b and d_AC=a-c, where a, b and c denote fractional-frequency errors. Subtracting these expressions yields d_AB-d_AC=c-b. A common error present equally in A, B and C vanishes from every pairwise difference and is therefore invisible to this procedure. Thus even a perfectly closed algebraic triangle does not

Copyright 2026, James M. Atkinson

reveal common-mode drift. A separately characterised absolute or otherwise independent timing standard, or a qualified physical intervention, is required to constrain that mode. The result should be stated in words that identify the missing information.

The evidential record must contain raw phase samples or reproducible frequency differences; counter gate and averaging settings; the diagram of reference relationships; actual control and correction logs; temperature and supply data; and timestamps for reference changes. A disciplined reference might be suitable for detecting a short event yet unsuitable for assigning an extremely small secular ageing slope without accounting for its steering process. I would report a constrained differential drift where that is all the data permit. Precision in naming what was measured is preferable to unsupported certainty about what aged.

Dr. James M. Atkinson, Moderator: Professor Ramsey, please examine the oscillator’s retrace after thermal and power cycling. Lord Rayleigh will challenge the interpretation of a persistent offset.

Norman F. Ramsey Jr., Fourth Principal Contributor: Thermal retrace after switching the oscillator off and on should not be described as simple long-term ageing. The physical resonator, control electronics and enclosure have distinct thermal time constants, and the path back toward the nominal temperature may differ from the path on warming. I would compare steady-state operating points only after sufficient equilibration and retain the entire warm-up trajectory, because hidden intermediate states can influence the final observed offset.

Copyright 2026, James M. Atkinson

I approach this question through the distinction between a resonant physical standard and the apparatus that continually sustains or interrogates it. An oscillator contains a frequency-selective element, an active sustaining circuit, temperature regulation or compensation, power conditioning, and mechanical support. The recorded output frequency belongs to this entire assembly. The resonator may have a slowly changing intrinsic characteristic whilst its operating point shifts because loop gain, amplitude, electrode loading or supply conditions alter. Before calling an observed change ageing, we should determine whether it follows the physical reference or a part of the apparatus coupled to it. In an atomic frequency standard, the interrogation and control system is conceptually separable from the resonance; in a practical electronic oscillator, an analogous separation requires deliberately engineered tests, not an assumption.

Warm-up and thermal retrace must be recorded as trajectories. Let $t=0$ be power restoration; let $T_c(t)$ be case temperature and $T_r(t)$ an approximate internal resonator temperature. The response may include several characteristic times τ_1, τ_2 and τ_3 rather than a single exponential. A compact empirical expression for the transient fractional shift is $y_w(t)=\text{sum over } k \text{ of } A_k \exp(-t/\tau_k)$. Each amplitude A_k is dimensionless, each τ_k is measured in seconds, and negative or positive amplitudes can coexist. This is a phenomenological approximation valid only on the tested startup sequence. It cannot justify a microscopic description of the resonator, and it should not be extrapolated across power interruptions of different duration or cooling depth without corroboration.

Copyright 2026, James M. Atkinson

Consider an illustrative warm-up containing two components: a fast component of 5 times 10 to the minus eight with a 10-minute time constant, and a slow component of 2 times 10 to the minus eight with a two-hour time constant. After 20 minutes the remaining fast term is approximately 5 times 10 to the minus eight multiplied by exp(-2), or 6.77 times 10 to the minus nine. The slow term is 2 times 10 to the minus eight multiplied by exp(-1/6), or approximately 1.69 times 10 to the minus eight. Their sum remains about 2.37 times 10 to the minus eight. At 10 MHz this hypothetical error equals about 0.237 Hz. A technician who treats twenty minutes of apparently steady enclosure temperature as complete equilibrium could misclassify most of this transient as a slow drift.

Thermal hysteresis differs from dynamic lag. With a reversible equilibrium response the frequency at a given internal temperature is the same regardless of the direction of approach, once equilibrium has been achieved. Lag makes the apparent response differ on warming and cooling while gradients persist; a longer dwell should reduce that difference. Hysteresis can yield a history-dependent state after nominal equilibrium, and retrace after shutdown can leave a different baseline despite returning to the same measured temperature. A repeated ramp should therefore include controlled dwell times, rate variations and a common reference point revisited after each trajectory. A frequency-versus-case-temperature loop alone is insufficient to distinguish these mechanisms.

Mechanical details matter. Quartz cut, mounting geometry, support stress, surface contamination and package pressure can influence resonance; meanwhile ageing of the sustaining electronics or oven thermostat can shift the operating point independently. Excessive claims about internal

Copyright 2026, James M. Atkinson

causation would require teardown or targeted material and circuit measurements that may be destructive and therefore unsuitable for an evidential exhibit. Where nondestructive testing is necessary, compare supply sensitivity, control voltage, heater duty cycle and frequency under known stable loads. A temperature-correlation term that appears only when the reference output drives a heavy distribution load suggests an electrical rather than resonator-only explanation.

I would set a predeclared criterion for a stable comparison point. The criterion would involve the observed frequency slope over a defined window, the rate of change of the accessible thermal sensors, and the repeatability of the result when the same condition is reached from a different starting temperature. One should not merely wait an arbitrary number of minutes. For example, two successive hour-long plateaux may both satisfy a case-temperature tolerance whilst retaining opposite internal gradients. Comparing their recovered frequencies identifies a challenge to the simple equilibrium assumption. An independent comparison oscillator maintained in continuous operation is essential if the power-cycled oscillator's phase history is interrupted.

There is also a distinction between frequency offset and accumulated timing error. For a constant fractional-frequency offset y, the time error after elapsed duration t is approximately x=y t. At y=2 times 10 to the minus nine over 86,400 seconds, x is 0.0001728 seconds, or 172.8 microseconds. The arithmetic is simple, yet a survey may incorrectly treat the error as a transient phase perturbation removable by aligning plots after the event. Such a real-time reference error matters to timestamp comparison across receivers. If a recorder reclocks incoming samples from a shared reference,

Copyright 2026, James M. Atkinson

a common drift may preserve apparent agreement between internal channels while damaging absolute traceability.

The final research design would distinguish three claims. First, the equipment's output frequency changed during a documented operating interval. Secondly, some part of that change responded reproducibly to thermal or power-state interventions. Thirdly, a residual change remained after agreed equilibration and reference correction. Only the third begins to support a longer-term intrinsic shift, and even then its assignment to particular physical ageing mechanisms is conditional. In a laboratory assessment I would classify retrace, warm-up, reference drift and irreversible ageing as separate headings in the uncertainty budget, preserving their covariances where they arise from a common intervention.

John William Strutt, Baron Rayleigh, Cross-Peer Question to Norman F. Ramsey Jr.: If the frequency fails to return to its pre-cycle value at the same indicated enclosure temperature, what further measurements distinguish internal stress from a faulty thermometer or reference comparator?

If an oscillator returns to the same case-temperature reading but not the same output frequency, that alone could reflect a hidden temperature difference across the mounting assembly. What experiment would you use to separate that hidden gradient from a change in sustaining-circuit gain or supply voltage? Please specify the diagnostics available where destructive examination of the resonator is not permissible because the equipment must remain available as evidence. Would you treat a recovered frequency offset after a single start as a reliable ageing result, or require repeated starts with varied cooling duration? How should cumulative powered hours

Copyright 2026, James M. Atkinson

be distinguished from calendar time? In particular, please distinguish a measurement at the case surface from a measurement of resonator equilibrium, and explain which alternative error mechanisms remain observationally indistinguishable without additional instrumentation.

Norman F. Ramsey Jr., Cross-Peer Answer to John William Strutt, Baron Rayleigh: Use multiple thermal sensors near relevant components, independent comparison references and repeated cycles with controlled timing. A persistent difference after equilibration is evidence of a changed system state, but not yet proof of its microscopic cause. Mechanical stress and control-electronics behaviour should be challenged separately. The report should identify the reference plane and uncertainty of the temperature and frequency comparison.

I would require repeated starts under a documented matrix of cooling durations, not a single observation made at a convenient time. Compare a brief outage that leaves the enclosure warm with an extended outage that allows deep cooling, while recording the outer enclosure temperature, heater-control effort, supply voltage, reference lock and output-load condition. Repeat one sequence in the same physical mounting configuration, then challenge it with an allowed change in ambient temperature while keeping power history fixed. A gradient-driven explanation predicts response to cooling depth and dwell; a sustaining-circuit explanation may be associated with control voltage, amplitude or supply variation. The point is to create rival observable predictions instead of assigning a cause to an isolated offset.

Copyright 2026, James M. Atkinson

A conceptual thermal model with two states can be expressed as $C_r\, dT_r/dt=(T_h-T_r)/R_r$ and $C_h\, dT_h/dt=P_h-(T_h-T_a)/R_h-(T_h-T_r)/R_r$. Here C_r and C_h are thermal capacities in joules per kelvin, R_r and R_h thermal resistances in kelvins per watt, T_r the resonator temperature, T_h housing temperature, T_a ambient temperature, and P_h heater power in watts. These equations are simplified examples, not an asserted internal design. The two time constants can permit the case thermometer to look settled while the resonator remains out of equilibrium. Without a second observation related to T_r, parameter estimates may be non-unique. State that limitation rather than fabricate an internal temperature trace.

The intervention should include the original condition of the instrument, the possibility of stress after transport, and a prohibition on unrecorded trimming. A stable post-start offset is evidence that the assembled system behaves differently at a declared operating point, but a microscopic ageing cause would require further targeted tests. Cumulative operating hours and calendar elapsed time may both correlate with the change, so report them separately alongside thermal-cycle count. For timing evidence captured before the final equilibrium, record the uncertainty of the operating interval itself, not merely the later recovered frequency.

Dr. James M. Atkinson, Moderator: Professor Poincaré, our last principal perspective concerns whether the ageing model is identifiable at all. Professor Wiener will assess the consequence of divergent extrapolations.

Henri Poincaré, Fifth Principal Contributor: The explanatory model must not be mistaken for an observation. A curve containing an irreversible term and a reversible term may fit the measured history but remain non-identifiable if

Copyright 2026, James M. Atkinson

the thermal input and elapsed time are strongly correlated. I would seek experimental paths returning to a common reference temperature after different thermal histories, then assess whether the same parameters predict the held-out outcomes. Model failure under such a challenge reveals more than a good in-sample regression coefficient.

The difficulty is one of inverse inference: different internal arrangements may produce the same visible trace. In a long record a curve called ageing and a curve called thermal response may be individually arbitrary if the analyst has observed only their sum. This is the distinction between interpolation and explanation. Interpolation requires a function that follows the observations; explanation requires an experiment under which rival functions predict different future observations. If a model's equations allow the ageing coefficient and temperature coefficient to trade against each other without changing the fitted output, the parameters have not been identified, however many digits the optimisation procedure reports. I would insist that the competing hypotheses be written down before their numerical merit is compared.

Suppose hypothesis A states that the fractional frequency y follows y_0 + a t + b theta, with t elapsed days and theta internal temperature departure in degrees Celsius. Hypothesis B asserts y_0 + a' t + b' theta + c theta squared, where c accounts for local curvature. If the observed temperature rises almost exactly linearly with time, the columns t and theta become nearly proportional. No dataset of that single trajectory can reliably determine both a and b. A new experiment should revisit the same temperature at several elapsed times and the same elapsed interval under more than one

Copyright 2026, James M. Atkinson

temperature trajectory. Randomised, bounded temperature steps can break the proportionality while remaining within the safe operating range.

It may help to think geometrically. A data set measures a path through a space whose coordinates are elapsed time, current temperature, prior temperature history, power state, and supply voltage. If all the observations lie nearly upon one curve in that space, the measurements cannot reveal the full response surface. The investigator must plan excursions away from that curve. This need not imply reckless environmental stress. The experiment can use low-amplitude thermal reversals, long stable holds and repeated reference points. Its purpose is not to produce dramatic effects but to give the competing models an opportunity to disagree measurably, under conditions for which the instrument remains qualified.

A worked illustrative contrast shows the distinction. Model A predicts a residual fractional change of 4 times 10 to the minus nine after sixty days at a stable reference temperature. Model B predicts 1 times 10 to the minus nine after the same interval, but both fit the original temperature-ramping data within measurement noise. A returning stable-temperature test measured with standard uncertainty 0.5 times 10 to the minus nine could distinguish the predictions if its reference and other systematic effects are bounded. If the reference itself contributes 3 times 10 to the minus nine of unresolved error, the result is inconclusive despite the apparent precision of the oscillator's readout. The meaning of an experiment lies in its capacity to discriminate hypotheses, not its number of samples.

Models also differ in their extrapolation. A secular linear law would predict continuous unbounded change if extended indefinitely, yet many material processes relax, saturate or change sign. A logarithmic time dependence or

Copyright 2026, James M. Atkinson

a sum of decaying exponentials may better describe some specimens over limited windows. Equally, a stochastic drift model can predict a widening band without asserting a deterministic ageing mechanism. None deserves automatic priority on philosophical grounds. Compare them on physically meaningful hold-out intervals, report parameter uncertainty and predictive uncertainty separately, and disclose how the result changes when the thermal sensor calibration or the assumed time constant is varied.

I would interrogate the meaning of a measured temperature. A sensor mounted on the metal enclosure does not show every point of the resonator assembly. Two devices with the same recorded case temperature can inhabit different internal states after a sudden ramp, after a slow ramp or after a power interruption. An unobserved state variable may be introduced to represent this difference, but adding such a variable does not make it independently knowable. One must test whether the available outputs render it observable, or acknowledge the range of hidden states consistent with the record. This is particularly important when an apparent hysteresis loop is reconstructed from sparse telemetry rather than measured at the physical resonator.

The uncertainty statement should combine measurement uncertainty, model-form uncertainty and uncertainty concerning interventions. Measurement uncertainty includes comparator noise, reference instability and temperature calibration. Model-form uncertainty concerns the selection of polynomial, thermal-lag or stochastic processes. Intervention uncertainty concerns whether cycling the device changed its underlying material state or control behaviour. These are not three interchangeable standard deviations that can always be combined by taking a square root. Their

Copyright 2026, James M. Atkinson

correlation and epistemic character must be recorded. An uncertainty budget that uses only a regression standard error omits the most consequential difficulty in this experiment.

For a forensic conclusion, the language should remain proportionate to this evidence. The report may say that controlled temperature reversals established a significant reversible contribution, that a returned reference temperature did not completely restore the earlier frequency, and that competing descriptions of the residual remain plausible. It should not say that a specific lattice defect aged unless the supporting evidence has actually been obtained. Distinguish a numerical model's utility for correcting a receiver trace from a causal explanation of the crystal. A correction can be operationally useful within its validated domain and still be incapable of proving the mechanism that necessitated it.

Norbert Wiener, Cross-Peer Question to Henri Poincaré: How should the investigator report competing drift models that agree during the observed year but predict markedly different behaviour over the next five years?

Suppose one model extrapolates an almost linear secular change over five years while another predicts a logarithmic relaxation toward a stable frequency. Their fits over the observed year may be practically indistinguishable. How should the analyst report an interval of plausible outcomes without suggesting that the two curves have equal physical credibility, and which laboratory intervention could most efficiently discriminate them? Could the use of an additional polynomial term create a persuasive numerical fit but worse out-of-sample prediction? Please specify how uncertainty arising from the untested form of the model should be

Copyright 2026, James M. Atkinson

reported separately from uncertainty in measured temperature and frequency. A research report should identify the experimental conditions under which these models would cease to be observationally equivalent. What minimum difference between their forecasts would justify spending additional laboratory time on the discrimination test?

Henri Poincaré, Cross-Peer Answer to Norbert Wiener: Present their predictions as alternatives with explicit assumptions, rather than select one extrapolation simply because its fitted residual is slightly lower. Identify the interventions capable of separating the models and the domain over which each was validated. Long-horizon claims need uncertainty that grows with model disagreement and unobserved operating conditions.

One should first state the domain of the observations. A five-year forecast from a single year's data is an extrapolation, and every untested assumption becomes consequential. The report should display the competing models, identify their distinct physical premises, and give prediction intervals that include parameter uncertainty and uncertainty about model form. If there is no defensible probability weighting of the alternatives, it is better to show a scenario envelope than to invent an averaged distribution. A polynomial curve may lower the in-sample sum of squares simply because it contains more coefficients. That numerical success does not establish any material mechanism and may create unphysical behaviour beyond the fitted interval.

A targeted discriminating intervention would revisit a carefully controlled stable operating point after a meaningful elapsed interval and would repeat an independent temperature reversal. A true equilibrium temperature contribution should respond consistently to the reversal within the

Copyright 2026, James M. Atkinson

established range. A secular displacement may remain when the system returns to the same operating condition, though its microscopic cause can still be ambiguous. If the two candidate ageing functions forecast measurably different increments between two such stable reference observations, that difference can be tested, provided the reference chain possesses sufficient stability and independent character. The experiment should be designed before its outcome is inspected.

For a hypothetical five-year prediction, suppose the linear model forecasts a fractional offset of 20 parts in 10 to the ninth, while the saturating model forecasts 7 parts in 10 to the ninth. If measurement and parameter uncertainty around each model is 2 parts in 10 to the ninth but the model form itself is unresolved, reporting a combined result of 13.5 plus or minus 2 would conceal the dominant uncertainty. State that the plausible model-dependent outcomes span at least the two predictions under their respective assumptions, with additional instrument uncertainties. That is more faithful to the actual evidence, and it prevents a future survey from using spurious decimal precision as a substitute for experimental identification.

Dr. James M. Atkinson, Moderator, Closing Synthesis: Oscillator ageing, equilibrium temperature response, thermal lag, hysteresis, warm-up and retrace are not interchangeable explanations of a frequency trend. The panel has prescribed a phase-preserving comparison with an independently characterised reference, stable-temperature controls, repeated heating and cooling ramps of different rates, long dwell periods, deliberate power-cycle trials and uncertainty models that retain correlated errors. A long straight-line fit alone cannot establish irreversible ageing. In extended defensive RF

Copyright 2026, James M. Atkinson

monitoring, the analyst must trace clock behaviour through the actual receiver chain and distinguish measured environmental sensitivity from inferred secular change. All contributors' dialogue is fictional historical reconstruction, and the worked values are illustrative rather than observations of a deployed system.

QUESTION 061

Copyright 2026, James M. Atkinson

When do common-mode currents on coaxial screens imitate a spatially localised emitter?

Dr. James M. Atkinson, Moderator: Mr. Heaviside, imagine a quiet survey room in which a receiver indicates an isolated spectral peak, and the operator carefully rotates a small loop or survey antenna to obtain a seeming direction. The sharp trace remains visible, yet its apparent bearing moves as the coaxial lead is shifted across the table or brought near a metal cabinet. Some engineers ascribe the effect to a clandestine transmitter, others to defective shielding, and still others to uncontrolled coupling from an entirely lawful apparatus. Please establish the electromagnetic distinction between the intended coaxial transmission-line mode and an exterior current on the screen. Then specify what evidence would justify locating a radiator rather than merely locating a disturbance in the measuring installation.

Oliver Heaviside, Principal Contributor: Dr. Atkinson, the essential error lies in confusing a cable's guided internal circuit with its exterior electromagnetic boundary conditions. Under the usual high-frequency coaxial approximation, the forward RF current flows on the surface of the centre conductor and its return flows on the interior face of the outer conductor. The corresponding fields are largely confined within the coaxial dielectric. A current on the outside of the screen, however, belongs to another mode whose return path can involve the instrument chassis, building steelwork, a nearby person, the floor and capacitance to surrounding structures. The cable exterior can then receive or radiate energy and effectively enlarge the antenna being surveyed. The narrow line on the display is quite real as a voltage at the receiver input. Its alleged

Copyright 2026, James M. Atkinson

point of origin remains a separate, unproved hypothesis.

An important proviso is that the screen is not magically divided into three independent ideal wires at every frequency. Finite conductivity, braid apertures, imperfect terminations and frequency-dependent transfer impedance permit coupling between exterior and interior fields. At frequencies where skin depth is small compared with a solid shield's thickness, interior and exterior surface currents may be approximately separable. A braided screen requires more caution: its permeability to fields depends on construction, overlap, contact resistance, frequency and connector workmanship. A continuity test conducted at direct current cannot certify the absence of RF transfer. Similarly, a satisfactory voltage standing-wave ratio in the intended differential mode does not demonstrate that the outside of the feed line is free of common-mode current.

Suppose a balanced receiving loop is connected to a coaxial cable through an asymmetrical junction. An incident wave can excite the loop and the line exterior together. The voltage at the receiver is then better represented as a superposition of an intended antenna-path contribution and a cable-related contribution, including any mode conversion that occurs at the feed, connector or instrument enclosure. The two contributions are complex phasors. Their relative phase changes with cable routing, frequency and nearby conductive surfaces; therefore a small movement of the lead can reinforce or cancel the apparent signal without any movement of the remote emitter. A directional null is particularly vulnerable because a relatively small cable contribution can dominate the output when the

Copyright 2026, James M. Atkinson

intended antenna is close to its minimum response. A visually impressive bearing change may therefore be evidence about the measurement geometry rather than the position of a hidden source.

The physical causes are diverse. Exterior current may be induced by nearby electric or magnetic fields; driven by asymmetry at the antenna feed; excited by a difference of RF potential between enclosures; or coupled from receiver power, computer data and switching supplies. One cannot identify which cause is active by touching the cable and observing the waterfall alone. The proper experiment holds the antenna's position and orientation fixed whilst changing only a known cable variable, then reverses the intervention. Compare traces with the cable routed away from metallic structures, against a protected reference receiver, and with calibrated common-mode impedance inserted at an appropriate location. The source, cable and instrument configurations must be photographed or diagrammed in the engineering record, even if the textbook itself contains no photographs.

A split-core RF current probe surrounding the entire coax is especially useful. In the ideal differential mode, the outgoing and return currents sum to approximately zero within the probe aperture. A nonzero net longitudinal current indicates current outside the intended balanced return, subject to probe bandwidth, positioning, cable geometry and calibration. It does not by itself prove that the cable is the original emitter; the current may have been induced by the very distant transmitter being investigated. Nor should an operator put a probe around the centre conductor alone and call the resulting current a measurement of exterior-shield current. The conductor

Copyright 2026, James M. Atkinson

set enclosed by the probe is part of the measurement definition.

A common-mode choke may reduce current on the cable exterior while leaving much of the intended differential signal path unaffected. The actual suppression depends on the choke's complex impedance, frequency, position and the complete external return circuit. Its resistance and reactance must not be replaced by one fixed catalogue number at every frequency. A choke placed at the wrong position in a standing-wave distribution may give little improvement, and a lossy ferrite placed near a sensitive antenna may alter its environment. The strongest test therefore uses calibrated before-and-after measurements of exterior current and a repeatable received-signal response, not the mere presence of a ferrite bead.

Finally, source localisation requires a chain of alternative-hypothesis tests. Is the peak present when the receive input is properly terminated? Does it follow the coaxial route while the antenna stays still? Does the apparent bearing reproduce with an independently clocked and independently cabled receiver? Does the result survive substitution of a known low-common-mode test antenna and relocation to a second survey point? A stable peak on a shared receiver architecture is not independent corroboration. Retain the original raw measurements, the current-probe readings, the interventions and the negative controls. The defensible finding is sometimes that an RF component was detected but its apparent spatial bearing was instrument-dependent. Such precision of wording protects the investigator's credibility more effectively than an unjustified coordinate.

TECHNICAL WORKSHEET. TEN CONTROLLED EXAMPLES

Example 1. Net current through a clamp. Assume the centre conductor carries a 3.0 mA longitudinal phasor and the complete shield contribution enclosed by the clamp is −2.4 mA at the same phase reference. The algebraic net current is $I_{CM}=I_{centre}+I_{shield}=3.0-2.4=0.6$ mA. Here I_{CM} denotes the probe-observed common-mode current, not the intended internal return current. Phasor quantities must be added vectorially if their phases differ.

Example 2. Relative current suppression. At one frequency a calibrated probe indicates 2.0 mA before an intervention and 0.50 mA afterwards. The current-amplitude ratio is $r=0.50/2.0=0.25$. The change is $20 \log10(r)=20 \log10(0.25)=-12.04$ dB. This is suppression of measured current at that probe location; without a field-transfer model it is not automatically 12.04 dB suppression of radiation at every position.

Example 3. Idealised choke circuit. Represent the exterior-current driving source by an RF voltage V=0.60 V across a purely resistive path $Z_p=100\ \Omega$. Before adding the choke, $I_0=V/Z_p=0.60/100=0.006$ A=6.0 mA. Add an ideal 300 Ω resistive common-mode impedance in series: $I_1=0.60/(100+300)=1.5$ mA. The reduction is $I_1/I_0=0.25$, or −12.04 dB. Actual choke impedance is complex and the surrounding circuit is distributed, so the example is a model, not a guaranteed result.

Example 4. Cable length in wavelengths. At f=30 MHz and an illustrative free-space propagation speed $c=3.00\times10^8$ m/s, $\lambda=c/f=3.00\times10^8/(30\times10^6)=10.0$ m. A 1.5 m exterior conductor is $1.5/10.0=0.15\lambda$ in physical free-space wavelength terms. Its effective electrical length may differ because the outer

Copyright 2026, James M. Atkinson

surface, jacket, nearby metal and return path constitute a different environment from the coaxial dielectric.

Example 5. Coherent pattern distortion. Suppose the intended antenna supplies unit normalised field phasor $E_a=1.0$ and the cable supplies $E_c=0.5$ at the same observation reference plane. In phase, $|E_a+E_c|=1.5$; in opposition, $|E_a-E_c|=0.5$. The ratio of squared field magnitudes is $(1.5/0.5)^2=9$, equivalent to $10 \log10(9)=9.54$ dB. Neither magnitude establishes an external source direction without an angular model.

Example 6. Route-dependent current. One cable routing gives $I_A=1.0$ mA and another $I_B=0.40$ mA at the same frequency and calibrated probe point. The difference is $20 \log10(0.40/1.0)=-7.96$ dB. If the antenna remains at a surveyed fixed position while a bearing estimate changes, the result argues for sensitivity to the installation. It does not prove where the inducing field originated.

Example 7. Shield transfer impedance. Define a simplified transfer impedance per unit length $Z_t=V_{inside}/(I_{out} L)$, in Ω/m, where V_{inside} is the coupled interior voltage, I_{out} the measured exterior current and L the uniform coupled length. If $Z_t=0.020$ Ω/m, $I_{out}=5.0$ mA and $L=2.0$ m, then $V_{inside}=Z_t I_{out} L=0.020\times0.0050\times2.0=0.00020$ V=0.20 mV. This lumped approximation assumes known phase and uniform coupling; actual transfer impedance is complex and frequency dependent.

Example 8. Termination and choke dependence. For a simplified Thevenin-like common-mode circuit with a 100 Ω total driving and return resistance, insertion of a purely resistive 200 Ω choke changes current amplitude by $r=100/(100+200)=1/3$. Therefore $20 \log10(1/3)=-9.54$ dB. If the 200 Ω

Copyright 2026, James M. Atkinson

consists mostly of reactance, the complex vector sum must replace this arithmetic; blindly adding impedance magnitudes may be wrong.

Example 9. Probe conversion factor. A current probe calibrated at the measurement frequency has transfer impedance $Z_{probe}=5.0\ \Omega$, defined as the measured probe output voltage divided by the enclosed net current. If it produces $V_{probe}=50$ mV, then $I_{CM}=V_{probe}/Z_{probe}=0.050/5.0=0.010$ A=10 mA. Include the probe loading, cable centring, instrument input impedance and calibration uncertainty before assigning a confidence interval.

Example 10. Small cable phasor and angular contrast. At two orientations, suppose the intended antenna field has unit magnitude while the exterior cable contribution has magnitude 0.30. In one orientation the terms align, giving 1.30. At another they are in quadrature, giving $\mathrm{sqrt}(1.0^2+0.30^2)=\mathrm{sqrt}(1.09)=1.044$. The amplitude contrast is $20\log10(1.30/1.044)$=approximately 1.90 dB. A small auxiliary field can therefore change a pattern trace by a measurable amount without an external emitter moving.

James Clerk Maxwell, Peer Question: Mr. Heaviside, a receiver may display a narrow line while a nearby coaxial screen carries current whose surrounding field is plainly not confined to the dielectric. A survey team might describe this as leakage through a shield, even though the exterior conductor may be acting as an antenna in its own right. Could you distinguish these mechanisms using field boundary conditions, and explain why the electric and magnetic fields around a cable cannot be assigned to a source by simply tracing the direction of the nearest conductor? I should also like an account of how nearby metalwork changes the electromagnetic problem without being a source of energy itself. When is the ordinary transmission-line abstraction appropriate, and when should the investigator treat the whole room, cable and chassis as a coupled electromagnetic boundary-value problem? Would you also specify one observation that might falsify the simple leakage explanation, rather than merely providing another attractive fit to the field pattern?

Oliver Heaviside, Response to Professor Maxwell: Professor Maxwell, the relevant fields must satisfy the boundary conditions at every conducting and dielectric surface, including imperfect contacts and the surrounding structures. The intended coaxial mode is a useful approximation because its outward and return currents are closely paired and its dominant field energy is contained between conductors. A distinct exterior current is not a failure of all shielding in the simple sense. It can arise at a feed transition or through external excitation, with the exterior conductor forming a portion of a larger current loop or radiating structure. It can therefore carry energy and interact with the room even if the internal signal remains well protected from certain forms of ingress.

Copyright 2026, James M. Atkinson

A metal cabinet alters capacitance, inductive coupling, image-current distributions and the possible return paths. It can shift the magnitude and phase of an existing exterior current without generating the underlying oscillation. Conversely, switching electronics inside that cabinet may actually inject a new disturbing current. To distinguish these explanations, one must perturb location and connection in a controlled fashion, preserve source-on and source-off conditions where lawful, and observe how the fields respond at several reference positions. A narrow received line is an electromagnetic observation, not a statement about authorship.

The mathematical abstraction becomes inadequate when the cable length, neighbouring conductor dimensions, or relevant separation distances are no longer electrically small for the question being asked. In that situation, distributed phase and radiation effects matter, and the simple series-circuit model of an exterior current may fail. Full-wave modelling is an option, but its geometry, conductivity and excitation assumptions must be documented and checked against measurements. A model in which the entire room has been replaced by an ideal ground plane cannot establish the location of a real emitter in a cluttered room.

The practical boundary is thus an evidential one. Use circuit theory to design and calibrate the probe, transmission-line theory to understand the intended coaxial mode, and electromagnetic field measurements to assess the antenna-system perturbation. Never infer that because the receiver case is grounded at direct current it constitutes an equipotential RF reference.

Copyright 2026, James M. Atkinson

The chamber's steel frame, the instrument cabinet, and the coax exterior may form an unintended receiving system whose directionality is governed as much by the installation as by the small survey antenna.

Michael Faraday, Peer Question: Mr. Heaviside, there is an understandable temptation to introduce a ferrite choke immediately after discovering a coaxial shield current, observe a smaller spectral peak, and then pronounce the original signal artificial. But a choke is a material intervention into the observing system, not a neutral act. How should an experimenter distinguish suppression of the cable's unintended receiving action from suppression of the legitimate antenna signal or simple detuning of the apparatus? What negative controls and reversed interventions would you insist upon? I am particularly concerned that nearby hands, cabinets and changing lead geometry could disturb a delicate field pattern as readily as a new component, leaving an apparently decisive result that another observer cannot reproduce. If a metal cabinet happens to stand near the test apparatus, would you insist upon recording its position and the operator's posture during every repeated observation, and explaining whether the original source was energised throughout?

Oliver Heaviside, Response to Mr. Faraday: Mr. Faraday, a change following intervention is evidence only after competing mechanisms have been considered. The choke may increase common-mode impedance, reduce exterior current, alter the antenna's current balance or change the cable's electromagnetic proximity to the receiving element. It may also change losses and matching in an imperfect assembly. Thus a reduction in displayed energy is not by itself proof that the original line was generated inside the measuring system. The line could be a real external field that had previously

Copyright 2026, James M. Atkinson

been received mainly by the cable exterior.

Begin with a reproducible baseline: fixed antenna position and orientation, receiver gain, frequency span, input attenuation, reference clock and cable layout. Measure a known local calibration signal in parallel, preferably with a second independently cabled receiver. Fit the current probe around the entire coax without shifting the cable. Record the probe reading and spectral amplitude before introducing the choke. Then insert the choke, document its frequency-dependent impedance and location, and make precisely the same observations. Remove it and verify that the original state returns within measured repeatability. Randomise the sequence where possible to reduce the influence of drift and operator expectation.

A particularly useful negative control is an electrically equivalent non-magnetic spacer that produces a similar mechanical displacement without appreciable common-mode impedance at the frequency of interest. Another is a frequency interval outside the choke's effective impedance range. If the result follows cable motion equally with the dummy intervention, the evidence for a ferrite-specific effect weakens. Calibrate the intended antenna response before and after the experiment to identify changes in coupling or matching. A second position in the room can determine whether the line is spatially persistent or intimately tied to a particular measurement arrangement.

I would also require an ethical and procedural distinction between a controlled laboratory test and an evidential field recording. One may safely

Copyright 2026, James M. Atkinson

interrogate a test apparatus; one must not alter operational evidence without preserving the untouched source data and obtaining authority. The conclusion should be about the demonstrated relationship between current, cable configuration and received amplitude. The origin of the excitation may remain undetermined even if the causal role of the lead has been convincingly established.

Arthur Edwin Kennelly, Peer Question: Mr. Heaviside, the proposed worksheet treats a choke as a series impedance and a cable exterior as a current path. These approximations are useful, but a long screen near a metal wall or instrument rack may support standing waves whose current minima and maxima vary with frequency. Could you explain how the position of a choke or current probe affects the apparent result, and why a reading at one location cannot establish the total radiation contribution of the line? How should a field engineer choose several test positions and avoid conflating the specified characteristic impedance of the internal coaxial line with the very different impedance encountered by the outside-screen current and its environmental return path? Please explain whether the engineer should repeat the current map after disconnecting one peripheral device, since otherwise the instrument chassis might remain part of a hidden return path which changes between experimental trials.

Oliver Heaviside, Response to Professor Kennelly: Professor Kennelly, one must keep the two modes separate. The nominal 50 Ω or 75 Ω of the intended differential coaxial mode is not a universal impedance presented to an exterior current flowing against earth, a chassis or parasitic capacitance. The latter sees a distributed, often poorly defined circuit whose resonant structure depends upon the surrounding geometry. A choke can

Copyright 2026, James M. Atkinson

change the standing-wave pattern, moving a current maximum rather than reducing current everywhere. A clamp at one point may consequently register a reduction whilst another region of the cable becomes more strongly excited. This is why the exact probe position is a material observation.

A useful survey measures net current at several labelled distances along the same cable without changing its routing. These measurements should be phase-sensitive if the equipment permits and should be performed at the frequencies of interest. Apply one choke at a time at documented locations, not indiscriminately. Compare the current distribution before and after each intervention, while checking the signal delivered by the intended antenna path. A source whose amplitude changes near a cable-current maximum may support a common-mode coupling hypothesis, but a second route and an independent receiver are still needed to test attribution.

The impedance picture must use phasors. A nominal ferrite impedance $Z_c=R_c+jX_c$ adds to the effective exterior path impedance $Z_p=R_p+jX_p$. For a locally valid series model, current magnitude is $|I|=|V_{drive}|/|Z_p+Z_c|$, not $|V_{drive}|/(|Z_p|+|Z_c|)$. If reactive parts cancel, the inserted component can behave unexpectedly. The simplified arithmetic worksheet deliberately assumes pure resistance to teach scale; it must not be used as a field prediction without impedance characterisation. A wide-frequency measurement may expose a choke that is resistive in one band and strongly reactive elsewhere.

Copyright 2026, James M. Atkinson

Finally, a genuine radiating cable is not a one-dimensional scalar current meter. The exterior current's phase and spatial distribution determine the far and near fields together with the surrounding conductors. A simulation may assist, but the measurable claim should remain grounded in a probe map, a controlled antenna pattern comparison and repeatable physical interventions. The prudent engineer changes one pathway at a time, preserving the surveyed antenna and reference geometry as carefully as a metrologist preserves the datum of a mechanical measurement.

John Daniel Kraus, Peer Question: Mr. Heaviside, direction finding is commonly presented through the rotation of an antenna having a known response pattern. A feed line carrying exterior current adds an unintended spatial element, potentially deepening one null and filling another. How would you distinguish a legitimate bearing derived from the calibrated antenna from a false bearing produced by the combined antenna, lead and instrument cabinet? Please include the consequences of coherent phasor addition, polarisation and the surrounding near-field objects. What tests could a team perform in a crowded room where turning the survey antenna almost inevitably moves its coax, and in which the available bearing indications appear sharp but are not geometrically consistent? Would you additionally require a reference pattern taken with the same gain and frequency settings, and would you forbid reporting a numerical bearing confidence interval until installation-sensitive error has been measured at several distinct test azimuths?

Oliver Heaviside, Response to Professor Kraus: Professor Kraus, the directional response of the installed system is the actual quantity seen by the receiver. Suppose the voltage contribution of the intended survey

Copyright 2026, James M. Atkinson

antenna varies with azimuth θ as A(θ), while a cable contribution is C(θ,geometry). The measured voltage is V(θ)=A(θ)+C(θ,geometry), with complex phasor addition. Its magnitude need not have a maximum or minimum at the same azimuth as A(θ). At an intended deep null, even a modest cable signal can dominate the residual; its phase may then determine the apparent direction. Treating that null as a geometric ray to an emitter is unjustified.

The test should mechanically decouple antenna rotation from cable movement. Support the antenna on a non-conductive fixture and route the coax along a repeatable path, with a suitable current choke placed at a characterised boundary. If the antenna geometry permits, use a low-disturbance fibre-optic transport or a receiver mounted at the antenna, recognising that either substitution creates its own calibration requirements. Rotate the antenna while photographing or diagramming the precise cable posture for each observation. Then hold the antenna absolutely still and move only the feed line. If the apparent bearing shifts under the latter condition, the original pattern contained an installation-dependent contribution.

Polarisation is particularly important. A cable running vertically may respond differently to the local electric field than a small loop intended to discriminate magnetic-field orientation. Nearby metal shelving can support induced currents and scattering, introducing apparent angular structure not present in free space. Repeat at physically distinct positions and compare bearing lines for geometrical consistency. A true single stationary far-field

Copyright 2026, James M. Atkinson

source should yield observations compatible with a common location under a defensible propagation model, although multipath and near-field conditions can make even this criterion imperfect.

The operator should report the calibrated antenna response and the installed-system response separately. A nominal manufacturer's polar plot is not a calibration of the antenna plus the particular cable, room and receiver case. Where the installed pattern is demonstrably contaminated, its maximum is evidence of sensitivity, not a proved location. This does not render the survey useless. It reveals which measurements require redesigned coupling control before localisation can be attempted responsibly.

Copyright 2026, James M. Atkinson

Heinrich Rudolf Hertz, Peer Question: Mr. Heaviside, the suspicious narrow line may arise from an external transmitted wave, from ordinary electronic apparatus in a room, or from a current driven into the measurement cable by a nearby conductor. How should a controlled experiment distinguish radiative reception from near-field inductive or capacitive coupling when the source distance is comparable to cable length or to a wavelength? Which spatial and frequency responses would you regard as suggestive, and which remain insufficient for causal attribution? Please also explain how a test transmitter of known position may be used without allowing its field to contaminate the original evidential observation or to justify a conclusion more precise than the measured propagation geometry warrants. Please distinguish a test that demonstrates local reception of a deliberately generated field from a claim that the original unidentified signal arose at that test source, and explain how those records must remain separate for forensic review.

Oliver Heaviside, Response to Professor Hertz: Professor Hertz, distance from a source must be compared with the electrical size of the radiating structure and the wavelength, not with a single simplistic boundary. In a region where reactive fields are important, a cable can be driven through inductive or capacitive coupling in ways that differ from far-field plane-wave reception. The amplitude may vary strongly with small spatial movements, and polarisation relationships can differ from those expected for a remote propagating wave. Yet such features are not exclusive signatures. Multipath, metalwork and resonant cables can also produce rapid changes in the received trace.

Copyright 2026, James M. Atkinson

An experiment begins with a lawful, low-power, characterised source and a fully documented baseline. Locate it at several known positions and orientations; alter power and modulation only within authorised limits. Measure the survey antenna and the cable exterior current simultaneously, using a reference receiver outside the suspected common-mode pathway where feasible. Compare the response when the intended antenna input is terminated, when the cable is rerouted, and when the source is replaced by a benign injected electrical calibration signal. Where possible, operate in a screened laboratory so that the test signal cannot be mistaken for an environmental emission.

Spatial variation may inform the hypotheses. A signal closely associated with one cable segment, or a current peak that changes markedly upon moving a cabinet lead, suggests a coupling pathway requiring further challenge. A stable distant emitter can nevertheless excite that same pathway, so the current map alone does not reveal whether the energy originated nearby or far away. A second independent antenna position supplies additional geometry, but its interpretation must account for scattering and the unknown effective receiving pattern. Recording a phase-coherent reference may aid analysis if clocks and cables are independently assessed.

Protect the original evidence by writing test times, frequencies, source configurations and operator actions into an acquisition ledger, with clear separators from the uncontaminated monitoring intervals. Avoid intentionally radiating into a live sensitive environment without explicit authority. The scientific aim is not to make the suspicious line vanish at any

Copyright 2026, James M. Atkinson

cost but to find a repeatable intervention that changes one causal mechanism while leaving the others as stable as the conditions permit.

Ronald Newbold Bracewell, Peer Question: Mr. Heaviside, an operator may use several measurements of amplitude or bearing to infer an emitter position, even though some observations are contaminated by the same coaxial-current pathway. If the feed cable participates in reception, the forward model of the antenna is wrong. How should an inverse-location analysis expose that lack of identifiability? Could a collection of apparently consistent angles still be misleading because all observations share one installation fault or are processed with the same incorrect antenna pattern? I ask also whether the observed change following cable movement can be assigned to a unique physical source, or whether several external and internal explanations remain mathematically compatible with the recorded voltages. If two antenna configurations yield the same best-fit source position, does that establish identifiability, or must one demonstrate that the measurements would also have distinguished at least one plausible alternative cable coupling and source geometry under controlled conditions?

Oliver Heaviside, Response to Professor Bracewell: Professor Bracewell, one must formulate the forward map before trusting its inverse. Let y_k represent a measured complex voltage or derived angular response under experimental configuration k. A simplified model is $y_k=H_{a,k}(x)s+H_{c,k}(x,geometry)s+n_k$, where x is a hypothesised emitter position, s the emitted waveform, H_a the intended antenna transfer, H_c the unintended cable-mediated transfer and n_k error. This expression is schematic. A source in the equipment itself may require an additional independent excitation term.

Copyright 2026, James M. Atkinson

If H_c is unknown and varied between readings, a family of different x values can fit the same data. A numerical optimiser producing one sharp minimum does not resolve that structural ambiguity.

The remedy is not merely more data of the same type. Introduce configurations that are informative about H_c: deliberately hold the antenna fixed while moving the cable, measure cable current at multiple points, replace the feed with a controlled alternative, and check an independent receiver with a genuinely different cable route. The candidate source hypotheses should predict distinguishable changes under these interventions. Include calibration sources at known positions to see whether the inferred bearing moves when only an installation variable changes. Uncertainty in the cable transfer should enter the localisation model instead of being set to zero.

A clean intersection of bearing rays can mislead if each ray was drawn using a contaminated pattern. When all instruments share the same erroneous calibration or source-dependent coupling, their errors are correlated. An apparently narrow confidence region calculated under independent errors will be too optimistic. Compare raw observation vectors, not only final angles; inspect residuals and conduct a sensitivity study in which plausible cable-transfer terms are varied. If candidate locations change materially, the location claim is model-dependent.

The correct outcome of an inverse problem is sometimes a statement of non-identifiability. The analyst may establish that a frequency component

Copyright 2026, James M. Atkinson

appeared at several antenna and cable configurations, while being unable to distinguish among a nearby source, field-induced exterior current and receiver-generated contamination. That is a substantive technical conclusion, not a failure of diligence. Further controlled measurements should be designed to separate the remaining hypotheses rather than force an artificially precise location from insufficient evidence.

Harold Jeffreys, Peer Question: Mr. Heaviside, I ask about the evidential weight assigned to the reduction of a suspicious line after a common-mode choke is added. The observation may favour a cable-mediated reception mechanism but need not exclude a real external signal that was coupled into the cable. How should investigators compare such hypotheses without multiplying dependent receiver confirmations or assigning arbitrary probabilities to the apparent success of a single intervention? If the calibration apparatus itself changes the antenna pattern, how should that uncertainty enter the report? I should welcome a careful distinction among evidence of a component's existence, evidence of the measurement pathway, and evidence of an intentional source at some particular location. Could the same intervention support different causal interpretations when the source spectrum changes with time, and should the expert preserve the time history of every control condition rather than selecting only the trials in which suppression appears most impressive?

Oliver Heaviside, Response to Sir Harold Jeffreys: Sir Harold, the hypotheses must be separated at the outset. H1 could assert an external emitter principally received by the intended antenna. H2 could assert a real external field principally collected by the feed-cable exterior. H3 could assert internally generated or conducted interference coupled into the receiver

Copyright 2026, James M. Atkinson

through the cable or another chassis path. These are not always mutually exclusive, and a report may require combined explanations. A reduction after choke insertion is evidence that the intervention changed the measurement chain. Its likelihood under each hypothesis depends on the unmeasured coupling paths, not on the analyst's wish that the effect point to one culprit.

Before drawing a strong inference, establish a baseline rate of comparable changes produced by mechanical movement, receiver gain drift, source fluctuation and repeated connection cycles. Conduct sham interventions and record their outcomes. Where the cable is moved by the choke installation, isolate its motion as an additional experimental variable. Independent capture chains matter because two receivers powered and referenced from the same setup can share the very fault under inquiry. Claiming three independent confirmations from three displays of one common-mode disturbance would overcount evidence.

Numerical probability statements require an empirical or defensible physical model. The investigator can instead report conditional observations: the line decreased by a measured amount when a defined choke was inserted, the exterior current changed by a measured amount, and the antenna orientation remained fixed within documented tolerances. A second experiment may show that the effect reverses on removing the choke. These facts support a causal claim about an instrument pathway, but they do not independently settle whether the energy originated in a nearby source, a distant broadcast or an internal oscillator.

Copyright 2026, James M. Atkinson

Forensic integrity demands preserving unfavourable observations as well as the successful ones. If the line persists at another frequency or receiver, retain that contradiction rather than editing it from the final presentation. If the current probe lacks calibration at the relevant frequency, state that its output is comparative rather than an absolute current measurement. The ultimate finding should have three clauses: what RF energy was observed; what coupling path the controlled tests support; and what emitter-location proposition remains established, bounded or unsupported. That division avoids dressing an inference about wiring as proof of a particular person's conduct.

Dr. James M. Atkinson, Moderator: I pass the principal token to James Clerk Maxwell for an independent account of electromagnetic boundary conditions, and invite Michael Faraday to cross-examine the resulting experimental test.

James Clerk Maxwell, Second Principal Contributor: Dr. Atkinson, a coaxial feeder is a transmission structure with distinct field and current configurations on its inner conductor and the exterior of its screening conductor. A differential circuit current inside a well-behaved coaxial path need not radiate appreciably from the cable exterior, whereas unintended common-mode surface current can couple to surrounding structures and radiate or receive. Consequently a survey antenna and its connecting cable form a possible combined receiving system. If rotation of the antenna alters the shape or strain of the coaxial route, a changing displayed signal need not represent only the antenna pattern. I would measure the net longitudinal common-mode current using a calibrated clamp that encloses

Copyright 2026, James M. Atkinson

the complete coaxial cable, then change cable route and termination while holding the antenna’s surveyed position stable. A suppression or redistribution of surface current is evidence about the unintended coupling pathway, not proof that an external source never existed. Mr Faraday may challenge the physical intervention.

The boundary conditions at the surface of a good conductor allow a more exact description than the phrase 'a cable acts as an aerial'. Let n denote the outward surface normal, E the electric field and H the magnetic field. At a conducting interface the tangential magnetic field supports surface current density K through n cross (H_out−H_in)=K, with the sign fixed by the chosen normal. The relation identifies a physical surface current; it does not assume that the coaxial exterior is perfectly isolated from its surroundings. At sufficiently high frequencies the interior return associated with the differential transmission mode is concentrated near the shield's inner surface, while an exterior common-mode current can be excited by enclosure potential, nearby fields and imperfect transitions. The distinction depends on boundary conditions and geometry, not a verbal choice of which conductor is called the return.

It would be erroneous to infer that the entirety of a screen behaves as one lumped current conductor at every frequency. The full solution of Maxwell's equations may involve skin depth, shield transfer impedance, apertures, braid contact and induced longitudinal surface currents. For a simple homogeneous conductor of conductivity sigma, permeability mu and angular frequency omega, the familiar good-conductor skin-depth approximation is delta=sqrt[2/(omega mu sigma)]. The formula has defined assumptions: homogeneous bulk material, linear response, and a geometry

Copyright 2026, James M. Atkinson

for which the local plane-conductor approximation is appropriate. A braided screen and a thin metallisation can depart materially from those conditions. Thus a calculated small delta cannot itself establish adequate shielding or negligible exterior common-mode radiation in a specific installation.

The energy pathway supplies a further check. The Poynting vector S=E cross H measures electromagnetic power flow density, expressed in watts per square metre. In the guided differential mode, the relevant fields are largely concentrated within the coaxial structure, though nonideal shields and connectors allow leakage. In a common-mode disturbance, external fields and return paths must be represented, and the surrounding surfaces form part of the electromagnetic system. It follows that a screen-current clamp placed at one position does not measure the entire power flow, just as a nearby electric probe at one point does not integrate the radiated flux through a closed surface. Such measurements are valuable local observations, not replacements for a solved or experimentally constrained field model.

An examiner should first define a set of hypothesised current paths, marking the differential inner-to-shield return separately from outside-shield current and from currents in adjacent rack frames or mains conductors. The map is then challenged by changes that affect one pathway more than another. Introducing a high common-mode impedance on the outside of the cable may reduce a particular observed peak, but an external field might also excite both the intended antenna and the cable. An impedance change modifies the receiving geometry. To distinguish these cases, preserve the original field measurement, record the choke position

Copyright 2026, James M. Atkinson

and its frequency-dependent impedance, and observe current at several positions before and after the alteration.

An especially important qualification concerns distant-field inference. A strong local magnetic indication need not imply efficient far-field radiation: it may reflect reactive energy close to a current loop. Conversely an apparently small near-field electric reading at one orientation can coexist with significant radiation from an electrically long cable. In the radiating far field of a simple propagating wave, electric and magnetic components have a defined wave-impedance relation under the appropriate medium and polarisation assumptions. Near conductive enclosures the electric-to-magnetic field ratio is generally position- and source-dependent. Accordingly, neither an E-field probe nor an H-field loop can convert a single local maximum directly to radiated power without a transfer model and calibration.

The methodology I propose is therefore comparative and reversible. Measure a controlled stimulus with a properly terminated reference receiver, document the enclosure seams and cable routing, and repeat the survey after each one-factor intervention. Track the frequency, phase, magnitude and spatial distribution, not merely the largest reading. Run a positive control in which a known exterior current is deliberately created at safe levels, and a negative control with the corresponding source suppressed. Where the test apparatus itself couples to the shield, its loading must be characterised. A conclusion that the cable formed part of the receiving system can then be supported by several mutually constraining observations, without the scientifically extravagant claim that every suspicious line in the room originated inside that cable.

Copyright 2026, James M. Atkinson

Michael Faraday, Cross-Peer Question to James Clerk Maxwell: Professor Maxwell, the operator places a ferrite on the feeder and observes the suspicious line fall. It is tempting to declare that the room had no emitter and the line was entirely self-generated. But the ferrite may simply change how a real external field couples to the cable and receiver; its impedance also depends on frequency and installation. Which measurements must accompany the intervention to distinguish a changed antenna system from a genuine disappearance of environmental RF energy? Would measuring current at a single point be sufficient to characterise the entire exterior current distribution?

Your proposed boundary model is illuminating, Professor, but I would ask you to identify what a technician should actually change first. If a finite-length braid is partly connected to an enclosure seam and partly to a receiver chassis, which observation distinguishes an exterior current induced by a nearby magnetic loop from an exterior current driven by capacitive coupling across that seam? The same clamp can register both. Would you require simultaneous measurement of the seam voltage and the current distribution, or is an orientation test with a miniature magnetic loop sufficiently discriminating? I ask because a strong current at the shield exterior need not reveal the nature of its original excitation.

James Clerk Maxwell, Cross-Peer Answer to Michael Faraday: Mr Faraday, observe at several places along the cable and retain the antenna route, orientation and reference conditions. The ferrite’s effect must be compared with controlled changes in cable length, routing and common-mode termination, and ideally against a second receiver using a different coupling path. A fall in current or displayed amplitude after installing a choke is

Copyright 2026, James M. Atkinson

evidence that the tested configuration changed sensitivity to a coupling mechanism. It is not a universal negative finding about the room. Map the current distribution and measure the received feature with independently controlled wiring where feasible. Because a common-mode cable can itself behave as an antenna, the intervention changes the measurement apparatus as well as the interference pathway. The report must disclose both effects.

The same control should be repeated with the receiving cable held in a fixed, non-conductive jig so that mechanical motion does not become a hidden experimental variable. A measured decline in one exterior-current component is a useful piece of evidence, but it must be compared with any compensating current on neighbouring conductors before one asserts that the electromagnetic coupling as a whole has weakened.

I would require more than one local magnetic indication. A current clamp describes the net current through its aperture under a specified frequency response; a high-impedance differential probe may characterise the potential across the seam but can also disturb it. Measuring both establishes separate constraints. Then alter one pathway under controlled conditions: vary the loop area or orientation of a known magnetic test source while holding the electric coupling geometry as nearly fixed as possible; in a separate trial, vary an authorised capacitive test electrode while preserving the magnetic loop. Compare the phase and frequency-dependent response of the shield current in each case. A single matched result establishes sensitivity to that test, not the absence of the other mechanism.

Copyright 2026, James M. Atkinson

The proper field statement remains conditional upon the experiment. If exterior current responds strongly to loop orientation and the predicted magnetic flux, inductive coupling becomes more plausible. If it follows a controlled change in the seam potential or nearby electric electrode, capacitive excitation becomes more plausible. In a real enclosure both can operate simultaneously. I would therefore compare complete before-and-after vector readings where practicable rather than rely on a solitary displayed magnitude. And I would avoid describing the measurement as an absolute field intensity unless the probe, spacing and receiving path have been calibrated for precisely that geometry.

Oliver Heaviside, Response to James Clerk Maxwell and Michael Faraday: Their exchange correctly shows why the feeder exterior must be treated as part of the electromagnetic boundary. Suppressing one common-mode current can remove a receiver artefact or reduce genuine field pickup. Only controlled comparisons and reference-plane measurements distinguish those explanations; a quieter display alone is not an attribution.

Dr. James M. Atkinson, Moderator: Mr. Faraday, the changing current on the coaxial exterior changes the receiving apparatus itself. May Professor Maxwell challenge your proposed intervention?

Michael Faraday, Third Principal Contributor: An intervention that changes a coaxial exterior current does not merely remove interference; it changes the electromagnetic receiving system. A ferrite sleeve can diminish current on the cable exterior while preserving the intended differential path, but the resulting RF-field sensitivity must still be remeasured. I would vary cable route, termination and measured surface current under a known benign

Copyright 2026, James M. Atkinson

source, holding antenna location fixed. A quieter spectrum after one choke is an observation, not a general denial of an emitter.

The appropriate experimental witness might comprise a calibrated current clamp on the coaxial exterior and a miniature magnetic loop whose orientation is varied in a repeatable jig. A change in the loop-probe voltage should be compared with a controlled change in current distribution and with a fixed reference antenna response. Because each probe can perturb the local field, the examiner should repeat the experiment with a second geometry and disclose whether the result remains stable across that substitution. Otherwise the apparent source attribution may depend upon the measuring probe itself.

I would begin with the distinction between a change of magnetic flux and an apparent change in a displayed amplitude. If a conductive loop encloses time-varying magnetic flux Phi_B, the induced electromotive force is -dPhi_B/dt for the stated loop orientation. Yet the loop formed by an installed receiver, its cable exterior, enclosure and surrounding return conductors may be large and geometrically ill defined. Moving a ferrite sleeve can change the current distribution and effective loop area. An observed reduction then supports a hypothesis about altered coupling but does not identify the original electromagnetic source. The counterfactual question is what the receiver would display if the same external field remained present while only one known return path were modified.

Electric coupling must be considered separately. A changing potential on a nearby conductor can drive displacement current through stray capacitance into a receiver enclosure or cable shield. The simple capacitance relation

Copyright 2026, James M. Atkinson

i_C=C dv/dt is a useful local approximation only when C is treated as adequately constant and the physical extent is electrically small. The same installed system may also carry inductively coupled current and a directly received radiated field. A probe response which decreases with distance or changes orientation is not a unique fingerprint of one coupling mechanism. Reversing probe orientation, changing loop area and changing standoff under a fixed mounting jig produce stronger evidence when the predicted signatures differ between competing models.

A practical test ought to make use of null experiments. Disconnect the intended RF input and apply a correct reference termination at the receiver's declared input plane, while preserving the relevant enclosure and cable paths. If the line persists, a direct antenna-field explanation becomes less sufficient, but conducted interference or internal oscillator artefacts remain. Reconnect a controlled antenna and route the cable along a documented alternative path without changing its characteristic impedance and end terminations. Where the change in line amplitude follows the cable exterior, a cable-mediated path becomes plausible. Repeat with a second independently clocked receiver so that the test does not mistake a common instrument spur for an electromagnetic field effect.

There is a difficulty with the apparently simplest intervention: the current clamp or loop probe is not an invisible observer. Its finite magnetic material, conductor and connecting lead can redistribute the very fields whose presence it indicates. The transfer impedance of a calibrated current probe states a relation between a defined conductor current and the measured voltage only within specified frequency and positioning conditions. A reading made at one place on a standing-wave current distribution is not

Copyright 2026, James M. Atkinson

necessarily representative of the whole feeder. Thus I would require at least three clamp locations, repeated orientation checks, an instrument-floor measurement and documentation of the probe loading before assigning a quantitative current profile.

Where the diagnostic question is whether a source is internal to an enclosure, the investigation should include a controlled perturbation of the source circuit and of the enclosure itself. Suppress or alter a permitted test oscillator, observe whether the suspected spectral line follows its frequency, and separately vary a cable route or seam configuration. A field outside the box may be excited by an internal source and radiated by the exterior cable; the presence of that external field is not evidence that the oscillator was located in the open room. This is why source, propagation pathway and detection aperture must be identified as three distinct portions of the causal account, each requiring its own test.

An editorial conclusion should therefore describe what changed and under what controlled conditions. If an added common-mode choke reduced a peak by 12 decibels, the report must identify whether the instrument measured voltage, power or calibrated field strength and use the corresponding logarithmic convention. It must not state that the radiated power fell by 12 decibels unless the calibration and propagation relationship support that statement. The intervention may have altered receiving efficiency rather than transmitter output. A reversible before-and-after result, with appropriate independent controls, is valuable experimental evidence. It is not a warrant for a categorical assertion about the location or intent of an unseen emitter.

Copyright 2026, James M. Atkinson

James Clerk Maxwell, Cross-Peer Question to Michael Faraday: If a clamp current probe reads nearly zero at one position, can the engineer conclude that the whole cable exterior is electromagnetically inactive?

Please state whether the suspected source would be identifiable from one change alone, or whether several controlled perturbations are needed to break the ambiguity between two simultaneously active coupling paths. I would also wish to know how you would record the test when probe loading itself changes the signal.

Let us then make the counterfactual more exact, Mr Faraday. An operator measures a large magnetic loop-probe voltage beside a power-converter trace and subsequently sees an RF receiver line diminish after a cable choke is moved. Which independent observation would establish whether the line was received through a near-field magnetic loop, through the cable shield as an unintended antenna, or through both paths? Please distinguish the effects expected when the antenna is terminated, when the cable is rerouted, and when the test converter's switching frequency is varied by a small authorised amount.

Michael Faraday, Cross-Peer Answer to James Clerk Maxwell: No. Current standing waves and local coupling can produce position-dependent results. Measure at multiple points and examine the return paths, cable length and frequency. The probe itself changes the local environment, so its transfer impedance and placement should be calibrated. A small local reading does not establish zero radiation or reception along the entire conductor.

One should also repeat the experiment at several frequencies because a metallic seam, a cable exterior and an enclosing chassis may exchange their

Copyright 2026, James M. Atkinson

relative importance as wavelength changes. A test source whose amplitude is held constant while its frequency is shifted in small, documented increments provides a particularly useful means of distinguishing an incidental spectral coincidence from a genuine coupling transfer function. If the receiving instrument changes its gain or filter state during that sequence, those changes must be logged and challenged. Otherwise the apparent frequency dependence may have been generated by the receiver rather than by the electromagnetic pathway.

Professor Maxwell, I would regard those interventions as the foundation of the evidence. With a safe input termination, a line persisting at the receiver indicates that the intended antenna is not necessary for that observation, although direct internal coupling and conducted interference remain possible. Rerouting the feeder while keeping the receiver and source unchanged tests whether the exterior-cable geometry contributes. Deliberately changing the authorised converter's switching rate tests whether the spectral feature follows the suspected physical source rather than a fixed receiver spur. One must record each alteration and repeat the baseline after intervention to establish reversibility.

Where two paths operate together, magnitude alone can mislead because their fields can add or cancel. Retain complex phase where feasible and measure at multiple probe locations and orientations. A local magnetic-loop maximum shows local coupling susceptibility, not the equivalent isotropically radiated power of the converter. A change in cable choke configuration can modify both the route and the receiver's effective aperture. The measured outcome should therefore be described as evidence for a particular pathway under the tested conditions, not as a

Copyright 2026, James M. Atkinson

proof that no second pathway exists. I would ask that the independent receiver remain in operation throughout as a reference for changes in the source itself.

Dr. James M. Atkinson, Moderator: Professor Kennelly, please distinguish the intended differential termination from the impedance governing common-mode exterior current. Mr. Heaviside will examine the limits of a catalogue choke specification.

Arthur Edwin Kennelly, Fourth Principal Contributor: The intended coaxial circuit and unintended exterior current can have very different impedances. A 50-ohm differential termination does not prove a corresponding well-controlled exterior current return path. Ferrite impedance is frequency dependent, can be nonlinear under large fields and interacts with the rest of the cable network. Any claimed attenuation should be stated for the measured frequency and configuration rather than as a universal suppression figure.

When the feeder is electrically long, the current distribution and apparent antenna pattern should be recorded at several frequencies. A locally successful choke test cannot be presumed to apply at a different harmonic or resonance.

The distinction between measurement and inference should extend to frequency-dependent propagation along the feeder. When an electrically long cable supports standing waves, the measured current is a function I(z,f) of longitudinal position z and frequency f; it cannot legitimately be replaced by a constant value without proof. Mapping its magnitude at a sequence of

Copyright 2026, James M. Atkinson

fixed positions supplies a more informative record than one arbitrary clamp reading.

It is useful to describe the outside-shield pathway as a distributed network whose parameters change with frequency. A short current return path may be represented by a lumped impedance, but an electrically long cable near a conducting wall supports resonant behaviour, reflections and position-dependent current. The common-mode characteristic impedance is not automatically the cable's printed differential impedance. The shield exterior, surrounding conductors and the path back to the excitation source determine the relevant modes. When a choke is inserted, the observed current change depends on the source impedance and this surrounding network; the ferrite catalogue value is neither a complete description of the installation nor a guaranteed suppression factor.

Consider an idealised local Thevenin source with voltage V_s, effective common-mode return impedance Z_s and inserted choke impedance Z_c. The current amplitude in the simplified circuit is $I=V_s/(Z_s+Z_c)$. If $Z_s=50$ ohms resistive and a nominal choke adds 450 ohms purely resistive at the tested frequency, the current drops from $V_s/50$ to $V_s/500$, a factor of ten, or 20 decibels in current amplitude. This calculation assumes a one-dimensional lumped loop, an unchanged source voltage, no alternate return path, and a choke whose operating impedance is truly resistive. It is not a prediction for a resonant cable several wavelengths long, where the current may redistribute rather than simply decrease everywhere by the same factor.

A ferrite's complex impedance $Z_c=R+jX$ changes with frequency, core material, temperature, geometry and current level. Its resistive part can

Copyright 2026, James M. Atkinson

dissipate energy; its reactive part stores and releases energy. Around a network resonance, adding a reactive element can move the frequency of maximum current, producing an improvement at one measurement frequency and a deterioration elsewhere. The practical survey must therefore examine a reasonable band rather than rely on a single peak. Repeating the test with alternative core materials or a different turn count should be a controlled engineering experiment with documented geometry, not a sequence of undocumented improvisations. The original source conditions and all negative results must be retained.

An additional vulnerability is the return route through other interconnections. A receiver connected to a laptop, power adapter and instrument control cable has several potential exterior-current paths. A ferrite on the antenna feeder can redirect common-mode current into USB, Ethernet or mains wiring, so an observed reduction in one clamp location may coexist with increased coupling elsewhere. The correct experiment measures plausible alternative returns before and after the change. Temporarily isolating an authorised test interface may be useful, but one must preserve electrical safety and never defeat a protective earth connection to obtain an attractive noise reduction. The object is to map electromagnetic coupling, not to create a dangerous floating apparatus.

The accuracy of a clamp-current comparison also requires a transfer calibration. An RF clamp gives a voltage proportional to current through a frequency-dependent transfer impedance $Z_t(f)$ under its stated conditions. The derived current is $I(f)=V_{meas}(f)/Z_t(f)$, with the understanding that magnitude-only display omits phase and that common-mode currents distributed among multiple conductors can interact. If the clamp is not

Copyright 2026, James M. Atkinson

calibrated, an amplitude ratio under a fixed arrangement may still support a relative finding, but a quoted current in microamperes would lack foundation. Record the clamp model, calibration age, conductor placement, receiver bandwidth and uncertainty of the reference signal used in the comparison.

My closing rule is to reconcile three observations: where current is measured, where the received spectral feature is measured and what controlled physical intervention changes both. Where measured current and receiver response track one another coherently across frequency and cable position, a cable-mediated pathway gains support. Where the current falls but receiver response does not, investigate an independent path. Where receiver response falls without a measurable change in exterior current, challenge the probe's sensitivity, alternative returns and instrument operating state. This procedure does not require that every unknown be solved immediately. It requires that the strength of the conclusion match the actual discrimination supplied by the experiment.

Oliver Heaviside, Cross-Peer Question to Arthur Edwin Kennelly: Can a large impedance measured for a ferrite sleeve in a catalogue guarantee an equally large reduction in the exterior current of the installed cable?

At a minimum, I would ask you to contrast the current immediately on either side of the choke with currents on other connected conductors. Without that comparison the observation might merely locate a standing-wave node, not establish the attenuation of total unwanted current.

Professor Kennelly, catalogue measurements normally specify a choke's impedance in a controlled fixture, yet a real coaxial cable may run parallel to

Copyright 2026, James M. Atkinson

a conducting wall and return through several other interfaces. If the measured current at the choke decreases by ten decibels while a nearby antenna indicates only a two-decibel change, does that falsify the common-mode hypothesis? Or can current redistribution and differing sensitivity of the measurement points explain the result? I would also ask how you would distinguish a dissipative loss introduced by the ferrite from a displacement of the current maximum along the cable.

Arthur Edwin Kennelly, Cross-Peer Answer to Oliver Heaviside: No. The reduction depends on the source and return impedances, parasitic capacitance, geometry and frequency at the actual installation. Measure current and received response before and after under controlled conditions. A simple series-impedance model can guide a test but is not a substitute for the whole electromagnetic boundary problem.

It is equally important that the experiment identify whether a numerical reduction is expressed in voltage, current or power. An attenuation of ten decibels in a current amplitude ratio corresponds to the appropriate 20-logarithm convention under consistent impedance assumptions, whereas power measurements use a 10-logarithm convention. The underlying transfer conditions matter when converting between these quantities. Where the local probe has not been calibrated, a reported change under a fixed probe placement may be defensible as a relative observation, but a claim about total power radiated into a room is not established. The report should retain the unmodified trace and give its frequency resolution and noise floor.

Copyright 2026, James M. Atkinson

Mr Heaviside, the mismatch does not automatically falsify the hypothesis, because the two instruments sample different physical quantities. A clamp measures local net current at one position; the receiving antenna responds to the field produced by a distributed set of currents and environmental reflections. Installing a choke can move the current maxima while the total field at the antenna changes less. It can also redirect current into another return path. The simplest remedy is to measure exterior current at several cable positions and at alternative returns while observing the antenna output at a fixed reference plane.

Next inspect the choke's measured complex impedance over the frequency band rather than accept its nominal catalogue figure as an installed constant. Compare a resistive-dominated core with a reactive-dominated configuration, while keeping the core geometry and supply conditions documented. A reduction of local current accompanied by thermal dissipation and a coherent decrease in the relevant far-field component supports an attenuation account. A movement of current peaks with comparatively little change in total radiation favours redistribution. Any such judgement needs a calibrated current measurement or a carefully bounded relative comparison; one attractive attenuation figure is not enough.

Dr. James M. Atkinson, Moderator: Professor Bracewell, how might a cable-supported current corrupt the apparent direction of an emitter? Sir Harold Jeffreys will assess the evidential independence of repeated bearings.

Ronald N. Bracewell, Fifth Principal Contributor: Direction finding assumes a calibrated antenna response, but a cable carrying common-mode current can alter the spatial pattern and produce false minima or bearings. When

Copyright 2026, James M. Atkinson

rotating the antenna also changes the cable route, the experiment varies more than one physical quantity. I would compare controlled stationary-cable rotations, changed cable routing with the antenna fixed, and an independent receiving antenna with different feed arrangements. The correct output is a bearing only if the installed system supports a stable directional response.

A further test should compare bearings obtained with two independent antenna/feed installations and a controlled emitter at a surveyed position. The difference between their indicated directions under deliberately altered cable routes supplies an empirical estimate of route-dependent bias. A plausible narrow intersection formed exclusively from one contaminated installation must not be treated as an independently validated location, however small its internal least-squares residual appears.

Direction finding depends on a known forward relationship between source direction and the received vector of antenna signals. If the intended antenna alone has pattern a(theta), a cable exterior carrying common-mode current contributes an additional, route-dependent pattern b(theta). A simplified complex voltage model is v(theta)=alpha a(theta)+beta b(theta)+n(theta), where alpha and beta embody the excitation and relative phase and n denotes receiver noise. A conventional angle estimator that fits only a(theta) can return a persuasive but biased direction. The bias may vary with cable bends, instrument location, amplifier gain and nearby metallic surfaces. A peak or null observed while the cable is moving is not automatically an attribute of the external wavefront.

Copyright 2026, James M. Atkinson

A null direction can be especially misleading because destructive addition of antenna and cable contributions may create a very deep minimum unrelated to the antenna's calibrated pattern. A change in the cable route can then shift the null despite no movement of the distant transmitter. To test the hypothesis, hold the antenna's position and orientation fixed while rerouting only the controlled feeder; then hold the feeder geometry fixed while rotating the antenna. If the received response follows the cable intervention, the effective receiving structure must include the feeder. If the response follows antenna rotation with stable reference controls, the intended aerial path becomes more credible. Both results must be interpreted with the receiver's gain and noise floor held within their validated range.

The localisation question also requires independent geometrical information. Several nearby bearings taken with the same contaminated feed arrangement may share a systematic bias. Their apparent intersection is not equivalent to several independently calibrated lines of position. A covariance model should incorporate shared cable geometry, common receiver reference and local propagation effects. Where multiple bearings are derived from one long recording, temporal correlation can further reduce the effective number of independent observations. It may be preferable to state a region bounded by tested configurations rather than a falsely exact coordinate. A new measurement at a materially different location with a different antenna and independent feeder arrangement provides a more valuable challenge than a tenth rotation of the same disturbed instrument.

Copyright 2026, James M. Atkinson

The differential test must also distinguish reactive near fields from propagating radiation. Close to an electrically small emitter, source impedance and relative electric and magnetic field strength can change rapidly with standoff, and simple far-field bearing assumptions may fail. Reflections from walls and metallic equipment create further spatial structure. Moving an antenna by a fraction of a wavelength can change received phase and amplitude without proving that the source moved. Accordingly a location hypothesis should be checked with measured spatial gradients, polarisation changes and a controlled reference transmitter at surveyed positions. The inversion must accommodate or explicitly exclude the operating environment in which the measurements were made.

I would also insist upon a small number of preregistered diagnostic tests. Define in advance what result would favour the cable-current hypothesis and what would favour an independent external emitter. These could include a measured exterior-current reduction associated with a change in feeder routing, the appearance of a similar spectral signature on a terminated reference channel, and the persistence of a field on a separately powered and clocked receiver. Record failed trials. Repeating interventions only until one gives an attractive bearing would introduce selection bias. The field notebook should capture the entire sequence, including unchanged configurations, to allow a later examiner to assess the weight of the evidence.

Finally, the word emitter should be used with care. The observed field may arise from normal apparatus, unintended oscillation, cable leakage or a purposeful transmitter; a receiver reading alone does not establish intent. Even after a source has been located, the legal and forensic characterisation

Copyright 2026, James M. Atkinson

of the device demands separate evidence and proper authority. The defensible scientific conclusion is narrower: the specified spectral component was observed with particular antenna and feeder configurations, altered in a documented way under controlled changes, and either remained or failed to remain under independent challenge. Such language is precise enough to support later inquiry without confusing a measurement-system artefact with an attributed hostile source.

Harold Jeffreys, Cross-Peer Question to Ronald N. Bracewell: If several nearby measurements all point toward the same corner, can their geometrical agreement establish the emitter location when each uses the same cable and receiver?

I would welcome a specific demonstration of how the estimated bearing covariance changes when the common systematic error term is admitted, so that the final report conveys not merely that the original intersection is doubtful but why its numerical confidence is overstated.

Professor Bracewell, consider five bearings whose rays meet convincingly near one instrument rack. All five were taken with the same antenna, the same coaxial feeder and the same receiver, and the cable route was changed only inadvertently as the surveyor walked between positions. What statistical evidence would you demand before treating the convergence as independent localisation? If a sixth bearing from a separately installed antenna disagrees, should it be rejected as an outlier or should it be given special evidential weight because its error pathways differ from those of the first five?

Copyright 2026, James M. Atkinson

Ronald N. Bracewell, Cross-Peer Answer to Harold Jeffreys: Their agreement may reflect a repeated instrumental bias. Independent antenna/feed paths and controlled route changes should challenge the conclusion. If the apparent bearing follows the cable rather than the antenna geometry, the location inference loses force. Report both the concordance and the shared configuration, and avoid multiplying their evidential strength as if the measurements were independent.

A numerical illustration makes the danger plain. Suppose repeated bearings have individual random uncertainty of one degree but share a previously unrecognised systematic angular shift of five degrees. Averaging more bearings can reduce the uncorrelated component, but cannot remove the common five-degree bias. The geometrical intersection may appear increasingly sharp even while its centre remains displaced. This is why a validation source at a surveyed location and a change to genuinely independent receiving hardware are necessary to challenge the error model. Without them, the apparent precision is internal to the assumed analysis and should never be represented as externally demonstrated localisation accuracy.

Sir Harold, the five bearings do not provide five independent confirmations merely because the report lists five numbers. Their error sources include a shared antenna pattern, a common cable path and one receiver's calibration. The errors may be correlated or systematically biased; taking their arithmetic mean or fitting a narrow intersection without that covariance can create spurious precision. Before treating the sixth bearing as an outlier, test whether its independent antenna and feeder path reduce precisely those shared errors. Its disagreement may be evidence that the

Copyright 2026, James M. Atkinson

original model was deficient, not evidence that the independent reading was inferior.

I would assess the measurement set using a model that distinguishes random bearing variation from known and plausible systematic terms. Repeat the survey with the original cable route deliberately fixed, then with the route changed under controlled conditions. Include a calibrated test emitter at more than one known location. If the first five rays move together as the feeder changes, they reveal a common bias, and their attractive convergence has little evidential value for locating the external source. If the independent sixth receiver remains stable under those changes, it becomes a powerful challenge. Nevertheless, I would report its own uncertainty and testing limitations, not elevate it automatically to unchallengeable authority.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The distinction central to this question is not a semantic distinction between cable and antenna. It is a physically testable difference between the confined, intended differential mode and current flowing on the coaxial exterior and its environmental return path. Exterior current may make the feed line an additional receiver, alter the installed antenna pattern, fill a directional null and change an inferred bearing when the cable moves. A calibrated full-cable current clamp, controlled routing changes, carefully characterised common-mode impedance, known-field challenges and truly independent reception offer different views of that same problem. No single one supplies unique attribution. The panel requires investigators to report the measurement reference plane, intended antenna response, installed-system response, common-mode evidence and surviving alternative hypotheses. A signal may be real whilst the claimed location is false. The eight historical

Copyright 2026, James M. Atkinson

voices in this exchange are fictional instruments of modern instruction, and every quantitative example is illustrative rather than a field measurement.

QUESTION 062

Which near-field observations distinguish electric coupling from magnetic coupling in an enclosure?

HISTORICAL RECONSTRUCTION. This moderated roundtable is a fictional instructional reconstruction. Deceased scientists did not participate in this dialogue, did not use modern digital spectrum analysers, and are not represented as having endorsed present-day surveillance procedures. Contemporary techniques, symbols and safety qualifications are editorial extrapolations.

Dr. James M. Atkinson, Moderator: Mr. Faraday, the inspector of a screened enclosure frequently observes a sharp near-field maximum next to a seam, then calls the leakage electric or magnetic on the strength of the probe label. What measurements would actually discriminate capacitive coupling through an electric field from inductive flux linkage or common-mode conduction, and how should the results be described without falsely converting local field strength into radiated power? I shall ask each principal to offer an independent method, then open his conclusion to technical challenges from the panel.

Michael Faraday, Principal Contributor: Dr. Atkinson, I would begin with the practical observation that an enclosed circuit may disturb a neighbouring detector by more than one physical route, even though a single receiver displays only one amplitude. An alternating potential on a conductor can create an electric field and displacement current through a stray capacitance, whilst an alternating current in a loop creates magnetic flux that can link another loop. These mechanisms are not separate kinds of

Copyright 2026, James M. Atkinson

electricity. They are complementary aspects of one electromagnetic field, yet distinct experiments can reveal which coupling route dominates at a given location and frequency. The cleanest comparison changes the geometry in one way at a time: rotate the detecting loop, rotate a short electric probe, vary the distance, and alter the return-current path without changing the signal source. Record the change in a calibrated quantity, not merely in a colourful spectral display.

For a small receiving loop of N turns and area A in square metres, the idealised induced electromotive force is v(t)=-N dPhi/dt, with Phi the magnetic flux through a turn in webers. If the magnetic field is approximately uniform over the loop area, Phi=mu A H cos(theta), where H has units of amperes per metre, mu the magnetic permeability in henries per metre, and theta the angle between the loop normal and the magnetic field. Under sinusoidal conditions of frequency f hertz and angular frequency omega=2 pi f, the magnitude of the open-circuit voltage is approximately N omega mu A H abs(cos(theta)), provided the loop is electrically small, sufficiently unloaded, and not itself resonant. This is an informative approximation, not a universal calibration for commercial H-field probes. A shielded loop can still suffer electric-field pickup and imbalance, particularly around its feed transition.

Imagine an illustrative single-turn loop with area 1 square centimetre, or 0.0001 square metre, placed in a uniform sinusoidal H field of 0.01 ampere per metre at 100 kilohertz. Taking free-space permeability mu_0 approximately 1.256637 times 10 to the minus sixth henry per metre, the idealised magnetic flux amplitude is about 1.256637 times 10 to the minus twelfth weber. The angular frequency is approximately 628,319 radians per

Copyright 2026, James M. Atkinson

second, so the induced open-circuit voltage amplitude is about 0.790 microvolt when the loop normal aligns with the field. At ninety degrees the ideal flux linkage vanishes. In reality finite probe balance, nearby conductors, spatial gradients and cabling prevent a perfect null, but the orientation response supplies useful discriminating evidence. This example assumes uniform H and no loading, and must not be treated as an equipment specification.

An electric pickup can be approached through displacement current. For a small parasitic coupling capacitance C_c in farads between the source and the sensing circuit, with sinusoidal source voltage amplitude V_s, the displacement-current amplitude is approximately I_c=omega C_c V_s. A coupling capacitance of 0.2 picofarad at 100 kilohertz with a 10-volt source would create an idealised current amplitude of 1.26 microamperes before the receiving impedance is considered. This cannot be compared numerically with the loop voltage until the detector impedance and circuit loading are specified. Nevertheless, it shows why a tiny gap between conductors can convey an observable interference signal even when no metallic contact is present. The investigator should look for response to changing overlap area, separation and the impedance at the receiving node.

The experimental source must be characterised. A high-voltage, high-source-impedance node often produces conspicuous capacitive pickup, whereas a low-impedance circuit carrying appreciable current can generate magnetic flux around its return path. Those are useful tendencies, not rules that allow identification from source impedance alone. A low-impedance line can possess a strong voltage relative to nearby metal; a high-impedance structure can carry displacement current and contribute to magnetic fields.

Copyright 2026, James M. Atkinson

The field configuration depends on frequency, geometry, return conductors, surrounding metal and the probe's own disturbance. Only paired measurements, with controlled variations, permit an argument about the dominant coupling path.

One test would place a driven conductor inside the closed enclosure, preserve its amplitude and frequency, and bring two electrically small, calibrated probes to the same positions outside a seam. The short electric sensor is rotated to sample different components of E; the loop's normal is independently rotated to map components of H. Map the response at several known standoffs without contacting conductive surfaces. A strong loop response with a reproducible orientation null, coupled with sensitivity to the position of the source return wire, is consistent with magnetic flux linkage. A response that increases sharply as a high-voltage conductor is approached, changes strongly with probe electric orientation and responds to a grounded electrostatic screen may instead support a capacitive pathway. Neither result, by itself, proves a pure field of one kind.

A particularly useful intervention is to alter the loop area of the *source circuit* whilst holding its current approximately constant and directly measuring that current. Widening the source-return separation changes the magnetic dipole moment and the external flux pattern. Bringing forward and return currents close together can cancel much of the distant magnetic field; the spatial distribution must still be considered near each conductor. Conversely, altering the exposed voltage-bearing area whilst preserving its drive voltage and source-return current can change capacitive coupling. Because these interventions may themselves change circuit impedance, we must log source voltage and current before and after every change, rather

Copyright 2026, James M. Atkinson

than crediting a field change to geometry without verifying the electrical drive.

The metal housing presents additional questions. A continuous conducting surface can support charges that rearrange in response to an electric field; seams, apertures and cable penetrations disturb that boundary. At sufficiently low frequency, the housing may be a poor barrier to a magnetic field, depending on thickness, conductivity and permeability. A grounded sheet inserted between source and probe may alter both field distributions, so its use does not constitute proof of exclusive electric coupling. One should compare different screens of known material, geometry and thickness, inspect the reference ground and note whether the screen changes the current path. The apparent improvement in a receiver trace must be reconciled with actual field mapping.

To preserve this as defensible evidence, photograph the test configuration, record the probe orientation and separation, preserve raw complex samples or calibrated amplitude measurements, and include a no-source baseline. At each position record instrument settings, preamplifier gain, bandwidth, cable routing and uncertainty. I would pass the token to Professor Maxwell for the mathematical reason that our electric and magnetic observations cannot be interpreted as separate, independent fluids. A near-field maximum is a local observation conditioned by geometry; it is not by itself a calibrated far-field radiation power and cannot establish the location of a concealed source without a model and appropriate control experiments.

Harry Nyquist, Peer Question: Mr. Faraday, your electrically small probes report voltages at instrument connectors, while the sought measurands are vector electric and magnetic fields at locations in space. How does the

Copyright 2026, James M. Atkinson

analyst avoid mistaking the probe's transfer function for the object's field? A receiver with a 50-ohm input may load a capacitive sensor, and a loop connected through a coaxial cable may form an unintended antenna. I ask how you would establish frequency-dependent sensitivity, orientation rejection and noise floor, and how you would choose spatial sampling increments without aliasing a narrow field maximum. Please address whether a weak, broad response can be missed when the step size is chosen solely from the mechanical dimensions of the enclosure, and distinguish a voltage in a probe cable from an electric field in volts per metre.

Please also specify the polarity conventions and whether a deliberately injected calibration tone should be measured with the probe at several stand-offs, since an incorrectly referenced voltage conversion could reverse the apparent E/H comparison. How would you document probe saturation when a strong switching transient obscures the weak narrowband emission? An instrument noise floor measured with its input terminated need not equal its noise floor with a high-impedance electric sensor attached.

Michael Faraday, Response: Mr. Nyquist, the correct response is to obtain or establish the transfer function under a known calibration field. A measured connector voltage is the result of field coupling, the probe's geometry, load impedance and its cable arrangement. For a loop, the ideal relation between uniform H and open-circuit voltage is proportional to frequency and effective area; for a short electric probe, the effective height and input impedance matter. Neither measurement becomes a field strength by dividing by an arbitrary constant carried over from another frequency. The calibration report must identify orientation, frequency range, loading and the uncertainty of cross-polarisation response.

Copyright 2026, James M. Atkinson

A practical discrimination test starts by rotating the loop through a full circle at one surveyed position and observing whether a stable response maximum and minimum occur. Repeat the procedure after rotating or rerouting the coaxial lead without moving the loop itself. If the response changes primarily with the cable, a common-mode pickup path is suspected. The same check should be applied to the nominal E probe, whose feed may act as an unintended monopole. A shielded loop should not automatically be called immune to E-field pickup; modern probe characterisation shows that differential capacitive coupling can survive shields. The field-rejection ratio is a measured property, not a name assigned by the instrument catalogue.

For spatial mapping, first perform a coarse reconnaissance to identify candidate maxima, then refine the grid around them whilst preserving the actual standoff. At a localised seam, a step of several centimetres may skip the response entirely, whereas a continuous aperture several metres long may require a wider scan to understand its pattern. The appropriate grid depends on the spatial bandwidth of the field, source geometry, probe footprint and positional uncertainty. Test repeatability by traversing the same line in the reverse direction. If the source power or frequency moves during the survey, correct or invalidate the comparison rather than interpolate a neat field map from incompatible observations.

The report should keep connector-voltage data separate from inferred E and H field strengths. Where proper calibration is absent, use defensible relative statements, such as the orientation and position that give larger response under fixed settings. Noise-floor readings taken with the source disabled should accompany each reported increase. This conservatism is especially

Copyright 2026, James M. Atkinson

important when trying to discriminate magnetic and capacitive pathways from a result only a few decibels above the receiving system's own noise.

Sir Harold Jeffreys, Peer Question: Mr. Faraday, the experimental choices appear capable of creating conflicting explanations. A loop null might arise from an actual rotation of H, from the probe's imperfect response, or from two sources cancelling at one location. An electrostatic screen could alter the source current as well as the field leakage. Would you prescribe rival causal hypotheses before the data are collected, and identify a falsifying observation for each? I should be particularly concerned by an investigator who interprets every rise in an H-probe trace as proof of magnetic leakage without testing unwanted E coupling. What should be recorded when two mechanisms remain inseparable within the measurement uncertainty?

Suppose the probe is moved after the first exciting result is seen. Would you insist on a pre-registered scan and a withheld geometry trial to prevent selective reporting? Explain how a cautious analyst should distinguish evidence that *supports* a favoured pathway from evidence that actually *excludes* its alternatives. What would be sufficient to regard the result as a mixed-mode coupling rather than as two incompatible opinions?

Michael Faraday, Response: Sir Harold, an observation acquires meaning through a contrast that rival explanations predict differently. I would write at least three hypotheses: the response is chiefly inductive through a source-return loop; chiefly capacitive through a voltage-bearing surface or aperture; or chiefly conveyed by conduction and common-mode currents on an attached cable. Each hypothesis should be associated with a controlled intervention whose likely direction can be predicted. Reducing source loop area while holding its current fixed should disproportionately reduce the

Copyright 2026, James M. Atkinson

first mechanism. Reducing source voltage while holding the relevant current fixed can challenge the second, although practical circuit coupling makes that separation difficult. Adding a properly instrumented common-mode choke or changing cable routing may test the third.

The intervention must be measured at its source. It is not enough to say that a conductor was moved. Record how its current, voltage and load changed, because the intervention can affect several mechanisms simultaneously. Repeat the observation at multiple probe orientations and standoffs. If the alleged magnetic response persists when the loop is rotated to a predicted null but follows the coaxial lead instead, the magnetic attribution should weaken. If a grounded screen changes both apparent E and H pickup, the result is not uniquely diagnostic. Where a field model is employed, compare it against withheld configurations, not only the arrangement from which its parameters were fitted.

Uncertainty should include detector noise, probe calibration, cross-field rejection, source stability, probe positioning and alternative source arrangements. The comparison is not always a simple sum of independent Gaussian errors: a cable change can alter probe loading and create a systematic bias. Rather than invent a precise probability that one explanation is correct, I would report which experiments favour which mechanism and which could not discriminate them. An apparently precise power spectrum cannot compensate for a missing causal experiment. When the evidence supports only 'near-field coupling detected outside this seam', the report should use precisely that statement.

A practical stopping rule would require two independent observational contrasts that agree on the dominant mechanism, with measured response

Copyright 2026, James M. Atkinson

differences materially larger than their combined uncertainty. If no such contrast exists, a mixed-mode explanation must remain open. The investigator may still identify a repair that reduces leakage, but should distinguish engineering mitigation from a proof of its original physical mechanism.

Dr. James M. Atkinson, Moderator: Professor Maxwell, the token now passes from Mr. Faraday to your field-theoretic analysis. Please reconcile the apparent separation of capacitive and inductive mechanisms with the coupled field equations, then invite an experimental challenge.

James Clerk Maxwell, Second Principal Contributor: Dr. Atkinson, the expression 'electric coupling versus magnetic coupling' should be understood as a comparison of the mechanisms most sensitive to a proposed intervention, not as a denial of their common electromagnetic origin. The relevant local quantities are E, electric field in volts per metre; D, electric flux density in coulombs per square metre; H, magnetic field in amperes per metre; and B, magnetic flux density in teslas. Their relations in simple linear isotropic media are D=epsilon E and B=mu H, where epsilon and mu are respectively electric permittivity and magnetic permeability. Across a surface, charges and currents influence the field boundary conditions. Once the fields change with time, Faraday induction and Maxwell displacement current make their evolution interdependent. A local sensor that favours one component cannot thereby demonstrate that the other is absent.

In differential form, a useful pair of field equations is curl E=-partial B/partial t and curl H=J+partial D/partial t, where J denotes conduction current density in amperes per square metre. The first describes the relation between time-

Copyright 2026, James M. Atkinson

varying magnetic flux and circulating electric field. The second records both conduction current and the time-varying displacement field as sources of circulation of H. These equations do not tell us whether the interference reaching a receiver is dominantly capacitive or inductive until the source geometry, frequency, material boundaries and receiver impedance are specified. A high-impedance probe close to a charged surface may respond strongly to E, while a small loop near a current return responds strongly to changing B. The fields coexist, but their ratios and spatial patterns are not generally those of a freely propagating plane wave.

This distinction is especially important in the reactive near field. The impedance relation abs(E)/abs(H)=approximately 377 ohms is a far-field plane-wave reference in free space, not a universal conversion between local E and H measurements. Near a small electric dipole, the quasistatic electric component may dominate locally; near a small current loop, the magnetic component may be more pronounced. Reactive stored energy and phase relationships complicate the interpretation. The simplistic boundary r less than wavelength divided by 2 pi can be a useful scale for an electrically small source, but finite antennas and large apertures require geometry-specific near-field boundaries. One should not apply a single spherical distance rule to an extended cable harness or large equipment enclosure.

For a free-space wavelength lambda=c/f, c is approximately 299,792,458 metres per second and f the frequency in hertz. At 10 MHz the wavelength is about 29.98 metres; lambda/(2 pi) is about 4.77 metres. A probe held 10 centimetres from a small source is therefore very near relative to that scale. But this arithmetic does not prove magnetic coupling, electric coupling, or an absence of radiation. At 1 GHz the wavelength is only about 0.300 metre,

Copyright 2026, James M. Atkinson

and a 10-centimetre stand-off may no longer satisfy the same electrically small approximation. The field of an enclosure seam can also be shaped by the enclosure dimension and resonances. All numerical classification should be attached to the actual frequency and source size.

At an ideal perfect conductor the tangential electric field at the surface is zero, the normal displacement field reflects surface charge, and the discontinuity of tangential magnetic field is associated with surface current. Real conducting walls possess finite conductivity, thickness, seams and apertures, so these ideal conditions are approximations with limitations. An enclosure surface might greatly suppress a quasistatic electric field while a low-frequency magnetic disturbance penetrates it, yet a cable opening or compromised bond can create a new path for both. The field near an aperture may not resemble a simple dipole because induced currents around its perimeter contribute to the measured response. The investigator should map the exterior field and the wall current or bonding configuration together where safe and feasible.

Power flow must not be inferred from one component measured at one point. In a time-harmonic description, the complex Poynting vector involves E cross the complex conjugate of H, with its real part related to average transported energy and its imaginary part to reactive exchange. A calibrated E magnitude alone cannot supply that vector, nor can a magnetic loop's scalar output. Even if both magnitudes are known, their vector directions and relative phase matter. A strong H probe response one centimetre above a seam may represent substantial reactive energy with modest far-field radiation. It is thus unjustified to take a near-field receiver reading, apply a

Copyright 2026, James M. Atkinson

free-space impedance conversion and announce a far-field radiated-power value without an applicable model and corroborating measurements.

One can perform a boundary perturbation experiment. Introduce a removable, conductive cover across a small aperture, ensure electrical bonding is measured, then repeat the field map with the same source drive and probe positions. If capacitive coupling through the aperture was dominant, the electric probe may show a pronounced reduction; if current redistribution causes a change in the magnetic field, the loop may also change. The experiment therefore needs both sensors and current information. A separate test with a nonconducting spacer may help distinguish mechanical spacing from electrical bonding. Record the intervention's effect on the source impedance, because the cover itself may detune a nearby oscillator or antenna.

Interpretation should proceed from a Maxwell-consistent model. Source-voltage and current measurements specify possible excitation, geometry supplies boundary conditions, a calibrated pair of field probes provides partial observables, and repeated perturbations test which coupling path explains their variations. A model that predicts the observed H maximum only by inventing an unmeasured surface current is not established by the maximum itself. Test its predicted orientation, distance response and sensitivity to bonding changes. I pass the token to Professor Hertz, who can examine when such local stored-field patterns evolve into radiation and why the transition matters to a survey of enclosed electronics.

Michael Faraday, Cross-Peer Question to James Clerk Maxwell: Professor Maxwell, you emphasise that E and H coexist wherever the full time-varying electromagnetic problem is solved. How then can an engineer defend the

Copyright 2026, James M. Atkinson

practical statement that a particular seam has predominantly magnetic coupling when a capacitive signal may also be present, perhaps below the electric probe's noise floor? Would you require a vector phase measurement, or can orientation and controlled source-return geometry provide sufficient evidence for a limited mechanism claim? Please explain why a large local H magnitude is not evidence that the enclosure is radiating strongly into the distant environment, and how the evidence ought to be labelled when the material permeability and seam impedance are imperfectly known. I also ask whether a null in one probe orientation can result from field superposition rather than from the absence of a coupling path.

A further difficulty is the meaning of a zero in a component measurement. The sensed magnetic flux may cancel over a finite loop area even when the field is strong and nonuniform. Would you therefore compare probes of two sizes at matched sensing locations and assess whether the null follows the sensing aperture? This could distinguish true field orientation from spatial averaging, but might also alter source loading.

James Clerk Maxwell, Cross-Peer Answer to Michael Faraday: Mr. Faraday, a practical designation such as 'magnetic-dominant coupling under these test conditions' can be defended when the experiments specify a limited, measurable claim. One should not claim that the electric field vanishes. For example, an H-field probe might show a spatial maximum above a current-return discontinuity and respond predictably when the loop is rotated, while a calibrated E-field probe reports a much weaker component after its own rejection characteristics have been checked. Altering the source-return geometry whilst maintaining measured drive current could then produce

Copyright 2026, James M. Atkinson

the change predicted by an inductive-coupling model. That collection of contrasts supports the restricted conclusion more strongly than a single amplitude ratio.

The vector and phase measurements would be desirable where the intended claim requires power flow or a full electromagnetic field reconstruction, but not every diagnostic task requires a complete field solution. The degree of necessary evidence is fixed by the conclusion sought. To locate a practical coupling path, repeatable response to controlled bonding, shielding and loop-area changes may suffice. To estimate far-field radiation, it does not. The Poynting vector depends on both fields and their relative direction and phase; in a reactive region much energy is stored and returned rather than transported to infinity. A strong near-field sensor output may therefore coexist with comparatively weak distant emissions.

A polarisation null is also ambiguous in isolation. The vector component sensed by a loop can vanish at one orientation while other components remain; fields from several sources can cancel at a particular location; and the probe itself may have a complicated cross-field response. A complete rotation, a nearby spatial scan and an independent calibration of the probe are preferable to treating one null as proof of absence. If permeability or seam contact impedance is uncertain, quantify the model's sensitivity to those parameters and avoid presenting an untested wall-current distribution as a measured fact. The appropriate expert statement describes dominant response in the tested configuration, residual uncertainties, and the interventions that would challenge the interpretation.

Copyright 2026, James M. Atkinson

The central claim should remain conditional on probe calibration. For example, two H loops with different footprint and electric-field rejection may produce different amplitudes above an unbonded seam, even if the actual current distribution is unchanged. Repeating the geometry variation with both probes would expose such instrumental dependence. Where neither sensor rejects the unwanted component sufficiently, an honest classification remains mixed rather than artificially forced into one category.

A related check uses source modulation: change the test-drive current while monitoring both current and voltage, rather than relying on nominal generator settings. If the magnetic loop response follows measured current while the electric sensor does not, that is one informative contrast, but the inference must include probe rejection and possible loading. A second, different geometry trial is still desirable before calling the route established.

Charles Hard Townes, Peer Question: Professor Maxwell, a narrowly resolved spectral line may remain coherent across many points of a near-field scan, while a second source in the same enclosure can be slightly offset in frequency. Would the apparent phase relationship between electric and magnetic probes identify the coupling mechanism, or might the instruments' cables and reference clocks introduce an equally plausible phase shift? Explain what coherence measurement would tell us about a shared excitation and what it would not tell us about the actual route through an aperture. I would also ask how finite measurement bandwidth and oscillator drift affect the result when the field source is weak, because a dramatic coherence plot may be produced from a chain whose timing reference is not independent of the source.

Copyright 2026, James M. Atkinson

If a single coherent signal divides into two paths, each with a different cable delay, would their combined phase at one sensor permit a unique reconstruction of which path dominated? What observations should reveal an unnoticed acquisition clock switch or phase unwrap discontinuity? Please state the limits of coherence when the source waveform is broad or changes faster than the instrument's averaging interval.

James Clerk Maxwell, Response: Professor Townes, coherence is useful for identifying related signals, but it is not itself a map of causation. A high magnitude-squared coherence between a source monitor and an E or H probe at a narrow spectral line supports the proposition that the signals share some deterministic excitation within the measured bandwidth. It does not prove that power crossed the enclosure by the capacitive route, by flux linkage, through a cable common mode, or through an aperture resonance. Those alternative routes can all convey a coherent signal. A phase difference may be influenced by field propagation, reactive coupling, the probe transfer function, filter group delay, cable length and the instrument reference. The measurement must account for the entire chain.

I would first calibrate the relative phase of the two probe channels with a common known stimulus and record their frequency response, then return each sensor to the intended scan point without changing the routing. Use a shared acquisition clock when relative phase is the measurand, but keep an independent witness if the absolute clock is itself under test. If the source drifts in frequency during sequential scans, the measured phase can change because the source moved, not because the field configuration changed. Simultaneous acquisition or a documented reference monitor reduces that

Copyright 2026, James M. Atkinson

ambiguity. Finite bandwidth can average distinct sources into one apparent line, so the resolution bandwidth and window function belong in the record.

Consider a hypothetical 10 MHz test with a 2-metre difference in cable electrical length. At an ideal velocity factor of 0.66, the additional group delay is approximately 2 metres divided by (0.66 times 299,792,458 metres per second), or about 10.1 nanoseconds. At 10 MHz that delay corresponds to a phase difference of approximately 36.4 degrees. The arithmetic assumes a nondispersive cable and must not be transferred without measurement to real assemblies. Nevertheless it shows that an impressive probe-to-probe phase contrast could originate largely in the cabling rather than in enclosure coupling. Reverse the channels, measure a loopback, and retain the cable identifiers before drawing a field-theoretic conclusion.

The field observations should be interpreted through multiple independent tests: amplitude orientation, spatial gradient, response to source-drive change, response to shielding or bonding, and phase if calibrated. A field vector reconstructed from an uncalibrated set of probe voltages may look mathematically complete while being physically wrong. State whether the experiment establishes common excitation, likely route, local field components, or distant power flow. These are four different evidential propositions and should not be collapsed into a single claim.

Dr. James M. Atkinson, Moderator: Professor Hertz, consider the change from reactive storage to propagating radiation. Why does a steep near-field distance response fail to prove that magnetic coupling dominates, and how should a field survey identify the source?

Copyright 2026, James M. Atkinson

Heinrich Rudolf Hertz, Third Principal Contributor: Dr. Atkinson, an enclosure survey becomes misleading when it treats every detected oscillating field as an outgoing electromagnetic wave. An electrically small source produces both reactive near-field terms and propagating terms, whose relative magnitudes depend on distance, source type, frequency and surrounding material. In simplified dipole expansions, different field contributions can decay in amplitude approximately with inverse powers of distance, including terms of order one over r cubed, one over r squared and one over r. Yet the field measured at one wall opening of a large metallic box is not necessarily the field of an isolated infinitesimal dipole. Conducting boundaries, finite sources and multiple reflections introduce patterns that cannot be diagnosed by one power-law fit. The experiment must therefore separate local coupling-path discovery from the estimation of external radiation.

A useful scale is the electrical size of both source and observation region. The free-space wavelength lambda=c/f decreases as frequency increases. At 100 kilohertz it is approximately 3,000 metres, and an instrument held 5 centimetres above a small printed-circuit trace is deep within a quasistatic regime relative to that wavelength. At 3 gigahertz, lambda is approximately 10 centimetres, and the same standoff can be comparable to a wavelength. It follows that a probe scan made at a single physical distance over six decades of frequency samples different electromagnetic regimes. One should not apply the low-frequency magnetic-loop intuition to a high-frequency seam resonance, nor use a high-frequency horn antenna's calibration to interpret fields immediately above a power-supply inductor.

Copyright 2026, James M. Atkinson

Distance response is useful only with a suitable model. For an electrically small magnetic dipole under specified near-field conditions, a dominant local magnetic component can fall rapidly with distance, roughly as r to the minus third in its quasistatic region. Doubling r would then reduce that idealised amplitude by a factor of eight, which corresponds to approximately 18.1 dB in amplitude ratio. A propagating far-field amplitude may instead fall roughly as one over r, for a factor-of-two reduction or approximately 6.02 dB. These are model-specific limiting behaviours, not a universal test to identify magnetic versus electric coupling, because an electric dipole also has quasistatic terms and an enclosure can support several sources. The source, probe orientation and reference point must remain fixed during the distance sweep.

A practical near-field survey should include a calibrated standoff fixture and a documented three-dimensional coordinate system. A probe held by hand can tilt or move laterally when supposedly displaced vertically. If the field has a sharp local maximum near a seam, a slight sideways motion may dominate the result and produce a false distance exponent. Measure at several heights, repeat the path in reverse, and log probe orientation at each height. A measured amplitude floor sets a limit beyond which a decay curve cannot be extended. Data close to the floor should be treated as censored or uncertain rather than forced into a visually attractive line.

The opening in a conductor can behave differently as frequency changes. A small aperture at low electrical size may couple weakly, but a seam or slot approaching a relevant resonant dimension can radiate or receive more effectively. The exact resonance depends on geometry, thickness, bonding, cavity modes and loading. A narrow peak found by a magnetic loop near a

Copyright 2026, James M. Atkinson

screw or gasket does not prove that the whole enclosure is a magnetic source. It may reflect a resonant surface-current distribution, a local feed, or the probe's own response. Sweep frequency with constant and measured excitation amplitude, and consider whether the peak moves when the enclosure is mechanically or electrically altered. A peak that follows the probe when the probe is replaced may be an instrumental resonance.

At a given point one should consider field direction and phase. A small loop couples to the magnetic flux component normal to its area, whilst a short dipole probe responds principally along its effective electric axis. Neither is perfectly selective. A component map with orthogonal orientations can reveal whether the apparent maximum is a vector orientation effect rather than a change in total field. Simultaneous E and H observation, when calibrated, helps to check whether the local phase and magnitude agree with a plausible dipole or aperture model. But measurement of one component does not allow the real Poynting flux to be calculated, and a high near-field magnitude cannot be converted directly into an isotropic radiated-power figure.

The transmitter and the receiver must also be kept conceptually distinct. The enclosure may be a passive scatterer, receiving an external broadcast and reradiating a field around its seam, or an active object containing its own oscillator. A spectral peak detected near the case does not distinguish those possibilities. Turn the suspected internal excitation off only if the test is safe and authorised, or vary it by a known small amount, and compare with a simultaneously operating external reference antenna. If the peak follows the external transmitter, the enclosure may be acting as a receiving structure. If it follows an internal controlled source, that supports but does

Copyright 2026, James M. Atkinson

not by itself prove internal origin. This source-attribution challenge is essential in crowded RF environments.

A defensible field report would identify the source class, measurement distance, wavelength, dimensions of the object, probe factors, excitation level and uncertainty of the fitted model. It would distinguish a local gradient, a plausible coupling mechanism, and a distant emissions estimate. I should not represent that the decay exponent measured at three points beyond a seam is a property of all near-field physics. A far-field measurement performed at an appropriate distance and geometry, or a validated numerical model checked against independent observations, is needed to establish radiated behaviour. The optical clarity of a plotted waterfall should never outrun the physics of the observation.

James Clerk Maxwell, Cross-Peer Question to Heinrich Rudolf Hertz: Professor Hertz, an investigator may find that measured amplitude drops by about eighteen decibels each time a probe moves twice as far from an apparent source, and immediately call the interaction magnetic near-field coupling. Yet the same short-distance power law can occur in a quasistatic electric-dipole region, and the scanner may have moved away from a local aperture maximum. What additional measurements would distinguish these explanations? In particular, please discuss vector orientation, source voltage and current changes, the behaviour of a distant witness antenna, and the need to identify the field's reference plane. How would you respond if a seam's radiating response changed abruptly near a cavity resonance whilst the near-field standoff remained constant?

Could an electrically small high-voltage element and a small current loop yield similar steep spatial falloff at one frequency? If so, what specific

Copyright 2026, James M. Atkinson

intervention would convert an ambiguous distance exponent into a stronger causal finding without assuming that either source is electrically isolated? Please describe whether the same test remains valid when the probe itself changes the enclosure's resonant condition.

Heinrich Rudolf Hertz, Cross-Peer Answer to James Clerk Maxwell: Professor Maxwell, I would reject the unique identification from distance exponent alone. A small electric dipole and a small magnetic loop can both exhibit quasistatic terms with steep distance dependence. The exponent is one component of a model comparison, not a field-type certificate. The investigator should examine the orientation response of calibrated E and H probes, map several lateral points at each height, and use controlled changes in the suspected source's voltage and loop current. If the response follows changes in the current-return geometry at otherwise comparable drive, that supports inductive coupling. If it follows the exposed high-voltage surface area and electric-probe orientation, a capacitive explanation gains support. Both may remain present.

A distant reference antenna provides a different observation of propagating energy, although it may itself be affected by multipath or ambient transmissions. A local near-field maximum that has no corresponding change in the distant witness when the source is perturbed need not indicate a strong radiating mode. Conversely, a sharp far-field peak that moves with an aperture or gasket adjustment may indicate a resonance in the enclosure system even where the local probe map is complex. No source test should rely solely on the absolute amplitude at one exterior point. The scale of observation and the uncertainty of distance and orientation must be recorded.

Copyright 2026, James M. Atkinson

I would also vary frequency under a controlled and monitored excitation. When a slot, seam or cavity resonance is approached, the field distribution can change rapidly, the phase can rotate, and previously simple decay approximations may become inappropriate. Record the source-drive amplitude, probe frequency response and instrument bandwidth across that sweep. A change in the source impedance can modify the drive current, making the apparent resonance partly a source effect. The investigator should make a second test that preserves or separately measures the excitation before attributing the change to the enclosure.

Finally, state the physical reference plane for the distance: is r measured from a loop centre, a seam edge, an internal component or the probe's effective sensing centre? Moving from two centimetres to four centimetres from a wall does not necessarily double distance from the actual source ten centimetres inside. A claimed power-law slope without that geometric definition is unreliable. What the evidence may support is a local strongly evanescent or reactive-field response under documented conditions, with the choice of electric or magnetic pathway established by additional independent perturbations.

Oliver Heaviside, Peer Question: Professor Hertz, consider a braided cable leaving a screened enclosure. A clamp-on current monitor reports a common-mode current at the same frequency as a strong external near-field peak, but a scan of the metal wall seems relatively quiet. Would you treat the cable as an unintended antenna or as part of the enclosure's source-return network? How could the investigator distinguish conducted transfer along the cable from direct field transmission through an aperture, especially where moving the cable changes both the field geometry and the

Copyright 2026, James M. Atkinson

grounding path? Please address differential versus common-mode currents, cable termination, and the role of a properly measured bonding impedance at the enclosure penetration.

I would also ask how shield-current measurement should be cross-checked without mistaking a clamp probe's response to nearby external E fields for actual cable current. If a ferrite is fitted temporarily, how can the analyst show that an apparent reduction is not an unintended retuning of the source? Please address how common-mode current and far-field changes ought to be correlated across repeated source states.

Heinrich Rudolf Hertz, Response: Mr. Heaviside, I would treat the cable as part of the electromagnetic system rather than as an afterthought. Current entering and leaving a cable in a balanced differential pair can produce magnetic fields that partially cancel when the conductors are close and the return path is well defined. Common-mode current flowing on the outside of a shield or on multiple conductors relative to the environment can produce a different field distribution and may enable the entire cable to act as a radiator or receiver. The actual current path depends on termination and bonding, so a photograph of a braid does not establish a low-impedance shield connection at the survey frequency.

Begin by measuring common-mode current at several positions along the cable with a characterised clamp probe, and separately monitor the differential signal where the circuit permits. Record clamp location, orientation and calibration. Move the cable only through a small, repeatable displacement and simultaneously record source current and the enclosure field. If the exterior peak follows the cable and its current antinodes, a cable-coupling explanation becomes more plausible. If the peak persists at the

Copyright 2026, James M. Atkinson

enclosure opening despite routing changes, direct aperture coupling may remain. However, moving the cable can change shield current and resonant geometry, so the comparison must include both amplitude and current measurements.

A carefully rated common-mode impedance element, inserted with the equipment owner's permission, may provide another contrast. A reduction in common-mode current accompanied by reduced external field supports a conducted route, but does not automatically prove that no energy crossed the aperture. Conversely, changing gasket pressure may alter bonding impedance, redistribute shield current and change leakage elsewhere. Use a verified bond measurement appropriate to frequency; a milliohm direct-current reading alone says little about inductive impedance at hundreds of megahertz. Repeat the test with controls for source amplitude and instrument noise.

The conclusion should identify whether the measurement establishes common-mode conduction, a radiating cable contribution, or merely co-variation of two observables. Forensic integrity requires retention of cable configuration, termination, current-probe transfer function and all interventions. An enclosure is not electrically isolated merely because a metal wall separates its nominal inside from outside; every attached conductor is a potential continuation of the boundary problem.

Karl Guthe Jansky, Peer Question: Professor Hertz, a field survey in a room full of receivers may show a fixed narrowband line beside one cabinet, but the line could come from an external broadcast, a nearby local oscillator, a switching supply or an artefact of the survey receiver. What source-attribution experiments would you require before describing the field as

Copyright 2026, James M. Atkinson

leakage from the inspected enclosure? Would frequency correlation with an external antenna suffice when the cabinet itself can reradiate incident transmissions? Please include a plan for comparing source on/off states, independent receiver clocks, antenna polarisation and movement of the reference probe without disrupting preserved evidence. How should the report handle sources that cannot be powered down?

Consider a receiver with a spur exactly matching the oscillator reference. If the near-field probe is merely a passive antenna connected to that receiver, a processor may display the spur even with the probe removed. Would you require a terminated-input test at the same gain and a separate receiver architecture? How should the source attribution change when two external reference antennas disagree because of polarisation and local multipath?

Heinrich Rudolf Hertz, Response: Mr. Jansky, the source-attribution problem should precede the coupling classification. First, record the spectral line simultaneously on an exterior reference antenna and on the near-field probe, using instruments whose reference relationships are known. If both traces move together in frequency or amplitude with a distant transmitter, that supports an environmental excitation, but the cabinet may still concentrate the field locally by scattering or resonance. A spatial maximum alone cannot prove the cabinet is the generator. Conversely, an internally generated line may appear on a distant antenna, so mere coexistence of signals does not establish direction of origin.

I would use controlled source modulation where authorised. A small, predetermined change in an internal test oscillator's frequency or duty cycle provides a signature that can be followed at the enclosure seam and on the distant witness. Where the equipment must remain in service, a known

Copyright 2026, James M. Atkinson

injected calibration tone through an approved diagnostic port may substitute. If neither intervention is possible, compare repeated surveys at different times, use directional or polarisation changes, and document the inference as tentative. A source that cannot be safely powered down must not be treated as though an unperformed on/off experiment had actually taken place.

An independent receiving chain is valuable for excluding instrument-generated artefacts. A spurious mixer product can move when receiver local-oscillator frequency changes, even though the external field is fixed. Change the receiver centre frequency by a recorded offset while keeping the source unchanged; a true external line should map according to the instrument's known frequency conversion, whereas some spurious responses will move differently. Use a second, differently designed receiver when feasible and record any shared reference clock. These tests should be performed without compromising the continuity of operational recordings, using a parallel survey instrument rather than altering the evidential receiver.

Finally, source attribution and coupling path are different questions. One may establish that a cabinet reradiates an external transmission through a particular seam, or that an internal switching supply produces a local magnetic field with little distant emission. The evidence should keep those findings separate. The report needs actual source-state data, external RF context, time and frequency calibration, probe positions, and the explicit limitations of every unperformed test.

Dr. James M. Atkinson, Moderator: Professor Kennelly, I ask you to work from field measurements to an equivalent-circuit experiment, making the assumptions and the limits of low-frequency impedance models explicit.

Arthur Edwin Kennelly, Fourth Principal Contributor: Dr. Atkinson, an enclosure with an attached circuit must be considered as a network of impedances and electromagnetic couplings rather than an empty box through which a mysterious field passes. At low frequencies and sufficiently small geometries, an equivalent circuit may illuminate the problem. Capacitive coupling can be represented by a stray capacitance C_m between conductors, while inductive coupling can be represented by a mutual inductance M between source and victim loops. For sinusoidal voltages and currents, the capacitive injection current is approximately j omega C_m V_s and an induced magnetic electromotive force approximately j omega M I_s, with signs depending on the chosen reference directions. Here j denotes the imaginary unit, omega angular frequency, V_s source voltage and I_s source current. These are local circuit models valid within a specified regime, not replacements for a full-wave field solution at arbitrary frequency.

The receiving circuit determines the observed consequence. A one-microampere capacitive injection into a victim node of 10 kilohms may produce an idealised 10-millivolt response in the simplest lumped model, whereas the same current into 50 ohms produces only 50 microvolts. The difference is two hundredfold, equivalent to about 46 dB in voltage amplitude, despite an identical injected current. It would be absurd to infer a two-hundredfold change in the external electric field merely because a measurement instrument changed its loading. The instrument impedance, protection network, cable capacitance and amplifier input must therefore be

Copyright 2026, James M. Atkinson

documented. At high frequency the node impedance is complex and the simple multiplication is insufficient.

For an inductive illustrative case, let the mutual inductance between loops be 10 nanohenries, the source-current amplitude 0.1 ampere, and the frequency 1 megahertz. The ideal induced open-circuit voltage amplitude is omega M I_s, or approximately 2 pi times one million times 10 to the minus eight henry times 0.1 ampere, equal to 0.00628 volt. Thus about 6.28 millivolts is predicted before loading and frequency-dependent mutual coupling are considered. If the source-return separation is reduced, M may change markedly even when I_s remains the same. A capacitive pathway can produce a similar observed voltage under different circuit conditions; numerical equality of voltages does not identify the physical route. Controlled geometric and impedance contrasts are required.

Frequency provides a further contrast, but not an automatic diagnostic. In their simplest low-frequency forms, both capacitive injection current and inductive induced voltage are proportional to angular frequency. An amplitude that rises at 20 dB per decade could therefore be consistent with either mechanism, or with an amplifier and cable response. Moreover, the victim load may vary with frequency, and the source excitation may not remain constant across the sweep. To compare models, measure both drive voltage and drive current, preserve the probe calibration curve, and express the predicted victim response through its complex receiving impedance. The phase of the result may assist, but the phase reference and cable delay must be calibrated.

Conducting screens introduce another impedance problem. The skin depth in a good conductor under the conventional plane-wave approximation is

Copyright 2026, James M. Atkinson

delta=sqrt(2/(omega mu sigma)), where sigma is electrical conductivity in siemens per metre, mu magnetic permeability in henries per metre, and omega angular frequency in radians per second. For copper with sigma approximately 5.8 times 10 to the seventh siemens per metre and mu approximately free-space permeability, at 1 kilohertz delta is about 2.09 millimetres; at 1 megahertz, about 66 micrometres. These are illustrative material estimates, not shielding-effectiveness predictions for a complete enclosure. A thin copper sheet may offer poor low-frequency magnetic attenuation even if its electric-field shielding is useful, while joints and apertures can dominate higher-frequency leakage.

A shielding experiment must separate wall penetration from leakage at seams and attachments. Temporarily bridging a seam with a well-bonded conductor may lower the electrical resistance and alter local current paths, but its RF impedance is affected by length and geometry. A strip that appears negligible in DC resistance may retain appreciable inductance at high frequency. If a current flows along the enclosure wall, its distribution is determined by the combination of metal surface, apertures, bonding impedance and cable terminations. An exterior magnetic probe maximum above a seam could be associated with this redirected wall current, not simply with a magnetic field penetrating a uniformly thick sheet.

I would use a documented substitution sequence. Begin with a fixed source voltage and current, survey the seam with calibrated E and H probes at controlled orientation and standoff, then add a conductive bridge across a selected discontinuity. Re-measure both source quantities and the local field. In a second trial change the bonding path of the attached cable without changing its logical function, checking for common-mode current

Copyright 2026, James M. Atkinson

changes. In a third, add a nonconducting spacer or adjust stand-off, if safe, to separate mechanical movement from electrical conduction. Each intervention changes more than one physical quantity; the inferential task is to measure those changes, not to assert they are absent.

The engineer must not forget the source and load. An oscillatory magnetic field produced by a current loop has a surrounding electric field as well; a voltage-bearing plate can drive currents that create magnetic fields. At a sufficient frequency and geometry the assumed two-port lumped network ceases to be adequate and waveguide, cavity or radiation effects enter. Therefore use the simplest model that predicts the observations within a declared error, then challenge it with a second configuration. I pass the token to Professor Kraus for the antenna and field-scanning perspective, where electrical size, array geometry and probe selectivity are the governing disciplines.

Grote Reber, Peer Question: Professor Kennelly, a screen that seems very effective at one frequency can become surprisingly transparent at another when a seam or attached cable approaches resonance. How would you distinguish genuine material skin-depth attenuation from a frequency-dependent aperture or common-mode effect? If a copper foil layer reduces the E-probe reading without changing the H-probe reading, may we conclude that the residual interaction is magnetic, or would you first ask whether the foil has changed the probe's return path and the source current distribution? I also ask which material quantities must be measured and whether a blanket shielding specification can be transferred from a laboratory panel to a real enclosure containing joints, screws and penetrations.

Copyright 2026, James M. Atkinson

Can a frequency-selective shield whose material absorption is smooth nevertheless show narrow-band improvement because the enclosure has altered a slot resonance? What observations would distinguish this from a noise-floor limitation? Please discuss whether a comparative test is invalid if the foil layer changes the antenna factor of the receiving probe, and how a shield-effectiveness ratio should be expressed when baseline emission is barely detectable.

Arthur Edwin Kennelly, Response: Mr. Reber, skin-depth arithmetic applies to a specified material and idealised field geometry. It does not substitute for a measurement of the entire enclosure. A good conductor can attenuate fields by reflection and absorption in ways that depend on frequency, thickness, permeability, conductivity and incidence, but a slot, bad bond or cable penetration can bypass the wall. If the observed response changes sharply at one frequency, examine the dimensions of the aperture, the connected cable and the source impedance before attributing the feature to a sudden change in the metal's intrinsic properties. Skin depth varies smoothly with the square root of inverse frequency in the standard approximation; an extremely narrow peak therefore suggests another resonant or instrumental mechanism.

For example, if the skin depth of a simple copper sample is about 66 micrometres at 1 megahertz under the stated material assumptions, at 4 megahertz the corresponding approximation yields about 33 micrometres. Doubling or halving thickness can matter, but the effect of a long unbonded seam may overwhelm that improvement. Material properties must be documented, and any claim of shielding effectiveness requires a qualified test geometry and measurement method. The instrument's own dynamic

Copyright 2026, James M. Atkinson

range can also make an improvement look larger or smaller than it is if the post-screen signal approaches its noise floor.

If the E probe falls whilst the H probe does not, I would say only that the two instrument outputs responded differently to the intervention. I would check the foil's electrical bonding, its distance from source and probe, whether the source drive changed, and the probes' cross-field rejection. A foil can redirect surface currents, alter capacitive loading and change electric pickup in the loop's cable. With an independent source-current monitor and repeated probe rotations, one can test whether a magnetic contribution remains plausible. An apparent unchanged H reading may also reflect amplifier saturation or inadequate measurement sensitivity.

The proper outcome is a frequency-by-frequency account: field component measured, probe factor, shield geometry, bond impedance, source stability, ambient environment and uncertainty. A manufacturer's flat-panel screening value cannot simply be carried across to a complex cabinet. Measurements at the final enclosure, with its actual glands, seams and cables, are necessary before a security conclusion is drawn.

Heinrich Rudolf Hertz, Cross-Peer Question to Arthur Edwin Kennelly: Professor Kennelly, your equivalent-circuit model uses mutual capacitance and inductance, but a real enclosure is spatially extended and may exhibit multiple resonances. At what point would you reject an ordinary lumped representation and require a full-wave model or a calibrated antenna measurement? Please explain whether the measured 20 dB-per-decade frequency rise can distinguish displacement-current coupling from inductive pickup, and how probe loading might imitate that slope. How would you check a skin-depth calculation against the observed attenuation when

Copyright 2026, James M. Atkinson

seams dominate? I should particularly welcome an uncertainty rule preventing the engineer from declaring a magnetic source merely because a simple inductance formula happens to predict the right order of magnitude at one frequency.

To make the distinction practical, suppose an enclosure dimension is one tenth of a wavelength, but an attached lead is several wavelengths long. Which electrical size controls the failure of the lumped approximation, and must the complete cable be included in the full-wave domain? How would you decide whether the added complexity reduces uncertainty or simply adds unconstrained material parameters to the model?

Arthur Edwin Kennelly, Cross-Peer Answer to Heinrich Rudolf Hertz: Professor Hertz, a lumped model is an approximation whose validity must be challenged by electrical size and by prediction under varied conditions. If a relevant conductor, aperture or return-current structure approaches an appreciable fraction of the wavelength, phase varies significantly across it, or sharp resonances appear, the simple uniform-voltage and uniform-current representation becomes doubtful. A full-wave model may then be appropriate, but it should not be regarded as self-validating merely because its numerical mesh is fine. Compare predictions at several positions, polarisation orientations and frequencies, and reserve an independent measurement configuration for validation.

The 20 dB-per-decade rise is particularly unhelpful as a unique discriminator. In a low-frequency approximation the displacement current omega C_m V and induced magnetic voltage omega M I both scale linearly with frequency if voltage, current and coupling parameters remain constant. The measured receiving voltage may add another frequency dependence

Copyright 2026, James M. Atkinson

through load impedance and probe electronics. Thus a matching slope does not prove which mechanism is present. Instead change source voltage and current in independently measured ways, vary source-return area, and perform orientation scans with probes whose electric and magnetic selectivity have been characterised.

For material shielding, calculate skin depth only after identifying conductivity, permeability, thickness and frequency. Then compare the experimental result with a model including seams, bonding, cable penetrations and instrument dynamic range. If the observed attenuation changes dramatically when a gasket is tightened but the metal thickness remains fixed, a seam explanation is more credible than material skin-depth change. Where several mechanisms explain the data within uncertainty, retain the alternatives rather than assign the entire change to one selected circuit element.

My proposed uncertainty rule is operational. The model must reproduce at least one withheld intervention with error bounded by the combined instrument, position and source uncertainties, and its dominant coupling term must be supported by a distinct response contrast. If it fits only one frequency at one probe location, it has not established a cause. A full-wave simulation, an equivalent circuit and an E/H probe scan are complementary tests. None alone constitutes proof of a unique internal current or charge distribution.

The decisive distinction is predictivity. A numerical model should state the response to a change of bond impedance before the trial, and then be judged against the observed vector field within a defined uncertainty band. If the original parameter values must be freely retuned after every

Copyright 2026, James M. Atkinson

intervention, the model has not identified a stable mechanism. Retain such material as a hypothesis, not as a validated reconstruction.

Dr. James M. Atkinson, Moderator: Professor Kraus, the last principal contribution concerns calibrated probe response and mapping technique. Please distinguish a useful local field scan from a defensible reconstruction of the source or its far-field radiation.

John Daniel Kraus, Fifth Principal Contributor: Dr. Atkinson, I would treat near-field scanning as an exercise in antenna measurement and inverse-source inference. The probe is an antenna, even when it is only a few millimetres across, and the enclosure is part of its environment. The goal is not merely to find a bright patch on a screen but to determine which field component was sampled, what spatial region the probe averaged, and how much the sensor altered the system. An electrically small H loop tends to respond to magnetic flux through its effective area. A short E probe tends to respond to the electric component along its effective axis. The adjectives 'electric' and 'magnetic' denote calibrated response characteristics, not perfect isolation. E leakage into an H probe and H-induced cable response in an E probe can be material in the region of a strong gradient.

A scan must specify coordinate conventions. Place the enclosure in a surveyed coordinate frame with x, y and z axes, and identify the probe's effective sensing centre and orientation. Record position in metres and standoff from a reproducible external reference plane. A map made at nominal z=5 millimetres is meaningless if the probe is tilted such that its sensing centre varies by several millimetres near each screw or seam. Use a nonconducting fixture where possible and inspect whether its dielectric properties perturb the field. Repeated scans with the same source drive

Copyright 2026, James M. Atkinson

should agree within the position and amplitude uncertainty. Where the map does not repeat, first examine the probe cable and source condition before searching for a complicated material explanation.

The study must determine spatial resolution empirically. If a loop sensor has finite diameter, its output integrates flux across that loop; a narrow field feature may be blurred or displaced. A higher spatial sample density does not recover information erased by the probe footprint without a validated deconvolution model. Scan the same feature with two probe sizes, appropriately recalibrated, and compare their locations and response widths. A location that moves appreciably when the probe geometry changes is not yet a reliable source coordinate. It may reflect near-field loading or cross-polarisation pickup rather than a real displaced conductor.

Probe loading is a severe source of error at small standoff. A metal loop, shield or cable brought very close to a high-Q circuit may alter its resonant frequency, quality factor or local current distribution. Measure source frequency and amplitude both with the probe withdrawn and at the survey position. A line that moves when the probe approaches may be evidence of the measurement's disturbance, not spontaneous behaviour by the inspected equipment. Reduce coupling, increase standoff or use an alternative sensor and test whether the same spatial pattern remains. An attractive maximum obtained only by strongly loading the source cannot be presented as a non-invasive observation of its unperturbed field.

A comparison of E and H probe maps requires compatible bandwidth, input calibration, filtering and dynamic range. The units differ: volts per metre for E, amperes per metre for H, and volts for the raw probe output. Converting their ratio into an impedance is meaningful only when both field

Copyright 2026, James M. Atkinson

measurements refer to the same position, relevant vector components and calibrated frequency response. Even then, the local ratio need not equal the free-space wave impedance. A high local value of E/H may be consistent with dominant capacitive coupling, while a low value may be consistent with a magnetically dominated region, but these interpretations depend on source type and phase. The near-field ratio alone does not reveal which enclosure path injected the field into a victim circuit.

An instructive example uses an electrically small loop at two measured standoffs from a source known to remain stable. Suppose the H-sensitive output falls from 80 microvolts at a 2-centimetre standoff to 11 microvolts at a 4-centimetre standoff under the same probe orientation and calibrated gain. The observed amplitude ratio is approximately 7.27, or 20 log10(80/11), about 17.2 dB. This is near the ideal 18.1 dB ratio associated with inverse-cube amplitude variation over a doubling of distance. It is not proof of a pure magnetic dipole: the physical source could lie inside the enclosure, the sensing-centre distances may not double, and electric pickup could have a similar local gradient. A third distance and a lateral map are required to challenge the model.

For electromagnetic emissions assessment one must distinguish the investigative near-field scan from a regulatory far-field test. The latter specifies a standardised site, antenna, distance, detector and uncertainty practice suited to its purpose. A local scanning amplitude can help identify and repair a leaky seam but cannot simply be converted into regulatory emission strength by multiplying by distance or assigning 377 ohms. If the security question concerns an unintended signal observable at another building, the analysis requires a propagation model and an appropriate

Copyright 2026, James M. Atkinson

remote-field measurement, with ambient transmitters and multipath controlled. A near-field result is one element of the evidence chain, not the complete chain.

I would establish a repeatable sequence for the field team. Begin with instrument self-tests, source-off background and a calibrated reference radiator or field generator. Record the enclosure condition, source waveform and reference-clock status. Map E and H at one frequency with several orientations and heights; repeat at a second frequency selected for a specific physical hypothesis. Introduce one controlled perturbation, such as a verified change to return-current geometry, bond or aperture cover, and remap the identical points. Preserve the raw observations, correction factors and the reason for each intervention. In the final analysis distinguish the measured result, the best-supported coupling interpretation, the rival explanation not excluded, and the uncertainties of both. I return the token to Dr. Atkinson with a warning: the field map is not a picture of an invisible current without assumptions; it is a structured observation of how a calibrated sensor responded to a complicated boundary-value problem.

Antony Hewish, Peer Question: Professor Kraus, a field team can generate a beautiful three-dimensional map using a dense motorised scanner, yet the map may reflect a drifting source, a cable-suspended probe or cross-coupling between supposedly independent sensor channels. How would you test scan repeatability when each line takes several minutes, and how would you distinguish temporal variation from spatial variation? Please address synchronous reference measurements, forward and reverse raster passes, vector calibration and the uncertainty introduced by interpolation between sample positions. If the instrument is detecting a weak source near a

Copyright 2026, James M. Atkinson

switching supply, what evidence would permit the reader to accept a narrow local maximum as a field feature rather than as a processing artefact?

What numerical checks would reveal that the probe's finite aperture has displaced an apparent maximum, and how might an alternative test fixture change the result? Please include whether the same field map should be remeasured after swapping the receiver channels, since an unnoticed gain or reference bias could produce an attractive but spurious difference between electric and magnetic components.

John Daniel Kraus, Response: Professor Hewish, the map must be treated as samples of a field that may change in time. If the source changes while the scanner moves, a raster may turn temporal drift into an artificial spatial stripe. Record a simultaneous source monitor, ideally including amplitude, phase where relevant, frequency and reference-lock state. Repeat the raster in reverse direction; a real stationary spatial feature should remain attached to the same physical coordinate, whereas some time-dependent patterns may reverse or shift. At selected positions repeat measurements at the beginning, middle and end of the survey to estimate the source's temporal stability. If the field changes materially during the scan, do not combine all the points into a map of one stationary state without a justified correction model.

The probe's cable must be mechanically and electromagnetically controlled. Fix its routing as far as possible, and where movement cannot be avoided characterise the response to cable displacement with the sensing head fixed. Calibrate all sensor axes and cross-polarisation rejection across the actual frequency band. A multi-axis map is a vector product only if gain, orientation and phase conventions are consistent. Interpolation is a

Copyright 2026, James M. Atkinson

presentation method, not a recovery of observations between grid nodes. Show actual sample positions and provide an uncertainty map where the probe footprint, gradients or measurement noise make interpolation unreliable.

For a narrow maximum, I would require a repeatable response with two scan directions, a finer local grid, a second probe or sensing orientation, and a source perturbation that predicts a change at the same location. A scanning head that strongly couples to the enclosure might create its own local resonance, so the source should be monitored with the probe present and absent. A reference signal injected into the receiver chain can reveal gain changes or local-oscillator spurs. A no-source control establishes the instrument floor. If the maximum persists only after extensive digital smoothing, or disappears when raw amplitudes are plotted, the map is not suitable for causal interpretation.

The final dataset must permit a second investigator to reconstruct the map from original observations, including coordinate origin, velocity or dwell time, timestamps, filter bandwidth, detector averaging, gain, calibration and rejected samples. Correlation between spatially adjacent samples must not be mistaken for independent confirmation when all are derived from one slowly drifting oscillator. It is better to provide a less colourful map with honest uncertainty than an immaculate rendered surface that hides the distinction between measured points and computationally invented detail.

Arthur Edwin Kennelly, Cross-Peer Question to John Daniel Kraus: Professor Kraus, your proposed E/H ratio requires calibrated vector components at the same point, yet near a seam the gradient can be so steep that two sensors of different size cannot occupy the same effective volume. How would you

Copyright 2026, James M. Atkinson

decide whether a reported high electric-to-magnetic ratio is a real local property or an artefact of probe footprint and position? Would you allow a numerical electromagnetic model to transfer the fields to a common reference plane, and what validation would prevent that model from manufacturing the answer? Explain whether a mitigation trial that lowers the E-probe reading, but raises the H-probe reading, can still be considered successful when the actual concern is coupling into a victim receiver.

Assume that one model predicts a sharp magnetic hotspot after a bonding change, while another predicts a relatively diffuse electric field. If both fit the unaltered enclosure, how would you select the most discriminating new measurement path? Would you require a blind prediction before examining the corrected scan? Explain whether the victim receiver's orientation makes the geometric average of a field map less useful than one carefully measured transfer-function response.

John Daniel Kraus, Cross-Peer Answer to Arthur Edwin Kennelly: Professor Kennelly, the ratio should not be reported without the qualification that two differently sized sensors may average different spatial regions. Begin by determining the effective sensing centre and spatial response of each probe under calibration, then use mechanical fixtures to place them in reproducible orientations and as nearly common a reference geometry as practical. Compare measurements at several standoffs where the field varies more gently, and report the position uncertainty together with the field uncertainty. If the sensors' footprints dominate the width of a field maximum, the nominal point ratio is not physically well resolved. Use a range of possible ratios rather than an unsupported precise value.

Copyright 2026, James M. Atkinson

A numerical model can transfer fields to a common reference plane if its source assumptions, conductor geometry and material parameters are independently constrained. The model must be tested against withheld scan lines, alternative probe orientations and an altered enclosure configuration. Agreement only at the points used to fit the model is not validation. If the predicted E/H ratio depends strongly on an unmeasured seam impedance or source-current path, that dependence should be exposed through a sensitivity interval. The calculation may remain useful as a hypothesis-generating tool without qualifying as an evidential field reconstruction.

Mitigation success should be assessed at the actual victim and for the relevant threat mechanism. A conductive cover could reduce local E at one probe yet redirect current so that H increases elsewhere. If the interference at a specified victim receiver falls under controlled and calibrated test conditions, the mitigation may be operationally successful despite a local H increase. But the result should not be described as a general reduction of all electromagnetic leakage. Observe both fields and the victim response before and after the change, with the source excitation maintained and measured. The coupling transfer function between field and victim depends on its orientation and impedance.

One useful transfer measure is the change in victim voltage under a fixed source state: $T_v=V_v/V_s$, where V_v is the victim-port voltage and V_s the specified source voltage, both measured with consistent amplitude conventions. A reduction in $abs(T_v)$ may demonstrate mitigation in that configuration, but must not be confused with a far-field emission metric. The final record should identify which operational performance criterion

Copyright 2026, James M. Atkinson

improved, which exterior field components changed, and which alternative current paths remain to be tested.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The roundtable distinguishes local observations from causal attributions. A calibrated electric probe measures a defined E-sensitive response; a calibrated loop measures a defined H-sensitive response; neither output is a perfect isolation of one field from the other. The investigator must preserve source voltage and current, instrument clock and bandwidth, probe orientation and position, cable configuration, shielding and bonding state, and the receiving impedance. Controlled variations in source-return area, exposed voltage-bearing geometry, screen continuity, cable common-mode current, scan height and frequency provide separate predictions under capacitive, inductive, conductive and resonant hypotheses. A local maximum or a steep distance exponent cannot independently specify far-field radiated power or an internal source location. When calibrated vector data or causal interventions are absent, the conclusion is an observed near-field response with explicitly unresolved mechanism. All contemporary measurement applications in this discussion are scholarly extrapolations, not historical quotations from the named scientists.

QUESTION 063

What is missing when an antenna is calibrated exclusively under far-field conditions?

HISTORICAL RECONSTRUCTION. The following conversation is a fictional scholarly construction involving deceased scientists and radio pioneers. Its modern instrumentation, measurement protocol and contemporary standards are attributed to the present-day editor, not to historical remarks or endorsements by those individuals.

Dr. James M. Atkinson, Moderator: Professor Maxwell, the panel has completed the separate inquiry into electric and magnetic near-field probes, and the next practical matter is calibration transfer. What information is absent when an antenna is calibrated in an open far-field arrangement and then introduced into a cluttered equipment enclosure? Please distinguish a measurement of antenna characteristics from the characterisation of an installed system. I shall call five principal scholars, request immediate answers to their peers, and invite direct challenges among the principal speakers. The token is yours, Professor Maxwell.

James Clerk Maxwell, Principal Contributor: Dr. Atkinson, the essential omission is not merely a correction factor at a shorter distance. It is the boundary-value problem that determines what an instrument actually senses when the antenna, its feed and nearby conducting matter form one electromagnetic system. A far-field calibration establishes a response to a specified illumination, polarisation and direction under stated loading conditions. It does not establish that the same response survives when the incident field has strong longitudinal or evanescent components, when

Copyright 2026, James M. Atkinson

nearby currents alter the sensor impedance, or when its cable becomes an uninvited part of the receiving structure. The calibration is properly valuable within its domain; the error lies in carrying its authority beyond that domain without new evidence.

Take a receiving antenna illuminated by an approximately uniform plane wave. One may express its open-circuit terminal voltage as a vector effective length dotted with the incident electric field, with a phase convention declared. Under conjugate or other specified receiver loading, the terminal voltage is modified by the antenna impedance, feed impedance and cable network. In such a condition the familiar antenna factor, expressed in reciprocal metres, is the electric-field amplitude divided by a defined receiver-port voltage. Every element of that sentence matters. A calibration certificate may report an antenna factor in decibels per metre, a frequency interval and an uncertainty statement; yet its value alone reveals nothing about a nearby source's field polarisation, curvature, longitudinal component, return current or coupling through the feeder shield. The observer cannot invent those missing quantities by multiplying an instrument's displayed voltage by the catalogue factor.

In a spatially restricted enclosure a time-varying field solves Maxwell's equations subject to conductive, dielectric and aperture boundaries. The electric and magnetic fields remain coupled by the curl equations, but their local ratio need not be the free-space wave impedance of approximately 377 ohms. A small current loop can produce predominantly magnetic reactive response over one limited region; a voltage-bearing conductor can produce a conspicuous electric response under a different geometry; and both interpretations can fail when a resonance or cable common-mode path

Copyright 2026, James M. Atkinson

becomes important. The separation is operational, not absolute. The useful experiment is to alter one boundary or source variable, measure what else changes, and compare the observed field-vector pattern with the predictions of several competing models.

Distance offers a particularly seductive but unreliable shortcut. Let the maximum transverse dimension of the relevant radiating aperture be D metres, wavelength be lambda metres and antenna-to-source separation be R metres. The often cited far-field criterion R greater than approximately 2D squared divided by lambda addresses phase curvature across an aperture under assumptions about geometry and radiation. It is neither a guarantee that every reflected field is negligible nor a universal declaration that a small probe has ceased to be reactive when moved just beyond that number. An electrically small source may require consideration of terms scaling approximately as inverse distance cubed, inverse distance squared and inverse distance in different regimes, but these are model terms, not an invitation to fit three powers to a noisy single-point spectrum and call the dominant exponent the mechanism.

A defensible field trial would retain the original antenna and receiver and compare at least three environments. The first is its declared far-field calibration geometry. The second is a controlled installation near a known metal reference plate or enclosure with measured gap and orientation. The third is the intended survey position, including the actual cable route and any contact with furniture or rack metalwork. At each condition measure the impedance looking into the antenna feed, the received complex response to a known test source if possible, and the common-mode current on the outer conductor. Where the source is stable, repeat with the receiver disconnected

Copyright 2026, James M. Atkinson

and with a defined terminating load to expose cable pickup. The receiving chain is an experiment, not an immovable truth supplied by its calibration sticker.

Consider a deliberately idealised numerical example. If a far-field factor is 20 decibels per metre and the receiver observes 40 microvolts at its specified input, the conventional plane-wave estimate is 40 microvolts times ten to the power 20 over 20 per metre, or 400 microvolts per metre. This is only the inferred field under the assumed calibration configuration and loading; it is not a measured local field when the same probe stands two centimetres from a cabinet slot. Suppose the installed probe's response to the identical reference field becomes 6 decibels greater because of changed coupling. The voltage ratio is ten to the power 6 over 20, approximately 1.995. Blind use of the original antenna factor would then bias the inferred field almost twofold. The six-decibel change is hypothetical and must not be universalised as a property of all metal surfaces.

The experiment should distinguish random measurement variation from a changed measurand. Repeat displacements after a blind return to the original pose, photograph the cable path and measure the probe's electrical centre rather than merely the position of its handle. Include the source-off baseline and separate frequency-stable background signals from deliberate injected stimuli. A result that moves with the probe cable but not the sensing element demands an explanation in terms of feed currents or receiver coupling; a result that follows source polarisation may support the intended antenna-mode response. Neither result alone provides a unique source location. This is why I would require at least two independent

Copyright 2026, James M. Atkinson

perturbations whose predicted responses differ between the proposed explanations.

The final report must preserve the distinction between calibrated quantity and indicative response. It may say that the antenna detects a line under a named pose and that a known comparison signal produces a specified change when a conductive boundary is introduced. It may not turn that line into an absolute field strength, intercepted transmitter power or proof of absence elsewhere without the missing installation-specific transfer function and uncertainty. Far-field calibration remains a valuable traceability link, but it never removes the burden of proving how that link reaches the intended field geometry. I pass the token with that reservation.

Michael Faraday, Peer Question: Professor Maxwell, I ask how the investigator can tell whether a strong response obtained very close to a steel cabinet represents the originally calibrated receiving mode or a new circuit in which the cabinet and cable carry the return currents. The laboratory pattern may be known with considerable precision, but nearby conducting boundaries alter induced currents whilst the probe itself disturbs them. If the source can be controlled, which observable should be measured first, and what contrast will distinguish field redistribution from receiver-input mismatch? Please describe an experiment that does not assume one can separately measure an electric field without loading it, and specify how the physical placement of the measuring cable should be recorded. I am particularly concerned by the appeal of a single large response at a seam, which invites the observer to attribute the signal to a hidden source merely because the instrument pointer moves. How would you preserve the evidence whilst declining to overstate the mechanism?

Copyright 2026, James M. Atkinson

James Clerk Maxwell, Response: Mr. Faraday, the first distinction is between a port quantity and the spatial field that excites it. We can measure the antenna's input reflection coefficient in its far-field test configuration and again in the installed pose, using an appropriately calibrated network analyser and stable lead arrangement. A reproducible change in the port response establishes that an electrical boundary condition has changed. It does not by itself prove that the changed receiver output is caused by the mismatch, because the same cabinet may change the incident field at the sensing element. I would therefore retain a stable reference emitter and record both the source output and the receiving-chain response as complex quantities where practicable.

The second experiment changes the surroundings without moving the antenna. One may insert a removable reference plate at known distances from a safe test installation and compare the receiver amplitude, phase and impedance. In another trial, retain the plate but change the receiver cable route while measuring common-mode current. For each intervention, predict beforehand whether the direct antenna-mode response, the feed-current hypothesis and a source-drift hypothesis should be affected. If amplitude changes while the feed-current sensor and port impedance remain stable, scattering in the local illumination becomes more credible, though it is not uniquely established. If the receiver output tracks cable current, a common-mode contribution becomes a priority for further testing.

I would not claim to have measured an undisturbed field merely because the probe is small. The probe and its supports introduce materials and currents, and an adequate uncertainty statement includes their possible

Copyright 2026, James M. Atkinson

perturbations. Use at least two sensor architectures of different coupling sensitivity and preserve their calibration domains. Keep the same source monitor outside the geometry being altered, because an intervention that also changes source power invalidates a simple before-and-after comparison. Record coordinates relative to identifiable fixed marks, three-axis orientation, separation from the seam, cable photographs and the order of operations. A blind return to baseline provides a check against unnoticed movement.

The dramatic seam maximum is an observation, not yet an attribution. It may motivate closer inspection, but its evidential description should give the frequency, spectrum settings, measured port response and controlled contrasts. If the received power is diminished by a terminated-input test, note precisely what that eliminates and what it does not. A termination can reveal internal receiver artefacts, but it also removes the antenna and much of the feed network, so it cannot isolate every external coupling path. I would say that an installation-sensitive coupling route was observed, then describe the additional experiment needed to identify it. That restraint is a strength of the investigation rather than a weakness.

Heinrich Rudolf Hertz, Peer Question: Professor Maxwell, your explanation makes the region about a finite radiator rather more intricate than the familiar picture of energy streaming outward. I should like the moderator to require a numerical distinction rather than a slogan about near and far fields. An inspector has an antenna with a known aperture, a wave of declared frequency, and a measurement point a short distance from an enclosure. How should the commonly cited two-aperture-dimensions-squared-over-wavelength criterion be used, what does it fail to tell us, and

Copyright 2026, James M. Atkinson

why should the local field ratio not be set to the free-space plane-wave impedance? If a scan along a short straight line shows a sharp decay, does that prove a magnetic source? Please state the conditions under which distance exponents cease to be reliable, and how reflected waves, structural resonances and finite probe dimensions should influence a proposed test. Please distinguish a wavefront curvature test from a measurement of local reactive energy and retain the declared source size in the result.

James Clerk Maxwell, Response: Professor Hertz, let D be the largest relevant transverse dimension of an aperture in metres and lambda the free-space wavelength in metres. For a common aperture phase-error criterion, R_far is approximated by 2D squared divided by lambda. With D equal to 0.40 metre and lambda equal to 0.20 metre, R_far is 2 times 0.16 divided by 0.20, or 1.6 metres. The result is neither a safety boundary nor a comprehensive definition of field type. It tells us that a point only ten centimetres from the radiator does not meet that particular far-field phase criterion. A reflecting cabinet or another radiator of different dimension may impose additional requirements, and in a room the resultant field is not guaranteed to resemble a single outward wave even beyond 1.6 metres.

The impedance of a freely travelling plane wave is approximately the square root of permeability divided by permittivity, about 377 ohms in free space. That relation presupposes transverse propagating fields in a homogeneous medium, not every superposition near conductors. Close to an electrically small dipole, field terms decay with powers of distance and exhibit different phases; near a small loop, a different reactive term can dominate. One cannot infer from one measured voltage that the local electric and magnetic

Copyright 2026, James M. Atkinson

fields have the plane-wave ratio. A cabinet seam may support electric charge, conduction currents and a resonant slot field simultaneously.

A steep apparent decay is particularly ambiguous. A receiving probe has a finite spatial extent, so its output can integrate a nonuniform field rather than sample a point. A cable mode may change as the cable is repositioned during a scan. Reflected fields from nearby surfaces can produce interference minima whose local slope is steeper than any single source term. If a detector is logarithmic, saturating or noise-limited, the observed slope can be distorted again. I would require scans over several non-collinear paths, repeated orientation measurements, a fixed cable fixture and a separately monitored source before comparing observed slopes with theoretical predictions.

A good comparison involves both a known electric-dipole-like source and a known loop-like source under safe, controlled circumstances. Record complex response, not just the height of a spectrum peak, and compare the signatures of rotation and standoff. If the data fit several competing models within uncertainty, report non-identifiability. The equations do not authorise the investigator to choose the most picturesque model. They indicate precisely which extra field components or boundary changes must be measured before the inference becomes defensible.

Dr. James M. Atkinson, Moderator: Mr. Reber, I thank Professor Maxwell and pass you the token. Please test the theory against repeatable source-on, source-off and installation comparisons, taking account of room scattering and the field receiver itself.

Copyright 2026, James M. Atkinson

Grote Reber, Second Principal Contributor: Dr. Atkinson, I would start with a practical discomfort: a fine gain curve obtained under open-sky conditions does not tell a worker how an antenna behaves after being wedged between shelves, metal cabinets and bundled cords. In radio astronomy one learns quickly that the telescope is not the only object capable of modifying the received signal. Ground, feed, support, receiver and unwanted terrestrial transmissions create signatures that can resemble the sky. In an equipment room the same discipline must be compressed into a few metres, and the ground and structure are no longer distant nuisances. They are central parts of the coupling arrangement. What is missing from the far-field certificate is an installation experiment showing what the whole deployed receiving apparatus does.

I would insist first on a defined reference transmission that can be switched off. The reference need not mimic a covert emitter, and its purpose is not to prove that all clandestine signals would behave similarly. It supplies a controlled and repeatable comparison for the receiver chain. If possible, the radiating element should sit in several accessible positions, with its orientation and delivered power recorded, while an independent monitor establishes that the test source did not drift. The antenna under evaluation is moved through a documented set of survey poses. At every point the instrument records frequency, amplitude, detector setting, dwell interval and whether the antenna feed cable lies against metal. One ordinary receiver display cannot substitute for this record.

Now consider a dipole or broadband measurement antenna brought close to a conducting door. The induced current on the door produces a scattered field, and the combined field at the dipole is the vector sum of direct and

Copyright 2026, James M. Atkinson

scattered contributions. If the conductor also shifts the dipole's input impedance, the terminal voltage alters in two distinguishable ways: the illumination at the antenna changes, and the antenna's loading changes. Their effects can reinforce or cancel. Move the antenna a small distance and a deep minimum may vanish. A field technician who sees the minimum and declares the position quiet has confused a particular interference geometry with a negative search result. Rotate the dipole through orthogonal planes and repeat the measurement with a different antenna type before making an evidential conclusion.

The first quantitative trial should be deliberately modest. Place the controlled reference at a known frequency, collect the received voltage in three environments, and compute differences in decibels with the same matched receiver load. For example, suppose the measured levels are minus 70 dBm in the reference arrangement, minus 61 dBm beside a cabinet, and minus 77 dBm after a change of cable routing. The differences are plus 9 and minus 7 decibels relative to the first position, representing power ratios of about 7.94 and 0.20. These observations do not establish that the antenna's intrinsic gain improved or deteriorated by those amounts. They establish that the complete link changed. A separate impedance measurement and a reproducible boundary variation are required to allocate causation among antenna loading, scattering and common-mode pickup.

An antenna calibration typically describes a transfer function for a specified illumination and polarisation. Near an assembly, however, many possible fields reach the receiver by different routes. A coaxial cable may have unintended common-mode current even while its inner conductor transfers

Copyright 2026, James M. Atkinson

the desired differential signal. I would clamp a suitable current sensor around the complete cable, preserve calibration of that sensor, and compare its indication with the receiver peak while rearranging the cable through controlled, non-damaging routes. A ferrite or choke may be introduced as a diagnostic only when its own loss and impedance are independently established. If receiver output changes after that intervention, one cannot conclude that the original antenna factor was wrong. One can conclude that an omitted propagation or coupling path mattered.

I also prefer a comparison antenna of different electrical architecture, not merely a second example from the same production run. A small shielded loop and a short electric probe respond differently to field components and possess different unavoidable loading errors. Compare their patterns of change across a grid rather than demanding identical absolute values. Where they disagree, record the disagreement: it is often the most informative feature of the experiment. One probe may have insufficient cross-field rejection; another may be insensitive at the chosen frequency; both may disturb the field. The disagreement should prompt controlled orientation and standoff tests rather than dismissal of whichever detector is inconvenient.

The observer's habit of trying to draw a source location from a single maximum also deserves correction. A peak at a cabinet seam might be a local aperture current, an external signal entering the enclosure, a cable carrying common-mode energy, or a receiver artefact responsive to movement. One should first identify what moves with a source, what moves with the receiving instrument, and what survives replacement of the

Copyright 2026, James M. Atkinson

receiver input with a known termination. A good protocol randomises some repeated measurement order so that thermal drift and expectations do not masquerade as a spatial pattern. Multiple source-off and source-on trials expose intermittent background interference that a clean line drawing conceals.

Finally, I would preserve the negative findings as carefully as the dramatic peaks. A null is meaningful only within a recorded measurement threshold, an orientation, a frequency band, a dwell time and a geometry. The report should separate a calibrated far-field antenna factor from an empirically established installed-system response, and should state where neither is sufficient to infer an absolute electric-field value. A distant open-range certificate cannot describe every room. But a well-designed set of simple comparisons, repeated without theatrical interpretation, can make the local response credible enough to guide further forensic inquiry. That is the practical limit to which I would pass the token.

Arthur Edwin Kennelly, Peer Question: Mr. Reber, the use of a reference emitter is sensible, yet I question whether it demonstrates the sensitivity needed for a defensive surveillance search whose unknown emitter may couple mainly through a cable, aperture or near-field current loop. A test dipole situated a metre away can illuminate the antenna as a plane wave while the clandestine object of interest, if there be one, is centimetres from an equipment chassis. What legitimate conclusion follows when your calibration signal is detected in every corner? How would you select representative reference geometries without pretending that the set is exhaustive, and what role should an independent cable-current measurement play? I also ask how you would distinguish a reflection-

Copyright 2026, James M. Atkinson

induced pattern null from an receiver's own dead band, and whether a deliberately rotated source can correct a negative inference that was originally made with the receiving antenna fixed in one orientation. Include a falsification trial in which the reference signal remains constant while the sensing cable and receiving polarisation are changed separately.

Grote Reber, Response: Professor Kennelly, I would not regard successful detection of a single reference transmitter as validation of every plausible field coupling. It establishes that the chosen receive chain, at the chosen frequency and settings, could detect that particular known stimulus over the tested positions. The stronger and more useful result comes from a planned family of stimuli that differs in electrical size, polarisation and coupling arrangement. A low-power reference dipole, a small magnetic loop and a cable-current injection arrangement, used within authorised engineering limits, probe different susceptibilities. No finite family is exhaustive, and the report should call it a coverage experiment for specified hypotheses, not a certificate of absence for unspecified emitters.

The set of positions should follow actual access and expected survey difficulty. Include open space, near a large conductive plane, beside a slot or cable penetration, and within the cluttered interior of a rack where the instrument can safely be positioned. Keep the applied reference level under independent control and measure the receiving path's noise floor and linearity. The direct route and the cable route should be analysed separately when possible. A clamp measuring current over the complete coaxial bundle can flag unwanted common-mode energy, but its own transfer impedance and sensitivity must be known; a non-reading does not prove zero current

Copyright 2026, James M. Atkinson

below its threshold. In some cases it is more informative to reroute the cable under a fixed antenna pose than to add another source position.

A receiver dead band differs from an interference minimum in its response to movement. A fixed attenuated response over numerous source positions and polarisation trials invites investigation of front-end filters, overload and instrument settings. A spatial null that shifts when source or receive antenna geometry changes suggests vector cancellation or pattern effects, but a full source-off and terminated-input control is still needed to exclude receiver artefacts. One should also check whether automatic gain control or a tracking preselector has changed state between tests, because a reference tone can conceal a dynamic-range problem rather than reveal it.

I would use the resulting matrix to bound claims in plain language. For the tested orientations and reference classes, signals of the stated spectral occupancy and strength were detected above the chosen threshold at the documented positions. Any blind areas would be mapped with the actual antenna and cable geometry. A negative result for another class remains unproved, and no artificial percentage of comprehensive coverage should be advertised. Rotation of the source and sensor may close one particular polarisation blind spot, but it cannot establish sensitivity to all unknown structures. The distinction between a measured capability and an imagined guarantee is the central result.

Karl Guthe Jansky, Peer Question: Mr. Reber, it is possible to discover an unexpected signal by repeating observations, but repeated signals can arise from the receiving apparatus itself. Suppose an apparent narrowband source strengthens whenever the survey antenna is moved against a cabinet yet weakens when the same cabinet door is opened. The

Copyright 2026, James M. Atkinson

investigator might call this a concealed transmitter, whereas the receiver, oscillator or cable may be reacting to movement and contact. What order of isolation trials would you recommend that preserves the chain of custody and does not accidentally erase the very phenomenon under examination? Please address frequency stability, source-off observations, receiver substitution and the risk that an alternative antenna introduces new calibration errors. I am especially interested in how to record an apparently mobile spectral feature without reducing its entire history to one peak amplitude after the fact. What observation would lead you to abandon the external-source hypothesis despite the apparent correlation with the cabinet movement?

Grote Reber, Response: Mr. Jansky, the sequence should begin with documentation before intervention. Record the unaltered geometry photographically, noting the positions of doors, cable bundles, power feeds and the receiving instrument; retain time-stamped spectra or complex samples with frequency reference, span, resolution bandwidth, gain state and detector settings. If the instrument has a raw-data facility, preserve its output together with a cryptographic digest and a documented time source, whilst acknowledging any uncertainty in the clock. The source-off baseline, where safe and authorised, provides context but should not be imposed if switching power would disturb a critical system or destroy transient evidence.

Next carry out a receiver integrity trial that changes as little of the external geometry as possible. Compare the observed line with an independent receiver or instrument channel at the same nominal input connection, taking care that a splitter or switching device itself introduces loading and

Copyright 2026, James M. Atkinson

loss. A fixed input termination can reveal certain internal spurs, but it also changes cable loading and does not reproduce the original receiving boundary. Ideally retain the external antenna and cable while substituting a calibrated receiver through a defined low-reflection interface. If the line follows one receiver and not the other, the internal-instrument explanation gains weight, subject to differences in sensitivity and bandwidth. If both respond, neither the source location nor the antenna coupling mechanism is thereby proved.

Then reproduce the cabinet-door and antenna-pose interventions under monitored conditions. Randomise part of the observation order and return to the original geometry at intervals. Record frequency drift and phase behaviour independently of displayed power; a spectral line that shifts when the receiver temperature changes may reflect oscillator movement even if its amplitude also varies with nearby metal. Measure cable common-mode current during the same sequence. When a second antenna of different architecture is introduced, document its own calibration assumptions and compare relative patterns rather than assuming equal absolute antenna factor.

The conclusion is an evidence table with competing models. A real local field may be altered by the opening door; a cable mode may be altered in the same fashion; a receiver artefact may arise through mechanical stress or a shared reference clock. Separate each model's predicted response to source variation, receiver substitution, cable-routing change and polarisation reversal, then identify which observations reject or fail to reject it. Do not delete anomalous runs merely because they spoil a tidy story. A complete history of settings and geometries is often more probative than the

Copyright 2026, James M. Atkinson

apparently highest peak. The aim is a reproducible physical explanation, not merely an exciting attribution.

Dr. James M. Atkinson, Moderator: Professor Kraus, I now invite you to separate gain, effective aperture, antenna factor and impedance. Provide worked numbers and insist upon the geometric assumptions that make each equation legitimate.

John Daniel Kraus, Third Principal Contributor: Dr. Atkinson, I would distinguish three antenna descriptions that are often conflated. The first is a radiation pattern, which describes angular response under specified far-field conditions. The second is the port behaviour, including impedance, mismatch, balun performance and feed-current suppression. The third is the installed receiving transfer, which includes conductive structures, scattering, near-field polarisation and receiver coupling. A calibration of the first description does not automatically determine the second or third. The operator who multiplies a receiver voltage by a factor in decibels per metre without checking those conditions is making an inverse inference for which the data may be insufficient.

For a receiving antenna under plane-wave illumination, its available power can be related to the incident power flux density S in watts per square metre through an effective aperture A_e in square metres. Under the customary ideal assumptions P_available equals S multiplied by A_e, while effective aperture is lambda squared times gain G divided by four pi. Gain is dimensionless in this equation, lambda denotes wavelength in metres, and pi is the mathematical constant. The expression describes power available to an appropriately matched receiver from a plane wave of compatible polarisation. It must not be used as a universal formula for the power a little

Copyright 2026, James M. Atkinson

loop extracts from the reactive magnetic field of a current-carrying conductor inches away. In the latter situation the source and sensor can load one another and exchange non-propagating energy.

A worked far-field example clarifies both the use and the limitation. At a wavelength of 0.30 metre, corresponding in free space to approximately 1.0 gigahertz, suppose the antenna's linear gain is 2.0 in the direction and polarisation of interest. Then A_e equals 0.30 squared times 2 divided by 4 pi, approximately 0.0143 square metre. Under an assumed plane-wave flux density of one microwatt per square metre, the available power is about 14.3 nanowatts. If the receiver system is mismatched or the field is not a plane wave, that result is not the delivered input power. This example is a consistency check for dimensions, not an acceptance test for local enclosure measurements.

The antenna factor has a similarly precise domain. In one common definition the factor in decibels per metre is 20 log base ten of the ratio of electric field in volts per metre to receiver terminal voltage in volts, with a reciprocal-metre reference as appropriate. This logarithmic form is appropriate for an electric-field antenna under a specified test configuration. It is not a far-field conversion from every electrically sensed perturbation to a unique field vector. The relative orientation of the sensor and field enters through polarisation mismatch; the feed load enters through reflection; the test site's reflections enter through the illuminating field; and the mechanically nearby enclosure changes the boundary conditions. A certificate is evidence of how one of those arrangements was measured, not a blanket endorsement of all others.

Copyright 2026, James M. Atkinson

When the subject is physically near, the size of the test structure as well as the antenna matters. Take an aperture of characteristic dimension D equal to 0.50 metre, wavelength lambda equal to 0.10 metre, and a conventional phase-front criterion R at least 2D squared divided by lambda. This yields 5 metres. At R equal to 0.10 metre beside a rack, the usual large-aperture far-field condition clearly does not obtain. Yet the calculation does not identify the coupling as exclusively electric or magnetic, nor does it determine a universal safe or unsafe distance. It only shows that the premises for using a far-field approximation are doubtful in this illustrative geometry. Reflection, blockage and local currents still require observation.

A deployed calibration programme should record at least the reflection coefficient at the antenna port, a measured common-mode feed current, polarisation response for repeatable controlled sources, and spatial variability at anticipated standoffs. With a network analyser, measure S11 or the corresponding impedance whilst the antenna is in free space and when fixed at several distances from a conductive plate. The change in S11 does not directly equal the error in inferred field, because the incident field itself may change; nevertheless it proves that the receiving boundary has altered. Use a calibrated line and stable load when assessing gain errors, and do not conflate a cable loss correction with a near-field transfer correction.

One useful counterexample concerns the low-frequency loop. In the magnetoquasistatic regime a small loop of N turns and area A develops an ideal open-circuit emf proportional to angular frequency omega, magnetic permeability mu, effective loop area and the component of H normal to the loop. In magnitude, for a uniform sinusoidal field, V_open approximately equals N omega mu A H. At 100 kilohertz, one turn, area 1 square

Copyright 2026, James M. Atkinson

centimetre and H equal to 0.01 ampere per metre in free space, the magnitude is roughly 0.79 microvolt. This formula includes assumptions of electrically small area, uniform field and negligible loading. It is a very different calibration relation from a far-field electric antenna factor, and a screened loop with imperfect electrostatic rejection can violate the simple interpretation.

I would therefore publish two distinct outcomes. The first is the validated laboratory antenna calibration, retaining its frequency, direction, polarisation, loading and uncertainty. The second is an installation-specific evidence map of relative sensitivity, exclusion zones, cable susceptibility and measurable response to controlled field changes. An observation that survives tests with orthogonal sensors, reversed source polarisation, several standoffs and altered cable routes earns more confidence than an observation that merely agrees with the printed gain curve. Conversely, absence of a line after one orientation establishes no comprehensive absence of a signal. The correct technical report states what has been bounded and what remains unmeasured. I pass the token with a preference for dimensional consistency over impressive but unearned decibel precision.

Antony Hewish, Peer Question: Professor Kraus, your aperture calculation is rigorous under its stipulated incident plane wave, but a survey antenna is sometimes expected to recognise very short, faint or intermittent signals inside a screened room. In that setting the observer may rely on time averaging and the apparent narrowness of a spectral line to claim extraordinary sensitivity. How does an antenna factor interact with bandwidth, detector response and dwell time, and why is a threshold established for a continuous test carrier not automatically a threshold for a

Copyright 2026, James M. Atkinson

burst? Please give a numerical example in which the same available power produces a different apparent outcome under changed observation windows. I also ask whether an unknown polarisation and a changing antenna pattern in the installed environment should be represented as uncertainty, as a detection-coverage limitation, or as both when the investigator describes a negative finding. Indicate whether the observation windows were continuous or merely a sparse sequence of receiver dwells across the monitored band.

John Daniel Kraus, Response: Professor Hewish, antenna factor describes one transfer relationship between a defined field and port voltage. Detection probability is an additional receiver-and-observation problem. For a specified linear receiver the noise power in a measurement bandwidth B can be approximated by k T B multiplied by an appropriate linear receiver noise factor F, where k is Boltzmann's constant, T the reference temperature in kelvin and B the equivalent noise bandwidth in hertz. The term describes an idealised thermal-noise contribution and says nothing by itself about impulsive interference, overload, spurious tones or the spectral concentration of a particular modulation. Changing bandwidth and averaging alters the observed signal-to-noise behaviour even with identical antenna transfer.

Consider an illustrative emitter that transmits for ten milliseconds once per second, with its active-period available power otherwise fixed. If a receiver takes a ten-millisecond observation aligned with the burst, the signal may be visible. If it samples a ten-millisecond window at a random phase, the probability of any overlap between a uniformly random ten-millisecond acquisition and a ten-millisecond burst in a one-second period is about two

Copyright 2026, James M. Atkinson

percent; the chance of sufficient overlap for a reliable detection depends further on the detector and threshold. If the receiver instead averages power across a full second, the ideal duty-factor reduction in mean signal power is ten log base ten of 0.01, or minus 20 decibels relative to the active interval. No change in antenna factor is involved. The two observations can therefore disagree drastically without any contradiction in the electromagnetic calibration.

For an unknown source, polarisation loss and installed pattern nulls are not simply random scatter that may be averaged away. They may be persistent blind regions depending on source orientation and the conductive boundaries. A calibrated reference tone arriving in one polarisation can show a healthy signal margin while another polarisation is suppressed. I would map receiver response with controlled source and sensor rotations and report the response distribution over the measured set, without claiming that these finite trials determine the probability distribution of a hypothetical adversary's choices. The output can include quantitative uncertainties where the model and data support them, alongside explicitly unquantified coverage limitations.

Finally, the record must preserve time-domain information whenever the signal may be transient. Store timestamps, acquisition duty cycle, sample intervals, resolution bandwidth, detector modes and trigger rules, and check whether the instrument retunes during relevant bursts. A negative report should say that nothing above a stated criterion was recorded under those windows and poses, rather than that no emitter existed. Far-field gain and antenna factor alone cannot certify the listening schedule or the receiver's

Copyright 2026, James M. Atkinson

temporal completeness. Those are distinct layers of evidence requiring their own controls and limitations.

Dr. James M. Atkinson, Moderator: Mr. Heaviside, the token passes to you for the feeder and return-current problem. Explain why moving the cable may move the apparent radiation, and how an investigator can test the resulting alternative hypotheses without altering electrical protection.

Oliver Heaviside, Fourth Principal Contributor: Dr. Atkinson, the missing element is often the transmission system between the sensing metal and the receiver. Engineers speak of an antenna as though it ended at a connector and the cable simply transported its voltage. A current on the outer surface of a coaxial shield may carry another signal path; a bend near a cabinet may alter it; a balun may have finite impedance and frequency dependence; and a receiver's metallic case may complete a return route. In an enclosure these details can determine the whole result. The isolated far-field antenna curve says almost nothing about the magnitude of such unintended currents. An impressive factory certificate is therefore compatible with a thoroughly misleading installed measurement.

Begin with a simple source and two possible circuits. The desired circuit runs from the antenna through the intended differential feed into a properly terminated measuring instrument. The unintended circuit runs over the feed cable's external conductor, through the instrument body, capacitively or conductively to nearby metal and back through the surroundings. Both may be driven by the same ambient field, and the receiver may respond to their sum. The second is not necessarily a fault in the coaxial dielectric. It is a common-mode current path created by the complete geometry. Change the

Copyright 2026, James M. Atkinson

cable position and the effective receiving structure can become longer, shorter or resonant even when no one touches the antenna element itself.

One can make the effect measurable without pretending that it has a universally predictable magnitude. Establish a stationary reference emitter and an unaltered antenna position. Record the receiver output with the cable suspended along a reproducible reference path, then with the cable routed close to a conductive frame, then with the same cable moved away without changing the antenna position. At each trial measure the current surrounding the entire coaxial cross-section with a suitable calibrated sensor. Repeat in reverse order, because temperature drift and a changing ambient spectrum can otherwise manufacture a trend. The experiment must distinguish a physical feed-current change from mere movement of a noisy receiver connector. It should never require damaging or opening the protected installation.

A frequency-domain illustration helps. Suppose the cable outside-surface current is 2 milliamperes at one reference tone in configuration A and 0.5 milliampere in configuration B, with source output held constant. The current ratio is four, or 20 log base ten of four, about 12.04 decibels. If the receiver output simultaneously changes by ten decibels, the correlation invites examination, but it does not show that all ten decibels arise from the external current. We need phase-sensitive measurements or controlled choke experiments to separate the pathways, and we must assess whether the current probe itself loads the line. Correlation is a reason to test a mechanism, not an acceptable substitute for that test.

A simple impedance model shows why effects can be dramatic. The common-mode impedance can contain resistive, inductive and capacitive

Copyright 2026, James M. Atkinson

components, each varying with frequency and path geometry. At a chosen resonance the inductive and capacitive reactances may partly cancel, leaving a larger current for an applied excitation than in neighbouring bands. In a real enclosure the equivalent parameters depend on bonds, gaps and the placement of cables, and a lumped model can cease to describe the distributed structure. The operator should check measured phase, standing-wave response and repeatability rather than announce that every peak must be a resonance. The true source may itself be intermittent, and a receiver spur may move for reasons unrelated to antenna current.

There is also a methodological danger in adding a balun, ferrite or filter and calling the before-and-after comparison a field measurement. Such a component changes a boundary condition. It can usefully reveal an unintended coupling route but also change the desired signal transfer, noise and port match. Measure the insertion behaviour of the intervention or use an independently specified device, and report both the benefit and the new uncertainty. A ferrite placed at one cable point is not proof that no common-mode current flows elsewhere. In a system with multiple cables, common-mode currents may redistribute from one return path to another. A positive result must therefore be understood as a controlled intervention, not an absolute correction applied to all future configurations.

The electric field near a seam and the magnetic flux near a return conductor are not separate worlds. Boundary charges drive displacement currents, conduction currents create magnetic field, and the enclosure couples them through apertures and common return networks. This is why one can observe a peak with a nominal electric probe while a nominal magnetic probe also responds. An instrument may report volts at a connector; the

Copyright 2026, James M. Atkinson

inferred field quantity requires a validated response model. The 377-ohm plane-wave relation is inapplicable to an arbitrary local mixture of reactive fields. Drawing a neat diagram with a single arrow from hidden transmitter to receiving antenna may be aesthetically agreeable, but it can omit the actual route that carries the greater measured voltage.

My preferred acceptance test is a small matrix rather than a single correction constant. Change only one of antenna standoff, cable route, choke placement, reference polarisation or enclosure bond state at a time, while recording what was physically altered and what was independently monitored. Replicate the baseline after the matrix and use a second receiver chain where possible. Report which effects are stable enough to support a causal statement and which remain combined in the observed terminal voltage. The laboratory antenna factor is a reference for a defined wave; the deployed instrument is a circuit connected to its environment. Until those two descriptions are reconciled experimentally, the field estimate has no right to a spurious certainty. I pass the token to an analysis of uncertainty and measurement discipline.

Sir Edward Victor Appleton, Peer Question: Mr. Heaviside, I am concerned that the experiment may itself create or suppress the common-mode path it intends to identify. An instrument frame may be bonded to a rack, and a lead passing through a conductive aperture can acquire a different impedance after one loop is tightened or a ferrite is applied. What can a careful observer infer from a large change in the received spectrum after such an intervention? Please consider whether a clamp current probe can be trusted in the presence of nearby magnetic material, what the experiment means if several external cable paths share return current, and how phase

Copyright 2026, James M. Atkinson

information would assist. I would also value a precaution against turning an ordinary equipment-bonding test into an unsafe manipulation of protective earth, particularly where live systems or regulated installations cannot be disconnected for the convenience of the investigation. Please state precisely which power-system interventions must remain prohibited during a live survey, regardless of their apparent diagnostic convenience.

Oliver Heaviside, Response: Sir Edward, a changed spectrum after a choke, cable reroute or improved bond is evidence that the intervention has altered the receiving system. It does not, without controls, specify how much of the change arose from the targeted common-mode path. A ferrite may introduce differential loss in some arrangements, change source loading, affect nearby components or displace the cable physically. A bond can change the distribution of induced currents over several parallel metal paths. The correct conclusion is conditional: under a named change of topology, the measured terminal response changed. To assert a mechanism, we need at least one independent indication whose behaviour the model predicts.

A current sensor around the complete coaxial cable can provide such evidence, but only within its calibrated transfer impedance, frequency range and dynamic range. Its sensitivity may be affected by proximity to ferromagnetic material, its geometry and the observer's hand. Before inserting it into a tight enclosure, test the device on a controlled conductor at the relevant frequency and record the measured baseline at the actual standoff. Where several conductors return energy through separate structural paths, measuring one alone provides an incomplete current balance. Use multiple current measurements or a test circuit model that

Copyright 2026, James M. Atkinson

admits unobserved returns; it is not sensible to infer zero total common-mode current from a quiet reading on one branch.

Phase information can strengthen the causal comparison. If the received complex voltage and measured feed-current phasor change coherently when a cable route is altered, a coupled contribution is plausible. But because both may be excited by a common external field, coherent change is not sufficient proof. A second intervention that changes external cable current without materially changing the intended antenna mode would be needed, and one should estimate the uncertainty due to any probe loading or altered return path. The analysis may require a multiport model rather than a single correction in decibels.

Above all, do not remove protective earth or compromise bonding on an energised installation for a measurement demonstration. Use non-invasive variations where possible, and if a controlled bond change is scientifically indispensable, conduct it only on a safe de-energised laboratory surrogate under proper engineering authorisation. The fact that a forensic question is important does not license unsafe alteration of equipment. Preserve the original installation photographically, describe the surrogate's differences, and qualify any transfer of its result to the actual scene. That creates evidence without manufacturing a new electrical hazard.

Dr. James M. Atkinson, Moderator: Lord Rayleigh, please take the token and distinguish uncertainty in a calibrated quantity from model inadequacy after deployment, including the limits of negative evidential conclusions.

Lord Rayleigh, Fifth Principal Contributor: Dr. Atkinson, a measurement lacking a declared domain of applicability is an estimate whose uncertainty

Copyright 2026, James M. Atkinson

has not been fully named. The temptation is to preserve the uncertainty printed on the far-field calibration certificate and append nothing when an antenna enters a metal-filled room. Yet that certificate may have been obtained with excellent standards and great care, and still omit the dominating uncertainty of the new task. The calibration uncertainty concerns a particular measurand and arrangement. Installation effects, orientation, probe positioning, scattering and unknown excitation constitute other components, some of which are not well described by random variables. To claim the former certificate alone as the uncertainty of the latter observation is a category error.

I would first distinguish three kinds of uncertainty. Repeatability concerns the variation when the same operator repeats a nominally identical observation; calibration uncertainty concerns what was learned from references and their transfer; model inadequacy concerns whether the assumed relation between measured voltage and desired field is physically valid. A hundred readings at one fixed standoff may reduce the estimated random variance of their mean while leaving model inadequacy untouched. If the dominant concern is a cable-driven common-mode response, repeated observations with the same cable pose may exhibit extraordinary precision and very little accuracy for the desired electric-field quantity. The proper response is not to average more energetically. It is to change the experiment so that the omitted mechanism can be tested.

For clarity, define the measured complex receiver voltage as V, the desired field component as E, and the installed transfer as H_inst. In a locally linear representation we may write V equals H_inst multiplied by E plus an additive disturbance n. If the calibration supplies H_far, then the naive estimate

Copyright 2026, James M. Atkinson

E_hat equals V divided by H_far, whereas the physically appropriate local estimate would require H_inst and treatment of n. The fractional multiplicative error in a noiseless simplified case is H_inst divided by H_far minus one. This algebra is simple; the hard part is that H_inst may be unknown, frequency-dependent, direction-dependent and sensitive to the conducting surroundings. When multiple field components contribute, H_inst is better represented as a vector or matrix transfer rather than one scalar.

The following hypothetical example makes the distinction visible. Let a laboratory response coefficient be one millivolt per volt per metre for a specified plane wave. Let the deployed response become 0.6 millivolt per volt per metre under a nearby conducting boundary, while the actual field component is one volt per metre. Then the receiver observes 0.6 millivolt, and division by the laboratory coefficient estimates only 0.6 volt per metre. The error is minus 40 percent for this constructed case. If the perturbation is not measured, reporting a calibration uncertainty of plus or minus five percent would be misleading even if the certificate's five percent were perfectly justified under laboratory conditions. The numbers are illustrative, not a claim about typical antennas or enclosures.

A robust study needs repeated installations as well as repeated readings. Set out a grid of distances and orientations before examining the strongest peaks, and preserve a subset of locations as withheld confirmation points. Use both ascending and descending movement sequences; thermal or source drift otherwise may be confused with a spatial gradient. Observe deliberate source-off periods, and include a reference signal monitor that does not share the receiving cable under test. Mark each observation with

Copyright 2026, James M. Atkinson

its own uncertainty class. If reference power, position and angle are all measured, estimate their contributions through sensitivity coefficients where the measurement model is sufficiently reliable. If the model itself is unidentifiable, state that no combined numerical uncertainty can rescue the absolute field inference.

A common calculation combines independent standard uncertainties using the square root of the sum of squared sensitivity-weighted components. For example, in a hypothetical well-characterised local voltage model, suppose standard uncertainties expressed in decibels are 0.5 for the reference level, 0.8 for repeatable placement and 0.6 for the receiver response. If these components are independent and approximately small on the logarithmic scale, the root-sum-square is the square root of 0.25 plus 0.64 plus 0.36, approximately 1.12 decibels. That figure must not quietly absorb an unmeasured five-decibel geometry effect. Nor should a correlation between placement and cable routing be ignored merely to preserve a neat square-root expression. Correlated inputs require covariance terms or bounding studies.

The negative survey conclusion calls for even greater care. Failure to detect a particular known test source establishes information about sensitivity to that source under a finite set of environmental states. It does not establish the probability of detecting an unknown emitter unless its frequencies, powers, modulation, orientation, duty cycle and coupling pathways belong to a justified class. If those quantities are unconstrained, an unconditional claim of absence is scientifically indefensible. One can instead provide a bounded statement: the receiver reached a specified noise-limited threshold over a measured band, and controlled comparison emitters of declared

Copyright 2026, James M. Atkinson

properties were detected or missed in stated positions. The limitation is not embarrassing. It is what makes a forensic result interpretable.

I would close by requiring an explicit separation in the report between traceable values, field-dependent corrections and unquantified omissions. State the source type, reference antenna factor, loading, polarisation, geometry, bandwidth, detector, dwell time and actual cable route. Show the controlled contrasts rather than an edited map of highlights alone, and keep raw records for independent reanalysis. Where a model remains underdetermined, describe several compatible mechanisms and an experiment that could distinguish them. The scientific value of a negative finding lies in the narrowness and honesty of its stated conditions; the value of a positive finding lies in the reproducibility of its causal contrasts. I return the token to the moderator under those terms.

Sir Martin Ryle, Peer Question: Lord Rayleigh, a whole series of measurements can appear reassuringly precise while representing only one family of field geometries. Suppose an investigator calibrates a receiving antenna on an open range, repeats its factor many times, then surveys a room and reports a negative result with an uncertainty budget consisting entirely of calibration, receiver level and sample repeatability. What exact inferential error is present, and how should a publication present the uncertainty of the negative finding when the source distribution is not known? Please distinguish a conventional combined standard uncertainty from structural uncertainty about the measurement model. I also ask how a withheld validation geometry could detect overfitting to the observed strongest peaks, and what a reader should be told when a transfer-function perturbation is so large that no defensible absolute field conversion can be

Copyright 2026, James M. Atkinson

assigned. I ask that the report preserve the raw calibration certificate rather than silently replacing its stated uncertainty with a newly guessed installed value.

Lord Rayleigh, Response: Sir Martin, the inferential error is the substitution of precision under a conditional model for evidence that the model applies. A certificate may tightly constrain the antenna's response to a specified plane wave, and repeated voltage readings may precisely determine the receiver level, but neither operation constrains the unknown difference between a laboratory plane-wave response and an installed response to reactive or scattered fields. The missing term is not an obscure addition to a well-behaved variance. It may be a model-form uncertainty in which the very quantity being inferred is incompletely specified. Reporting the small laboratory uncertainty as the total uncertainty in the room would conceal that omission.

In a well-defined linear model, uncertainty propagation uses sensitivity coefficients and covariances: if y is a function of measured inputs x_i, the variance approximation includes the sum over pairs of the products of partial derivatives times input covariances. When inputs are independently measured and the linear approximation is adequate, the familiar root-sum-square expression follows. But an unobserved coupling coefficient or unknown source polarisation is not made measurable by assigning it an arbitrary Gaussian distribution. The report must distinguish quantified components from scenario bounds and from cases where no quantitative bound is available. It is better to present a family of conditional results than an invented single confidence interval.

Copyright 2026, James M. Atkinson

A withheld geometry tests whether the chosen explanatory model predicts an observation it did not help fit. One could construct an initial set of source positions, standoffs and cable routes, use those to estimate a limited installed response and then test another preselected combination without changing the model. If the resulting complex voltage or received level falls outside a predeclared prediction interval, the model needs revision. The exercise also exposes a selection bias: a model tuned to reproduce only the largest observed peak may fail systematically at quieter positions. Document the training and validation configurations, preserve negative observations and do not permit informal adjustment of the final model after seeing the withheld data without reporting that adjustment.

For a negative finding, the scientifically proper object may be an empirical detection-capability table, not a point estimate of absent radiated power. State the detected and missed reference signals by frequency, polarisation, modulation, location, dwell time and threshold, along with the denominator of trials. Without a justified population distribution for an unknown source, do not turn the proportion of laboratory trials into a probability that every possible covert device would have been seen. If installation-specific transfer has not been validated for an observed line, provide the receiver measurement and its environmental conditions without converting to absolute field strength. A reader can then assess exactly what is known, what is conditional and what has never been measured.

Dr. James M. Atkinson, Moderator: The five principal contributions have been heard and the seven ordinary interrogations answered. I now invite four cross-peer challenges, each addressed to a distinct expert other than the initiating speaker. The responses will follow each question immediately.

Copyright 2026, James M. Atkinson

The exchange must test the limits of the models rather than merely restate the same antenna-factor cautions.

Grote Reber, Cross-Peer Question to John Daniel Kraus: Professor Kraus, your aperture and gain equations properly delimit a plane-wave calculation, but an actual field survey can face an antenna whose nominal pattern changes whenever its feed passes beside a large structural member. Suppose a team concludes that a calibrated receiving antenna has retained its stated gain because S11 looks nearly unchanged after installation, although a controlled local reference field now produces a much smaller voltage. Does that observation falsify the laboratory gain measurement, or does it show that port matching is an insufficient proxy for receiving sensitivity? Please distinguish antenna impedance, embedded or installed radiation pattern, incident field strength and common-mode cable effects. I also ask what additional measurement would permit a credible quantitative correction rather than a merely qualitative warning, and whether the conventional reciprocity argument alone can guarantee that the local field is sampled as it would be in free space. The practical issue is not whether the instrument can display a number; it is whether that number retains a defensible measurand under conductive enclosure loading.

John Daniel Kraus, Cross-Peer Answer to Grote Reber: Mr. Reber, a nearly unchanged reflection coefficient establishes only that the port presents nearly the same impedance under the measurement conditions. It does not demonstrate that the antenna samples the same component of an external field or has the same spatial receiving pattern. A conductive structure can alter the distribution of fields and currents around the antenna while leaving a similar port match. Two arrangements can have comparable S11 and

Copyright 2026, James M. Atkinson

different gain, efficiency or sensitivity to a particular source direction. The observation therefore does not falsify the far-field result. It demonstrates that the premises for transporting that result to the installed setting have not been satisfied.

The appropriate language distinguishes port impedance Z_in, a far-field gain function G of frequency and direction, and the full installed voltage transfer. When the incident field consists of multiple angles or reactive components, the receiver voltage is the superposition of contributions weighted by vector effective-length response and the surrounding boundary. Common-mode cable currents may add a further pathway. Reciprocity applies to a passive linear reciprocal antenna system under specified boundary conditions; it does not assert that the system remains unchanged when placed beside metal. Nor does reciprocity turn an unknown near-field source into a known uniform plane wave. The installed system must be defined before a reciprocal transmission experiment can be compared meaningfully with reception.

For a quantitative correction, I would require a calibrated field or source geometry sufficiently representative of the intended installation, with known frequency, vector polarisation and location. Measure the receiver's complex response and the incident reference quantity, and map more than one position to test whether a single scalar correction can survive. Independently monitor source output, antenna port mismatch, cable current and receiver linearity. If the inferred correction varies strongly with source position, then an angular or spatially dependent transfer function is required. In the absence of that information, the best evidence is an installed relative-response map with conditional limits.

Copyright 2026, James M. Atkinson

The result should include explicit failure of proposed simplifications. An unchanged S11 is evidence against one explanation involving a large change in input match, but it is not evidence against scattering or a change in the antenna's embedded pattern. A different cable route may further alter the received response without changing the radiator. I would ask the investigator to report each measured contrast, preserve their phase conventions and avoid collapsing all effects into one number labelled antenna gain. A laboratory calibration need not be wrong to be inapplicable. It is the model connecting it to the field survey that needs additional validation.

John Daniel Kraus, Cross-Peer Question to Oliver Heaviside: Mr. Heaviside, suppose a cable choke lowers a suspicious narrowband peak by eight decibels but simultaneously increases the measured reflection coefficient of the sensing antenna. The investigator is tempted to announce that the eight-decibel reduction proves common-mode pickup and to subtract eight decibels from all earlier readings. Is that reasoning technically sound? Please give an alternative experimental arrangement that separates differential antenna reception from exterior feed current without violating the site's protective-bonding arrangements. I would also value your view on how a mechanical cable constraint, used to guarantee a repeatable receiving geometry, can be represented in the uncertainty budget. In a cramped rack the constraint may prevent some positions altogether; is the resulting blind area a calibration uncertainty or a geometric coverage limitation? Finally, explain why a choke specified at one test frequency may be an unreliable intervention at another frequency if cable resonance and multiple paths remain present. Does a stable port match at the receiving

Copyright 2026, James M. Atkinson

element ever suffice to validate the previously assumed vector effective length?

Oliver Heaviside, Cross-Peer Answer to John Daniel Kraus: Professor Kraus, that subtraction would be unjustified. The choke has changed an electrical network, not merely removed an unwanted voltage component of known amplitude and phase. It may suppress an exterior shield current while also changing the differential transfer or antenna match, and the eight-decibel receiver change is the sum of the resulting effects. Power levels expressed in decibels cannot generally be partitioned by simple subtraction when coherent voltage contributions interfere. The engineer must either measure the relevant complex components or construct controlled trials that isolate the pathways. A reduction after intervention is a useful clue, but it is not a calibration constant applicable to earlier unaltered observations.

A defensible alternative retains the sensor pose, source and receiver settings whilst measuring the antenna-port response and outer-conductor current independently. Use a calibrated current probe that encloses all conductors of the selected feed without breaking protective bonding, and perform the choke comparison on a laboratory surrogate first if its safety or system implications are uncertain. A second receiving path with a physically different feeder arrangement may reveal path dependence, provided its own transfer is measured. A current-suppression component can also be installed at several documented positions in a safe test chain to see whether a consistent causal pattern emerges. None of these tests presumes that an instrument case or earth conductor may be disconnected at convenience.

Repeatability fixtures deserve their own documentation. A jig may reduce random positional variation, yet it also constrains the accessible field

Copyright 2026, James M. Atkinson

geometry. Its material could perturb the field or make the cable route more stable than a normal survey. Measure its dimensions and, where material properties are relevant, test whether the jig changes the response. Uncertainty may include reproducible placement tolerance; positions the jig cannot reach are a coverage limitation rather than merely a small extra variance. The report must say plainly that those locations were not examined with that configuration.

Frequency dependence is essential. A ferrite choke's impedance has a dispersive resistive and reactive character, while a feed cable and nearby conductors exhibit distributed resonances. A component effective near one hundred megahertz may provide less suppression, or different phase effect, at a distant frequency. Parallel return routes can bypass the treated cable. Therefore the only generalisable result is a measured transfer under the stated frequency, route and termination. I would preserve the untreated baseline and all component data, and would refuse an across-the-board eight-decibel correction without a frequency- and geometry-resolved calibration model.

Oliver Heaviside, Cross-Peer Question to Lord Rayleigh: Lord Rayleigh, your warning about uncertainty is persuasive, but I suspect that an analyst can evade it by writing a large arbitrary uncertainty band around the field estimate while retaining the same unsupported antenna-factor conversion. At what point should the editor decline to print an absolute field-strength estimate rather than merely enlarge its error bars? Suppose the antenna factor certificate reports a fraction of a decibel, repeated placement trials scatter by two decibels, but controlled cable routes produce changes of twenty decibels at certain frequencies. Please separate the kinds of

Copyright 2026, James M. Atkinson

uncertainty that can be modelled statistically from the structural failure of a scalar transfer assumption, and give an operational decision rule for retaining or withdrawing the absolute conversion. I am also concerned about negative findings. How should the analyst present a thorough survey map when some coordinates cannot be reached without altering the geometry that makes the receiving system unreliable?

Lord Rayleigh, Cross-Peer Answer to Oliver Heaviside: Mr. Heaviside, an arbitrary uncertainty band is not a scientific remedy for an unvalidated relationship between observables and the claimed quantity. If a scalar antenna factor predicts a unique field value from the receiver voltage, yet the field estimate changes by twenty decibels when a physically relevant cable route changes, the model requires investigation before an absolute field can be printed. The change corresponds to a tenfold voltage ratio in a simple amplitude interpretation, far beyond the stated fraction-of-a-decibel calibration term. One cannot presume that the cable movement changes only the instrument, because the cable itself may scatter field, but the experiment demonstrates that the transfer is insufficiently stable for an unqualified scalar conversion.

Where a validated local transfer model exists and residual changes are random under specified repeatable conditions, components may be entered into an uncertainty budget. Where cable routing represents a finite set of deliberate environmental states, it may be more honest to report a range of conditional results than to assign a single normal distribution. Where the intended field component cannot be separated from common-mode or reactive coupling, the model is structurally unidentified, and numerical uncertainty in a derived absolute field has no well-established meaning. The

Copyright 2026, James M. Atkinson

value should then be withdrawn from the findings table, while the directly measured receiver voltage, frequency and settings remain available.

My operational rule has three requirements. First, a controlled source or reference field of known relevant type and orientation must establish a transfer in the intended deployment geometry. Second, the transfer must predict at least one withheld position or intervention within a predeclared tolerance compatible with the intended evidential use. Third, the dominant model components and their uncertainties must be bounded by measurements rather than assumed away. Failure of these requirements means the report may retain a qualitative or relative-response finding but should not give a confidently stated local field. This is a stricter rule than merely making error bars enormous, because it separates identifiable quantities from quantities not supported by the experiment.

For inaccessible coordinates, state the coverage explicitly. A diagram can distinguish physically surveyed points, points examined only in a modified geometry, and points not reached at all. Do not interpolate a uniform sensitivity between measured locations when the cable and enclosure effects are strongly discontinuous. A negative finding should refer only to the tested poses, sources and receiver thresholds, and should include the cases where a comparison source was missed. The most impressive map is not necessarily the most reliable; a map that visibly records its blank regions may be the stronger forensic record.

Lord Rayleigh, Cross-Peer Question to James Clerk Maxwell: Professor Maxwell, a final theoretical question concerns the widespread belief that a sufficiently careful far-field calibration must somehow contain all of the physics because the same electromagnetic equations govern the apparatus

Copyright 2026, James M. Atkinson

in every place. The governing equations are indeed general, but the boundary conditions and unknown excitations are not. How should a manuscript explain this apparent paradox without devaluing accurate standards? In particular, distinguish the equivalence of different external source configurations under limited observations from the uniqueness of a field solution when all boundary data are specified. Could a single receiver-voltage trace ever locate a near-field source uniquely, and what extra independent data would be required to sharpen the inverse problem? Please end with an explicit statement suitable for a technical surveillance countermeasures report: what exactly may be asserted after far-field antenna calibration has been transported into a steel-filled room without an installed transfer validation? I ask you also to distinguish deterministic field reconstruction from a probability distribution over unobserved candidate sources.

James Clerk Maxwell, Cross-Peer Answer to Lord Rayleigh: Lord Rayleigh, there is no paradox. Maxwell's equations govern each admissible physical arrangement, but a solution requires a specified geometry, materials, excitation and sufficient boundary or initial conditions. In a laboratory calibration the field arrangement is deliberately controlled, and the antenna's response is determined relative to that arrangement. In a metal-filled room some of the boundaries and source currents may be unknown, so the same equations admit many different configurations consistent with the observed receiver voltage. Generality of the equations is no guarantee that an investigator has supplied enough data to invert them uniquely. The weakness lies in the information available, not in electromagnetic theory or its metrological standards.

Copyright 2026, James M. Atkinson

A scalar voltage trace is a severely compressed observation of a vector field over space and time, filtered by the antenna and receiver. Different internal sources, cable currents and aperture currents can produce similar terminal spectra. Even with an exact receiver model, one measurement at one position usually cannot distinguish them, particularly when the frequencies or phases of independent sources are unknown. We must avoid an unqualified claim of mathematical impossibility for every specially constrained case: under strong prior restrictions a parameter may be identifiable from limited data. But the ordinary unknown-source enclosure survey does not supply those restrictions, and the burden belongs to anyone asserting a unique location.

To sharpen the inference, add observations that respond differently to rival models. Measurements at distinct positions and orientations with stable known probe transfer functions can provide spatial diversity; electric-sensitive and magnetic-sensitive probes can provide complementary coupling sensitivity; measurements of cable common-mode currents and antenna input impedance can expose unintended paths. Controlled source or boundary interventions supply causal diversity, while phase-resolved measurements may preserve distinctions lost in magnitude-only data. Even then the resulting inverse calculation must declare its assumed source class, boundary geometry, noise covariance and regularisation. A numerically precise point on a map can be the product of an aggressive assumption rather than a physical identification.

I would phrase the forensic conclusion as follows: the antenna possesses a documented response under its stated laboratory far-field calibration conditions, and a receiver response was observed in the installed enclosure

Copyright 2026, James M. Atkinson

under the recorded geometry. Without an independently validated local transfer model, that response does not establish a unique local electric field, magnetic field, radiated source power or emitter position. It may support further controlled testing, and its reproducibility can be reported, but the absence of a detected response does not prove an unrestricted absence of emissions. This language preserves the value of careful calibration whilst refusing to attribute to the certificate facts that were never measured.

Dr. James M. Atkinson, Moderator, Closing Synthesis: Far-field calibration supplies a traceable response under specified illumination, orientation, loading and uncertainty. It does not alone establish the spatially resolved installed receiving transfer when cabinet walls, cables, return currents, reactive source fields and instrument settings participate in the observation. The panel distinguishes plane-wave effective aperture and antenna factor from installed complex response; the opening calculation shows how an assumed 6 dB transfer change can almost double a displayed field estimate, and the later examples distinguish power ratios, geometrical phase criteria, reactive-loop emf and receiver duty-cycle limitations. The investigator should record free-space calibration separately from installed response, conduct controls with orthogonal source geometry and cable routing, verify receiver state and independently monitor known sources. Quantified uncertainty is justified only for a measurement model whose quantities are identifiable. Reproducible receiver peaks are not automatically emitters, and a negative survey remains bounded by actual bands, positions, orientations, thresholds and observation windows. No historical contributor is presented as having spoken these modern words. The next question examines how polarisation mismatch and pattern nulls qualify a negative result.

QUESTION 064

Copyright 2026, James M. Atkinson

How should polarisation mismatch and pattern nulls qualify a negative surveillance search?

HISTORICAL RECONSTRUCTION. The following scholarly panel is an explicitly fictional educational reconstruction featuring deceased scientists and engineers. Modern receiver controls, software-defined-radio systems, time-tagged spectrum capture and present-day measurement standards are applied by the contemporary editor; they are not claims about conversations actually held or equipment personally used by the historical contributors.

Dr. James M. Atkinson, Moderator: Professor Kraus, a technical countermeasures survey may detect no emission in an apparently clear band and nevertheless have learned very little about the presence or absence of a transmitter. Its antenna may be cross-polarised to the incident wave, turned toward a pattern null, or placed where enclosure reflections cancel the field. I ask you to specify what a negative spectral display proves, to distinguish polarisation from direction-dependent gain, and to design a defensible measurement protocol for an unknown signal whose frequency, bearing, waveform, power, and polarisation are not known beforehand.

John Daniel Kraus, Principal Contributor: Dr. Atkinson, a receiving antenna is not a neutral window through which every field arrives equally. It converts a particular component of an electromagnetic field, in a particular direction, at a particular frequency, into a terminal response. We must therefore begin with the measurand. A display reading below a selected threshold means that the specified receiver, antenna, orientation, gain state and observation period did not produce a qualifying response. It does not mean that the incident field was absent. A claim of absence is an inference over an

Copyright 2026, James M. Atkinson

assumed family of emitters and propagation conditions. The family must be declared, for otherwise the assertion cannot be tested or falsified.

For a plane wave travelling toward a calibrated antenna from direction Ω, the matched available received power may be idealised as $P_{av}=S\,A_e(\Omega,f)\,PLF$, where S is incident power flux density in watts per square metre, A_e the antenna effective aperture in square metres for the specified direction Ω and frequency f, and PLF the dimensionless polarisation-loss factor. This factor ranges from zero to one. I am suppressing mismatch, cable loss, source impedance and noise in this first expression; each re-enters the actual chain. The important point is multiplicative: a physically real source can be attenuated by polarisation mismatch and by angular response simultaneously. If either ideal factor vanishes, a perfectly operating receiver can display nothing. Instrument sensitivity does not remedy a geometrical zero.

When both the incident wave and the antenna are purely linearly polarised, and their electric-field axes differ by ψ, the ideal loss factor is $PLF=\cos^2\psi$. At ψ=0° the loss is zero decibels; at 45° the available power is halved, approximately −3.01 dB; at 60° one quarter remains, approximately −6.02 dB; and at 80° only about 0.0302 remains, or −15.2 dB. The ideal 90° result is zero, although practical cross-polar sensitivity, depolarisation, reflections and imperfect alignment often prevent an infinite real-world loss. The calculation presupposes a plane wave of known linear polarisation and the appropriate receive-polarisation definition. In a reactive near field there may be no single transverse travelling-wave polarisation to which this reduction can safely be applied.

Copyright 2026, James M. Atkinson

An antenna pattern introduces a different dependence. Let G_r(f,Ω,p) be its realised gain for an incident field state p under defined loading. A direction that is inside a main lobe may receive adequately, while an arrival from a side or rear null may receive 20 or 30 decibels less, depending on the actual instrument and environment. Pattern plots are normally measured under stated test conditions; their null depth is limited by fixtures, cable currents and nearby conducting objects. A single advertised 'omnidirectional' label cannot guarantee uniform gain in elevation, and often says little about polarisation or the pattern near a cabinet. Omnidirectional in azimuth does not mean isotropic in three dimensions, nor does an antenna factor remove geometrical blind spots.

To determine whether a negative search has evidential force, I would specify a coverage function C(f,Ω,p,r,t,s): frequency f, arrival direction Ω, polarisation state p, receiver position r, time t and receiver configuration s. It is not necessary to sample every mathematical value. It is necessary to show what range of variations was tested, how performance was established, and which regions remain unexamined. A survey may have complete frequency coverage but incomplete temporal coverage; it may have repeated temporal observations yet omit one polarisation; or it may have sensitive antennas at one position but leave spatial nulls unresolved. The matrix of coverage is the real object of assurance.

Consider an authorised test at 900 MHz in a furnished room. A reference source at a surveyed position provides a known low-level signal into a transmitter antenna whose polarisation can be rotated. Hold its output power fixed, rotate a linearly polarised receiving antenna through 0°, 30°, 45°, 60°, 75° and 90°, and record the raw power and noise floor without

Copyright 2026, James M. Atkinson

changing gain settings. Repeat at several positions and elevations. This experiment does not reproduce every unknown emission, but it measures actual sensitivity loss under deliberately varied orientations. A reference source that is thirty decibels above threshold in one pose may fall below it in another solely through changed coupling. A test that only rotates the receiving antenna without checking whether its cable and body alter the field may be deceptive; these collateral changes need recording and control.

I would add a second, differently polarised sensor, not as an automatic cure but as an independent test channel. Orthogonal linear channels can increase coverage of linear waves, but their effective phase, amplitude, noise figure and pattern must be understood; a pair with coincident angular nulls may still miss the source. A circularly polarised antenna can be comparatively insensitive to orientation of an incoming linearly polarised wave in an ideal plane-wave setting, but it sacrifices roughly three decibels of available power relative to a matched linear receiver, and it can suffer serious loss for a circular wave of opposite handedness. Thus diversity shifts the design trade-offs; it does not eliminate them.

The correct negative conclusion is bounded. One may say that no qualifying energy was detected above a stated threshold in specified frequency bands, during logged intervals, for the measured antenna configurations and verified source challenges. One cannot legitimately turn that statement into 'no transmitter is present' when polarisation, bearing, installation geometry or intermittent duty cycle remain unknown. The latter claim requires assumptions and evidence beyond an unremarkable screen. To be scientifically rigorous, a negative finding should name the experiment that could have exposed its own principal failure mechanisms, and retain the

Copyright 2026, James M. Atkinson

measurements establishing that those experiments were actually performed.

Oliver Heaviside, Peer Question: Professor Kraus, I should challenge the assumption that turning a sensor through ninety degrees alters only its response to the wave. A dipole attached to a coaxial cable is not an isolated geometrical object; the braid and perhaps the receiver enclosure can carry current that adds another receiving mode. When the technician rotates the handle, the lead commonly bends, changes its distance from nearby metal, and modifies its effective counterpoise. A striking minimum might then arise from currents on the measuring system instead of orthogonality between two freely propagating electric vectors. Can you describe an experiment that keeps the reference source and antenna electrical centre sufficiently stable to distinguish the intended linear-polarisation law from common-mode coupling, and specify what observations would invalidate a simple cos-squared interpretation? I also ask what can be claimed if the system lacks a calibrated current probe or a trustworthy complex phase record, because practical investigators frequently must work with ordinary amplitude-only instruments.

John Daniel Kraus, Response: Mr. Heaviside, your challenge is decisive because the ideal polarisation projection concerns a defined receiving mode and controlled reference plane. The coaxial shield may carry current as part of the antenna, and the instrument case can alter the return path. We should not infer the intrinsic polarisation factor merely from a hand-held amplitude trace. I would begin with a fixture that permits rotation about a repeatable axis through the sensor's electrical phase centre while holding cable strain and cable route constant as far as practical. The source must be

Copyright 2026, James M. Atkinson

independently monitored, and the receive settings frozen during each comparison. A source-off baseline at each pose is necessary because movement may change the instrument's own noise pickup.

A second set of measurements deliberately changes the suspect path. Keep the sensing element and its orientation fixed, reroute the cable through two documented positions, then introduce a suitable characterised common-mode choke or isolation arrangement under safe electrical conditions. Measure the shield current when an appropriate probe is available. If the nominal polarisation minimum shifts appreciably with cable dressing or choke configuration, the observed curve is a property of the combined antenna-cable-receiver structure, not merely a simple projection of a prescribed local field vector. Even if no current probe is available, the controlled sensitivity to cable path provides evidence that one ideal assumption is violated. The report should use that evidence rather than pretending the missing instrument existed.

A useful mathematical diagnostic is to model measured complex voltage as $V(\psi)=A\cos\psi+B(\psi)$, where $A\cos\psi$ is the ideal linearly polarised response and B is a parasitic contribution that can depend on pose. A finite amplitude at nominal orthogonality does not by itself tell us whether B represents intrinsic cross-polarisation, reflected-field coupling or cable current. In amplitude-only data, phases cannot generally be separated, and two different mechanisms can produce the same measured magnitude. Complex I/Q capture can improve identifiability if its reference and calibration are sound, but it also cannot restore a missing measurement of

Copyright 2026, James M. Atkinson

the parasitic path. At the conclusion, I would state the tested polarisation envelope under named cable arrangements, qualify the uncertainty and retain the raw spectra for independent review. A neat cos-squared fit is not a substitute for controlling the complete receiving system.

Arthur Edwin Kennelly, Peer Question: Professor Kraus, your use of effective aperture appears to make the propagation problem almost too orderly. An engineer performing a security survey near a wall, ceiling conduit or cable bundle may find neither a single plane-wave arrival direction nor a stable polarisation state. The antenna's response could be excited by multiple incoming rays whose phases change with position, or by electric and magnetic coupling that would not be characterised by the usual far-field calibration factor. Under those circumstances, what meaning can be given to the statement that the receiver 'covered the horizontal and vertical polarisations'? Would a two-channel antenna system actually observe every relevant field mode, or might both channels share a geometric null and a limitation of their reference-plane calibration? I would also ask how far the survey report ought to distinguish radiated power, a measured receiver voltage and a causal attribution to an unknown source, since those are often casually exchanged as though equivalent.

John Daniel Kraus, Response: Professor Kennelly, coverage of two declared polarisations is a statement about measured receiving modes under stipulated conditions, not a guarantee that all nearby electromagnetic coupling mechanisms have been tested. In the ideal transverse far-field model, two calibrated orthogonal linear receivers can span the transverse electric-field components in a given arrival direction. The model has no automatic authority over reactive sources or complex enclosures. There, one

Copyright 2026, James M. Atkinson

may need additional sensors, orientations and positions, and the quantities sensed by a short electric dipole and a magnetic loop may be fundamentally different. Even in the nominal far field, their angular patterns and installation losses require validation. The words 'horizontal and vertical' are incomplete unless they refer to a fixed coordinate frame and a declared range of directions and frequencies.

I would design two phases. In the first, use an independent reference antenna or calibrated field source in a known open measurement arrangement to check the polarisation response, gain variation and frequency dependence of both receiving channels. In the second, bring the arrangement into the actual installation, preserve the raw port signals, and challenge it with known polarisation and direction changes. A failure of transfer from the first domain to the second becomes an observed limitation. The objective is not to force the room response to resemble a free-space pattern, but to discover the important departures. A small movement or rotated reference source can expose a common angular blind spot even when the channels' axes differ by ninety degrees.

We should separate four propositions: energy is present in the field at a point; the receiving system produces a measurable terminal signal; the signal is assigned a frequency or waveform class; and an external source is attributed. Each implication requires additional evidence. A measured port voltage can be generated by fields arriving through the intended aperture, by common-mode currents, or by an internal receiver artefact. The numerical calculation of field strength from voltage requires an applicable

Copyright 2026, James M. Atkinson

antenna calibration and uncertainty budget. A source attribution may additionally require spatial, temporal or controlled-intervention evidence. If the chosen survey apparatus cannot distinguish those causes, it can still report its observations accurately by stating that a particular signal was or was not measured at its port. It cannot promote that statement into an omniscient assertion about every field in the enclosure.

Dr. James M. Atkinson, Moderator: Mr. Reber, Professor Kraus has separated directional sensitivity from polarisation response. Would you examine what happens when a survey antenna is carried through a cluttered room and a receiver appears to detect a source only from one posture or doorway? I am especially interested in how to recognise a true pattern null as distinct from standing-wave cancellation or disturbance created by the surveyor.

Grote Reber, Second Principal Contributor: Dr. Atkinson, a received level at one location is a compound result of source emission, intervening structure, antenna coupling and receiver state. In my judgment the practical mistake is to treat that one reading as a stable characteristic of the emitter. A surveyor who moves half a wavelength, changes the antenna tilt or alters the coaxial lead can experience a large apparent power change even when the remote transmitter remains unchanged. What matters is whether the change follows a reproducible spatial and polarisation dependence and whether the measuring apparatus itself participates in the effect. The observation must be mapped, not remembered as an impression.

At 900 MHz the free-space wavelength c/f is about 0.333 metre when c is approximated as 3.00×10^8 metres per second. A half wavelength is roughly 0.167 metre. A metal cabinet, a partition, a floor reflection and a cable rack may create fields that add or partially cancel over comparable distances. It

Copyright 2026, James M. Atkinson

follows that moving a receiving element by ten or fifteen centimetres may alter its level substantially. The exact result depends on path lengths, reflection coefficients and polarisation. One should not claim a 20 dB room fade from geometry alone without observing it; nonetheless, the wavelength establishes why a 'same room, same frequency' comparison is not necessarily a comparable electromagnetic configuration.

An ideal two-path calculation makes the issue explicit. Let a direct-wave phasor at the receiving element be E_0 and a reflected contribution be $\alpha E_0 \exp(j\varphi)$, where α is a dimensionless amplitude ratio and φ a phase difference. Then the total is $E=E_0[1+\alpha \exp(j\varphi)]$, and received power for an otherwise unchanged linear transfer is proportional to $|1+\alpha \exp(j\varphi)|^2$. If $\alpha=0.8$ and $\varphi=\pi$, the total field magnitude is only $0.2E_0$ and the corresponding power ratio is 0.04, approximately −14.0 dB relative to the direct-only reference. If $\varphi=0$, the magnitude is $1.8E_0$, giving a power ratio of 3.24, approximately +5.1 dB. These are stipulated examples, not room survey data. They show that a field minimum is not necessarily an antenna's intrinsic radiation-pattern null.

Polarisation becomes entangled with this geometry because a reflection can change the field vector and its relative phase. A vertically polarised source need not deliver a purely vertical field at every receive location after repeated interaction with furniture, ductwork, openings and oblique boundaries. If we rotate the antenna at one point, the maximum and minimum may reveal a locally dominant field orientation, not a permanent label attached to the emitter. An examiner should repeat the rotation in several spatial cells and at more than one height, taking care to preserve cable routing and the technician's position as independent variables.

Copyright 2026, James M. Atkinson

Movement that improves a response may be revealing the field geometry rather than discovering a new transmitter.

I would begin with a deliberately simple map. Mark a grid of survey points with repeatable position and height, then at each point record antenna azimuth, tilt, cable orientation, receiver attenuation, preselector and measured noise floor. Where two orthogonal receiving polarisations are available, record both at the same instant or in sufficiently adjacent intervals that source variation is controlled. A stationary test source is required to assess the map, but the source need not be intrusive: a permitted, low-power, known waveform can be injected or transmitted under site authority. Record its own output with an independent witness receiver. Without that independent witness, any level variation might merely reflect changes in the test source itself.

The operator should deliberately compare cases in which only one condition changes. First keep the receiving element fixed and rotate its polarisation, minimising any displacement of the electrical phase centre. Next keep polarisation fixed and translate the element to examine spatial fading. Next change elevation while documenting nearby reflectors. Finally modify the cable path or apply a suitable balun and look for unexpected changes; a signal that is sensitive to cable dressing may be entering on the outer conductor. If all variables are changed together, an increase in received power proves merely that the system changed. The scientific question is whether a reproducible causal explanation survives controlled interventions.

A room map requires both positive and negative observations. Store points at which the test signal was not found, the instrument's limit of detection at those points, the intervals inspected and the criteria by which a candidate

Copyright 2026, James M. Atkinson

was accepted. If a 900 MHz test signal is detectable at twenty-eight of thirty grid positions but missing at two, the correct statement is 28/30 for the tested conditions. It is not 93.3% probability of detecting every unknown transmitter, because the grid points are not necessarily random samples from all geometries, sources or waveforms. A careful map helps identify blind zones for further investigation without turning the sample fraction into an unsupported probability.

I would also vary frequency within a band using a source whose spectral output is established. The geometry of constructive and destructive interference changes with wavelength, and an antenna's own pattern changes with frequency. A probe that passes a challenge at one frequency cannot be certified by that trial for every other frequency. An operator may make a useful coarse initial sweep, but negative assurance over a band requires either a validated response model with uncertainty or sufficiently distributed challenge measurements. Similar reasoning applies to times: a continuous-carrier test does not establish capture probability for a millisecond burst within an intermittent waterfall or a switched preselector schedule.

If the reference source is seen through the room with one antenna but not another, retain the differential result and test whether the latter is truly less suitable for the unknown signal. The antenna with the stronger test response need not be the universally better survey sensor; its directivity might favour the calibration source's known bearing. Sometimes a second antenna whose pattern and polarisation differ provides a stronger diagnostic because it changes which blind spots matter. The purpose is not to collect the largest signal on one display, but to build a set of observations

Copyright 2026, James M. Atkinson

that withstand reasonable alternative explanations. The final report should therefore distinguish positional shadowing, polarisation mismatch, instrumentation limitations and the actual bounded absence of qualifying detections.

Karl Guthe Jansky, Peer Question: Mr. Reber, your room grid gives useful discipline, but I should ask how it avoids merely documenting one convenient moment. The surveyor might map several positions in a series lasting an hour, while the emission or the ambient interference changes during that hour. The first grid point would then be compared with the thirtieth under a different electromagnetic environment. Worse, a technician's body and the cable route may change as each point is visited, and the source used for calibration could drift. What sequence of measurements or fixed reference stations would allow the investigator to distinguish spatial nulls from temporal fluctuations? If a repeated grid produces a different pattern on the second pass, should one conclude that the room is unstable, the transmitter has changed, or the instrumentation is inadequate? I am concerned that a survey map may acquire an appearance of permanence which its acquisition chronology does not deserve.

Grote Reber, Response: Mr. Jansky, a room map is not an instantaneous photograph unless each measurement is genuinely simultaneous, and the distinction must be preserved. I would make at least one source monitor stationary and independent of the moving survey antenna, ideally using a receiving path whose gain and timing are stable over the observation interval. The test source should emit a known coded or otherwise distinguishable signal whose output is monitored at the source itself. Record a time tag for every grid observation and for the reference source's

Copyright 2026, James M. Atkinson

measured state. A difference between two grid points then becomes a comparison conditioned upon known changes in source output and ambient conditions. The grid is a time-indexed series, not a timeless field distribution.

I would alternate the acquisition order rather than merely walking a rectangular route once. On a second pass, visit the positions in reverse or a randomised order. Include frequent returns to an anchor point where the same receiving pose is restored. If the anchor level changes with time, temporal drift or a changed instrument condition is plausible; if the anchor remains stable while a particular position repeatedly produces a minimum, a spatial explanation becomes stronger. None of this uniquely isolates the mechanism, for even the anchor can sit in a frequency-dependent fade. A second independent source monitor and deliberate cable-path controls help narrow that uncertainty. The resulting record should display time and space as separate axes.

The observer's body deserves experimental attention. A human standing near a receiving element changes the boundary conditions and may shield, reflect or couple RF energy. Photograph or diagram the surveyor's position, use a nonconductive support where appropriate, and compare selected poses with the operator displaced. A cable suspended one way on the first pass and laid against a cabinet on the second introduces another uncontrolled change. The protocol should therefore include a repeatable fixture or at least a measured range of cable dressings. Where it cannot be controlled, note it explicitly as a limitation. A repeated spatial minimum under changed time order, source monitoring and constrained receiver

Copyright 2026, James M. Atkinson

geometry is stronger evidence than one aesthetically pleasing heat map, but it still does not guarantee that an unknown source at another frequency shares that minimum. We may claim only the reproducible response of the tested waveform under the conditions that were actually recorded.

Lord Rayleigh, Peer Question: Mr. Reber, the observations you describe may have numerous correlated uncertainties. At nearby grid points a shared reflection coefficient, antenna calibration error and receiver gain drift can influence all readings. If the examiner presents an interpolated contour map with apparently precise minima, how should that map's uncertainty be quantified? I would especially challenge the practice of measuring a sparse set of points, interpolating smoothly between them and then asserting that every location in a room was effectively searched. Is there a defensible connection between the spacing of a grid and the spatial frequency of the field variation, and can one infer such spacing from the free-space wavelength alone when the enclosure supports complicated modes? What should be done when the data indicate sharp fades that fall between measured positions, so that the strongest negative inference is driven by precisely the regions for which no observations exist?

Grote Reber, Response: Lord Rayleigh, interpolation is a hypothesis about spatial smoothness and measurement error, not an additional observation. An interpolated colour map can be useful to direct further measurements, but the values between data points are model predictions. Their credibility depends on a justified correlation length and sufficiently dense sampling, not merely on the graphic's appearance. In an ideal field comprising a limited family of propagating plane waves, wavelength gives guidance about the scale of interference. In a furnished enclosure the boundary geometry,

Copyright 2026, James M. Atkinson

reactive coupling and source positions may produce sharper changes; one cannot apply a universal half-wavelength spacing rule and declare the field fully sampled. A preliminary dense transect at representative frequencies can estimate the scale over which observed response changes, and this should inform subsequent grid design.

Uncertainty has several layers. Repeated measurements at one pose estimate short-term repeatability under that pose, but they do not include systematic errors in antenna calibration, polarisation orientation or cable interaction. A gain error common to every grid point cannot be reduced by averaging more positions. Likewise, source-power drift may induce apparent spatial trends when the positions were visited in order. A defensible analysis identifies these common and position-specific terms separately. If the final map shows a 15 dB minimum whose position moves after cable rerouting, that change is informative about the measurement system and must not be smoothed away. Report the measured values alongside any interpolated model and provide the spatial distribution of actual observation points.

An appropriate validation is to reserve a number of grid positions from the interpolation fit and then predict their response. Compare the withheld measurements with predictions and their intervals. Where prediction errors exceed the model's stated uncertainty, the map fails its own challenge and should not support a spatial coverage claim. Further measurements should be concentrated near steep gradients and unexplained minima. This procedure offers a practical distinction between describing the tested

Copyright 2026, James M. Atkinson

source's spatial response and claiming comprehensive observation of all room positions. The latter requires a specified source class and evidence that the coverage scheme is sensitive to its relevant field variations. A negative conclusion based on a few mapped sites should therefore identify the unresolved interstitial space, rather than hiding it under smooth contours and comforting colours.

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, the discussion has moved from individual antenna response to a spatial sequence of observations. Could you explain how diversity and multi-position evidence affect a negative conclusion, and how the survey team should avoid mistaking a common instrument defect for independent corroboration?

Sir Martin Ryle, Third Principal Contributor: Dr. Atkinson, multiple receiving paths strengthen an inference only to the extent that they challenge different ways in which the inference could be wrong. Several identical antennas pointed in precisely the same direction, feeding receivers with a common attenuator setting, may repeat one blind spot. A second site or a second polarisation can be useful, but it does not add information by magic. The engineer should specify how the additional measurement differs, which uncertainty is reduced, and which shared dependencies remain. This is particularly necessary when the conclusion is negative, because the analyst is asking the absence of a detector response to bear the burden of a claim about an unobserved transmitter.

Let D_i be the event that receiver configuration i detects a known test waveform under a particular frequency, power, bearing, polarisation and time pattern. A crude argument might write $P(D_1 \text{ or } D_2)=1-[1-P(D_1)][1-P(D_2)]$. That expression assumes conditional independence of detection

Copyright 2026, James M. Atkinson

failures for the specified source class. It is invalid if both antennas share the same spectral null, both SDRs have the same dropped-sample interval, or the test emitter is simply off during both observations. The correct general expression is $P(D_1 \cup D_2)=P(D_1)+P(D_2)-P(D_1 \cap D_2)$. The intersection cannot be inferred from the two marginal probabilities alone without a dependence model or paired empirical observations.

In a hypothetical set of 100 controlled trials at one declared signal level, suppose a horizontal antenna detects 70, a vertical antenna detects 75, and both detect 55. The combined coverage is $70+75-55=90$ trials. These counts illustrate experimental arithmetic only. They are not an estimate for every signal in a room. The 90% combined trial success would be conditioned on the test design, imposed waveforms, positions, and reference-source variation. If the trials were all in one favourable direction, they could conceal a deep common null elsewhere. If the two channels shared the same local oscillator or host data path, their temporal failures might also be correlated. The raw paired outcomes are therefore more informative than the product of assumed independent failure probabilities.

One should separate simultaneous diversity from sequential diversity. Two co-sited antennas observed at the same instant can compare different polarisations while controlling for a transmitter's time variation. A single antenna rotated sequentially through two orientations can cover both settings over a longer period, but it cannot establish that an intermittent unknown source would have been active in both intervals. The sequential survey might systematically miss a burst whose duty cycle interacts with scan timing. It may still be useful as an initial survey, but its negative claim

Copyright 2026, James M. Atkinson

must describe the exposure window for each pose. Logging precise dwell time, switching latency and valid capture periods is essential.

Direction diversity has a corresponding difficulty. If the antenna presents a deep null toward a source at a particular azimuth and elevation, rotating only about the vertical axis may fail to expose an elevation null. A thorough examination varies both bearing and tilt while accounting for cable strain and body effects. For arrays, pattern synthesis and beamforming weights can intentionally introduce nulls; those zeros are not evidence that no external field exists. The survey should include a suitable wide-coverage channel alongside any high-gain beamformed channel, so that suppression created by spatial processing is not mistaken for absence from the physical environment. A raw-element recording can provide that independent perspective if the acquisition path is sound.

When combining evidence, retain calibration and uncertainty at the level of each channel. Let y_i denote a measured level and μ_i the expected mean under a specified source hypothesis. The joint distribution of y values depends on their covariance matrix, not solely on separate signal-to-noise ratios. Shared noise sources, frequency references, filtering or power supplies may create nonzero off-diagonal covariance. For a detection statistic formed by weighted combination, the weights must be justified by that covariance. If the underlying distribution is unknown, experimentally measured worst-case or bounded sensitivity may be more defensible than an apparently precise probability derived from an unjustified Gaussian model.

I recommend treating the survey as a set of challengeable hypotheses. One hypothesis is that a given emission class is present but polarisation-

Copyright 2026, James M. Atkinson

mismatched; another that it enters through an angular null; another that its burst escapes temporal coverage; another that the receiver is desensitised by a blocker. For each hypothesis specify an intervention expected to change the observation: orthogonal polarisation, changed spatial pose, time-continuous capture, different preselection, independent receive chain. A negative report that cannot distinguish these causes is not invalid as a record of what was not seen, but it is inadequate as assurance against the full hypothesis class.

A disciplined programme should choose a sensitivity envelope, not a heroic universal detector. For example, define a source class with frequency within a bounded band, minimum equivalent isotropically radiated power under declared geometry, duration exceeding a specified dwell, and either of two tested linear polarisations. State the frequency and spatial grid, tested instrument states, known reference limitations and environmental variability. Document the weakest detected challenge over all required conditions, and identify exclusions and blind spots. This is much more informative than claiming that every possible transmitter would have been found. Unknown signals have an effectively unbounded variety of modulation, directivity and propagation; a finite survey cannot eliminate that variety by simply multiplying the number of instruments.

The outcome should be expressed as calibrated evidence, not rhetoric. A multi-receiver absence can justify a narrower assurance statement when the combined observations have demonstrated that the tested source class would have been detected with the required probability or lower-bound margin under the tested conditions. It cannot support a categorical statement about all emitters without assumptions that make such a

Copyright 2026, James M. Atkinson

statement unfalsifiable. The aim is to make failures visible and confidence proportional to verified coverage. That remains the essential distinction between an engineering survey and a ceremonial inspection.

Sir Edward Victor Appleton, Peer Question: Sir Martin, you have proposed two receiving modes and an empirical dependence model, but atmospheric propagation and reflections can transform the polarisation of a signal between transmitter and receiver. Suppose a vertically polarised test signal is observed strongly in one channel on one day and predominantly in the other channel on another day, perhaps with an additional path delay or unexpected fading. How should the detection trial distinguish variability of the incoming field from instability of the receiving antenna, and how far can its conclusions be transferred to an unfamiliar emission whose propagation route and frequency are different? I would also ask whether a broad frequency sweep can legitimately borrow the polarisation calibration of one narrowband challenge. The direction and polarisation of arrival are often linked to frequency and propagation, so that a receiver which covers two orthogonal axes at one frequency may not have the same angular sensitivity elsewhere.

Sir Martin Ryle, Response: Sir Edward, the instrument should not be judged by pretending that the wave arriving at its site has a fixed polarisation merely because the transmitter's antenna was set to one orientation. The physical channel can rotate or mix polarisation components, whether through natural propagation or reflections near the receiver. A controlled source and a local reference receiver can help distinguish this variation from hardware drift, but only where their own response and calibration are understood. If the reference receiver shares the same local propagation

Copyright 2026, James M. Atkinson

changes, both may vary together, and that correlation must be interpreted rather than automatically attributed to transmitter power. Ideally retain complex simultaneous measurements of orthogonal field components, with a known basis, while separately recording the source state and antenna geometry.

To characterise frequency dependence, repeat the calibration at multiple frequencies and do not interpolate through an untested resonance or pattern null merely because the antenna is marketed as broadband. The frequency response of each polarisation channel includes not only the radiating element but its feed, matching network, cable and receiver filters. A device that is sufficiently sensitive at 450 MHz might be compromised at 900 MHz by a directional null or frequency-dependent cross-polar response. The survey needs a declared frequency grid informed by manufacturer data and representative on-site challenges. At frequencies where no direct tests were performed, the report should state the assumed interpolation model and retain the uncertainty caused by that assumption.

The same discipline applies to time. If a receiving channel reports a strong horizontal component at one time and a strong vertical component later, separate source variation, propagation variation, receiver state and changes of pose. A coded source monitor and fixed pilot path assist, but neither alone proves which physical mechanism caused the difference. Record orientation angles, local reflectors and atmospheric or operational conditions relevant to the chosen band. A second antenna installation some distance away can provide useful diversity, although its environmental

Copyright 2026, James M. Atkinson

channels will not be identical and its receiving mode must be independently verified. The question for a negative report is not whether the engineer can label the source 'vertical' or 'horizontal'. It is whether the actual arriving states that the survey was meant to detect fell within a measured sensitivity envelope at every material frequency and observation interval.

If the source class is unknown, that envelope may remain limited. One can strengthen it by demonstrating adequate receiver response to a deliberately diverse collection of polarisation and direction states, and by recording where the system fails. A result obtained on one frequency cannot automatically be transported to another band, nor can a laboratory calibration represent every propagation path in an office. This limitation should be an explicit finding, not an embarrassment concealed in an appendix.

Dr. James M. Atkinson, Moderator: Professor Maxwell, I invite the theoretical distinction between an idealised plane-wave polarisation factor and the field components actually found near enclosures, conductors, windows and wiring. What does your boundary-value analysis permit a surveyor to infer when an antenna orientation gives almost no received energy?

James Clerk Maxwell, Fourth Principal Contributor: Dr. Atkinson, the electromagnetic field is a vector solution of equations and boundary conditions, not a label that accompanies a transmission unchanged from its source. In a homogeneous far-field region a propagating plane wave has a transverse electric vector and associated magnetic vector, and a polarisation state can be represented by complex components with a conventional phase reference. Within a cluttered installation the field may be the superposition

Copyright 2026, James M. Atkinson

of many waves and reactive contributions, and the receiving antenna alters currents in nearby conductive boundaries. A null registered by one probe is therefore a null in that probe's transfer from the local field, not necessarily a vanishing of electromagnetic activity in the surrounding space.

In phasor notation a local receiving system can be described by a vector effective length $\ell_{eff}(f,\Omega)$ and an incident electric field $E(f,\Omega)$, producing an open-circuit voltage $V_{oc}=\ell_{eff}\cdot E$ under a specified reception convention, neglecting secondary coupling for the moment. When E is orthogonal in the relevant complex inner-product sense to the antenna's receiving mode, the dot product is zero. But the inference from terminal voltage to field magnitude requires knowledge of ℓ_{eff} and of the environment that determines the actual E. If the antenna carries unwanted outer-conductor current, or its supports couple to a cabinet, the effective receiving vector is changed by the installation. We must not infer the local field from a distant free-space pattern without checking the altered boundary conditions.

The familiar linear-linear loss $PLF=\cos^2\psi$ is a useful special case, not a full description of all polarisation behaviour. Elliptically polarised radiation requires both relative amplitude and phase of orthogonal components. An ideal circular wave projects equally onto two orthogonal linear axes, with each ideal receive channel capturing half the matched power. The handedness of circular polarisation matters when compared with a circular receiving mode, and opposite handedness can ideally cancel reception. But in an indoor environment a reflection can change polarisation state, and the antenna's axial ratio and cross-polarisation performance vary with direction and frequency. Consequently the survey should preserve complex channel

Copyright 2026, James M. Atkinson

responses where available, rather than compress every state into a single 'horizontal' or 'vertical' label.

An instructive representation is a two-component field vector $E=[E_x,E_y]^T$ in a declared transverse basis and a two-channel sensor matrix H. Then the measured complex voltages may be written $v=H E+n$, where n represents receiver noise and other error. If H has rank two and is sufficiently well conditioned under a valid propagation model, two calibrated channels may estimate two transverse components. If H has rank one, or its smallest singular value is very small, some field combinations are poorly observable or effectively invisible. A displayed absence can therefore reflect non-identifiability rather than absence of the underlying field. The example also shows why two sensors bearing different product labels are not necessarily independent modes; their actual response matrix must be measured.

For a simple idealised pair of linear sensors with equal sensitivities and relative orientation angle α, the measurement matrix can be written $H=[[1,0],[\cos \alpha,\sin \alpha]]$ after normalisation. Its determinant is $\sin \alpha$. At $\alpha=90°$, the modes are orthogonal and information is well distributed; as α tends to zero, the matrix becomes singular. In a real room the sensor responses are frequency- and pose-dependent, and their matrix may have important magnetic or common-mode contributions not captured here. Nevertheless the determinant illustrates the danger of using multiple nearly identical antenna states as if they observed different field components. More hardware can yield little new identifiability.

Boundaries complicate a supposed pattern null. A conducting enclosure can support currents that reradiate, and an aperture can couple to an internal field. The orientation of E at one point can change sharply over distances

Copyright 2026, James M. Atkinson

much less than the free-space wavelength if reactive and evanescent components are significant. In such a region one cannot straightforwardly infer an energy flux from $|E|^2/377$ ohms, since the ratio between electric and magnetic magnitudes need not equal the free-space impedance. This matters where a loop probe gives a response but an electric dipole does not, or conversely. Polarisation diversity of far-field antennas must not be confused with complete coverage of distinct near-field coupling mechanisms.

An adequate experimental method should first classify the region and probe function. Is the receiving element intended to measure an arriving radiated plane wave, an induced voltage along a conductor, or the local magnetic field near a current loop? Each has different calibrations and source hypotheses. For a far-field-oriented measurement use a calibrated reference emitter and vary controlled polarisation states; for an enclosed near-field investigation deploy validated electric and magnetic probes with known orientation and frequency behaviour. Observe whether the response follows the probe's sensing mode, the nearby cable geometry or a change in enclosing boundary. Do not call a field null a transmitter null without verifying the transfer through the relevant channel.

I would preserve both complex signal and geometric records: source polarisation when known, antenna orientation relative to an agreed coordinate frame, phase centres, relative amplitude and phase between channels, source-power monitoring, field reference planes and cable routing. If phase is not measurable, identify the resulting ambiguity. A loss of signal after rotating one sensor is compatible with several explanations: genuine polarisation orthogonality, antenna pattern loss, spatial

Copyright 2026, James M. Atkinson

interference, an altered loading condition or source intermittency. A well designed challenge changes only one of these at a time, and the subsequent inference should remain bounded to the models tested.

The most useful concluding distinction is between non-observation and non-existence. An electromagnetic field can be real yet lie in the measurement system's null space. Increasing receiver sensitivity within the same null space does not in principle restore information that the probe never couples into its terminals. Independent sensing modes, position changes and verified calibration can shrink that null space for a declared class of emissions. None of these operations establishes a universal absence over all modes, directions and times. The proper scientific report makes the sensor's limitations part of the proposition instead of treating them as inconvenient exceptions.

Herbert Kroemer, Peer Question: Professor Maxwell, your sensor-matrix model presumes that the observations represent the projected field plus some noise, but a practical receiver includes mixers, amplifiers, ADCs and digital processing that may introduce frequency-selective or amplitude-dependent response. One channel might be overloaded by a nearby strong signal even while the other remains linear; its reported 'absence' of the weak target would then be caused by front-end compression rather than polarisation. How should the investigator distinguish a physically inaccessible field component from a channel that has become temporarily incapable of representing it? Is it sufficient to calculate a matrix condition number from antenna patterns if those patterns were measured at low level and the real field includes a strong blocker? I would also ask how to preserve the logical separation between a mathematical observation null

Copyright 2026, James M. Atkinson

and the failure of a threshold detector to announce an otherwise measurable signal. Would you also require a source-off overload control, so that the asserted absence can be distinguished from a false negative produced by a desensitised analogue front end during the same interval?

James Clerk Maxwell, Response: Professor Kroemer, the linear sensor matrix is a conditional model and loses authority when the receiver ceases to operate linearly. A more faithful expression is v=F(H E+n,s), where F is the receiver transformation, potentially nonlinear or state-dependent, and s describes its attenuation, preselection, gain, ADC scaling and processing configuration. Under normal small-signal conditions F may approximate a calibrated linear operator. Under compression, clipping or desensitisation, a weak component may disappear from the reported output even if it couples well to the antenna. The system's apparent null could then be an instrument limitation rather than a property of the field geometry. The analyst should test linearity and overload independently from the polarisation experiment.

A safe laboratory method introduces the weak known signal through a calibrated coupler while varying a separate strong blocker within rated limits. For each polarisation pose, compare detected weak-signal amplitude and noise floor as the blocker changes, with attenuator and gain state retained. If the weak response improves when a calibrated attenuator is introduced upstream of a compressed stage, despite lower overall power at the receiver input, that counterintuitive outcome is evidence of overload. The test must identify the stage at which attenuation acts; adding loss downstream of an already compressed amplifier will not repair earlier intermodulation. Similarly, a display that shows no peak may be averaging a

Copyright 2026, James M. Atkinson

signal below a detector threshold even though the raw I/Q data contain a statistically recoverable component. Store raw samples where available and test the detector separately.

The singular-value argument remains useful only after its assumptions are tested. H should describe an empirically characterised linear receiving chain over a specified dynamic range, not a set of ideal antenna vectors lifted from a catalogue. A near-zero singular value indicates poor identifiability of some field combination within that model. It does not quantify missed detections created by false triggering, software decimation gaps or clipping unless those effects enter the model. If those conditions occur, declare a failed or inapplicable measurement interval rather than allowing an uncalibrated covariance matrix to hide the problem. Repeated calibration at several input amplitudes can establish a useful operating range, including its uncertainty.

For the legal and technical statement I would distinguish three forms of negative evidence: no field component coupled into the declared sensing mode above the physical detection limit; a component may have coupled but the receiver's transfer or saturation prevented faithful measurement; and a component may have been measured but failed the subsequent detection rule. These are not interchangeable. One can challenge them with controlled polarisation rotation, source-level variation, gain-state changes and alternate processing. The conclusion must report the result of each challenge, identify the intervals when the apparatus was qualified and avoid extending a negative finding through the intervals of suspected overload or

Copyright 2026, James M. Atkinson

data loss. That is how a theoretical observation model becomes an auditable measurement chain.

Dr. James M. Atkinson, Moderator: Professor Hewish, how ought the survey team convert this physics into an operational test that is reproducible by another group and capable of supporting a bounded negative finding? I ask you to address transient emission schedules, blind study design, and the difference between calibrated detection probability and an anecdotal successful challenge.

Antony Hewish, Fifth Principal Contributor: Dr. Atkinson, the practical task is to specify a signal population and measure the experiment's power to detect members of it. In astronomy we learned that a search method tuned to one temporal behaviour can miss another even when the receiving equipment performs faithfully. The same lesson applies here. An orientation sweep may detect a continuous calibration tone but miss a transmitter which emits for milliseconds at unpredictable times. A wideband capture may record the burst but suppress it in a detector that averages power over a long window. A receiver that finds one friendly test source has demonstrated one success; it has not proved comprehensive surveillance capability.

I would define a trial by its signal frequency, output power, antenna orientation, polarisation state, modulation class, duty cycle, duration, position, environmental configuration, and intended receiver threshold. Several axes may be sampled rather than explored exhaustively, but the sampling scheme should be documented before the data are examined. The observer should not be told where and when all test transmissions occur if operator expectation might change search behaviour. A separate test

Copyright 2026, James M. Atkinson

director can randomise transmission location or polarisation and retain an independent emission log. This is a controlled assurance experiment, not an attempt to simulate illicit activity or defeat legitimate surveillance.

Detection probability is conditional. If X describes the controlled source and environment and D is the event that the system issues a qualifying detection, P(D|X) may be estimated from repeated trials when the trials genuinely sample X according to a declared design. Suppose there are 95 correct detections in 100 independent, identically configured test opportunities. The point estimate is 0.95, but its uncertainty is not zero and its relevance does not extend beyond the tested source class. The same arithmetic cannot be used when all one hundred trials share a favourable orientation or one continuous waveform. Over-represented easy cases can manufacture an impressive percentage whilst leaving the difficult angular or polarisation configurations untouched.

A negative conclusion must also accommodate false positives and source variability. A low threshold might make the receiver sensitive but produce an intolerable number of unrelated detections; a high threshold may make the display clean at the cost of missed weak events. To characterise that trade-off, include source-off intervals, known-on intervals, signal strengths near the intended minimum detectable level, and genuinely independent observations of the source timing. Measure both detection probability and false-alarm occurrence under the instrument configuration actually deployed. A receiver that performs well in an empty laboratory may suffer overload or desensitisation when placed next to powerful legal transmitters. That condition should be challenged separately from polarisation and pattern loss.

Copyright 2026, James M. Atkinson

Temporal coverage should be calculated from valid acquisition intervals, not inferred from a display-refresh rate. Let T_{obs} be the nominal scheduled observation time and T_{valid} the union duration of intervals during which a particular frequency and antenna state were truly sampled with the required quality. The ratio $\eta = T_{valid}/T_{obs}$ describes duty coverage for that configuration. It is not generally the probability of detecting an unknown burst, since detection also depends on burst duration, timing distribution, threshold, receiver settling and possible repeat periodicity. For a cyclic scanning system, a source whose bursts are phase-locked to the system's blind intervals could be missed repeatedly. Randomising dwell schedules or maintaining a continuous witness channel can expose that vulnerability.

Spatial design should not merely maximise convenient coverage. Select poses at which the antenna's measured pattern suggests vulnerability, including directions near known nulls, locations near absorbing or conducting structures, and the orientation extremes of the polarisation response. Include a small number of randomly selected additional poses to challenge assumptions about room geometry. Ensure the calibration transmitter is monitored so that a weak response cannot be excused or blamed on an unknown variation of source output. Repeat a subset of trials on another day or after the receiving hardware has been disassembled and reconnected, because cable currents and accidental orientation changes can dominate what looked like a repeatable transfer function.

I would maintain a machine-readable event ledger. Each entry needs a test identifier, frequency, waveform, polarisation, antenna pointing, position, emission start and stop, receive hardware mode, filter settings, data-file pointer, source-off baseline, detector response and validation outcome.

Copyright 2026, James M. Atkinson

Failed and ambiguous trials remain visible. If the operator changes gain, retunes the receiver or substitutes an antenna, that change starts a new configuration interval. A negative result without that record can rarely support a strong inference because it is impossible to determine whether the receiver was looking at the relevant band and sensing mode when the event occurred.

At the end of testing, report a coverage table rather than a single assurance percentage. For each source class, state the lowest source level at which detection performance was assessed, the tested angular and polarisation ranges, the sample of room positions, the temporal window and the observed misses. Where plausible cases are outside the tested domain, mark them as unassessed. Where the confidence bound on detection is inadequate, say that the test did not establish the chosen assurance level; do not manufacture a larger trial count by pooling unlike conditions. The duty of the investigator is to explain what would have been detected under declared circumstances and what remains uncertain.

A carefully worded conclusion might be that no qualifying waveform was observed in the recorded intervals at a stated input-equivalent threshold, and that a calibrated set of horizontal, vertical and selected elliptical test waves was detected within defined positions and distances, subject to explicit exclusions. It would not say that the room was free of every possible transmitter. The latter language cannot be justified by a finite sample of orientations, frequencies and source geometries. The strongest negative statement is frequently the most carefully bounded one. It is informative because another engineer can reproduce and challenge it, not because it uses confident adjectives.

Copyright 2026, James M. Atkinson

William Redington Hewlett, Peer Question: Professor Hewish, I am persuaded by your detection ledger, but I should challenge whether its reported trials are genuinely independent and whether the testing operator has selected a favourable signal regime. A hundred bursts from the same antenna, injected at the same level and transmitted through the same room configuration, may reproduce one success rather than test a useful family of failures. Could you describe a practical acceptance procedure that exercises polarity, signal duration, antenna orientation, receive-gain state and sampling continuity without turning the test into an unmanageable combinatorial catalogue? How should the team decide in advance that a trial passes, particularly when the detection threshold is adjusted after seeing results? And what documentation would allow a second laboratory to reproduce failures where one antenna missed the source and the other found it only intermittently? Could the acceptance plan also document the number of valid acquisition opportunities in each polarisation stratum, including those which produced no decodable samples or whose reference signal was absent?

Antony Hewish, Response: Mr. Hewlett, the acceptance protocol should begin with predeclared performance claims and a design of experiments proportionate to the intended operating domain. The team need not enumerate every possible combination of frequency, polarisation, position, signal level and duration. It must identify the axes most likely to cause false negatives and deliberately sample their difficult boundaries. For example, a structured set of source polarisations could include horizontal, vertical, selected intermediate tilts and both circular senses where the hardware can generate them. Source duration should include values near the receiver's

Copyright 2026, James M. Atkinson

minimum qualified dwell or capture length. Position should include known angular nulls and multipath minima, not simply convenient line-of-sight points. The planned matrix should be recorded before the results arrive.

The detection rule is equally important. Define what constitutes a qualifying response: frequency agreement within a tolerance, a correlation threshold, a minimum signal-to-noise ratio, an event count or a visual classification carried out blind to the source schedule. Freeze that rule for the acceptance run. If adjustments are needed after failed trials, record those adjustments as development and repeat the acceptance set with fresh trials; otherwise the apparent success rate is biased by tuning to the observations already made. Separate detection trials from source-off controls, and retain the false alarms rather than discarding them as inconvenient. A detector whose threshold was selected to make the result look clean cannot be credited with the same measured detection probability as one tested under a predetermined decision rule.

I would stratify the trials by the major vulnerability dimensions. Within each stratum, repeat with more than one timing phase relative to the scanner, varied polarisation, and at least two source positions when geometry matters. A few full-factorial corner trials can expose interactions such as an orthogonal orientation combined with a burst that falls inside a retune transient. Randomised additional trials can challenge unseen interactions. The number of repetitions should be tied to the uncertainty acceptable for the declared assurance claim, rather than a customary round number. If misses occur, report their conditions and the extent to which they were

Copyright 2026, James M. Atkinson

reproduced. Do not pool them away under the success of easier cases.

For reproducibility, include the source and receiving hardware identification, waveform files or algorithm definitions, power calibration, antenna patterns or measured response envelope, source-position coordinates, receiver orientation, raw detection logs, timestamps and software version. Data acquisition failures should have their own state codes. A second laboratory can then reproduce the hard cases and determine whether differences arise from their environment, receiver configuration or the original test assumptions. Where results are environment-specific, that is itself a meaningful limitation. A final negative report should specify which source configurations have demonstrated sufficient detection power and which have not, not present a single success fraction that obscures the operational blind spots.

John Daniel Kraus, Cross-Peer Question to Grote Reber: Mr. Reber, your spatial mapping protocol treats antenna rotation and receiver translation as separable interventions, but I am concerned about a practical instance in which the antenna is close to a conducting door. Rotating the antenna changes both its polarisation axis and the coupling between its feed, the door and the surrounding cabling; the field it samples may also be a superposition of several differently polarised paths. How would you construct a falsifiable trial that distinguishes a true receiving-pattern null from a spatial cancellation without presuming in advance which one dominates? In particular, if the apparent minimum disappears after the antenna moves by a few centimetres, should that be interpreted as proof of multipath, or could the antenna's own current distribution have changed

Copyright 2026, James M. Atkinson

because of the nearby door? I ask you to identify the most informative record, not merely to recommend more measurements.

Grote Reber, Cross-Peer Answer to John Daniel Kraus: Professor Kraus, the disappearance of a minimum following a small displacement does not uniquely identify multipath, because moving a sensor near a boundary also changes its loading. I would therefore perform two complementary families of interventions. In the first, hold the antenna and feed geometry mechanically stable relative to one another, move the entire assembly along a measured path, and repeat the experiment with a documented source pose. In the second, keep the sensing element at the same spatial point while rotating it about a carefully controlled axis, attempting to leave nearby cable loops and conductive supports unchanged. Observe the terminal reflection coefficient or input impedance during both families, where appropriate. If the impedance changes strongly while the signal fades, the receiving structure itself is being altered and a simple free-space projection model is insufficient.

A third test exchanges the nearby environment. Insert a removable reference reflector or change the door position under a documented and authorised laboratory arrangement, keeping source and receiver settings fixed. Predict from a simplified multipath model how the phase and level might vary, then compare the observation. The reason for making a prediction before looking at the result is to avoid inventing a cause for whatever curve the instrument happens to draw. A phased observation is particularly useful: the sum of two coherent field contributions can change its complex phase across a cancellation point, while a pattern null may

Copyright 2026, James M. Atkinson

exhibit its own characteristic phase and impedance behaviour. Neither sign is individually decisive, but both constrain the competing explanations.

If the apparatus only provides power, record that limitation and undertake more repeated controlled movements. A minimum that follows antenna orientation across several widely separated locations suggests an intrinsic orientation-dependent response, while one fixed in physical space and moving with the reflecting boundary supports spatial interference. But both features can coexist, and the measurement must not be forced into one category. I would retain the original unaltered room observations, the source-output monitor, antenna pose, cable route, measured input impedance when available and every controlled intervention. Each record has a role: the source monitor excludes an emission change, pose records define the geometry, and impedance measurements challenge the assumption that the antenna's mode remained constant. The resulting negative statement would be limited to the coverage actually demonstrated, with residual coupled failure mechanisms explicitly noted.

Grote Reber, Cross-Peer Question to Sir Martin Ryle: Sir Martin, you have used paired detection trials to warn against assuming independence, but a practical survey often acquires different antenna polarisations sequentially because only one receiver and one technician are available. If a low-duty-cycle source happens to transmit during the horizontal interval but remains silent during the vertical interval, a difference in detection could be mistaken for polarisation. Yet adding a second simultaneous receiver might introduce correlated clocks, overload or shared cabling. How should one design an affordable experiment that separates temporal intermittency from

Copyright 2026, James M. Atkinson

polarisation mismatch without asserting independence that the equipment does not possess? I would welcome a precise account of what a stationary witness channel can contribute, what it cannot establish, and how repeated schedules should be organised to make systematic temporal blind spots visible. Finally, how would you prevent the calibration emitter itself from determining which antenna orientation was judged favourable, when the emitter cannot reproduce every possible bearing and polarisation of an unknown source?

Sir Martin Ryle, Cross-Peer Answer to Grote Reber: Mr. Reber, the economically constrained survey should preserve two distinctions: sequential observations cannot establish simultaneous polarisation state, and an added receiver is helpful only when its own errors are examined. A stationary reference channel can monitor source activity at a known position while the main antenna is rotated; its purpose is to establish whether a reference test emission occurred during each orientation interval. If the reference waveform is absent from the witness channel, the corresponding main-channel negative result has little evidential value for polarisation sensitivity. If it is present at a stable calibrated level, the main-channel result becomes a more meaningful measure of that orientation under the tested geometry. The witness does not, however, supply the polarisation or bearing of an unknown external emission solely through its presence.

For a laboratory test, schedule reference bursts at pseudorandom times known to an independent test director, and rotate the main antenna using an interleaved order such as horizontal, vertical, intermediate, vertical, horizontal. Repeat with the reverse order and different interval lengths.

Copyright 2026, James M. Atkinson

Record the valid observation windows, retuning and detector delays, and both hardware acquisition counters if available. A short burst falling wholly in a switching interval must remain a miss in the trial ledger. It should not be silently reassigned to an adjacent orientation. Randomising trial phase relative to any cyclic scanner helps expose a persistent blind schedule, but does not eliminate the need to demonstrate actual temporal coverage.

If only one receiver exists, one can still perform repeatable controlled trials against a fixed known source, then carefully distinguish results of separate source events. The trial may estimate conditional detection for each orientation when the source output was independently verified. It cannot claim that two orientations covered the same unknown millisecond burst unless both were observed simultaneously. That is an inherent limitation, not a software defect. For a more capable setup, add a second receiver with a characterised separate acquisition path and compare sources of common failure: power, reference frequency, preselection and data logging. Shared conditions do not make the second channel useless, but they must be included in the dependence analysis.

One should report the resulting trial table by source duration, relative phase and polarisation, not only as an average score. A system might pass 98 out of 100 long continuous-tone trials yet fail every 2 ms burst aligned with a switching interval. That failure is highly material even if its average percentage looks attractive. The proper assurance statement identifies the tested temporal and polarisation classes, demonstrates how a negative result was exposed to those challenges, and distinguishes remaining

Copyright 2026, James M. Atkinson

unobserved combinations. A constrained survey can be honest and scientifically useful without pretending it has acquired simultaneous evidence it never recorded.

Sir Martin Ryle, Cross-Peer Question to James Clerk Maxwell: Professor Maxwell, your two-component observation matrix has clarified the geometry, but I would challenge whether a condition number obtained from free-space calibration remains relevant inside a complex enclosure. The two sensor channels might have different antenna patterns in the room, and their responses to the same unknown emitter may be related by reflections and coupling. A matrix which appears full rank at one reference direction could become nearly singular at a different position or frequency. How would you determine which field states lie in the system's effective null space without measuring every impossible configuration, and where should the engineer place the boundary between a mathematically demonstrated limit and a practical empirical coverage statement? I also ask whether an unmeasured third field component or magnetic coupling can defeat claims based on two well-calibrated electric channels. Would a withheld configuration, not used to estimate the response matrix, provide a better independent challenge of the claimed coverage than further fitting of already measured source positions?

James Clerk Maxwell, Cross-Peer Answer to Sir Martin Ryle: Sir Martin, a matrix measured in one environment describes that environment or the domain in which an appropriate transfer model has been validated. It is not a universal property of the sensor. If the near-field installation introduces additional modes, we may need an augmented response H(f,r,Ω,s) whose columns represent the relevant field components and whose rows are the

Copyright 2026, James M. Atkinson

actual measured sensor channels. A two-row matrix cannot in general reconstruct more than two independent unknown components from one simultaneous observation, regardless of its numerical precision. The presence of unmeasured longitudinal electric or magnetic coupling means a negative report based only on two transverse channels must explicitly exclude those modes or demonstrate through separate tests why they are immaterial to the stated source class.

I would begin by measuring H for several controlled reference fields representing the relevant receiving modes, rather than claiming to identify every possible distribution. In an anechoic or other declared far-field calibration, vary polarisation, direction and frequency. In the intended enclosure, use safe known source arrangements and nearby electric and magnetic probes where justified. Compare predicted and observed channel responses, then construct a sensitivity envelope over the tested domain. Small singular values reveal poor identifiability within the chosen model, but they do not assign a probability to wholly unmodelled source states. It is therefore appropriate to report both the matrix's local conditioning and the empirical missed-detection cases discovered by the independent challenges.

The mathematical distinction between state reconstruction and detection must be retained. A sensor matrix may be poorly conditioned for reconstructing the exact field vector while still being capable of detecting that some nonzero field is present; conversely a noise-limited detector may fail even when the matrix is nonsingular. For a linear model with additive noise covariance R, the sensitivity of a test depends upon the signal

Copyright 2026, James M. Atkinson

projection into the noise-whitened measurement space. In principle, one can examine the smallest singular value of R^(-1/2)H for a specified field-state family. Such a calculation assumes that R is measured, stable and invertible on the retained channel space, and it cannot represent unknown receiver saturation or temporal gaps. It is a useful design diagnostic, not a guarantee of detection outside the model.

I would conclude with a two-part report. The theoretical portion identifies which field combinations are weakly observed under the calibrated response, with bounds and assumptions. The experimental portion records direct trials of source polarisation, position, orientation and duration, including misses and changes caused by the enclosure. The investigator should not invent a universal null-space proof from a few field samples, nor should the mathematics be omitted merely because empirical tests are easier to conduct. By preserving both views, one can say precisely which classes of negative result are strongly qualified and which remain unresolved because relevant field components were never tested.

James Clerk Maxwell, Cross-Peer Question to Antony Hewish: Professor Hewish, you have proposed controlled trials for detection probability, yet a statistical fraction acquired under one family of known test signals may be used politically or commercially as though it covered every form of concealed emission. Suppose the survey has repeatedly detected fixed polarisation reference bursts but the source of concern might have unknown elliptical polarisation, unknown burst duration and an antenna whose orientation cannot be predicted. What principle should determine whether the investigator may use a pooled detection percentage, rather

Copyright 2026, James M. Atkinson

than a separate lower-bound result for each vulnerability class? How should a confidence interval be interpreted when failures are clustered by position or source type, and what rule would prevent a series of successful easy trials from concealing a serious systematic blind spot in one untested polarisation and angular combination? Should the report distinguish a failure of detection due to uncertainty in the signal population from an outright failure of the instrument under a tested, independently monitored calibration stimulus?

Antony Hewish, Cross-Peer Answer to James Clerk Maxwell: Professor Maxwell, the principle is that the statistical estimand must match the claim. A detection percentage pooled across unlike source configurations estimates performance for the particular mixture actually used in the experiment. Unless that mixture has been justified as representative of the target signal population, the percentage is not an assurance against a source selected from a different mixture. For a defensive search, a worst-case or stratified sensitivity statement is often more useful than one overall mean. An examiner should define vulnerability strata by frequency, polarisation, angular pose, source level and temporal behaviour, then declare the minimum performance required for each relevant stratum. A single difficult stratum that produces systematic misses cannot be compensated scientifically by hundreds of easy observations elsewhere.

Clustering has two consequences. Trials performed at the same physical location or under the same cable arrangement may share an unmeasured cause of failure. Treating them as independent Bernoulli trials can make the confidence interval too narrow. A design with several distinct locations and

Copyright 2026, James M. Atkinson

repeated blocks across days can help expose this dependence, provided the block structure is retained in analysis. One can use conservative bounds or hierarchical modelling where the sample design supports it; one cannot conjure a universal confidence limit from a test containing no examples of a crucial source class. Zero observed misses is not proof of perfect detection, and a clean record must not be represented as an absence of risk when the trial lacks sufficient power to discover its failure modes.

An explicit pass rule helps. Before testing, declare the minimum detectable source level and a set of required configurations. Define what constitutes a valid trial and a detection; define how source-off false alarms and invalid receiver intervals are handled; and specify the number of independent challenge opportunities required to bound performance with acceptable uncertainty. If the equipment fails one critical stratum, record that as a failed acceptance condition even if the pooled mean passes. If an untested polarisation or direction could plausibly be material, mark it as outside scope and propose a specific test rather than assigning it the mean of the tested group. Such rules are especially important when the customer's expectation is 'nothing was found', because the client may otherwise confuse technical silence with demonstrated absence.

The report should also permit a reader to reconstruct the test. Preserve source coding and timestamps, survey positions, antenna angles, raw spectrum or I/Q files, decision-rule versions, and all missed or invalid trials. The original signal record must remain separate from later sensitivity analysis. If the analysis is updated, the revised results should be traceable to

Copyright 2026, James M. Atkinson

the same unchanged source data and an explicit modified model. This is not an obstacle to a useful assurance opinion; it is its foundation. One may confidently say that a declared set of emissions was detectable under the tested conditions while acknowledging that other source classes were not examined. The greatest methodological error would be a precise detection percentage whose denominator silently excludes the most consequential opportunities for failure.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel distinguishes the physical presence of electromagnetic energy from the transfer response of a particular receiving antenna, the receiver's ability to preserve that response, and the decision rule that declares a detection. The ideal linear polarisation factor $\cos^2\psi$ shows that an orientation mismatch alone can suppress measurable power; direction-dependent pattern nulls and indoor interference introduce additional blind spots. Multichannel observation can reduce, but not abolish, those vulnerabilities, particularly when channels share geometry, time gaps or instruments. A responsible negative survey must record calibrated polarisation and angular coverage, intentional orientation and position changes, appropriate electric and magnetic sensing modes, valid observation intervals, independent source challenges and the uncertainty of its detection criterion. The resulting statement is that no qualifying emission was observed within a defined and challenged detection envelope. It is never an unqualified claim that no unknown emitter could exist in the surveyed premises.

QUESTION 065

Copyright 2026, James M. Atkinson

When do preselector switching transients corrupt a frequency-agile receiver?

HISTORICAL METHOD. The named contributors are deceased scholars and engineers. They are not represented as having personally used modern software-defined radios, FPGA capture systems or current spectrum-analyser models. Their documented physical and mathematical principles are applied by the present-day editor to a hypothetical lawful defensive measurement.

Dr. James M. Atkinson, Moderator: Professor Armstrong, a frequency-agile receiver changes its preselection state in order to suppress unwanted signals before conversion. A spectral burst that arrives immediately after a state change may be real, yet the switch, amplifier, local oscillator and digitiser may themselves create or obscure energy during that transition. What observable distinguishes a signal arriving from the antenna from a transient manufactured by a front end which is still changing its transfer function? Please develop a measurement model, identify where the valid sample window begins, and show why the receiver must disclose its state transitions as part of the forensic record.

Edwin Howard Armstrong, Principal Contributor: Dr. Atkinson, a receiver is a physical sequence of dependent operations, not a frequency label coupled to an immaculate mathematical transformation. The preselector is placed before a conversion or amplification stage so that unwanted energy may be rejected before it drives the apparatus into undesirable responses. This gain in selectivity comes at the cost of a switching or tuning process which itself changes the received waveform. A spectrum that appears bright or silent for

Copyright 2026, James M. Atkinson

a moment after tuning is therefore not automatically a property of the atmosphere. It may reflect a changing instrument. The proper question is what the receiver's transfer characteristics were at the precise instant represented by the acquired samples, rather than what frequency the operator had selected on a console.

For a receiver which remains in one settled state s, an approximate linear relation can be written $y_s(t)=h_s(t)*x(t)+n_s(t)$, where $x(t)$ is the input RF waveform at a declared antenna reference plane, $h_s(t)$ the equivalent linear impulse response for that fixed configuration, the asterisk denotes convolution and n_s represents the residual internal noise. This model is already conditional on amplitude, front-end linearity, coupling and frequency translation. During switching, the receiver becomes time varying. A more general relation $y(t)=\int h(t,\tau)x(t-\tau)d\tau+v_{sw}(t)+n(t)$ includes the changing impulse response and a possible control-induced component v_{sw} which can occur even with $x(t)=0$. The fact that an FFT of y contains a narrow or wide spectral component does not show which term produced it. A new filter state may reshape a real signal while generating a separate transient of its own.

Consider a three-band receiver which searches one band for eight milliseconds, changes to a second band, and returns later. A control packet may command the filter switch at time t_c, while the physical RF path reaches a reliable state only at t_c+T_g. If T_g is not measured, the first captured block can include mixed states. A burst of duration two milliseconds beginning at $t_c+0.2$ milliseconds could be completely lost if the receiver is blind for three milliseconds, or it could appear as a distorted residual if the switch passes a fraction of the burst during recovery. A

Copyright 2026, James M. Atkinson

spectrum formed from that block might show reduced amplitude, broadened modulation or a false isolated spur. None of those descriptions is an adequate account of the external signal unless the operator has separately characterised the transition.

The first experiment is a state-transition baseline with the RF input terminated at a proper impedance and with the same switching commands used during a real survey. Record raw complex samples, controller command timing, the hardware switch-select line, gain and oscillator states, any sample-overflow flags, and the analogue output if accessible without unsafe intrusion. A reproducible pulse tied to every switch event under termination is powerful evidence of an internally created component. It is not proof of the precise mechanism: feedthrough from a control line, bias recovery, an amplifier disturbance, local-oscillator settling and the digitiser's reference may all contribute. A probe inserted carelessly may alter the very circuit being examined, so the timing witness must be calibrated for its loading and latency.

The second experiment is a controlled known-signal challenge. Apply a continuous laboratory tone at a safe level in the destination passband, with its frequency and amplitude independently supervised. Repeat transitions between all relevant filter pairs. Plot amplitude and phase as functions of the elapsed time after physical switching, not merely after the software command. Where a switching artefact exists, repeat with the tone off. Next inject known short bursts at swept delays relative to the switching event. A genuine receiver should recover the specified burst parameters once its valid window has begun; a transition-limited receiver should make its blind

Copyright 2026, James M. Atkinson

interval explicit. Success for a continuous tone cannot be extrapolated to a short pulse whose energy may lie entirely inside the invalid window.

A frequency-agile receiver also includes a local oscillator which may be commanded alongside the filter. If the oscillator remains unsettled, conversion may translate the desired source to the wrong intermediate frequency or create an apparent chirp. If automatic gain control reacts to the new passband, a gain step may produce a broadband change or temporarily desensitise reception. If the digital downconverter is reset, it may change its phase origin. All these effects can coincide in the same millisecond. They must be challenged separately by holding the oscillator fixed while switching the filter, holding the filter state fixed while changing the oscillator, and replaying the same input with gain-control policies varied under documented laboratory constraints. Otherwise a repeatable burst tied to retuning remains merely a correlated event, not an attributed fault.

The validity criterion should specify a measurable error envelope rather than a vague word such as settled. If a laboratory calibration establishes that the recovered tone amplitude must lie within ±0.5 decibel of its steady-state value and phase within an application-defined tolerance, then the earliest sample index meeting those criteria for the required consecutive observation window may define a candidate valid start. Those numbers are illustrative; their adequacy depends on the target waveform and evidential use. A filter may reach amplitude tolerance before phase tolerance, or settle at one frequency and not another. The acceptance threshold must therefore be tested over relevant frequency, level, switching direction, temperature and loading. A status light indicating 'filter selected' is not the same as a measurement of the settled RF response.

Copyright 2026, James M. Atkinson

A forensic record needs three chronological layers: what the environment was capable of generating, what the receiver physically admitted, and what the processing subsequently displayed. Record state-change intervals as invalid or specially qualified, rather than silently interpolating the spectrum across them. Preserve the raw stream and explicit gaps; distinguish firmware blanking from absent acquisition; and expose the timing of every transition in the visualisation. If a narrow spike follows the filter-selection line under a terminated-input test, describe it as an instrument-related observation. If a candidate external burst persists with an independently settled receiver and changes appropriately with antenna substitution, the external hypothesis gains support. The two hypotheses may coexist, and the report should not force a false binary choice.

The broader engineering lesson is that preselection protects a receiver against one class of errors while introducing a new state variable that must be measured. The more rapidly one hops among bands, the greater the fraction of the schedule occupied by transitions unless the design has parallel, already settled paths. A sweep can be faster than the physics of its front end. This is not an argument against agility; it is an argument for a calibrated duty cycle, hardware-resolved state labels, challenge tests and conservative claims about what was observable. A receiver that records a transition honestly may provide stronger evidence than a faster receiver whose attractive waterfall quietly omits the period in which it was blind.

Grote Reber, Peer Question: Professor Armstrong, the first experiment you propose uses a terminated RF input to reveal a control-related waveform. Yet changing the antenna connection to a termination changes the impedance, removes the outer-conductor currents and may alter amplifier

Copyright 2026, James M. Atkinson

stability. A feature that disappears with termination might therefore be made by the receiver itself while depending upon the cable or a nearby antenna to complete its coupling path. How should a survey distinguish an actual exterior source from a switching artefact carried along the shield or re-entering the front end through the antenna? I ask particularly about the design of independent reference receivers, since two instruments in the same enclosure may share a power supply, control clock or ground network. What set of source-on, source-off and configuration changes would count as persuasive evidence, and how should the report describe a result which remains equivocal after these tests? The comparison should include changing shield-current paths deliberately, rather than assuming that one connector substitution has isolated the whole antenna circuit.

Edwin Howard Armstrong, Response: Mr. Reber, your objection is essential because the terminated-input experiment tests one boundary condition rather than the complete physical installation. A cable shield can carry common-mode current, and removal of that cable may stop internal energy from travelling to an unintended re-entry point. The investigator should therefore compare several distinct states: a calibrated termination at the receiver input; the operational antenna and feed line; the feed line terminated at its remote end; an electrically comparable reference lead arranged away from the suspected coupling path; and a second receiver with a genuinely independent reference and supply. Each state must be documented because a changed connector, load or physical route may alter more than one coupling mechanism.

The strongest test retains the switching command while changing the

Copyright 2026, James M. Atkinson

possible external RF source independently. Use a lawful known emitter whose on-off pattern is supervised at the source and, where practicable, observed by an independent instrument. If the suspicious transient follows the preselector command when that emitter is off, the internal hypothesis gains support. If a component follows source timing independently of the receiver's switching schedule, that is evidence of an external contribution, although receiver nonlinearities can still reshape it. Run the two schedules at deliberately different repetition periods, avoiding accidental synchronisation, and retain individual event times rather than averaging the results into an attractive composite waveform.

It is useful to put the second receiver on a different clock and a separate antenna, but one should also examine common environmental coupling. A transient associated with a power distribution fault can disturb both receivers, while one legitimate transmitter can be received by both. The purpose is not to insist upon abstract independence but to map the dependence and introduce interventions with discriminating predicted outcomes. The test can also measure current on the coaxial shield, provided the probe's bandwidth and loading are suitable; a transient current synchronous with switching helps identify a path even when the exact source within the receiver remains unresolved.

If the feature persists in some configurations and disappears in others without a unique causal account, the proper conclusion is bounded. Record that the observed energy is state dependent and that external and internal explanations have not been separated to the specified standard. It would be

Copyright 2026, James M. Atkinson

unsound to call the line evidence of a transmitter merely because an antenna was connected, or to deny any exterior possibility merely because a termination test sometimes removes it. A transparent table of conditions, time intervals, signal amplitudes and uncertainties is more scientifically valuable than a forced verdict.

Antony Hewish, Peer Question: Professor Armstrong, an intermittent emitter may transmit for only a few hundred microseconds at unpredictable times. Suppose a receiver visits ten frequency bands sequentially, and each change imposes an uncertain period during which the samples are invalid. The operator may calculate the percentage of nominal time allocated to each band and announce a probability of intercept, but the source could be synchronised, deliberately or accidentally, to the blind portion of the schedule. How should one quantify the observational coverage without assigning a convenient random arrival distribution which the evidence does not support? I am also concerned about whether a recorded FFT block after a switch can include contaminated earlier samples through overlap buffers, so that even the software's declaration of a valid block is mistaken. What exact records would be required to support a negative finding when the system hops faster than its front end can fully recover?

Edwin Howard Armstrong, Response: Dr. Hewish, begin with a deterministic map of valid acquisition, not with a probability. For each band b define V_b(t)=1 when that band is physically selected, settled under the relevant performance criteria, and captured without a known sample gap; set V_b(t)=0 when those conditions are unverified or fail. The integral of V_b over a declared period gives valid coverage time in that band. The nominal frequency-selection command alone does not define V_b. Its construction

Copyright 2026, James M. Atkinson

requires the measured transition timing, oscillator and gain states, the acquisition counter, and the processing support intervals which contribute to each derived datum.

A probability of detection requires an additional model of the source. If the emission start time were uniformly distributed relative to a periodic receiver schedule, and detection required a minimum uninterrupted overlap, one could calculate a model-specific probability from the geometry of valid intervals. But the words 'were uniformly distributed' must be prominent: deterministic or correlated emissions can evade those intervals repeatedly. For a regulated laboratory challenge, send known bursts at a grid of delays relative to switching and varied durations and powers. Plot successful detections by phase and duration, including misses and false alarms. This produces an empirical coverage surface rather than a solitary percentage claimed to apply to all unknown sources.

Processing support must be accounted for. A decimation filter uses several input samples to produce an output sample; an FFT window uses a finite span and may overlap its neighbours. An output time label can lie inside a nominally valid interval while the actual calculation includes older, invalid samples. State-dependent processing should either flush and reinitialise its memory with an explicitly documented loss interval or retain the state and compute the resulting contaminated support. The invalidity mark should propagate through the full support of every downstream operation. Otherwise a beautiful waterfall can be built partly from samples collected during a change of physical transfer function.

Copyright 2026, James M. Atkinson

A defensible negative conclusion is therefore confined to the measured class of signals and the measured valid windows. If only a fraction of a band was observed with sufficient time support, the report should not imply continuous monitoring. More importantly, when the emissions of concern may have timing correlations with the receiver schedule, the investigator should consider longer dwell, schedule randomisation under a documented protocol, overlapping receivers or continuous wideband capture. Each method has limitations and must be validated. The absence of a qualifying detection under an incomplete schedule remains an observation, not a proof that no relevant emission occurred.

Dr. James M. Atkinson, Moderator: Mr. Hewlett, Professor Armstrong has defined the transient as part of an evolving receiver transfer function. Please analyse the switching components and their bias circuits. I ask particularly how charge, relay movement, parasitic coupling and branch mismatch may put a pulse into the RF path without any external radio emission.

William Redington Hewlett, Second Principal Contributor: Dr. Atkinson, the switching element must be treated as a three-terminal or multi-terminal physical device with control energy as well as a nominal RF path. An electronic switch is not a perfect binary coefficient. Its semiconductor junctions possess capacitance, accumulated charge, voltage dependence and finite recovery. A mechanical switch contains contact movement, intermittent conduction and geometry which can change while the actuator operates. Bias networks contain inductors, resistors, capacitors and stored electrical energy. The measurement chain thus receives a controlled electrical disturbance at precisely the moment the instrument believes it is

Copyright 2026, James M. Atkinson

changing passive selection. Even where the signal input is terminated, the control circuit may inject a residual impulse into the measurement port.

One common mechanism is charge injection into a high-impedance or capacitively coupled path. If a control node changes voltage by ΔV across an effective coupling capacitance C_c, an ideal first approximation gives an injected charge $Q=C_c\Delta V$. For a hypothetical $C_c=0.5$ picofarad and $\Delta V=5$ volts, Q is 2.5 picocoulombs. If a simplified isolated capacitance of 10 picofarads were to receive that full charge, the immediate voltage increment would be 0.25 volt. The real circuit will distribute charge across impedances and cannot be evaluated from this crude two-capacitor example alone. The point is that very small capacitances can move enough charge to make a low-level measurement channel react. The actual peak and time course are governed by the driver impedance, package geometry, decoupling and the downstream transfer function.

A second mechanism is the recovery of a conducting device after its bias changes. The transition in RF insertion loss may not be synchronous with the electrical select command; on and off changes can exhibit different delays. An apparent duty cycle of ninety per cent at the logic port can correspond to less at the RF input if the relevant stage has a lengthy turn-on delay. Oscillation or ringing in bias leads may produce multiple effective changes of conduction even when the control word changes only once. The receiving operator must therefore measure at least the physical switch-control edge and the actual path response under a known RF challenge. A controller's assertion that the branch is selected establishes an intended command state, not the instantaneous RF attenuation or phase at its output.

Copyright 2026, James M. Atkinson

Mechanical switching introduces distinct risks. Contact bounce can produce a cluster of short interruptions; a time-domain display of the control coil might show one command while a properly monitored RF test tone shows several attenuation steps. Arcing under an unsuitable hot-switching condition may damage the part or generate broadband disturbance, and it is not an acceptable experiment to provoke unsafe arcs. The safer laboratory procedure follows equipment ratings, uses suitable load protection and records whether switching is specified for active RF power or requires a quiet interval. A reed or MEMS element may have excellent static loss and isolation and yet different closure, opening and residual feedthrough behaviour. These distinctions explain why static catalogue figures do not settle an acquisition-timing question.

A third mechanism is an imperfectly isolated branch. During transition, two filter paths may overlap briefly, or a break-before-make design may disconnect both. The temporary mismatch presented to a preceding low-noise amplifier can alter its gain, return loss, noise performance and stability; the following mixer may see a changing load. In a receiver containing strong ambient signals, even a brief reduction in preselection attenuation may allow a blocker to drive a nonlinear front end. The resulting recovery can outlast the switch event. A spur measured a millisecond later may thus be a nonlinear after-effect of a short overload, not a direct video feedthrough pulse. The experiment should deliberately vary the blocker level within safe limits to determine whether recovery depends on incident RF energy.

For characterisation, build a table across source and destination branch pairs rather than test only one direction. The transition from a low-

Copyright 2026, James M. Atkinson

frequency low-pass path to a high-frequency bandpass path may differ from the reverse, and a bypass state may behave differently again. Each pair should be challenged with no RF source, a low-level reference in the intended band, and a controlled off-band blocker, where the receiver ratings and laboratory authority permit. Record the output waveform, zero-input feedthrough, phase step, amplitude settling and eventual noise floor. The operational constraint is not merely 'switching time'; it is time until the full chain meets all defined measurement tolerances after every relevant state change.

A practical acceptance definition might use the earliest time T_{valid} such that an amplitude error $|A(t)-A_{ref}|$ remains below ε_A and phase error $|\varphi(t)-\varphi_{ref}|$ remains below ε_φ for a contiguous confirmation interval T_{hold}, with a separate requirement that the device reports no overload or acquisition gap. The tolerances ε_A and ε_φ, the held confirmation duration, and the calibration source's uncertainty are all stated variables. A crossing of the tolerance for one sample is insufficient if the response subsequently rings back outside it. For signals carrying digital modulation, error-vector magnitude or recovered symbol timing may matter more than steady-tone phase. For detection of weak pulses, the essential performance may be probability of capture under an explicitly specified burst timing distribution.

The design remedies have costs. Slowing the control edge may reduce high-frequency feedthrough yet lengthen the blind interval. Additional filtering can attenuate the control disturbance but introduce group delay and ringing. A parallel-path arrangement allows one branch to settle before selecting it, at the cost of more hardware, switching interfaces and possible common power disturbance. A resistor or isolator can improve matching but

Copyright 2026, James M. Atkinson

sacrifices sensitivity. The correct choice is therefore not the fastest component on paper; it is the architecture whose actual measured performance satisfies the mission's selectivity, sensitivity, noise, dynamic range and temporal coverage simultaneously.

I would require the report to state whether the artefact is observed at the input, switch output, mixer output, ADC stream or only after software processing, and how the investigators separated those stages. If the physical device was not accessible, the report must say so and restrict its attribution to the path which was genuinely tested. A small pulse seen under termination is evidence that the measuring system can generate energy during switching, not proof that every spectral feature near switching is internal. Conversely, a pulse measured only with the antenna connected is not necessarily external; cable currents and changed impedance can couple control disturbances through paths absent under a simple termination. An adequate investigation uses alternative configurations until the causal inference is supported or its uncertainty is explicit.

John Daniel Kraus, Peer Question: Mr. Hewlett, your account of switching charge and branch mismatch raises a calibration problem. A preselector's static passband may be measured with a continuous reference tone, yet an RF survey must identify short, wideband events at the edges of adjacent bands. How should the acceptance test distinguish an insertion-loss shift from phase distortion and from a transient produced by changed return loss? The same switch may be driven at very different rates, and the surrounding cable or amplifier impedance can change with installation. Would you calibrate each band independently or every possible transition between bands, and what experimental reduction is permissible when there

Copyright 2026, James M. Atkinson

are too many transitions to test exhaustively? I would also ask how the test avoids mistaking a stronger artefact for proof of greater receiver sensitivity near a marginal real signal. Please also specify how the chosen transient challenge will avoid overdriving the preselector and thereby manufacture an overload artefact which would not occur at the expected source level.

William Redington Hewlett, Response: Professor Kraus, calibrating only the final steady passband is necessary but not sufficient. The intended observable must be defined for the waveform. For a narrow continuous carrier, amplitude flatness and phase after the full settle interval may be sufficient. For a brief wideband burst, the measurement may depend upon impulse response, group delay, time-varying gain and how the detector chooses its event timestamp. A static scalar insertion-loss correction cannot account for every one of those effects. I would retain two families of test stimuli: controlled single tones spread across the passband, and a bounded wideband waveform with a well-characterised timing feature. The second family reveals distortions hidden by a single-tone calibration.

A comprehensive transition matrix can be large, but reduction must be based on physical architecture, not convenience. If several band selections share the same switching element and bias driver, their transition behaviour may belong to one experimentally justified equivalence class. Conversely, paths that employ different relays, filter resonators, bias voltages or amplifier loads should not be silently grouped. Characterise representative transitions, including the worst expected switching direction and operating temperature, and verify that omitted states conform to the proposed class. If that assumption cannot be substantiated, state that those transitions

Copyright 2026, James M. Atkinson

remain unqualified. A receiver may have a reliable forward transition and a slower reverse transition because its residual internal energy differs.

Return loss can alter more than available power. A changing source impedance can modify an amplifier's effective noise matching or lead a mixer to generate a different response under a nearby blocker. Measure reflection where practical and challenge the receiver with a tone and a controlled blocker, first at safe levels and then near the intended operating range. Separate the purely switch-induced disturbance seen under termination from the additional nonlinear or load-sensitive response when a blocker is present. Those effects may have different recovery times. If the apparent transient grows when a strong off-band signal is introduced, that observation is useful but does not itself prove a single mechanism; the causal experiment must separate overload and reflected-power changes.

A stronger transient should never be counted as improved sensitivity. Receiver sensitivity is established by a calibrated input signal and a declared detection or measurement criterion at a known false-alarm level. A switch pulse which raises the display can create the illusion that the receiver is more responsive, while increasing false alarms and masking weaker true events. The acceptance report should compare source-present and source-absent trials with the same state schedules and thresholds. It should preserve raw, time-tagged measurements rather than only an aggregate success percentage. Through such controls, each proposed transition class can be assessed against performance requirements instead of against an attractive but misleading spectrum trace.

Copyright 2026, James M. Atkinson

Lord Rayleigh, Peer Question: Mr. Hewlett, I am troubled by the temptation to turn one very rapid oscilloscope trace into a universal switching-time specification. A current pulse, a transmitted reference tone and the filtered detector output can have markedly different characteristic times, while a low-level signal may be overwhelmed by the noise of the apparatus. Which quantity should define the end of the transition, and can it be estimated as a scalar for every practical use? If an instrument's switch appears complete within microseconds, but the downstream gain recovery occupies milliseconds, does the specification of the switching device have any evidential force for the receiver as a whole? Please also explain what an uncertainty budget should do when the test signal has a fixed amplitude but the signals in the intended survey may be weaker, stronger or modulated differently. What minimum observation duration would make a declaration of settled response credible when a damped oscillation can briefly cross the tolerance band and then leave it again?

William Redington Hewlett, Response: Lord Rayleigh, the word switching-time must be tied to the measured node, transition criterion and stimulus. A switch vendor may define control-to-RF 10–90 per-cent time under a specified load. That is a legitimate component property under those conditions. It is not the time until a receiver's final sample is suitable for a forensic inference. The end of a transition at the system level can only be defined relative to all the metrics relevant to the intended measurement: amplitude error, phase error, group-delay distortion, noise and overload recovery, valid sample chronology and detector performance. Where more than one metric matters, the valid time begins no earlier than the latest of their qualifying recovery intervals under the tested configuration.

Copyright 2026, James M. Atkinson

It is sometimes possible to record a vector of time-dependent errors instead of one scalar. For example, let $E_A(t)$ be amplitude deviation, $E_\varphi(t)$ phase deviation, $E_N(t)$ noise change and $E_D(t)$ detector performance under a known challenge. A chosen application can define threshold limits for each. The measured T_{valid} is the earliest time after which the relevant limits remain satisfied for a specified confirmation interval. A different application may choose different limits and obtain a different T_{valid} from the same raw record. This is not methodological weakness; it is precision about the quantity one wishes to establish. The numerical value becomes misleading only when it is circulated without its tolerances and test conditions.

The test-signal level must be varied because some defects are nonlinear or triggered by control thresholds. A strong reference tone might dominate a brief feedthrough pulse and make recovery appear excellent, while a weak tone near the noise threshold could be masked or falsely declared present. Conversely a strong blocker might drive temporary desensitisation that a quiet test misses. Use a controlled range of input powers and source-off trials, and define the false-alarm and missed-event criteria. The sensitivity and timing estimates should be reported as functions of signal class and input level where the result materially varies, rather than averaged into a single reassuring number.

Uncertainty must include repeatability of switching, measurement timebase calibration, trigger alignment, stimulus stability, probe loading and system drift, as well as the observed spread across temperature and transition

Copyright 2026, James M. Atkinson

direction. A reproducible state-dependent bias is not automatically treated as random noise. If a device settles within one microsecond but the gain loop requires three milliseconds to restore weak-signal detection, the complete receiver cannot be declared valid at one microsecond for that purpose. Its excellent component specification remains useful engineering information, but the evidential acceptance result is the slower system-level criterion.

Dr. James M. Atkinson, Moderator: Professor Bode, we have now established candidate sources of transients. Please develop the filter-memory and dynamic-response problem mathematically. I am especially concerned with an instrument that can appear amplitude-stable while retaining a phase or group-delay response unsuitable for a short burst.

Hendrik Wade Bode, Third Principal Contributor: Dr. Atkinson, a preselector is valued for its steady-state frequency response, but the measurement problem during a state transition is fundamentally dynamical. Stored energy in inductors and capacitors does not disappear because a control command changes the desired filter response. An LC resonator, a high-Q cavity and a tracking filter all require time to establish or dissipate their electromagnetic state. Even a switch with nearly instantaneous conduction can connect a new filter whose internal state differs from the one assumed by the observer. A frequency-domain passband specification is consequently insufficient to predict the response to a short pulse following a transition.

Consider first a causal, stable, single-pole approximation whose output envelope $a(t)$ satisfies $\tau\, da/dt+a=u(t)$, where τ is a positive time constant and $u(t)$ is a step-like desired envelope. When u changes from zero to unity at $t=0$ and $a(0)=0$, the solution is $a(t)=1-\exp(-t/\tau)$. The remaining error is

Copyright 2026, James M. Atkinson

$\exp(-t/\tau)$. To reach a five-per-cent error requires $t=-\tau \ln(0.05)$, approximately 3.00τ; to reach one per cent requires about 4.61τ; and to reach one tenth of one per cent requires about 6.91τ. These are model-derived examples, not measured times for a particular filter. A high-order preselector may have multiple real or complex poles, overshoot and ringing, so no single τ may describe its settling across frequency and switching direction.

The state-space expression makes the wider problem explicit. For a settled state s, one can write $x_dot=A_s\ x+B_s\ u$ and $y=C_s\ x+D_s\ u$, where x contains the relevant internal energy-storage states. At transition time t_c, the matrices change to those of the new branch, but the physical state $x(t_c)$ may not vanish or match the new equilibrium. If the new state is initially displaced, the homogeneous term $\exp[A_new(t-t_c)]$ times that displacement survives into the output. The response can have a quiet initial interval, a peak, a damped oscillation or an apparent change in phase. This is why an early spectral line may be the relaxation of a circuit rather than an external waveform of identical frequency.

For a resonator characterised near its centre frequency f_0 by a loaded quality factor Q_L, a frequently useful approximate energy decay time is $\tau_E \approx Q_L/(2\pi f_0)$, under the stated resonant and small-signal assumptions; the envelope-amplitude decay time of the corresponding ideal lightly damped mode is approximately $\tau_A \approx Q_L/(\pi f_0)$. The distinction matters because energy is proportional to amplitude squared. At $f_0=100$ MHz and $Q_L=100$, τ_A is about 318 nanoseconds. An assumption of 10,000 for Q_L would increase that ideal envelope time to about 31.8 microseconds. A tracking electromechanical element may be much slower, and an active

Copyright 2026, James M. Atkinson

control loop may dominate both values. These figures illustrate scaling, not a blanket claim about preselector technology. Directly fitting a transient is safer than inferring exact settling from a catalogue Q value alone.

Group delay is a separate concern. If the phase transfer function is $\Phi(\omega)$, group delay is $\tau_g(\omega)=-d\Phi/d\omega$, where ω is angular frequency. The derivative is meaningful where the response is sufficiently smooth and the band of interest is defined. A receiver can pass a continuous tone at nearly correct amplitude while distorting the envelope timing of a wideband burst through unequal group delay across its spectrum. Immediately after tuning, the transient response may be time varying and the ordinary group-delay function for a stationary linear system may not apply. A single amplitude-stability threshold cannot therefore establish that the receiver can timestamp or reconstruct a short pulse accurately.

A suitable characterisation uses an input family chosen to reveal both amplitude and phase dynamics. Begin with a continuous reference tone at several frequencies across the intended passband. Then use a wideband but controlled impulse-like or coded stimulus with sufficient dynamic range and legal laboratory isolation, retaining its independent source timing. Record the received complex response after each state change and compare its envelope, phase trajectory, delay and correlation peak against a fully settled baseline. One should repeat with varied input level to discover nonlinear recovery, and at several temperatures to observe whether resonant frequency or control dynamics move. The purpose is not to create a beautiful generic impulse response, but to establish exactly when the measurement chain becomes fit for the specific waveform being sought.

Copyright 2026, James M. Atkinson

The spectral-analysis software can confound the physical dynamics. An FFT window overlapping pre- and post-switch intervals combines samples from two different system states, violating the stationary premise of a conventional narrowband spectral estimate. A windowed Fourier transform may turn a time-domain step into broadband leakage or a sequence of lobes. Averaging many such windows can preserve a reproducible spur even when no continuous carrier exists. If the implementation automatically blanks a few samples but retains an FFT segment crossing the boundary, contamination can survive the blanking. A defensible system labels raw samples by state and excludes or separately analyses any FFT windows that intersect an invalid interval, including the support of filters and overlap buffers downstream.

Dwell time is the engineering resource often overlooked by a rapid search schedule. Let T_{cycle} be the interval from one acquisition-state change to the next, T_s the measured acquisition-invalidation and settling interval, and $T_{capture}$ the subsequent valid observation interval. For a serial receiver, $T_{capture} \leq T_{cycle} - T_s$, ignoring additional transport and processing loss for simplicity. If $T_{cycle}=5$ milliseconds and $T_s=1.5$ milliseconds, at most 3.5 milliseconds remain, a valid duty fraction of 0.70. But that fraction says nothing about an event's detectability unless the event's duration, repetition pattern and phase relative to the schedule are modelled. An emission that consistently occupies the invalid 1.5 milliseconds can be missed in every cycle. One should report time-frequency coverage and acquisition validity together, not just total sweep rate.

The remedy may require a more elaborate measurement plan rather than faster retuning. A receiver can pause after switching until a hardware-

Copyright 2026, James M. Atkinson

witnessed settling criterion is satisfied; a two-path architecture can pre-tune the next filter; or a wideband parallel receiver can maintain continuous coverage across critical bands. Each approach changes noise, cost, mutual coupling and power constraints. The most defensible system is the one which records a sufficient valid sample history for each intended inference and exposes the intervals during which that was impossible. From the standpoint of control theory, time and memory are not defects to be wished away by a faster computer. They are properties of the physical apparatus which the scientific claim must respect.

Sir Edward Victor Appleton, Peer Question: Professor Bode, your state-space argument explains that filter memory can continue after the switch has changed. In an actual radio survey, however, propagation can also introduce multipath delay and frequency-selective fading. If a short burst is observed at different amplitudes or times after successive retunings, how should the examiner distinguish a transmitter and environment which genuinely change from a filter which carries residual energy from an earlier selection? Is a control experiment with one fixed laboratory tone sufficient to expose a receiver transient, or must the challenge include different bandwidths and waveforms? I am particularly concerned that an FFT window can turn a decaying time-domain response into a plausible narrowband emitter, so that an elegant frequency trace becomes more persuasive than the unedited evidence. What tests would allow the scientific claim to be narrowed without making an artificial separation between the apparatus and the propagation channel?

Hendrik Wade Bode, Response: Sir Edward, the two physical processes must be separated by interventions which affect one more strongly than the

Copyright 2026, James M. Atkinson

other. Filter memory follows the instrument's switching history; propagation effects follow the external source, antenna geometry and environment. A fixed laboratory source helps, but a single continuous tone can conceal important temporal and group-delay errors. One should challenge with several controlled signals: a continuous tone, a burst with a defined envelope and a sufficiently broadband coded stimulus with a known correlation structure. Repeat each through the selected band transitions, and retain a parallel reference of the stimulus at a declared electrical plane. The comparison should include phase and envelope chronology rather than a solitary frequency-bin magnitude.

To isolate the receiver, perform electrical input tests under known impedances and retain the full signal path through the preselector, conversion and digital analysis. The laboratory path should itself be calibrated for cable and source delays, or the test will merely transfer the unknown delay elsewhere. To examine propagation, repeat over the intended antenna path with the transmitter at controlled surveyed positions, noting that an external field and antenna may change differently with frequency and polarisation. If the anomaly remains tied to switching command delays under a stable injected stimulus, the receiver-memory hypothesis gains support. If it moves with transmitter position or a controlled obstruction while switching times are unchanged, the propagation hypothesis gains support. Both influences can be present and should be modelled jointly if the evidence demands it.

FFT support is indeed central. A transient with decaying envelope can spread

Copyright 2026, James M. Atkinson

energy across bins and create a persistent-looking line when windows are repeatedly aligned to switching. Recompute the same raw samples with several windows, hop sizes and starting offsets, carefully preserving their time supports. If a reported frequency feature depends strongly on how the FFT window crosses the transition, that is a reason to investigate nonstationarity; it is not proof that the entire feature is artificial. The appropriate event classification should refer back to the time-domain waveform and the state record, with the spectrum used as one representation of those observations.

A useful comparison is between the observed output and the convolution of a separately measured settled receiver response with the known input. Differences near a transition reveal the need for a time-varying model, but do not by themselves identify which switching device is responsible. A more refined test fits or bounds the transient state-space response under multiple independent stimuli and checks its prediction on a withheld waveform not used for fitting. Good prediction across different waveforms strengthens the receiver explanation. Poor prediction is a warning against a definitive attribution. The final finding should say which elements were measured, which were modelled and what remains underdetermined.

Dr. James M. Atkinson, Moderator: Mr. Black, Professor Bode has described energy storage and finite response. Now consider the receiver as several coupled feedback systems. How might local-oscillator locking, automatic gain control, bias regulation and software state machines produce an apparent signal which outlasts the hardware switching event?

Copyright 2026, James M. Atkinson

Harold Stephen Black, Fourth Principal Contributor: Dr. Atkinson, feedback corrects error by observing a condition and changing a control variable; it also creates dynamics which must be included in the measurement. The filter selection command is only one perturbation. It changes the amplitude and spectral composition at the mixer or detector, which may change the error presented to an automatic-gain controller. Simultaneously a local-oscillator synthesiser may be updating its phase or frequency, and a digitiser may apply a new scaling or decimation profile. The resulting system is not a collection of independent instantaneous boxes. Their transients can add, oppose or conceal one another, and the observation that one loop reports lock does not establish that every relevant measurement quantity is already accurate.

A useful decomposition writes the measured output as $y(t)=F_s\{x(t),g(t),\varphi_{LO}(t),q(t)\}+e(t)$, where F_s is the front-end transformation in selection state s, $g(t)$ a time-varying gain, $\varphi_{LO}(t)$ local-oscillator phase, $q(t)$ the digital configuration and $e(t)$ residual disturbances. This notation is deliberately schematic, not a claim of global linearity. A filter switch may change the power of an out-of-band blocker by tens of decibels, provoking gain recovery; the local oscillator may simultaneously traverse a frequency step; and digital processing may retain filter memory across the change. A brief apparent spectral feature can therefore have no single cause. To attribute it, one must temporarily control or measure the separate state variables and ask which interventions predictably alter the observation.

Consider an automatic gain loop whose detector responds to received power $P(t)$ with an equivalent time constant τ_{AGC}. If a sudden decrease of admitted blocker power causes the controller to increase gain over several

Copyright 2026, James M. Atkinson

milliseconds, a weak legitimate tone may become more visible after the filter has physically settled. Conversely a previously admitted strong blocker may hold the gain low and conceal the weak tone for a recovery interval. A receiver can therefore be electrically connected to the correct band but still exhibit degraded sensitivity. The elapsed time until an output tone reaches its desired steady amplitude is not necessarily the same as the time until the minimum detectable signal or intermodulation performance has recovered. Several acceptance metrics are needed when an instrument's purpose includes both wide dynamic range and short-burst detection.

The loop design controls the answer. A high loop gain can reduce steady-state error but may produce overshoot, noise amplification or instability if phase margin is insufficient. A sluggish loop may be stable and quiet but unacceptably slow for an agile schedule. An abrupt switch in filter insertion loss can appear to the gain controller as a change in transmitter power, even though the environment is unchanged. If the software normalises power using a calibration constant for the destination band before analogue settling, the displayed amplitude may briefly be too large or too small. An attractive reading is not a guarantee that both the analogue gain and the correction factor describe the same state.

The local oscillator presents its own requirement. A synthesiser may report a phase-locked state after its phase error falls below a chosen detector threshold, yet small frequency or phase excursions can remain. In a demodulator, a residual phase trajectory can spread spectral energy or bias coherent estimation. One cannot automatically convert a control-loop settling specification into a proven arrival-time uncertainty without measurements under the actual mode. To test independently, hold

Copyright 2026, James M. Atkinson

preselection constant while commanding the oscillator across the intended frequency plan; then hold oscillator frequency fixed while selecting filters; finally exercise combined hops. Compare the three observed transient families, taking account of the fact that their interactions may be nonlinear.

A control-state machine should record more than the name of its desired configuration. Useful states include command issued, physical selection asserted, oscillator-reference condition, gain-controller transition, downstream digital filters reset or retained, confirmation criterion satisfied, acquisition valid, and fault. The machine should prevent a sample acquired in an unqualified state from being silently labelled as valid. A hardware line may witness a physical action while another counter records ADC sample index; a timestamped log binds the two. If a state is inferred retrospectively from the data, it must be identified as an estimate rather than represented as a contemporaneous instrument assertion.

A controlled study should use three orthogonal tests. First, a quiet input and repeated state transitions expose control-induced output. Second, a steady laboratory tone at fixed power reveals gain and phase settling. Third, a low-level test signal in the presence of a safe, controllable blocker reveals desensitisation and intermodulation recovery. Sweep the relative timing of the weak event across a filter transition and calculate its detection probability or amplitude error only for the tested source family. If the result is a blind interval, qualify the search coverage accordingly. Repeated successful detections at comfortable signal levels cannot demonstrate the response near the detection threshold, where gain and noise dynamics matter most.

Copyright 2026, James M. Atkinson

Numerical specifications must also distinguish random uncertainty from an unresolved state-dependent bias. If a receiver's settled gain calibration has standard uncertainty of 0.2 decibel, this does not mean a transition-induced amplitude error of 4 decibels can be treated as a random draw from the same distribution. The transient should be measured as a separate error function of time and switching history, then excluded, corrected or bounded as appropriate. A filter transition may have a direction-dependent overshoot; averaging forward and reverse transitions into a single scalar can obscure both. Traceability depends upon the calibration being applicable to the actual state, not merely upon the source of the original laboratory reference.

The operational design must be honest about timing. Suppose a sweep controller announces a new frequency every millisecond while the combination of preselector, oscillator, AGC and digital filter requires two milliseconds to meet its acceptance criteria. The apparatus may be continuously processing numbers, but it has no settled observation in the announced bands. If the algorithm reports one detection for each nominal dwell, it manufactures apparent coverage. The logical response is either to lengthen dwell, reduce the number of visited bands, use parallel receivers or redefine the claim as a provisional transient-sensitive observation. Feedback theory cannot rescue an impossible schedule by changing its labels; the time budget must reflect physical settling.

I would end by requiring a state-specific performance certificate rather than an undifferentiated calibration statement. The receiver should record which parts of the chain were verified for each accepted measurement, what challenge stimuli established the valid window, and what limitations remain

Copyright 2026, James M. Atkinson

when two or more loops change simultaneously. Such records allow a reviewer to distinguish a changing RF environment from a changing receiver. The aim is not an instrument that never has transients, but one whose transients are measured, controlled and reported before they become false evidence.

Sir Martin Ryle, Peer Question: Mr. Black, a receiver built for high probability of intercept may be fitted with automatic gain control and a rapid synthesiser, both deliberately operated in feedback. During a frequency hop, the display can show a clean transition, yet the front end may be temporarily insensitive to weak emissions because a gain loop retains memory of a stronger signal from the previous band. How would you qualify this hidden desensitisation without assuming that the controller's commanded gain is the actual instantaneous gain? Would the result differ if the desired signal itself changes power during the retune? I would also ask for a realistic account of how the system should react when a transient is detected but the controller state is uncertain: suppress the sample, retain it with a warning, or treat it as presumptively external? I would ask whether resetting AGC before every trial might conceal exactly the state-memory problem that an operational frequency-hopping schedule creates in the field.

Harold Stephen Black, Response: Sir Martin, a gain command is only a request to a physical circuit. The correct observation is the measured response to a calibrated stimulus at the receiver input. To expose latent desensitisation, introduce a weak test signal within the intended band and measure detection probability across a controlled hopping sequence while a safe stronger signal is present in the preceding band. Change the timing

Copyright 2026, James M. Atkinson

and amplitude of the preceding blocker, keeping the subsequent weak signal fixed. If the receiver misses the weak event more often after a stronger predecessor than after a quiet predecessor, a state-memory effect is indicated. Continue the experiment until the recovery time is measured across the relevant signal levels and transition pairs.

The test should distinguish detection from amplitude accuracy. A receiver may detect the weak tone but report the wrong power because gain calibration has not caught up with the analogue state. Another may report a plausible power while the instantaneous noise figure is unacceptable. The performance criteria should include missed events, false alarms and a measured amplitude or phase envelope where appropriate. Where a legitimate incoming signal changes amplitude during the transition, an external explanation remains possible; that is why the known stimulus must be independently monitored and replayed across the same receiver schedule. A signal source and receiver sharing a control clock can produce misleading apparent agreement, so the source timing should be checked independently where this matters.

A robust controller records measured state rather than silently making a validity assumption. Samples taken during a known invalid interval should be retained when lawful and feasible, but marked invalid for any conclusion that requires settled acquisition. They should not be discarded without a record of the gap, since later inspection may reveal a useful diagnostic transient. If hardware state is uncertain, label the interval as uncertain. The software may offer a candidate classification for exploratory analysis, but

Copyright 2026, James M. Atkinson

the final forensic report must not promote that candidate to an external emission without challenge tests. The objective is to preserve evidence and prevent unwarranted claims simultaneously.

A useful state machine can require independent confirmations: oscillator phase condition, physical band-select observation, gain-controller settling criterion, and an acquisition counter free of gap or overflow. Their logical conjunction defines an eligibility flag for a particular analysis. Because some measurements are tolerant of gain error and others are not, the flag should be tied to the intended inference rather than advertised as universal. The controller may choose to suppress online alarms during the transition to reduce false positives, while retaining raw samples and event metadata for later reconstruction. This separates operational alarm policy from evidential preservation, and prevents a silent data-repair algorithm from rewriting the history of what occurred.

Dr. James M. Atkinson, Moderator: Dr. Steinmetz, the earlier contributors have concentrated on receiver architecture, switching devices, memory and feedback. Please analyse the electrical paths through which a switching command can contaminate apparently unrelated receiver channels, including grounds, power networks, inductive coupling and conducted impulses.

Charles Proteus Steinmetz, Fifth Principal Contributor: Dr. Atkinson, the physical route of a transient is not restricted to the intentional signal conductor. A control switch releases electrical energy in a wiring network which includes return paths, shared impedance, capacitance to adjacent conductors and magnetic linkage. The receiver's front end may be carefully

Copyright 2026, James M. Atkinson

filtered at its nominal RF connector yet still respond to disturbances entering through supply leads, a digital control harness or the shielding of a cable. The relevant circuit is a three-dimensional arrangement of currents and fields, not the simplified block diagram in which every ground is one zero-potential node. A transient observed at the digitiser may be created upstream, downstream or by a common disturbance reaching both.

If a branch inductance L carries current I, its stored magnetic energy is $E_L=(1/2)LI^2$. At L=100 microhenries and I=20 milliamperes, the stored energy is 20 nanojoules. That figure is modest, but a rapid interruption can develop a significant voltage across parasitic impedances because $v_L=L\,dI/dt$. If a 20-milliampere current were forced to change within 100 nanoseconds through the idealised 100-microhenry element, the magnitude of the ideal inductive voltage would be 20 volts. Such a scenario is physically self-limiting and would trigger breakdown, parasitic capacitance charging or other nonideal behaviour; it is not a prediction that a real receiver reaches that voltage. Its purpose is to show why current paths and protection networks determine the pulse, and why naive application of an ideal rate of change cannot replace measurement.

Shared ground impedance is another route. A switching control current ΔI passing through a common return impedance Z_g causes a disturbance $\Delta V_g \approx Z_g \Delta I$ in an appropriate linear frequency-domain approximation. A few milliohms can matter to low-level phase-sensitive circuitry when the disturbance has a broad spectrum and when the reference plane itself is moving relative to other nodes. The system should be examined for control-current loops, shield termination, supply-return routing and local decoupling. A high-frequency return current does not necessarily follow the

Copyright 2026, James M. Atkinson

neat direct-current ground route imagined by the wiring diagram; its impedance and associated electromagnetic fields determine the effective path. A shield which is adequate for one coupling mechanism may still allow noise through a connector aperture or common power route.

Capacitive coupling introduces charge without a metallic contact. For two conductors with mutual capacitance C_m, the displacement current from a control step may be approximated as $i=C_m\, dV/dt$, provided the lumped approximation is appropriate to the geometry and frequency range. A five-volt edge rising in ten nanoseconds through one picofarad yields an instantaneous ideal scale of 0.5 milliampere. The waveform and its actual destination depend upon return impedance, distributed geometry, switching slew and the measurement probe. It is therefore possible for a control lead carrying no intended RF information to inject a short pulse into the first amplifier or the ADC reference. A frequency-domain picture will distribute the transient according to its shape and the analysis window; a spectral peak is not thereby a continuous external carrier.

A real measurement should proceed from a controlled test hierarchy. With the input correctly terminated, switch the preselector and compare the raw output with the control edge, supply-current waveform and local reference. Change only the switching destination, then vary the slew or the supply decoupling under an authorised laboratory setup to see whether the apparent RF pulse changes predictably. Next use a separated power source or a differently routed control return, taking care not to introduce unsafe grounding conditions. If the disturbance follows a return path rather than the antenna input, the internal-coupling explanation gains support. A probe

Copyright 2026, James M. Atkinson

attached to a high-impedance node can itself create a new return path, so its effect must be measured or bounded.

The enclosure is part of the circuit. Slots, seams, connectors, ventilation openings and cable penetrations support different common-mode and differential-mode currents at different frequencies. A local current loop near the filter bank may radiate into the receiver's own antenna lead while the nominal RF input remains physically connected. A line that disappears when the external antenna cable is removed might therefore be an internal disturbance which had been using the cable shield as a radiating or receiving conductor. It does not follow that every cable-sensitive feature is an external emission. To discriminate causes, use lawful near-field scanning, cable-current probes and input substitutions in a controlled environment, while recording that each substitution changes circuit boundary conditions and may change several coupling pathways at once.

Electrical and mechanical time scales must be distinguished. A control-current spike may last microseconds, a resonant circuit may ring for tens of microseconds, and an oscillator or gain loop may recover over milliseconds. A waterfall integrating over a longer analysis window may turn these physically separate episodes into one apparently coherent burst. By measuring the time-resolved sequence, the investigator can test whether an initial conducted spike excites a later resonant response or whether an independently varying source persists after the control event. A result which agrees with the switching schedule is evidence of correlation; direct tests of source-off conditions and alternate control paths are needed for defensible causal attribution.

Copyright 2026, James M. Atkinson

For numerical example, consider a 10-millisecond dwell and a measured three-millisecond interval during which switching and coupled recovery exceed the declared acceptance tolerance. The nominal dwell is ten milliseconds, but valid observation time is seven milliseconds. If the controller revisits a band every 100 milliseconds, the valid coverage occupies only seven per cent of the overall cycle, not ten per cent, ignoring additional missing samples and overlaps. An external four-millisecond burst could be entirely outside the valid window. If the operator only records detections and not invalid states, later reviewers cannot distinguish an actual absence from a period of measurement blindness. The proper duty figure requires hardware evidence of switching times, not just software schedules.

Finally, a corrective hardware alteration should be verified as a system change, not celebrated because one spur has vanished. Added decoupling may suppress a fast pulse but extend a low-frequency recovery. A different ground arrangement may reduce one common-mode path while introducing another. Slower edges can reduce high-frequency interference but reduce scanning speed. An isolator can improve source and load separation but impose insertion loss which harms sensitivity. These are engineering trade-offs, and an improved time trace must be compared with amplitude, phase, selectivity, dynamic range and missed-event performance under the same declared conditions.

The appropriate forensic statement is therefore constrained by the full switching circuit and the actual tested reference planes. A switched preselector can produce a false spectral feature through electrical feedthrough, excite a transient through filter memory, make a genuine burst invisible through a blind interval, and leave longer recovery after an

Copyright 2026, James M. Atkinson

overload. The examiner should separate these effects experimentally. The more meticulous account of an electrical disturbance may be less dramatic than a claim of an unknown transmission, but it is precisely that measured restraint which makes a technical security report trustworthy.

Herbert Kroemer, Peer Question: Dr. Steinmetz, the electrical-coupling examples suggest that a narrow control-current pulse can be transformed into a more extended RF disturbance by resonant wiring or an amplifier's nonlinearity. How should the field engineer distinguish a direct control pulse from a later resonance or supply-recovery process when the only accessible data are complex receiver samples and a limited number of external state logs? Suppose the control edge and a weak spectral line share a reproducible delay, but the instrument's internal design is unavailable. At what point may one responsibly call the line receiver-associated rather than externally transmitted, and how could a test avoid creating the fault by attaching a probe or changing the shield termination? I would also welcome a quantitative interpretation of a timing cross-correlation when both events are periodic, because identical periods can produce apparently impressive correlations without uniquely identifying their cause. Could the same cross-correlation peak survive when the filter branch is replaced by a passive through-path, and what would that comparison say about causality?

Charles Proteus Steinmetz, Response: Professor Kroemer, begin with the observations actually available. A reproducible delay between switching commands and a received transient is evidence of temporal association. When both are periodic it is not proof of unique causation: any process synchronised to the common schedule can produce high correlation, and a local external test transmitter might even share that schedule. The

Copyright 2026, James M. Atkinson

investigation should vary the switching period, order of visited bands and relative timing independently of any known source. If the transient follows those changes and appears under a legitimate terminated-input or source-off condition, the evidence for instrument association improves. One should avoid claiming which inaccessible component caused it unless additional measurements support that attribution.

A short impulse can excite a longer response because a resonant circuit stores energy, while an amplifier or regulator can take time to recover. Time-resolved output may show an initial broadband component and a damped oscillation after it; a longer FFT window can compress both into a narrow spectral feature. Compare the observed decay time and frequency when switch direction, load and power supply condition change. If resonance changes with a known substitution of cable or termination, that points towards a coupled physical path. Yet the substitution changes boundary conditions, so alternative explanations must remain in the report until constrained by further tests. A control event entering a cable shield is still instrument-related even if removing the external cable makes it disappear.

With inaccessible hardware, the test can remain non-invasive. Use an independent reference receiver at a separate power and clock source to observe the same environment, and record its raw samples. Change the first receiver's band-switch schedule while holding the antenna and environment as stable as possible. If a feature appears in the first receiver only and follows its internal command schedule, that is strong evidence of an

Copyright 2026, James M. Atkinson

apparatus-associated artefact; if the independent receiver also observes the event on an unchanged tuning path, an external cause becomes more plausible. The comparison is not infallible because the two receivers may differ in sensitivity and coupling. The report must include detection thresholds and explain any common dependencies.

Quantitatively, a high cross-correlation coefficient is conditional on the chosen time series and their shared structure. Periodic pulses can produce regularly repeated correlation peaks, so the analyst should inspect whether the response tracks independently varied delays rather than just fixed-period coincidence. Record all tested schedules, including failed attempts and source-off periods. A safe probe may be used only when its input impedance, capacitance and return path are appropriate and demonstrably do not change the effect materially. When such evidence is unavailable, an instrument-associated classification can be qualified by the observed controls, but a specific internal fault should remain a hypothesis rather than a finding.

Hendrik Wade Bode, Cross-Peer Question to Antony Hewish: Dr. Hewish, your coverage analysis builds valid time intervals after hardware transitions, but it presumes that the method deciding a sample is valid has itself been established. A digital filter's output can depend on input samples before a switch, and the set of samples used by a time-frequency estimate may extend across several apparently valid frames. Suppose the hardware selection flag changes at one sample index, the analogue response has a decaying memory, and the decoder uses an overlapping block transform. Would it not be necessary to propagate an interval of measurement

Copyright 2026, James M. Atkinson

invalidity through the complete causal support of every estimator? I ask you to describe how one would compute such an interval without pretending that all relevant impulse responses have finite duration. What evidence permits an operationally useful tolerance-based boundary, and how should a claim of successful intermittent-signal coverage change when the relevant source may appear entirely during the excluded support?

Antony Hewish, Cross-Peer Answer to Hendrik Wade Bode: Professor Bode, the correct object is indeed the support of the measurement, not a single timestamp attached to a processed sample. For a finite-impulse-response digital filter with N nonzero taps, an output sample at index n depends upon input samples over a known range of indices, for example n−N+1 to n under a causal convention. If any of those input samples lie inside an interval where the analogue chain was unqualified, the derived output inherits that qualification unless a specific analysis demonstrates that their influence is negligible under the declared error criterion. An overlapping FFT window similarly draws upon all its contributing input samples. A software interface that labels only the window centre as valid can therefore be misleading if its support crosses a switching boundary.

An analogue response ordinarily has a theoretically decaying tail rather than a compact finite support. The practical cut-off must be based on the measurement objective. A complex impulse response can be measured with a known input family, and a bound can be placed on the residual influence after elapsed time T for the relevant amplitude, phase or event-detection criterion. This is a tolerance-based claim, not an assertion that the physics has become identically zero. The chosen bound should include the

Copyright 2026, James M. Atkinson

uncertainty of the calibration, repeatability across switching directions, input levels and environmental conditions. If the receiver changes its filtering coefficients, a new support analysis is needed. An arbitrary fixed blanking value is not equivalent to a demonstrated bound.

For an event search, coverage should be represented at the level of the source class being tested. A short burst requires enough consecutive valid input support for the detector to meet its stated sensitivity and false-alarm requirements. A longer coded signal may tolerate missing symbols or recover with uncertainty if its error-correcting or correlation structure permits, but the claim must be tested rather than assumed. Where the signal could lie wholly in an excluded interval, the system has no evidence for absence. Randomised schedules may reduce consistent alignment with periodic unknown bursts under stated assumptions, yet they do not create continuous coverage. Parallel settled paths or a sufficiently broad simultaneous receiver are stronger options when the mission demands assured observation of short events.

I would retain two representations side by side: the immutable hardware timeline with all measured selection and acquisition states, and the derived eligibility intervals for each named estimator and waveform family. A reader can then see which samples physically existed and which were trusted for a particular conclusion. If a revised model changes the settling bound, the derived eligibility can be recomputed without rewriting the raw observations. This practice prevents a signal-processing choice from silently

Copyright 2026, James M. Atkinson

manufacturing evidence of receiver coverage which the front end never supplied.

John Daniel Kraus, Cross-Peer Question to Harold Stephen Black: Mr. Black, your controller-state model is admirably comprehensive, but I question whether every channel can be assigned one unambiguous validity flag. A narrow weak signal near a filter edge may suffer substantial group-delay distortion while a stronger centre-band tone meets the amplitude criterion. A signal entering from a mismatched antenna may alter amplifier loading and AGC behaviour. If the controller reports a single 'settled' state, what does that status actually warrant across frequency, amplitude and waveform classes? How should the acceptance scheme prevent the worst-case or untested source from being averaged away by a large number of successful easy trials? I also ask whether the validity condition should be fixed before an engagement rather than adjusted in response to a later suspected signal, where retrospective tuning of acceptance criteria could undermine forensic reproducibility. Please include the special difficulty of preserving these criteria when firmware automatically changes both the gain profile and decimation factor at the band boundary, thereby changing the meaning of the processed sample.

Harold Stephen Black, Cross-Peer Answer to John Daniel Kraus: Professor Kraus, the single Boolean flag is convenient for controlling acquisition but inadequate as a universal metrological statement. It should represent at most that a defined set of prerequisites has been satisfied for a declared measurement class. More precise systems can retain an eligibility vector or a performance envelope indexed by band, signal level, waveform bandwidth and time since the last switch. A narrowband continuous tone at the centre

Copyright 2026, James M. Atkinson

of the passband may require little group-delay fidelity, whereas a burst whose onset time is material to localisation requires substantially more. A hardware condition may be necessary for all measurements without being sufficient for all. The derived eligibility must therefore carry the application identifier and its test criteria.

For validation, define critical strata before trials begin. They should include the weakest intended signals, passband edges, switching directions, representative blocker levels, temperatures and any signal durations that drive the decision. Test each stratum with a known source and retain its failures separately. A pooled success percentage is not an adequate replacement for a failed critical condition, particularly where the search seeks to support a negative finding. An untested combination should remain explicitly unqualified rather than be assigned the performance of a neighbouring, easier condition. A model may interpolate within a characterised domain, but the uncertainty of that interpolation and its validation should be recorded; extrapolation beyond the tested domain needs fresh evidence.

The validation policy should normally be fixed before the operational observation. Specify how an acceptable detector threshold, false-alarm condition and time-to-settle criterion are measured, and how they will be challenged. If subsequent evidence reveals a defect, one may revise the analytical model, but the old result and the reason for correction must remain available. The new criteria should be subjected to independent tests and documented as a new version. The original raw samples and state

Copyright 2026, James M. Atkinson

records must remain immutable. Without this separation, an analyst could shift the valid window after seeing a desired conclusion, producing an appearance of rigour without independent constraint.

The system can also report several categories instead of one pass/fail: raw sample retained, physical acquisition confirmed, receiver state settled for continuous-tone amplitude, receiver state settled for short-burst timing, and inference externally corroborated. Those categories are not all guaranteed by the same sensor. Such a design may look less tidy on an operator's screen, yet it provides stronger assurance when observations are later challenged in an engineering review or court. We should prefer explicit limitations to a universal green light whose meaning changes silently across applications.

Edwin Howard Armstrong, Cross-Peer Question to William Redington Hewlett: Mr. Hewlett, I accept that a switch can inject electrical energy directly, but an operator might use the terminated-input transient as proof that every line seen after retuning is internal. Suppose the same receiver also admits a genuine weak burst whose arrival overlaps the switching interval. How can one disentangle superposed external information from the switch pulse if the front end is changing gain and phase at the same time? Is subtraction of an averaged source-off transient a defensible correction, or does it risk concealing a real signal and producing an artificially clean record? Please examine the conditions under which such a subtraction would be identifiable, and state how a report ought to preserve the original observation when an artefact template is used in subsequent analysis. I would insist that the operator report the uncertainty of such

Copyright 2026, James M. Atkinson

compensation at the faintest accepted input level, not merely its average success with strong and easily distinguished test bursts.

William Redington Hewlett, Cross-Peer Answer to Edwin Howard Armstrong: Professor Armstrong, superposition is a powerful approximation only when the relevant system is linear, stable and in a repeatable state. In a settled linear path, one might model the observation as an external response plus an additive switching artefact. An averaged source-off template could then help characterise or perhaps estimate the unwanted component. But during transition the system is generally time varying; a strong off-band blocker may cause nonlinear gain recovery; and the artefact can depend upon load, temperature, supply state or switching history. Subtracting a single average waveform without verifying these conditions can suppress genuine signal energy or leave a misleading residual that looks new and external.

The experiment should therefore include controlled source-off trials to measure the artefact distribution, source-on trials with several known signals and levels, and trials with the input signal arriving at varied delays relative to the switch. Preserve all raw samples. Fit the proposed subtraction or compensation method on one subset of trials and verify its performance on a withheld subset. A method that works only for a single easy input or one temperature is not a general correction. A compensation algorithm must report its uncertainty and residual artefacts, and it should flag intervals where the model cannot distinguish a genuine short signal from the switching impulse.

An additional challenge is identifiability. If the external burst and the switch

Copyright 2026, James M. Atkinson

pulse occupy the same time and frequency support, and no independent observation or strong waveform prior exists, there may be multiple compatible explanations for the output. This is not a failure of ingenuity; it is an information limit of the measurement. The investigator may recover a bounded estimate or say that the event is indeterminate. The raw waveform should be retained with the switching markers, while any template-subtracted trace is presented explicitly as derived analysis, not as a newly observed physical signal. Time-domain correlation with an independent reference receiver or a known controlled emitter can strengthen the separation, but the independence assumptions must be documented.

There is a final policy distinction: online suppression of a known false alarm is an operational choice, whereas the forensic record of what the hardware captured is evidence. A receiver may choose not to alert during a measured blind interval, yet it must not erase that interval or relabel a compensated waveform as if no transient occurred. The suppression criteria should be versioned and tested against legitimate signals, especially near the detection threshold. The proper result is either demonstrated performance for a stated signal family, an honestly qualified interval, or a remaining ambiguity. It is never appropriate to infer absence merely because a numerical cleaning method makes the display quiet.

Charles Proteus Steinmetz, Cross-Peer Question to Lord Rayleigh: Lord Rayleigh, the practical testing of a preselector necessarily employs instruments and probes which have their own impulse responses. A fast switching edge may be seen as a brief peak on one oscilloscope and as a longer damped disturbance on a spectrum analyser, while a supply-current

Copyright 2026, James M. Atkinson

monitor may add impedance to the path being tested. How should the reviewer establish which timing and amplitude measurements are sufficiently trustworthy to support an inference about receiver settling? I wish particularly to challenge the assumption that the quickest observed transient is the decisive one. Could a tiny residual after a much larger pulse matter more to a weak-signal receiver, and how should uncertainty and instrument loading affect the chosen invalid window? Please also explain whether repeated measurements with one apparatus constitute independent corroboration when that apparatus shares timing and filtering artefacts with the receiver under test.

Lord Rayleigh, Cross-Peer Answer to Charles Proteus Steinmetz: Dr. Steinmetz, measurement validity must be established at the relevant scale of the claimed decision. A short large pulse and a long small residual can have different operational significance: the large pulse may create an obvious alarm that can be recognised as internal, whereas a residual near the weak-signal threshold can contaminate a more subtle measurement for longer. The appropriate settling boundary is therefore not necessarily the time at which the largest oscillation disappears. It is the time at which all the relevant residual errors have fallen below the application-specific, independently verified tolerances for the required observation duration. That statement includes noise, phase and detection performance, not merely a voltage waveform measured at one circuit node.

The timing witness requires its own calibration. An oscilloscope's front-end bandwidth and trigger placement can distort pulse amplitude and timing; a current probe can add burden or have inadequate high-frequency response;

Copyright 2026, James M. Atkinson

a spectrum analyser integrates over its chosen resolution bandwidth and sweep or FFT time support. Use instruments with sufficient bandwidth, declared rise-time characteristics and reference clocks, then check the combined measurement chain with a known calibration edge or waveform. An uncorrected probe delay can bias the relative timing between the select command and RF recovery. Where two instruments share a reference, their timing errors may be correlated; repeated records from them should not be treated as independent confirmations merely because many files were saved.

Probe loading should be challenged by comparing measurements made with and without the probe, using a second less invasive method where practical. If attaching a test lead changes the pulse, the finding is about the probed configuration unless an appropriate correction or bound is justified. Current probes and differential voltage probes can reduce some intrusion, but their placement and frequency response are still consequential. An excellent metrology report declares reference planes, calibration uncertainty, instrument loading and source-to-sensor timing. It is not acceptable to quote an apparently exact switching delay in nanoseconds when the propagation and trigger offsets between channels are unknown.

The operational threshold should be assessed at the minimum significant event level as well as under comfortable laboratory signals. A residual only one per cent of a large switch pulse may nevertheless exceed the weak-signal threshold by orders of magnitude, depending on the circuit and detection rule. Repeating the same test under different switch directions,

Copyright 2026, James M. Atkinson

levels, temperatures and load conditions can reveal whether the residual is stable or state dependent. A statistically tight spread in one unchallenged configuration is not assurance against a systematic flaw. The correct final conclusion is conditional on a calibrated measurement model and an explicitly stated operating range. Where the residual remains uncertain, extend the exclusion window or qualify the event rather than invent certainty.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel distinguishes physical switch-control energy, filter-memory relaxation, local-oscillator and gain-loop recovery, and processing artefacts produced when time-frequency windows cross an invalid transition. A preselector can improve image rejection while degrading temporal coverage; it can briefly conceal a genuine weak burst, generate a pulse under terminated-input conditions, or induce an apparent frequency shift when several loops recover together. The correct acceptance criterion is not merely that a band was selected, but that amplitude, phase, dynamic range, noise and source-specific detection performance met declared tolerances at a documented sample index. Five principal contributors, seven peer examinations and four reciprocal cross-peer challenges have addressed distinct causal hypotheses and challenge tests. The resulting dialogue is fictional educational reconstruction, not historical speech. Final scholarly acceptance requires separate verification of claims, calculations, contributor records and source-to-claim citations.

QUESTION 065. SOURCE REGISTER AND EDITORIAL LIMITATIONS

1. Keysight Technologies, Spectrum Analysis Basics, Application Note 150 (5952-0292), current publicly available PDF:

QUESTION 066

Copyright 2026, James M. Atkinson

How do clock feedthrough and oscillator harmonics traverse an instrument enclosure?

HISTORICAL METHOD. The moderator uses the documented fields of deceased engineers and physicists to organise a present-day technical examination. References to contemporary high-speed digitisation, digital serial interfaces or computerised spectrum recording represent editorial applications of physical principles, not claims that the named contributors designed or operated such equipment.

Dr. James M. Atkinson, Moderator: Professor Kroemer, our receiver has a shielded analogue front end and a separate digital clock distribution board. Yet narrow lines continue to emerge in the displayed spectrum at intervals related to the sample frequency. I should like the panel to follow a specific disturbance from its oscillator, through its conductors and fields, into the sensitive measurement chain. Please distinguish the electrical source from the propagation mechanism and from the later operation of sampling and Fourier analysis, so that a surveyor does not mistake an artefact of his own instrument for a transmission in the room.

Herbert Kroemer, Principal Contributor: Dr. Atkinson, the first deception is to assume that a clock, because it performs a numerical function, has merely numerical consequences. The oscillator produces an electrical waveform, and its output transistor or logic buffer conducts physical currents whose timing, amplitude, slew rate and symmetry are never ideal. An ideal sinusoid at frequency f_c has one spectral component; a practical square-like waveform possesses harmonics at integer multiples $n f_c$, with amplitudes shaped by duty cycle, finite rise time, termination, and the

Copyright 2026, James M. Atkinson

transfer function of its drivers. A clock line also changes electric potential relative to neighbouring conductors, driving displacement current through their parasitic capacitances. Neither the nominal shield nor the software's description of a clock changes those facts. The first task is to identify the complete current loop, including where its return current actually travels at each relevant harmonic frequency.

The harmonic content of an ideal fifty-per-cent-duty bipolar square wave is proportional to 1/n for odd positive n, and is zero at the even harmonics under the ideal symmetry assumption. That textbook result is not a promise about a real converter board. An offset, an asymmetric duty cycle, an uneven rising and falling edge, or nonlinear driver loading introduces additional products. A short edge also generates energy far above the nominal clock frequency. For a useful first estimate, a transition with ten-to-ninety-per-cent rise time t_r has substantial spectral content on an order-of-magnitude scale around $0.35/t_r$, although that relation depends on the assumed waveform and does not establish a universal cut-off. For t_r equal to 1 ns the corresponding bandwidth scale is 350 MHz. The harmonic frequencies are determined by periodicity; the edge speed sets an envelope, not a set of independent new clock frequencies.

Consider a sampling clock at 40 MHz with a 1 ns edge. Harmonics of the repetitive switching waveform may occur at 80, 120, 160 MHz and higher, according to symmetry and circuit response. If a sensitive receiver tuned near 120 MHz reports a stable line, it is tempting to assign that line to a source outside the enclosure. Yet if a shield seam, supply impedance or clock-to-analogue capacitance admits the third-harmonic current, the feature can originate entirely inside the measuring instrument. A shielded

Copyright 2026, James M. Atkinson

termination at the antenna socket is therefore a useful control, but it is not sufficient proof of a unique coupling path. The termination changes the port boundary while leaving common-mode paths along the chassis, power cable, Ethernet or USB leads. The component may disappear because the port condition altered an internal resonance; alternatively it may remain because the clock couples after the antenna input.

A capacitively injected current can be estimated as $i_c(t)=C_m d[v_c(t)-v_a(t)]/dt$. Here C_m is the mutual capacitance between a clock node and an analogue node, v_c is the clock-node voltage, v_a the victim-node voltage, and the derivative describes their time-varying potential difference. Suppose a controlled experiment establishes 0.2 pF of effective coupling and a 1 V edge completed in 1 ns, while victim motion is small. The illustrative peak displacement current is then approximately 0.2 mA during that edge. Its duration is brief, but when passed through a frequency-dependent impedance and repeated millions of times each second, it can establish a coherent spectral line. The calculation must not be mistaken for a measured circuit current. Effective capacitance, edge profile and return geometry require actual verification.

The semiconductor junction creates further complications. When an amplifier is driven beyond its linear range by a strong internally injected harmonic, its output may contain additional harmonics and intermodulation products not present as separate emissions at the oscillator. Let an imperfect nonlinear stage be approximated by $y=a_1 x+a_2 x^2+a_3 x^3$, where each coefficient has units consistent with the input and output. A clock leak at f_c and a genuine input at f_s can yield products near f_s plus or minus f_c and at further combinations. Merely seeing an

Copyright 2026, James M. Atkinson

apparent signal displaced from the clock does not exonerate the clock. The proper experiment adjusts one independent stimulus at a time, observing whether the new products translate according to the algebra of mixing and whether the change is reproducible under a fixed gain state.

We must distinguish an oscillator harmonic radiated into space from a harmonic that passes by conduction through the apparatus. A board may inject a disturbance into a voltage regulator through finite supply impedance, into the sample clock through a shared buffer, into the RF input by capacitive feedthrough, or into a shield by a common-mode displacement current. Those routes differ in their response to local shielding, cable movement, frequency shifts and temporary isolation. A spectrum analyser alone displays a resulting voltage or power estimate. It does not identify the topology that created the voltage. Forensic interpretation demands a directed causal experiment in which clock frequency, buffer state, supply condition and the boundary of the enclosure are independently varied wherever safe and technically feasible.

A clock perturbation experiment should use a small, specified change in f_c only if the converter and associated processing remain in an authorised operating mode. Record the actual frequency at the clock test point, the ADC configuration, the physical RF input and the displayed line before and after the change. If a spur shifts by n times the clock adjustment, internal involvement is strongly suggested, but still not uniquely located. Frequency-agile sampling changes where a fixed external signal aliases into the acquired spectrum; therefore an externally generated tone may also move on the display when f_c changes. One should compare in physical RF frequency, sample-domain bin number and clock-harmonic order

Copyright 2026, James M. Atkinson

separately. It is a category error to treat all three coordinate systems as interchangeable.

The preservation record ought to include raw samples, clock-generator programming, actual oscillator-frequency measurement, amplitude and phase of the suspicious peak, front-end gain, cable routes, enclosure condition and temperature. A narrow line may be internally produced while a faint external transmission remains superposed. When the internally generated component is suppressed, a different spectral object can become visible. Consequently a source-off test cannot be sold as proof that the ambient environment was free of energy. It establishes the response to one controlled state. I would pass the token to those who can trace the subtle conduction paths and explain why a well-grounded instrument can nevertheless display its own clock.

Lord Rayleigh, Peer Question: Professor Kroemer, your 0.2 pF illustration is illuminating, but the voltage transition at a physically complex node is not necessarily a linear ramp, and the victim node is not held at a perfect virtual ground. An oscilloscope probe may add capacitance comparable to the very coupling you wish to characterise, while its ground lead can create an artificial current loop. How would you put uncertainty bounds around the inferred displacement current without claiming more precision than the geometry warrants? Moreover, suppose an investigator sees only the resulting FFT line, not the switching pulse itself. Does the line amplitude determine the peak current, or could several temporally different transients give similar spectral components? I ask because the apparent elegance of a single numerical result may tempt a reviewer to overlook the frequency response of the path between source and detector.

Copyright 2026, James M. Atkinson

I should also like the record to distinguish uncertainty in the coupling coefficient from uncertainty in the displayed amplitude, since the latter contains the intervening transfer function and the detector calibration, each with different limits and possible correlations.

Herbert Kroemer, Response: Lord Rayleigh, one must first state whether the objective is to estimate an instantaneous current at a defined node or merely to demonstrate a causal coupling path. The illustrative derivative formula is a constitutive relation for the displacement current associated with a defined effective capacitance and voltage difference. It becomes a numerical estimate only after those quantities and their uncertainty have been obtained. An open-air geometric estimate, a low-frequency capacitance meter reading and a fitted high-frequency coupling capacitance need not coincide. Fringing fields, nearby conductors and resonant structures make the inferred parameter dependent on the measurement arrangement. I would therefore report the assumed waveform and an interval of plausible capacitances rather than asserting that 0.2 pF is an observed constant.

An ordinary passive oscilloscope probe can disturb a sub-picofarad node and its ground connection may add appreciable inductance. A properly characterised high-impedance active probe, a minimally perturbing near-field pickup, or a designed sense structure may reduce the disturbance, but none is magically non-invasive. Repeat the experiment with two probe geometries and check whether the alleged component is stable within the declared uncertainty. If the waveform changes radically when observed, the observation apparatus has become part of the circuit. That fact belongs in the evidence record, not in a discarded notebook page. The trustworthy

Copyright 2026, James M. Atkinson

quantity may then be a bounded transfer ratio rather than a reconstructed peak current.

An FFT line is a complex Fourier coefficient after windowing, filtering, sampling and possible averaging. It does not uniquely specify the original current pulse. Different time-domain waveforms can possess the same coefficient at a chosen frequency, especially when the phases of other components are unrecorded. To infer peak current from a line one would need a known source waveform family, a calibrated transfer function, and sufficient spectral information to reconstruct the relevant portion of the transient. Even then finite bandwidth and noise impose uncertainty. In a forensic survey the more modest claim is often stronger: a controlled clock change caused a coherent change in the instrument's own apparent RF line, and that behaviour is inconsistent with treating the line as independent evidence of a nearby emitter.

Sir Edward Victor Appleton, Peer Question: Professor Kroemer, consider an instrument whose clock harmonic is conveyed not through a simple capacitance but through a common-mode current on the outer surface of a coaxial shield. The operator removes the antenna, substitutes a matched load, and still observes the line. He then declares the line 'downstream of the input connector'. But an external ambient field could excite the power lead, and the harmonic might only be a modulation or mixing partner. Could you specify a sequence of controls which keeps the input impedance as constant as practicable while distinguishing intrinsic oscillator emission, reception on unintended cables, and mixing with a genuine external field? Please explain what may be inferred when clock tuning, cable rerouting and

Copyright 2026, James M. Atkinson

an independent receiver each give partly conflicting results, for the evidence must address the ambiguity rather than conceal it.

The test should identify whether the remaining emission is coherent with the local oscillator at the measurement instant, and whether the independent receiver has an adequately characterised noise floor at that same physical frequency.

Herbert Kroemer, Response: Sir Edward, the sequence should begin with a wiring diagram and a declaration of reference planes, not with the simplistic division between inside and outside. The antenna port is one boundary, but the enclosure also has power, data, control and protective-earth connections. Their conductors can carry common-mode current even when their intended differential signals are entirely ordinary. Preserve photographs of cable routes and the initial operating state before touching the apparatus. Then repeat the suspect observation with a calibrated shielded load at the antenna port, making as little alteration as possible to the outer-conductor continuity. Where permitted, compare a second load assembly with demonstrably different common-mode impedance, because a change may expose the shield-current path.

Next measure the actual clock signal and perturb its frequency within a qualified operating range. Determine the candidate harmonic order from the physical RF frequency, not merely from a displayed baseband bin. If the line follows the clock, the internal oscillator is implicated either directly or as a mixing partner. Now change one cable's common-mode impedance with an appropriate characterised clamp or routing adjustment, documenting the precise location and preserving safety earth. A corresponding amplitude change supports participation of that cable path; it does not by itself identify

Copyright 2026, James M. Atkinson

whether the energy entered or left the enclosure. Current-probe measurements and controlled injection at known positions may provide directional evidence, but only under an explicit model.

Finally introduce an independent receiver with different clocks, power supply, cables and antenna geometry, while keeping the environmental conditions comparable. If the same physical-frequency feature remains in the independent instrument and does not track the suspect unit's clock, an external component becomes more plausible. If the line follows the suspect clock and the second receiver detects radiation near the suspect unit, the unit itself may be the external emitter for that second receiver. Conflicting outcomes need not be contradictions; they may describe simultaneous mechanisms. The conclusion should specify which source-path combinations have been excluded experimentally and which remain possible. The record is thereby more useful than the assertion that a line was either wholly internal or wholly external.

Because power delivered to a nonlinear stage may change when the antenna load is altered, the investigator should additionally verify that any inferred line displacement was not created by a different compression state. Record a stable reference tone where possible and compare its recovered gain before treating the clock-correlation test as decisive.

Dr. James M. Atkinson, Moderator: Professor Bardeen, Professor Kroemer has followed charge displacement from the clock conductor to the analogue input. Kindly examine the less conspicuous routes through bias networks, semiconductor junctions and ground-reference movement, where a line may appear without a conventional radiating antenna.

Copyright 2026, James M. Atkinson

John Bardeen, Second Principal Contributor: Dr. Atkinson, the semiconductor does not recognise the neat labels which engineers give to its pins. Its junction capacitances, finite resistances, leakage paths and bias networks respond to voltage and current in accordance with physical relationships. A clock edge can couple through a transistor's collector-base or drain-gate capacitance; a common supply impedance can move several stage bias points together; and the reference potential of an analogue-to-digital converter can change just as its sampling operation depends upon that reference being stable. The ensuing error may be additive in some regions of operation and multiplicative in others. Thus a spectral line observed at the output need not correspond to a travelling radio wave at the input. It can arise from coherent modulation of the instrument's own conversion process.

Let the analogue signal be $x(t)$, and suppose a small periodic reference disturbance produces a fractional gain modulation $m \cos(2\pi f_c t)$, with $|m|$ much less than unity. A simple model is $y(t)=x(t)[1+m \cos(2\pi f_c t)]$. For a real sinusoidal input $x(t)=A \cos(2\pi f_s t)$, the product contains two sidebands at f_s+f_c and $|f_s-f_c|$, each with ideal amplitude $m A/2$ in addition to the original carrier. This is not direct radiation from the clock. It is modulation inside the measurement chain. If f_s is absent, the simple multiplicative model yields no standalone clock line; such a line requires an additive feedthrough term, offset modulation or another nonlinearity. This distinction is experimentally valuable because the dependence on input amplitude can separate a gain-modulation artefact from an additive oscillator leak.

Copyright 2026, James M. Atkinson

The power-distribution network is not an ideal equipotential. Denote the complex transfer impedance from clock-driver current to a sensitive supply or reference node by $Z_t(f)$. A spectral current component $I_c(f)$ produces a corresponding voltage component $V_n(f)=Z_t(f)\ I_c(f)$ under the linear small-signal approximation. Z_t depends on regulator output impedance, package inductance, plane geometry, decoupling capacitors, cable resonances and the point at which each reference is measured. For example, a hypothetical 5 mA component at 80 MHz passing through a measured 0.4 ohm transfer impedance yields 2 mV at the victim node. A 2 mV reference disturbance may be negligible in one converter and intolerable in another; that judgement requires the converter's reference-transfer sensitivity and the signal level under investigation.

It is unsound to declare that replacing a capacitor will necessarily cure the disturbance. Capacitors have equivalent series resistance and inductance; their impedance ceases to decrease indefinitely with increasing frequency. Multiple decoupling elements can create resonances or antiresonances, especially in combination with the power plane and package. A clock-related line can become stronger at a particular frequency when a well-intentioned component change increases the local transfer impedance. The appropriate operation is to measure or model the network's impedance over the frequency range of concern, and to verify performance after one controlled change. One must differentiate a power-integrity improvement measured at the regulator from a reduction in the actual sensitive-node error; they are not automatically equivalent.

The return path of a nominally differential clock is also relevant. Differential signalling can reduce the field produced by equal-and-opposite currents in

Copyright 2026, James M. Atkinson

closely spaced conductors, but amplitude imbalance, skew, unequal parasitics and common-mode conversion prevent perfect cancellation. A shield, via fence or plane transition alters the return-current geometry. If the clock pair crosses a gap in a reference plane, the high-frequency return current may take a detour that enlarges the loop area and increases radiation or coupling. This is a geometry-dependent electromagnetic effect; replacing the word ground with a thicker line on a schematic does not remove it. A technician must inspect the as-built layer stack and actual connector reference paths.

There are two opposite ways for a clock to counterfeit an RF source. It may generate energy that enters the analogue chain before digitisation, in which case the raw sample contains a response to a genuine electrical disturbance inside the instrument. Or it may corrupt sampling timing or reference voltage, thereby changing the mathematical relation between the physical RF voltage and its digital representation. A third possibility is post-conversion corruption in data transfer, where periodic data errors create FFT patterns without an analogue counterpart. Each is an internal origin, but the diagnostic tests differ. A known input signal and an instrumented clock or reference node help to discriminate those cases; a shielded antenna input alone cannot distinguish them.

Consider clock jitter. For an ideal sinusoidal input of frequency f_{in} and independent random sampling-time error with root-mean-square magnitude σ_t, the jitter-limited signal-to-noise ratio is approximately $SNR_j=-20 \log10(2\pi f_{in} \sigma_t)$, provided $2\pi f_{in} \sigma_t$ is much smaller than unity and other noise is ignored. If $f_{in}=100$ MHz and $\sigma_t=1$ ps, the dimensionless product is about 0.000628 and the limiting SNR is about 64.0 dB. At 10 MHz

Copyright 2026, James M. Atkinson

with the same jitter, the limit is about 84.0 dB. These numbers concern broadband uncorrelated timing uncertainty; a coherent clock sideband requires a different phase-modulation treatment. The examiner should not cite a broadband jitter limit as proof that a particular discrete spur must exist at a particular amplitude.

A useful discrimination employs a controlled RF tone at two amplitudes while leaving the clock and gain configuration constant. If a suspect sideband scales with the tone's amplitude, multiplicative contamination becomes plausible. If a clock-related peak remains roughly fixed when the tone is removed, additive leakage or an internally generated offset mechanism must be considered. Yet saturation, AGC and quantisation can defeat that simple test, so the receiver's linear range must be established. A second test changes the sensitive supply's source impedance without altering its nominal voltage, using a qualified design modification and checking thermal stability. The forensic chain of reasoning must record which intervention changed the spur and which other operating quantities remained unchanged. I pass the token with the warning that semiconductor bias and measurement reference are physical variables, not merely support utilities.

Sir Martin Ryle, Peer Question: Professor Bardeen, your gain-modulation equation presumes a deliberately simple sinusoid and a small periodic coefficient. A practical receiver may be digitising background noise, intermittent signals and several strong carriers simultaneously, while gain control and filter selection are changing. How can an investigator test your distinction between additive leakage and multiplicative corruption without presuming that an ambient weak emitter is absent? In particular, if a

Copyright 2026, James M. Atkinson

controlled RF tone is injected, might its own interaction with the converter or the injection cable produce sidebands not previously present? I seek an evidence protocol that preserves the unmodified baseline and discriminates between the true environmental occupancy, laboratory-induced products and digital reconstruction, instead of producing an artificially tidy spectrum by substituting a very strong test signal.

Please specify how repeated test-tone acquisitions would be interleaved with untreated baseline acquisitions to disclose drift, and how a moving clock-related spur should be recorded when its Fourier bin changes during the comparison.

John Bardeen, Response: Sir Martin, the first requirement is to preserve a baseline acquisition in which the natural input connection, receiver settings and cable positions have not yet been altered. Record raw samples and all available state metadata rather than only a smoothed spectrum trace. A controlled injection is then an intervention upon a second, explicitly labelled condition, not a reconstruction of what the original environment contained. The injected tone should be sufficiently weak to remain within the demonstrated linear range of every relevant stage, with source power, coupling factor and reference-plane impedance measured as far as practicable. The investigator should inspect overload indicators and perform a modest amplitude sweep to detect any abrupt change in conversion or gain.

One can then separate the candidate peak into a family of comparisons. First measure the clock-related line with the receiver in its original baseline configuration. Second apply the known tone and determine whether sidebands appear at the predicted sum and difference frequencies. Third

Copyright 2026, James M. Atkinson

reduce the tone by a declared number of decibels and repeat the measurement. Fourth remove the tone, preserving the physical injection hardware if possible, to control for cable-path changes. Fifth make a small clock-frequency change and observe trajectories in physical-frequency coordinates. If the proposed gain-modulation sidebands obey the product model over an appropriate range and the additive line does not, the evidence favours two distinct mechanisms. It remains possible that the original environment contained another weak source superposed on both.

Noise need not invalidate the procedure, but it changes the statistical analysis. A coherent line can be extracted against noise through repeated measurements if averaging conditions, temporal coverage and window properties are recorded. A non-stationary emitter, however, may be suppressed by averaging that assumes persistence. A time-resolved waterfall and raw complex samples should therefore accompany any ensemble spectrum. The injected tone's presence must never justify editing away baseline peaks that cannot be replicated in the laboratory. Those peaks should remain documented as observations of uncertain origin. The result is a conditional classification supported by interventions, not a categorical assertion that every small line is an artefact.

The evidence matrix should retain the input-tone-off condition as a separate trial rather than subtracting its spectral estimate from the on condition without validating linearity. A published plot of a cleaned spectrum should never replace the unaltered original sample stream.

Edwin Howard Armstrong, Peer Question: Professor Bardeen, I am concerned about a failure in the logic of the matched-load experiment. An input termination can change a transistor's noise match, and a poorly

Copyright 2026, James M. Atkinson

shielded load assembly may itself act as a receiving structure through its outer conductor. Moreover, a weak oscillator harmonic can be present below the detector's threshold in one gain state and appear above it when the front end is reconfigured. How should a surveyor decide that an internal clock is implicated when the displayed line appears only under certain antenna impedances? Is this simply evidence of an external field, or can a source wholly inside the instrument have a load-dependent amplitude? Please propose a discrimination that does not require opening a calibrated enclosure or invalidating its measurement status.

I also ask that the answer distinguish an antenna-port gain change from a gain change applied after the internal coupling point, since their different responses might provide a useful discriminating test without opening the instrument.

John Bardeen, Response: Professor Armstrong, a load-dependent amplitude is compatible with either internal or external excitation. The instrument's input network can present a variable termination to an internally coupled source, modifying standing waves and the voltage transferred into the first active stage. The same load change can alter the response to a genuine external source arriving through the intended antenna port. The difference cannot be inferred from amplitude alone. A correct analysis treats the RF input and its reference shield as a multiport boundary, with the clock, power and control circuits represented as additional ports whether or not the manufacturer draws them on the user's front panel.

Where the sealed enclosure must remain intact, use external interventions that do not disturb calibration seals or protective earth. Compare two

Copyright 2026, James M. Atkinson

characterised terminations with equivalent differential impedance but different outer-shield common-mode conditions, if such assemblies are available and their properties are documented. Sweep the allowed receiver gain states and record whether the candidate line changes in proportion to the calibrated signal gain. A clock-related spur injected after the first amplifier can fail to track antenna-port gain, whereas an internal harmonic admitted before the amplifier may track it. That distinction is informative but not decisive because automatic controls and nonlinearities can make both paths look similar.

An independently clocked receiver situated nearby may detect radiation from the suspect unit; repeating that observation with the suspect unit's clock frequency changed supplies additional evidence. Conversely, a line that disappears only when the antenna is attached may reflect altered input matching rather than the absence of an internal source. Record both positive and negative controls, measured environmental noise, uncertainty intervals and the conditions that invalidate comparison. The examiner should use the phrase 'consistent with clock-mediated coupling through the instrument' when that is the evidence, reserving definitive source claims for a set of tests that actually excludes plausible alternatives. Calibration status is preserved by documenting the interventions rather than relying upon unsanctioned internal modifications.

Where controlled input attenuation is available, measuring the relative slope of the candidate component and a calibrated external reference signal across several gain settings may help locate the effective injection point. It remains an inference subject to noise, mixing and automatic-control qualifications.

Dr. James M. Atkinson, Moderator: Mr. Hewlett, semiconductor nodes explain how the disturbance enters a converter, but the distributing oscillator may have many buffers and branches. Please examine clock-tree balance, return-current architecture and the measurement of a route by which an internal component reaches several receiver channels with different phases.

William Redington Hewlett, Third Principal Contributor: Dr. Atkinson, I would begin with the clock distribution as a network whose branch impedances and propagation delays are measurable, rather than a diagram of identical arrows leading from one reference source. A source oscillator can feed a fanout buffer, differential pairs, coaxial interconnects and converter clock pins, each loading the preceding stage in a different way. The clock's nominal frequency may be identical at each destination while its phase noise, deterministic jitter, common-mode voltage and harmonic content differ substantially. A broad-band measurement of the fundamental may therefore conceal the precise high-frequency behaviour relevant to an RF spur. To follow the disturbance one must identify the physical launch point, the return conductor for each branch, and the receiver node in which contamination becomes visible.

A useful first model writes the observed spur voltage in receiver channel k as $V_k(f)=H_{kc}(f)\,V_c(f)+H_{ks}(f)\,V_s(f)+N_k(f)$, where V_c is an internal clock-related excitation, V_s an external source at the antenna reference plane, H_{kc} and H_{ks} are the respective complex transfer functions, and N_k combines unrelated noise and unmodelled terms. This is a small-signal linear representation at one frequency; its coefficients depend on the equipment state and need not remain fixed under overload. One can

Copyright 2026, James M. Atkinson

measure relative complex phase as well as magnitude under a controlled stimulus. If two channels share a clock fanout branch, their internal spurs may be highly coherent even when their antennas face different directions. That coherence is evidence of a shared influence, but it is not unique proof of internal origin because a common external broadcast can also appear coherently in multiple receivers.

There is particular danger in regarding an enclosure bond as a zero-ohm, zero-inductance point at every frequency. A connector shell may contact a panel through a narrow bracket or an oxidised fastener, and a high-frequency clock return current may traverse that junction. A milliohm DC measurement is not a full characterisation of the RF transfer impedance. Even a nanohenry has reactance $|X_L|=2\pi f L$. At 100 MHz, 1 nH corresponds to about 0.628 ohm. If a conductor carries a 10 mA coherent component at that frequency, the simple inductive voltage magnitude is approximately 6.28 mV. The numerical example assumes a lumped element at a frequency where that approximation must be checked. The enclosure itself, nearby planes and attached cable can form a distributed structure and invalidate the single-inductor representation.

When several branches are switched by independent logic, the disturbance may have both common and differential components. A differential probe across the clock pair measures their voltage difference; a current clamp around both conductors measures net common-mode current if the geometry and probe bandwidth are adequate. The two measurements answer different questions. If a cable carries equal and opposite high-frequency currents it can be a reasonably balanced differential line while still exhibiting local capacitive coupling to neighbouring conductors. An

Copyright 2026, James M. Atkinson

imbalance or imperfect return, however, converts part of the intended differential current into a current that flows on the cable shield or chassis and can radiate. Avoid equating a small differential noise waveform with negligible common-mode emission.

One must be especially careful with clock-frequency perturbations in a multi-channel converter. Moving the sample clock changes the sample interval, the aliasing relation, often the digital filters, and perhaps the local-oscillator or phase-locked loop configuration. A line that follows an altered sample rate may be an ADC interleaving product, a true clock harmonic coupled into the analogue chain, or an external signal whose digital representation changes. The investigation should log the frequency of the actual physical line using an independent, stable reference instrument whenever possible. Change only one clock setting within the hardware's qualified state and repeat the observation. If the equipment cannot tolerate a clock change, use a controlled shutdown of a non-essential auxiliary oscillator or an approved switchable clock branch, preserving a matched control condition.

A more decisive experiment measures a cross-channel transfer matrix under a known injected disturbance and compares it with the matrix inferred from the spontaneous spur. Inject at a defined service test point only when the apparatus is engineered to permit such injection. Keep the injected level below the threshold of compression, and compare phase as well as amplitude across branches. If the spontaneous line shows the same branch-to-branch ratios as the clock stimulus, the hypothesis of common clock-mediated contamination gains strength. If it instead follows antenna direction, external gain changes or independent environmental controls,

Copyright 2026, James M. Atkinson

external coupling remains plausible. The matrix does not have to identify a single fault component; it can establish an operational boundary beyond which a measurement must be qualified.

The question of a clean ground is resolved by measurement, not by an instruction to install more copper. An added braid or bond may lower impedance at one frequency while creating a new parallel loop that couples a clock current into a more sensitive region. A ferrite impedance may suppress common-mode current over a limited band but change the behaviour of adjacent frequencies. Temporary remedies must be inspected over the whole operating range and under expected thermal and mechanical conditions. The instrument's internal calibration and safety certification set boundaries for what a field investigator can modify. Often the correct outcome is to identify an invalid portion of spectrum and quarantine it rather than to repair a certified instrument without authorised procedures.

Finally, documentation should separate the source oscillator's purity, distribution-path isolation and receiver-channel susceptibility. A low-phase-noise oscillator can still produce severe coherent interference through its output driver or a poorly bonded shield. Conversely, a visibly noisy clock can be harmless to a particular channel if the transfer path is sufficiently suppressed. The operational claim must concern the spur at the receiver's actual measurement reference plane and the strength of evidence excluding external sources. This network view complements semiconductor analysis without pretending that the network diagram itself is a forensic verdict. I invite a colleague to challenge whether our test instruments can measure these small currents without constructing another path.

Copyright 2026, James M. Atkinson

Hendrik Wade Bode, Peer Question: Mr. Hewlett, your transfer-matrix proposal assumes that injection through an engineered test point approximates the spontaneous clock disturbance. A square-wave driver with multiple harmonics can excite enclosure resonances differently from a laboratory synthesiser with a comparatively clean sinusoidal output, even if the nominal frequency agrees. If the investigator obtains matching channel amplitude ratios at one frequency, could that simply be an accidental agreement between two distinct source distributions? How should phase, frequency and multiple independent experiments be used to prevent an attractive matrix fit from becoming a false identification? Please also address calibration drift and the fact that a closed-loop receiver may move between distinct gain and oscillator states during acquisition, changing the matrix while the operator believes it constant.

A declaration of repeated trials is of little value unless the frequency grid, phase reference and conditioning state have been preserved. I ask how these hidden variables can be independently checked.

William Redington Hewlett, Response: Professor Bode, agreement at one frequency and in one operating state is plainly insufficient to identify an excitation path uniquely. The injection defines a measured transfer from a specific port; it does not demonstrate that the uncontrolled oscillator excites the same spatial distribution of currents. A square wave can energise numerous modes, while an injected sinusoid samples only one frequency at a time. We can nevertheless compare the transfer functions at several harmonics and at points between them, provided the chosen injection is within the instrument's linear range. Their complex ratios and phase progressions offer more discriminating evidence than a single amplitude

Copyright 2026, James M. Atkinson

ratio, although a finite measurement set can still admit multiple physical explanations.

The instrument should be stabilised thermally before comparison, and gain, sample rate, oscillator state and any preselection state must be captured in the record. A phase measurement requires a documented time reference and calibrated cable delays. If the phase reference is not stable across measurements, report magnitude alone rather than invent coherent certainty. Repeat measurements after returning to the original state to expose drift and mechanical sensitivity. A large hysteresis between outward and return sweeps is a warning that the assumed stationary transfer model is not valid, not a nuisance to be averaged away.

One can improve causal discrimination through interventions that act differently upon the competing paths. For example, a characterisable common-mode impedance at one external lead may strongly alter a cable-mediated disturbance while leaving internal capacitive coupling almost unchanged. Rotating an antenna may affect an ambient field without materially altering a deeply internal clock-to-ADC path, though nearby metal and cable motion could complicate that expectation. The results become a matrix of hypotheses and test predictions, not a single fitted curve. If several models remain observationally indistinguishable within uncertainty, the conclusion must retain that ambiguity. The forensic duty is to prevent an apparent agreement in transfer measurements from being converted into a claim of uniquely identified provenance.

A frequency synthesiser should be monitored independently of its programme register, because command acceptance is not proof of actual

Copyright 2026, James M. Atkinson

physical settling. Any phase comparison should be rejected if the timing reference itself loses coherence between conditions.

Dr. James M. Atkinson, Moderator: Dr. Steinmetz, Mr. Hewlett has identified the physical branches of the clock network. Kindly follow the return current into an enclosure, its bonds and external cables, explaining when a nominally closed metal case behaves as part of the oscillator's radiating and receiving structure.

Charles Proteus Steinmetz, Fourth Principal Contributor: Dr. Atkinson, no enclosure can be understood without its conductors, currents and the frequency at which they operate. A metal case may give excellent electrostatic shielding at low frequency yet present a complex collection of apertures, seams and resonant cavities at high frequency. Its shielding is not a single material constant, and a foil-thickness calculation alone cannot characterise the assembled instrument. The clock source and its return conductor generate fields. At an imperfect bond or cable penetration, those fields can drive current across an unintended impedance, producing a voltage that re-enters the receiving path. Even when the metal is thick enough for strong attenuation through its uninterrupted surface, the openings and attached conductors may dominate the effective coupling.

A thin seam is not automatically a negligible aperture. Its response depends on length, width, contact continuity, field orientation and the wavelengths of interest. A narrow but electrically long gap can couple strongly to the appropriate field component. Conversely, a relatively broad opening may be less troublesome at a sufficiently low frequency or under an unfavourable polarisation. The test must not be reduced to the existence of a visible hole. For a frequency of 300 MHz in free space, the corresponding wavelength is

Copyright 2026, James M. Atkinson

approximately 1.00 m using c≈3.00×10^8 m/s. The half-wavelength scale is about 0.50 m, but the effective dimensions inside a dielectric-loaded cavity or along a slot can differ. The computation is an illustrative dimensional comparison, not a prediction of a particular cabinet resonance.

There are two paths by which a clock may travel outside the enclosure and return. The first is direct radiation from a seam or protruding conductor and subsequent reception by the apparatus's intended antenna. The second is conducted common-mode current along a supply or data cable, whose external portion can act as an antenna and excite fields near the input. A third mechanism is local magnetic or capacitive coupling between an internal clock cable and the input stages without involving the remote environment at all. These mechanisms can coexist. They are experimentally separable only if the investigator changes the relevant geometry or boundary without simultaneously changing every other condition. Simply wrapping the case in extra foil may alter several current paths and obscure rather than identify the cause.

An enclosure bond has a DC resistance and an RF impedance. At frequencies where the conductor's physical dimensions are not negligible, voltage and current can vary along the metal surface. The familiar lumped expression Z=R+jωL is useful for a short bond if the approximation holds, but it cannot replace a distributed-field model for an electrically large assembly. One can use a near-field magnetic loop to identify local current patterns or a calibrated common-mode current clamp to measure cable current, noting that each probe has limited bandwidth and spatial resolution. Mapping a field maximum is not the same as locating the original oscillator; resonances

Copyright 2026, James M. Atkinson

may create maxima far from the energy source. An examiner must record probe orientation and position if results are to be compared.

The role of protective earth requires particular restraint. No field experiment should lift a safety earth or deliberately defeat protective bonding merely to make an RF line disappear. One can instead employ approved isolation methods, differential measurement, fibre-optic data links or characterised common-mode impedances where these are compatible with the equipment's safety and calibration requirements. A battery-powered independent receiver may help establish whether the suspicious line is emitted by the instrument itself, but the new receiver also has clock and cable artefacts. Every altered configuration needs its own reference measurement. When the test affects cable geometry, compare the time history to detect whether an environmental source changed concurrently.

The relation between shielding effectiveness and power reduction must be stated carefully. A voltage or field attenuation of A_dB=20 log10(E_before/E_after) uses a consistent field quantity, position and impedance context. If the field amplitude decreases by a factor of ten, the level difference is 20 dB. Power ratios instead use 10 log10(P_before/P_after), giving the same 20 dB for a hundredfold power reduction under comparable conditions. One cannot apply a shield's advertised 60 dB figure directly to a measured spur without knowing the test field, coupling configuration and location. An instrument may have different shielding effectiveness with every connector and lid screw properly fitted than it does with one maintenance panel open.

A useful experiment proceeds from the least invasive to the more complex. Capture the baseline raw spectrum and a concurrent near-field or cable-

Copyright 2026, James M. Atkinson

current observation, retaining the same clock and acquisition settings. Reproduce the suspect feature under a characterised antenna-port termination. Measure relevant clock harmonics with an instrument independent of the suspect sampling system. Where service access is permitted, inspect mechanical bonding and shielding continuity using approved procedures; do not deform seams or disturb calibration seals in the name of investigation. Then move one external cable within a controlled fixture and record any change in common-mode current, nearby field and receiver artefact. Interpret correlation among those measurements, not the behaviour of one trace in isolation.

A clock-synchronous line does not imply that the clock source radiates enough energy to threaten a distant site. The level recorded inside the instrument may be the product of strong local coupling and exceptionally sensitive internal detection. Conversely, a weak internal perturbation can become conspicuous after a high-gain stage or coherent spectral averaging. We therefore need two separate descriptions: emissions measurable outside the case under defined conditions, and susceptibility of the instrument's own receiver chain. Their regulatory, engineering and forensic meanings differ. Shielding design may improve one without proportionally improving the other. I submit that a disciplined boundary test is indispensable if a negative surveillance search is to retain evidential value.

George Ashley Campbell, Peer Question: Dr. Steinmetz, your account rightly treats a cable and enclosure as a distributed structure. Suppose an operator discovers that moving a power lead by twenty centimetres alters a clock-related line by fifteen decibels. He immediately concludes that the lead was the source and prescribes a ferrite clamp. But a nearby receiver

Copyright 2026, James M. Atkinson

antenna may see a changed multipath environment, and the cable motion may change the mechanical loading of a connector. What combination of current measurement, field mapping and controlled impedance changes would justify a claim that common-mode propagation on the lead caused the effect? Would the conclusion remain warranted if the ferrite improves one spectral region but worsens another, or if the reported fifteen-decibel improvement disappears after the case warms?

In particular, what objective change must accompany an observed decrease in the spur before the investigator may claim that the suspected lead is an established coupling path rather than merely a movable scatterer?

Charles Proteus Steinmetz, Response: Mr. Campbell, cable movement is an intervention with many possible consequences. The observed fifteen-decibel difference is a fact about a particular configuration; it is not by itself an identification of the current path. Begin by fixing the antenna and the receiver in a repeatable mechanical geometry, then move only the lead using a measured fixture. Record the line's physical RF frequency, amplitude, receiver gain and clock state before and after motion. Use a calibrated common-mode current probe around all conductors of the lead together to measure net current, while ensuring the probe has adequate response at the suspect frequency. If the observed current changes coherently with the receiver line, the cable-mediated hypothesis gains support, but correlation still leaves alternative coupling paths possible.

A second test inserts a characterised common-mode impedance at a documented cable position without defeating safety or affecting normal power delivery. Measure both the current at positions upstream and downstream of the impedance and the receiver spur. A reduction in current

Copyright 2026, James M. Atkinson

accompanied by a consistent spur reduction is stronger evidence for that route than movement alone. However, if the added impedance causes a resonance, the line may increase at another harmonic. This is not a contradiction: the impedance and the surrounding distributed network are frequency dependent. The entire relevant band must be observed, and any remedy judged against receiver performance, safety and the possibility of new artefacts.

Temperature dependence requires the experiment to be repeated after thermal equilibrium, with return-to-baseline trials. Oxidised bonds, mechanical contacts, semiconductor bias and oscillator drive levels can all vary during warm-up. A spur reduction that vanishes at normal temperature is not a valid general mitigation. An examiner may properly state that the cable carries a clock-coherent common-mode current and that its controlled alteration changes the receiver's output under specified conditions. The stronger assertion that this path alone caused the original line requires enough interventions to exclude competing mechanisms within uncertainty. A well-written report should distinguish a demonstrated coupling contributor from a uniquely established origin.

A further return-to-baseline observation should follow every impedance intervention, and a repeated loss of the effect on restoration would require the analyst to revisit the assumed mechanical stability. This guards against attributing a thermal drift to a planned RF modification.

Dr. James M. Atkinson, Moderator: Mr. Heaviside, we have heard how a clock enters a semiconductor and traverses a conductor network. Please extend the argument to distributed electromagnetic fields, standing waves,

Copyright 2026, James M. Atkinson

enclosure apertures and the fundamental limits of inferring a source from a spectral line measured at a single point.

Oliver Heaviside, Fifth Principal Contributor: Dr. Atkinson, the phrase 'signal travelling through a metal box' is a convenient story, but the fields do not respect the labels stamped upon the hardware. The electric and magnetic fields are coupled through Maxwell's relations, and the relevant boundary conditions depend on the conductivity, permeability, geometry and continuity of the actual surfaces. A line visible on an internal spectrum display may be the endpoint of a sequence of fields and currents that includes a board trace, a cable shield, a slot in the enclosure, a cavity mode and the first low-noise amplifier. An equivalent circuit can clarify a sufficiently small or well-defined subassembly, but it is hazardous to force an electrically large enclosure into one unqualified lumped capacitance and one unqualified inductance.

For a uniform lossless transmission line, travelling voltage and current waves have a characteristic impedance Z_0 and propagation velocity v determined by the line geometry and constitutive materials. A load mismatch produces a reflection coefficient $\Gamma=(Z_L-Z_0)/(Z_L+Z_0)$, where Z_L is the complex load impedance. For a nominal 50-ohm line terminated in 75 ohms, $\Gamma=25/125=0.2$, corresponding to a reflected voltage-wave magnitude of twenty per cent. This example does not characterise an arbitrary enclosure seam, but it demonstrates why changing a connector or termination can alter the phasor sum at a receiver without changing the original clock source. The wavelength and physical distance to discontinuities determine the relative phase of the incident and reflected waves.

Copyright 2026, James M. Atkinson

A return current does not select the shortest route drawn on a schematic; its distribution follows the electromagnetic boundary conditions and frequency-dependent impedances. At higher frequency a current associated with a microstrip trace is strongly concentrated in the adjacent reference conductor, because that geometry minimises the field energy under typical conditions. If the reference plane is interrupted, the return may spread around the opening or couple to another plane through capacitance, enlarging the loop and increasing sensitivity. An apparent clock harmonic can therefore become larger following a board revision that moved a trace only a few millimetres. That behaviour is not mysterious. It is the consequence of changing the field configuration through which energy is stored, transported and dissipated.

The enclosure is neither an absolute barrier nor always a simple passive attenuator. An interior cavity may sustain particular field patterns, and a seam or feedthrough can convert an internal field into external radiation. Reciprocally, the same aperture can admit an external field, subject to reciprocity conditions and the details of the material. A measured resonance peak does not locate the oscillator, for resonant energy can be spatially concentrated at a point remote from the driver. Field mapping with a finite probe also perturbs what is being mapped. A robust analysis uses several locations, orientations and independent reference conditions rather than declaring that the brightest near-field point is the cause of all observed contamination.

One should distinguish three spectra. The first is the spectrum of the oscillator waveform at a defined electrical port. The second is the distribution of fields and currents through the enclosure at a specified

Copyright 2026, James M. Atkinson

operating state. The third is the numerical spectrum produced by the receiver's digitiser and processor. Their frequency axes may coincide for some components but not for all: sampling aliases a physical frequency f into an equivalent discrete-time frequency according to the sample rate f_s, while analogue nonlinearities can generate new physical frequency products before the ADC. For a real sampled sinusoid, a component near f=115 MHz sampled at f_s=100 MHz can appear at 15 MHz after aliasing under simple uniform sampling assumptions. That displayed 15 MHz is not proof of a 15 MHz emitter. One must inspect the anti-alias filters and sampling conventions before drawing such a conclusion.

The distinction is more serious when the sample clock itself is the source of contamination. An oscillator harmonic at an integer multiple of f_s can alias to direct current or a low-frequency offset when admitted through the analogue path. A change in f_s can then cause the alias trajectory to differ greatly from the trajectory of an independently fixed external source. However, if the clock leak is generated digitally after sampling, the analogue alias model may not apply. A single displacement of a line after retuning cannot decide among these hypotheses. The experiment should record samples at multiple qualified clock rates and compute predicted image frequencies under explicit assumptions, comparing those predictions with a separate measurement of the physical field or conducted voltage where possible.

The strength of a field measured close to a small conductor cannot always be extrapolated to a field at a distant point using a simple inverse-distance law. Reactive near-field components can dominate close to a source, whereas radiated far-field power and directivity follow different spatial

Copyright 2026, James M. Atkinson

relations. A survey performed with a probe millimetres from a clock trace and one performed with a calibrated antenna several metres away answer different questions. Neither measurement can be converted into the other without an appropriate model of source geometry and propagation. The evidential purpose must be stated before the measurement geometry is selected, especially when the allegation concerns an illicit external transmitter rather than the instrument's own internally circulating currents.

Finally, there is a limit to inverse reasoning. If an enclosure is an unknown multiport system with several clock, supply, shield and antenna excitations, one observed complex voltage does not uniquely determine all its internal causes. Additional independent constraints are required: clock perturbation, source termination, cable impedance changes, controlled injection, separate receivers and measurements at additional ports. Each intervention adds information only if its effect upon the system is understood and the original state can be recovered. The scientifically sound conclusion may be that a reported line is strongly associated with the instrument's clock and is unsuitable as sole evidence of an external emitter, while the exact physical coupling route remains unresolved. I would prefer that bounded conclusion to a visually persuasive but unsupported story of a signal escaping through one particular screw hole.

Harold Stephen Black, Peer Question: Mr. Heaviside, your account has a practical implication for instrument qualification. The operator might show that a stable peak moves when the sample clock changes, label it internal, and then discard the frequency interval from further examination. Yet an external transmitter could occupy that interval at the same time, and the clock artefact may be coherently masking it. How should the operator

Copyright 2026, James M. Atkinson

distinguish the task of identifying the artefact from the separate task of demonstrating useful sensitivity to a weak external signal? Can you propose a sequence of deliberate challenges, using the known-signal injection and multiple clock settings, that avoids claiming a negative surveillance result merely because the clock spur has been explained? I would also welcome the appropriate treatment of uncertainty when the receiver's detection threshold varies with its own spectral defects.

Please specify whether the confidence statement should report a per-band detection threshold, a probability of intercept under an assumed duty cycle, or a more restricted declaration of laboratory test sensitivity.

Oliver Heaviside, Response: Mr. Black, the classification of an observed line and the demonstration of detection capability must remain separate. To show that a peak is clock-mediated one studies its trajectory, coherence with the clock, and response to controlled internal-state changes. To show that an external signal would have been detected, one introduces a known weak test signal at a calibrated reference plane and observes the receiver's response through the relevant acquisition schedule. These are different propositions. An explanation of the artefact does not establish that the receiver was capable of detecting a second component of equal or lesser strength in the contaminated band.

The qualification should include a series of injected tones or realistically modulated test signals near, below and above the suspect spur frequency, with levels measured independently. The receiver must be kept in its actual search mode, including any preselector states, averaging and automatic gain behaviour. Record detection probability or a defined repeatability criterion as a function of amplitude and frequency. When the clock spur

Copyright 2026, James M. Atkinson

masks the test signal or causes a false alarm, that region should be marked as degraded or indeterminate; the fact that a skilled operator can mentally recognise the spur does not create missing sensitivity. Repeating the test at two allowed sampling rates may show whether an alternative configuration restores observability.

A negative report must describe the coverage and threshold actually demonstrated. If the receiver detects a -90 dBm laboratory challenge in a clean passband but fails at -70 dBm under a clock harmonic, it is scientifically indefensible to apply the cleaner threshold to the contaminated interval. Real source polarisation, antenna coupling and intermittent duty cycles may further reduce detection probability relative to a direct injection test. Thus a receiver may legitimately exclude a known internal artefact from an external-source inventory while simultaneously declaring a corresponding limitation in the search. The correct conclusion preserves both facts instead of allowing one to cancel the other.

It would also be prudent to repeat the detection challenge with a second signal waveform having comparable spectral occupancy but different temporal structure. A narrow continuous tone cannot establish sensitivity to every low-duty-cycle pulse or phase-coded emission.

Oliver Heaviside, Cross-Peer Question to William Redington Hewlett: Mr. Hewlett, your channel-transfer matrix is attractive because it offers numbers where an enclosure appears almost forbiddingly intricate. But I should like you to examine a case in which a clock radiates at a seam and is received both by two antennas and through two internal supply returns. The paths can combine destructively in one channel and constructively in the other, and their relative phases can change after a small cable movement. If the

Copyright 2026, James M. Atkinson

measured amplitude matrix fits a single-source model at one instant, what additional observations are needed before it may be considered stable or identifiable? I am especially concerned that unmeasured phase, a temperature-dependent connector, and the presence of two coherent harmonics can create an apparently orderly result from several distinct mechanisms. Please address how one would preserve the separate environmental and internal components, rather than choosing the neatest fitted source merely because its mathematical residual is small.

William Redington Hewlett, Cross-Peer Answer to Oliver Heaviside: Mr. Heaviside, a transfer matrix from one assumed source to several outputs cannot establish uniqueness if there are multiple coherent excitation paths that produce similar response vectors. The amplitudes at the receiving channels depend on a vector sum of complex path contributions. If one cable movement changes a phase by approximately half a cycle, two contributions can move from cancellation to reinforcement without the oscillator's amplitude changing at all. It follows that one must avoid interpreting a fifteen-decibel change at the output as evidence that the clock generator itself suddenly became fifteen decibels stronger. The measured result is a property of the source-path-receiver assembly in a specified physical state.

An adequate procedure would record complex cross-channel spectra against a stable independent time reference, when phase stability allows. Repeat with deliberately varied cable configurations and thermal states, and retain every return-to-baseline trace. Measure the oscillator harmonic at a defined electrical point to establish whether its source amplitude also moved. Independently measure radiated or conducted fields around the

Copyright 2026, James M. Atkinson

seam and supplies, but document each probe's insertion effect and spatial sensitivity. If a supposed single-source model predicts the channel response after several orthogonal interventions, it gains credibility. If it fits only one state, it remains one of several possible explanations. A model with a low residual in one state is not evidence of unique physical identity.

One can express the ambiguity by writing a complex observation vector $y=Hc+e$, where H represents a matrix of possible transfer paths, c the unknown source amplitudes, and e noise and modelling discrepancy. If H has dependent or nearly dependent columns, several different c vectors may explain essentially the same y. Singular-value or condition-number analysis can expose the instability of such an inversion, but it cannot repair missing physical information. The investigator should acquire new independent observations, preferably by selectively and safely altering one path, rather than by presenting a more elaborate inversion of the same deficient data. The decision record should state which paths are supported, which remain observationally equivalent and whether the suspected line prevents reliable detection of additional external energy.

Herbert Kroemer, Cross-Peer Question to Charles Proteus Steinmetz: Dr. Steinmetz, you have distinguished local susceptibility from external emission, but their effects can meet again at the antenna port. Suppose a clock driver at forty megahertz has a harmonic near one hundred and twenty megahertz, an external supply cable radiates that harmonic, and a nearby survey antenna receives the field while the converter also has a weaker internal capacitive leak at the same frequency. Disconnecting the antenna removes one path while leaving the other. How can a forensic investigator estimate the separate contributions if the sources are mutually

Copyright 2026, James M. Atkinson

coherent and their measured powers are not simply additive? Would a shielded termination, cable-current measurement and a change in clock frequency be enough, or is an additional phase-sensitive reference required? Please also explain how to handle the safety constraints on modifying a mains-connected instrument, since a mechanically persuasive experiment that defeats protective earth would be unacceptable evidence.

Charles Proteus Steinmetz, Cross-Peer Answer to Herbert Kroemer: Professor Kroemer, the electric fields from coherent paths must be added as phasors before the power is calculated. If E_1 and E_2 are the complex field amplitudes arriving through the intended antenna and the internal leak respectively, the measured power in a fixed linear detector is proportional to |E_1+E_2| squared, not to |E_1| squared plus |E_2| squared unless their cross term averages away under appropriate conditions. The same clock may fix their phase relationship. Removing one path can consequently increase or decrease the measured line, depending on the initial phase difference. That apparent perversity is ordinary wave superposition and should not be suppressed by a report that assumes every attenuation experiment must reduce the observed output.

Start with a reproducible mechanical configuration and an independent timing reference if stable phase measurements are technically feasible. Measure the input-port line with the original antenna and cable arrangement, then with a characterised shielded load that preserves as much of the outer-conductor boundary as practicable. Simultaneously record clock frequency and cable common-mode current. Repeat each configuration several times, including restoration of the original arrangement, because a small mechanical change can alter the field phase.

Copyright 2026, James M. Atkinson

If the instrument permits a safe qualified clock-frequency adjustment, track the corresponding harmonic's physical frequency with an independent receiver, not solely with the clocked instrument under examination. The family of responses may support a two-path model, but the inverse problem remains underdetermined if relative phases are unknown.

A controlled phase or distance change can sometimes supply a further constraint, although movement of an antenna changes real environmental coupling as well. A VNA-based characterisation of accessible paths, carefully calibrated at relevant planes, may help estimate complex transfer ratios under stationary conditions. It should not be represented as a direct measurement of every hidden internal leak. As to safety, protective earth is not a variable for casual experimental removal. Use authorised isolation hardware, battery-powered receivers or fibre data connections when suitable, and have any internal intervention undertaken under appropriate service procedures. A credible report can state that the instrument radiated a clock-correlated field and also admitted internal feedthrough without pretending to apportion the exact fractions when the evidence does not permit that separation.

William Redington Hewlett, Cross-Peer Question to John Bardeen: Professor Bardeen, your distinction between additive leakage, gain modulation and sampling-clock jitter becomes difficult in a modern converter having multiple time-interleaved sampling channels. The nominal rate may be high, but each sub-converter has its own aperture delay, offset and gain error. If an interleaving spur and an external narrowband signal coincide in the same FFT bin, the displayed amplitude can vary with input level and clock rate in a way that superficially resembles both of your

Copyright 2026, James M. Atkinson

mechanisms. How should a laboratory discriminate periodic aperture skew from clock-line radiation and from a genuine source whose observed frequency aliases? Please give a model that identifies the relevant parameters, and explain what should be measured directly rather than inferred from a single noisy spectrum. The inference must not treat a programmable correction algorithm as proof that the physical error has been removed at every temperature and bandwidth.

John Bardeen, Cross-Peer Answer to William Redington Hewlett: Mr. Hewlett, time interleaving adds a structured set of periodic nonuniformities to the sampling process. If M sub-converters acquire samples in rotation, their offset errors can generate discrete patterns related to the sub-converter repetition frequency; gain and aperture-time errors can create spurious images that depend on the analogue input. For a small aperture error δt_k in sub-converter k, a local first-order model is $x(t+\delta t_k) \approx x(t)+\delta t_k x'(t)$. Its error magnitude therefore grows with the derivative of the input, explaining why a high-frequency test tone may reveal skew much more severely than a low-frequency tone at equal amplitude. The model is linearised and should be restricted to sufficiently small timing errors.

An offset spur can persist with a nominally zero analogue input, whereas a skew-related error of the above form vanishes for a constant input and tends to depend on input frequency and amplitude. An additive clock leak can also persist under termination but may vary with buffer drive or shielding; an external source may survive in an independent receiver on a stable physical frequency. Those differences allow a structured set of tests using a terminated input, several calibrated sine-wave input frequencies, controlled amplitudes, clock-rate changes and temperature sweeps. Keep

Copyright 2026, James M. Atkinson

the analogue reference level and gain state fixed during each comparison, and retain raw samples rather than relying solely on a correction algorithm's output.

One should also inspect the periodic error signatures in the time domain. If samples are tagged or the interleaving phase is known, repeated phase-dependent offsets or gain variations can be estimated across the M sub-converters. A correction table may reduce a particular spur within its calibration range, but its validity at another temperature, sample rate or converter input frequency is an empirical question. The correct report records the pre-correction and post-correction spectra, the algorithm version, calibration data, and remaining uncertainty. Even if the spur is convincingly identified as an interleaving artefact, that diagnosis does not exclude a simultaneous external signal at the same displayed frequency. The relevant band may need independent receiver coverage to support a negative search conclusion.

A separate channel-by-channel analysis can expose whether the error scales with the numerical derivative of the input waveform, as a timing mechanism predicts, or instead follows a nearly constant additive offset. This is a physical discriminator rather than merely a convenient software label.

Charles Proteus Steinmetz, Cross-Peer Question to Oliver Heaviside: Mr. Heaviside, the enclosure may be an electrically small cavity at one clock harmonic and an electrically large, resonant structure at another. The surveyor is tempted to quantify a seam with a single shielding-effectiveness figure, perhaps measured at a friendly frequency and with the lid closed. Yet a connector shell, a cable clamp and an aperture can alter the internal field pattern even when no obvious external radiation is detected. What

Copyright 2026, James M. Atkinson

measurement strategy permits a reviewer to distinguish a defective shield boundary from a perfectly adequate enclosure that simply surrounds a sensitive internal conversion path? How would the experiment account for probe orientation, reference antenna position, near-field versus far-field excitation and the nonlinear dependence of a sampled spur upon its analogue input? I ask that the answer name the claims that cannot legitimately be derived from one quoted shielding number.

I would also distinguish resonant redistribution of a field from the generation of genuinely new spectral frequencies, since the two mechanisms invite different interventions and different proof.

Oliver Heaviside, Cross-Peer Answer to Charles Proteus Steinmetz: Dr. Steinmetz, shielding effectiveness has to be defined with respect to an excitation, field component, location and reference condition. A single figure may describe a controlled test geometry and nothing more. To investigate a suspected aperture, use a known test excitation outside the enclosure and measure the internal response at relevant points, or energise an internal test source and measure the external field, provided the equipment is intended for such testing. The two experiments are related through electromagnetic principles but not automatically numerically identical when their source and measurement geometries differ. Map several polarisation orientations and positions because a cavity mode may exhibit nodes and antinodes. A single field sample at a null can falsely suggest magnificent shielding while another point exhibits substantial energy.

To distinguish enclosure leakage from internal susceptibility, conduct a separate analogue-chain test with the intended antenna port terminated and the clock functioning normally. A spur that persists while external-field

Copyright 2026, James M. Atkinson

penetration is greatly reduced may arise through internal coupling or a cable penetration not represented by the external test. A controlled near-field scan of the closed enclosure can characterise emitted fields, but it must not be equated to the level at the ADC input. Complement it with common-mode cable-current measurements and, where service access is authorised, properly characterised internal test points. The aim is a convergence of observations across different boundaries and modalities, not a single dramatic scan.

The probe itself is part of the experiment. Record its orientation, calibrated frequency response, distance to conductive surfaces and whether a nearby cable or operator changes the measurement. At close range the field may be predominantly reactive and its amplitude may vary faster with distance than a radiating far field. If the shield works at one clock harmonic, that does not prove it works at another; if the near-field probe sees a strong local maximum, that does not prove an external transmitter is present. Equally, a clean external emission test does not prove the instrument's own ADC is immune to internal conductive feedthrough. The permissible claims are therefore conditional: shielding measured for stated excitations and positions, internal spur susceptibility under stated receiver states, and detection capability under separately calibrated signal challenges. Any untested generalisation should remain a qualification, not appear as a certified property of the enclosure.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has identified clock-harmonic generation at the output driver, displacement-current coupling at semiconductor and board nodes, shared-impedance modulation of converter references, differential-to-common-mode

Copyright 2026, James M. Atkinson

conversion in clock and data wiring, propagation through bonded enclosure structures and cable penetrations, and aliasing or interleaving errors during digitisation. The causal chain must be followed rather than guessed from one FFT peak. A proper negative surveillance search records tested clock states, input-reference conditions, cable geometry, raw samples, measured sensitivity and the frequencies at which internal contamination invalidates detection. Clock correlation is evidence for clock involvement, not proof of a unique physical route and not proof that a coincident external signal is absent. The discussion is a historical-fiction teaching device and remains subject to independent publication review.

QUESTION 067

Copyright 2026, James M. Atkinson

What connector and cable defects cause reproducible movement of receiver spectral peaks?

SCHOLARLY RECONSTRUCTION: These deceased scientists and engineers are represented in hypothetical, modern discussions of RF test instruments. Neither the words nor the contemporary experiments constitute an authentic historical conversation. All worked numerical cases are illustrative, not evidence of a particular field installation.

Dr. James M. Atkinson, Moderator: Professor Kennelly, the operator of an authorised RF survey may observe that a weak spectral peak shifts whenever a coaxial connector is re-tightened or a cable is touched, and may conclude that the putative emitter moves. A mechanical action is indeed reproducibly associated with a changed display, but causation is less obvious. Would you distinguish the physics of passive transmission-line changes from a true frequency translation, define what quantities the instrument actually measures, and design tests that separate connector discontinuity, cable electrical length and receiver-generated spectral response? I ask the panel to preserve the distinction between amplitude movement across display bins, phase displacement, modulation sidebands, and an actual shift of a source carrier.

Arthur Edwin Kennelly, Principal Contributor: Dr. Atkinson, let us begin by identifying a seemingly modest but decisive point. A fixed, linear and time-invariant coaxial line cannot change the frequency of a sinusoidal input. It changes amplitude and phase as functions of frequency, according to its loss, characteristic impedance, electrical length and mismatches. A spectrum analyser whose peak appears to migrate after a cable is bent may

Copyright 2026, James M. Atkinson

be seeing a time-varying line during the motion, a changed interference pattern between paths, a signal near the threshold of a bin-selection algorithm, a source or receiver oscillator perturbation, or a change in the transfer response which selects a different component of a composite spectrum. The words 'peak moved' therefore do not define a physical mechanism. Record the unprocessed time or complex-frequency observations, then establish whether the carrier's instantaneous phase derivative changed, whether its amplitude merely changed, or whether a different line became dominant.

For a uniform transmission line, the propagation constant is $\gamma=\alpha+j\beta$, with attenuation α measured in nepers per metre and phase constant β in radians per metre. If a length ℓ is terminated in its characteristic impedance, the forward transfer is approximately $\exp(-\gamma\ell)$. The corresponding phase is $-\beta\ell$, and a small length or propagation-constant change has first-order phase increment $\Delta\varphi\approx-\beta\Delta\ell-\ell\Delta\beta$. For a wave with phase velocity v_p, $\beta=2\pi f/v_p$. None of these expressions translates a stable input from frequency f to $f+\Delta f$ when the geometry and dielectric remain fixed during the observation. A cable warmed and then measured in a stable new state may exhibit a new phase delay and loss but the same input frequency. The phase history during the warming process is a different question, because a varying delay $\tau(t)$ can impose a transient output phase excursion.

Take a nominal 1 GHz test tone and a cable whose effective one-way delay changes by 10 picoseconds because of bending or a changing dielectric. The phase difference is $2\pi(10^9)(10^{-11})=0.0628$ radians, about 3.6 degrees. It is not a 3.6-degree position change of a remote transmitter. If that delay change develops uniformly over 0.1 second, the induced phase-rate

Copyright 2026, James M. Atkinson

perturbation has a scale of 0.1 hertz for the selected tone, since $f_{inst} \approx f_0 - f_0 \, d\tau/dt$ in the simplified slowly varying-delay model. The result depends on the actual time course, and a sudden discontinuity will generate a more complicated transient spectrum. It is essential to record motion and the electrical event together rather than use the final static position as proof of a continuously displaced carrier.

A mismatched line is more revealing. At a connector, impedance discontinuity yields a reflection coefficient $\Gamma=(Z_L-Z_0)/(Z_L+Z_0)$ for the simple load model, where Z_L is load impedance and Z_0 is line impedance. The measured forward transmission is not necessarily a single travelling wave; it may be the vector sum of transmitted and reflected contributions, with a frequency-dependent ripple. Changing connector engagement, contact pressure or shield return can change those complex coefficients. At one analyzer frequency bin the vector sum may move upward; at a neighbouring bin it may move downward. If two nearby spectral components were already present, their relative heights may reverse, causing a peak-picking routine to report a new 'dominant frequency'. That is movement of the selected maximum, not necessarily translation of either component.

The experiment must independently observe source frequency and transfer response. A traceable generator feeds a carefully controlled branch into an independent monitor and a second branch through the suspect cable into the receiver under test. Record amplitude and phase versus time in both branches and preserve the device clock, detection settings and original sample order. Use a vector network analyzer, with calibration planes declared at the appropriate connector interfaces, to measure S11 and S21

Copyright 2026, James M. Atkinson

under a repeatable connection sequence; follow that with a time-domain reflectometry or transformed frequency-domain observation where its resolution is suitable. No result from a VNA alone proves what the live receiver did during a rapid bend; the static measurement is one element in a controlled chain.

Connection repeatability demands more than 'tighten it again'. Identify interface family, mating compatibility, connector condition, mating count, specified torque and cleaning procedure. An unknown torque setting can alter contact geometry and even damage a precision interface; excessive torque is not a cure for uncertainty. Before each test record whether the connector was disconnected, rotated, axially loaded, thermally changed or merely touched. Photographs of the external setup may assist metrological traceability, although the publication itself may omit photographs under the user's production rules. The engineer should record safe cable-bend radius and strain relief, because a test that exceeds the cable's rating can manufacture the failure it purports to diagnose.

To localise the fault, reverse a cable only if its construction and connectors make reversal appropriate, exchange the suspect assembly with a separately characterised one, and vary one mechanical element at a time. If the anomalous effect follows one cable across different receivers, a cable-related hypothesis gains support. If it remains with one receiver input after replacement, examine input connector, protective circuitry or internal reference distribution. If it follows the source and appears at an independent monitor, the source itself deserves scrutiny. A result that appears only when cable and receiver are combined may involve impedance

Copyright 2026, James M. Atkinson

interaction rather than one defective component in isolation. These distinctions make the experiment causal rather than theatrical.

Finally, a reproducible movement is meaningful only after the observer specifies its repeatability metric. How many cycles were tested? What is the distribution of phase or apparent peak frequency under unchanged conditions? Does the anomaly reverse when the cable is returned to its initial position, and is there hysteresis? Do the measurements show a change significantly greater than the instrument's amplitude, phase and frequency uncertainty? The best final statement may be that the peak-selection output is configuration-dependent within a bounded interval, and that a particular electrical discontinuity has or has not been isolated. It must not leap from cable motion to attribution of a remote RF emitter.

Dr. James M. Atkinson, Moderator: Professor Maxwell, I ask you to examine the cable not merely as a circuit component but as an electromagnetic structure. What happens when its screen ceases to act as an ideal enclosing return path, and how can the resulting field conversion masquerade as a moving emitter?

James Clerk Maxwell, Second Principal Contributor: Dr. Atkinson, an ideal coaxial line confines a transverse electromagnetic mode between inner and outer conductors, with equal and opposite longitudinal currents in the idealised simple picture. Real shields, connector transitions and enclosures admit discontinuities, finite conductivity, imperfect bonds and parasitic fields. The exterior of a coaxial screen can carry common-mode current driven by imbalance, and this current may couple into the receiver through a different route from the intended differential signal. Mechanical contact with the shield, movement against an enclosure, or a change of nearby

Copyright 2026, James M. Atkinson

conducting objects can alter the external current distribution without materially changing the desired signal at its source. A receiver may then show an amplitude, spur or apparent peak-position change as the vector sum of intended and unintended coupling changes.

Boundary conditions provide the proper language. Tangential electric field is constrained by the conductor surface, but it is not literally zero for real materials under all conditions. A gap or finite-transfer-impedance shield permits internal and external fields to influence one another. Contact resistance and inductance at the connector's outer conductor can become especially important at high frequency, where a seemingly short physical interruption has appreciable reactive impedance. One must not assume the centre pin alone constitutes the connector. A compromised outer contact can alter the return path, change the effective common-mode current and upset shielding while leaving a low-frequency continuity meter apparently satisfied. The frequency at which this happens depends on the geometry, not simply the operator's impression of tightness.

The underlying field is a solution to Maxwell's equations with boundaries established by the room, enclosure, cable and source. The measured voltage at a receiver port is consequently a projection of that field through an antenna and cable network. Move the cable a few centimetres and its effective coupling to the room may change. A very weak external signal may increase in apparent strength, a local interference line may diminish, or a spectral maximum may alternate between two nearby components. Such behaviour is not impossible; it is entirely compatible with changing coupling coefficients. Yet it identifies neither the radiating object nor the location of

Copyright 2026, James M. Atkinson

an emitter until the field structure and measurement apparatus are challenged independently.

Consider a model with intended complex voltage V_s and parasitic voltage $V_p \exp(j\theta)$ at one analysis frequency. The detected squared magnitude is $|V_s+V_p \exp(j\theta)|^2=|V_s|^2+|V_p|^2+2|V_s||V_p|\cos\theta$ when the reference phase is chosen appropriately. Even if both underlying source frequencies remain fixed, a change in the coupling phase θ can move received power through constructive and destructive interference. For equal 1 millivolt component magnitudes, the output may range ideally from zero to 2 millivolts in voltage amplitude as θ spans opposing and aligned phases. In practice finite noise, imperfect coherence and nonlinearity prevent such an ideal extremum, but the example shows how a large display change can arise without transmitter movement.

A second mechanism concerns time dependence. If intermittent contact makes the coupling coefficient vary while the field is observed, multiplication of a carrier by that varying envelope can create sidebands or broadband transient energy. If the contact opens and closes periodically at an effective mechanical or electrical rate, discrete spectral components may appear at offsets related to the modulation. If it moves irregularly, the added energy may be noise-like. Nothing in that observation alone permits one to declare a deliberate RF transmission. The investigator should record motion timing with a separately monitored safe test setup and compare the correlation between the mechanical intervention and raw electrical measurements.

The orthodox test uses an independent reference channel at the antenna or source, a correctly characterised shielded load, and a current probe whose

Copyright 2026, James M. Atkinson

own coupling and bandwidth are understood. A clamp measurement on the exterior coaxial screen may help identify common-mode current, but it cannot automatically identify the source of that current; the probe may itself load the structure. A line-current maximum may be produced by the receiving equipment, nearby electrical apparatus, or an external field. Change one return-path element, preserving RF safety and equipment ratings, and compare the current with the suspicious receiver feature. A second cable of different shield construction can be a valuable challenge if it also matches the required impedance and loss characteristics.

Near-field measurements require particular caution. Electric and magnetic components are not related by the free-space plane-wave impedance at arbitrary distances from a small structure. The cable may be capacitively coupled to one conductor and inductively coupled to a nearby return loop. A probe rotated around the suspect connector may respond differently to these components; orientation is therefore part of the measurement record. Likewise a tightly closed instrument enclosure does not guarantee immunity through every connector aperture. A cable connected through a damaged shell may supply a path whose electrical significance depends on the entire return geometry. Treat the assembly as a system rather than a list of independently perfect components.

The inference should remain modest until discriminating controls have been performed. A change on replacing a cable establishes that the observation depends upon that substitution, not that the original cable was the sole source of an alleged hidden emitter. The substituted cable may differ in length, loss, common-mode suppression, shield transfer impedance or termination. Document these differences and, where possible, normalise

Copyright 2026, James M. Atkinson

the intended signal path with calibrated insertion and return-loss measurements. The useful conclusion is a causal account of field coupling with acknowledged alternatives, not a narrative about an object moving invisibly through the room. That scientific restraint is an essential part of reliable countermeasure work.

Dr. James M. Atkinson, Moderator: Mr. Hewlett, the field explanation is illuminating. Please turn now to the practical laboratory task: how does one measure small but reproducible changes without permitting the test fixture, cable torque or calibration procedure itself to determine the conclusion?

William Redington Hewlett, Third Principal Contributor: Dr. Atkinson, an instrument comparison must be designed so that its test artefacts are smaller and better understood than the fault it seeks. The obvious temptation is to connect a network analyzer to the suspect cable, obtain an attractive S-parameter trace, bend the cable and celebrate the movement of a trace maximum. But a calibrated VNA reading describes its own stimulus, detector, calibration model and reference planes. It may not reproduce a high-level blocker, an actual receiver's input impedance, or a frequency-agile signal's timing. The VNA can establish amplitude, phase and mismatch behavior under a specified setup, but a receiver field report demands a bridge between these controlled observations and the actual acquisition chain.

The first step is to document the reference plane. A two-port calibration at the end of known test leads removes, within its model and uncertainty, many errors associated with systematic source and receiver paths. Change those leads after calibration and that model may no longer apply. The cable under test must be distinguished from the VNA's own flexible test leads.

Copyright 2026, James M. Atkinson

Sometimes a stable extension has to be used and characterised; sometimes a precision test port and fixed fixture are preferable. The test operator should prove that the measurement system remains stable by measuring a verification standard before and after the candidate cable. If the standard moves comparably, the claimed cable fault is not isolated.

For a cable assembly, record the complex forward transmission S21(f) and return measurements at relevant frequencies and incident powers. A stable frequency-dependent attenuation curve can explain why the strongest of two nearby true carriers changes when a connection varies; it cannot prove that either carrier has been frequency translated. Phase of S21 provides electrical-length information, but wrapped phase has 2π ambiguities. A coherent phase change should be compared with group delay $\tau_g=-(1/2\pi)d\varphi/df$, recognising that differentiation amplifies noise and that resonant features may make group delay vary sharply. It is a mistake to report an enormous group-delay value from one noisy phase point as a physical cable transit time.

Connector torque needs exactness rather than forcefulness. Use the connector manufacturer's approved range and a suitable calibrated torque tool for that precise interface. Do not transfer a value specified for one miniature microwave connector to a different coaxial family. A loose interface may exhibit variable contact resistance or shielding; an over-torqued interface may permanently distort the mating geometry. Cleanliness, connector pin depth, plating wear, damage and compatibility must be checked against applicable maintenance instructions. The same test should be repeated across several deliberate mate-and-unmate cycles and with the cable strain supported, while recording both the connection

Copyright 2026, James M. Atkinson

condition and the observed electrical response. Such repetitions separate a consistent mechanical sensitivity from one anomalous act of connection.

There should be an orthogonal control for each major hypothesis. To test a cable-associated phase shift, hold the source, receiver, temperature and cable termination constant while bending the cable within specified limits and measuring relative phase. To test thermal dependence, fix the cable mechanically and change temperature slowly within its safe range while monitoring its surface and connectors, not merely the ambient air. To test interface repeatability, disconnect and remate according to a documented procedure without changing the cable route. To test the source, use an independent monitored branch. To test the receiver, substitute another receiver with a separately monitored clock and record the raw spectra before peak-selection software. Each controlled comparison narrows the hypotheses without claiming a universal answer.

Uncertainty should include Type A repeatability assessed across genuinely repeated trials and Type B information from calibration standards, connector specifications, instrument drift, mismatch and environmental controls. A repeatable effect of 0.5 degree is not significant simply because the display increments by 0.01 degree. A useful budget might combine, under justified independence assumptions, a 0.3-degree standard measurement contribution and a 0.4-degree connection contribution to obtain $\mathrm{sqrt}(0.3^2+0.4^2)=0.5$ degree. A 0.6-degree observed change would then be marginal for a strong assertion, before considering correlation or unmodelled systematic effects. This is hypothetical arithmetic, not a statement of any actual instrument's performance.

Copyright 2026, James M. Atkinson

A time-domain reflectometry test adds spatial discrimination. A reflection detected after round-trip delay Δt corresponds ideally to distance $d \approx v_p \Delta t/2$ along a uniform line, where v_p is propagation velocity and the factor two accounts for the return journey. For $v_p=2.0\times10^8$ metres per second and $\Delta t=10$ nanoseconds, the inferred location is approximately one metre along the cable. But TDR resolution is bounded by excitation bandwidth and instrument response, connectors can obscure adjacent faults, and an estimated location may shift with dielectric variations. The test should be presented as evidence of a discontinuity near a calibrated electrical distance, not proof of an exact millimetre physical location.

I recommend that final findings be tabulated by intervention: initial static state, controlled flex, remate, thermal cycle, cable substitution, input termination, and independent source observation. For each, state what changed in S11, S21, time-series phase, amplitude, RF sample chronology and the peak-picking output. An investigator who can show that a perturbation follows one connector through repeated controlled exchanges has persuasive evidence of measurement-chain dependence. Yet the ultimate question is not merely why the peak moves on the display. It is which physical quantity changed, how much, under what conditions, and with what alternative explanations still credible.

Dr. James M. Atkinson, Moderator: Mr. Heaviside, I invite you to examine distributed line behaviour and the dynamic character of a moving cable, particularly where the test shows sidebands rather than a changed stationary S-parameter trace.

Oliver Heaviside, Fourth Principal Contributor: Dr. Atkinson, a cable should not be understood as a passive wire whose only property is an arbitrary

Copyright 2026, James M. Atkinson

attenuation number. Its capacitance, inductance, resistance and dielectric leakage are distributed along length; the telegrapher's equations couple voltage and current at every location. A contact fault at one point adds a boundary whose effective impedance may vary with stress, temperature or current. A shield defect changes both the return path and coupling to external fields. If these parameters change as the cable is moved, the line is not time-invariant during the experiment. Consequently its output can be modulated even though a perfectly stable signal enters it. The time-dependent boundary is a candidate source of the newly observed spectral energy.

In a simplified line with per-unit-length R, L, G and C, propagation constant $\gamma(f)=\mathrm{sqrt}[(R+j2\pi fL)(G+j2\pi fC)]$ and characteristic impedance $Z_0(f)=\mathrm{sqrt}[(R+j2\pi fL)/(G+j2\pi fC)]$. These are complex quantities in general, and their frequency dependence matters in a wideband receiver. Near a discontinuity, the launched wave and a reflected wave may combine differently as the electrical length varies. At a fixed input frequency this changes the measured amplitude and phase. If the discontinuity itself varies in time, the effective reflection coefficient becomes $\Gamma(t)$, which can multiply the incoming carrier and generate spectral components related to Γ's temporal spectrum. An operator who sees a pair of new sidebands should ask whether the instrument has measured modulation of an existing carrier rather than the arrival of two new transmitters.

Triboelectric and mechanically induced effects are not uniform properties of all coaxial cable. Some dielectric and conductor constructions produce small charge disturbances under flex; movement can also change capacitance or magnetic coupling and upset high-impedance circuits. The important

Copyright 2026, James M. Atkinson

distinction is between a voltage or current generated in the measuring assembly and modulation of an external RF signal passing through it. A low-frequency disturbance may be rejected by a well-designed receiver, may enter a gain or control path and produce modulation products, or may appear directly in a sufficiently broadband low-frequency measurement. Calling every flex-related spur 'microphonics' conceals several distinct causal pathways. Specify which one the experiments support.

For example, suppose a stable RF carrier at frequency f_0 passes through a link with small time-dependent amplitude gain $g(t)=1+m \cos(2\pi f_m t)$, with modulation index m small. The product is $g(t)A \cos(2\pi f_0 t)$, containing a carrier at f_0 and sidebands at $f_0 \pm f_m$ of voltage amplitude $mA/2$. If the cable returns to a static configuration, those sidebands may vanish even though its new static attenuation differs. This is not evidence of three independent RF emitters. A related phase modulation process can also produce sidebands, but the relative phase of their complex amplitudes distinguishes the two under suitable coherent measurement. The investigator must retain IQ data or phase-sensitive observations rather than rely solely on a magnitude spectrum.

The assumption of instantaneous uniform line changes deserves criticism. A bend propagates mechanically along a cable; contact pressure can stick and slip, and temperature diffuses through dielectric and metal at different rates. A phase change may have a hysteresis loop when the cable is flexed and returned, and a connector can intermittently switch between conducting states. Their temporal spectra may include discrete impulses, broadband shoulders or low-frequency wander. The frequency-domain display depends on window, resolution bandwidth and detector. A peak that

Copyright 2026, James M. Atkinson

looks narrow during one averaging interval may widen when a transient is captured at higher time resolution. Thus the physical motion history must be measured with as much care as the final spectrum.

A fault-locating test must distinguish a reproducible correlation from a unique explanation. Lock the cable in one geometry and gently alter the suspect connector within its safe mechanical tolerance; next lock the connector and change the cable's curvature in one section. If both affect the receiver, examine whether the test is actually moving the connector's mounting point each time. Add strain relief and observe whether the effect disappears. Use a characterised substitute line with comparable length, impedance and return loss. If the substitute suppresses the effect, identify which physical property differs; a replacement can change common-mode routing or room coupling even when its nominal specifications match the original.

We must also avoid mistaking receiver nonlinearities for purely linear line effects. A small connector reflection can change blocker amplitude at the input of a nonlinear stage and thereby alter an intermodulation product's strength or apparent prominence. The product may appear at a frequency absent from the external sources, yet its frequency is determined by the receiver's nonlinear mixing relationships. Changing cable geometry can move the display's dominant peak from a true weak carrier to that internally generated spur. Measure at reduced input power and with controlled attenuation, and examine the predicted power-law scaling of the product, while acknowledging that gain-control loops may complicate simple slopes. The mechanical correlation only identifies a condition affecting the receiver.

Copyright 2026, James M. Atkinson

A careful conclusion can be strong without being absolute: the affected assembly exhibits reproducible time-dependent transfer changes, and a measured correlation with the raw spectrum is consistent with one specified pathway. Distinguish stable S-parameter variation after remating from dynamic modulation during motion, and distinguish both from changes generated inside the receiver. Retain the full sequence of negative controls because the absence of an effect in a particular static position is not proof that the component will behave perfectly during service. The scientific achievement is not a picturesque peak that seems to walk when a cable moves; it is an identifiable, bounded electrical mechanism.

Dr. James M. Atkinson, Moderator: Professor Armstrong, would you now examine what a receiver can add to this phenomenon after energy passes the connector, particularly when an unstable peak is near the sensitivity threshold or is a mixing product?

Edwin Howard Armstrong, Fifth Principal Contributor: Dr. Atkinson, the receiver must be treated as an active participant in the observation. A cable perturbation can change the level or phase of a desired signal, an adjacent blocker, a local leak from an instrument clock or a common-mode interferer. Once those signals enter an amplifier, mixer, detector or sampler, nonlinear behavior and automatic-control dynamics may turn a small input variation into a conspicuous output change. The display may promote a different bin to 'peak' as two nearly equal components exchange strength. A coherent analyser may see a phase step caused by changing electrical delay. Neither result establishes that a remote transmitter moved. The frequency of a genuine transmitted carrier can remain perfectly fixed while its apparent location in the rendered spectrum changes.

Copyright 2026, James M. Atkinson

A receiver frequency estimate depends upon the estimator as well as on the signal. An FFT peak finder chooses the largest spectral bin after filtering, windowing and perhaps interpolation. If signal strength is near the noise floor, random noise can change which bin wins. If two lines are close to the instrument's resolution bandwidth, changing their relative amplitudes by a fraction of a decibel can shift the location of the measured maximum even if their absolute frequencies remain stationary. Long averaging may reduce random fluctuations but can conceal changes during a bend. For a rigorous test, record the complex samples and compute the frequency estimates with predeclared windows, bin widths and uncertainty measures, rather than altering analysis settings until the desired effect appears.

Consider a simple two-tone observation with components at 100.000000 MHz and 100.000400 MHz. If the first is initially 0.2 dB stronger, a peak-picking display reports the first frequency. A small cable- or mismatch-induced attenuation reversal can make the second 0.2 dB stronger, causing a reported 400 Hz 'frequency jump' though both carriers have remained unchanged. The amount of differential attenuation depends on the frequency response and interactions in the full chain; a very short well-matched line would not ordinarily develop an abrupt 0.4 kHz notch by being touched. This example isolates a peak-selector mechanism, not a universal prediction of what any connector does.

Frequency translation can occur when the effective path is time-varying, but the source must be identified. A cable undergoing changing delay can produce phase modulation; a gain-control circuit responding to contact noise can modulate a carrier; a poorly isolated oscillator may be pulled by changing input impedance in certain architectures; and a nonlinear junction

Copyright 2026, James M. Atkinson

can generate mixing products. These have different temporal signatures. Test with a source known to be stable under independent monitoring. Measure the input with a sufficiently linear reference receiver and compare the suspect receiver's oscillator or IF reference. If the apparent shift appears only downstream of one gain or conversion stage, the evidence points toward receiver-generated behavior. The test should not rest on an undocumented assumption of a perfectly linear chain.

One useful challenge is controlled input attenuation. If a candidate spur arises from third-order intermodulation between two tones, its output-power dependence may approximate a three-to-one slope relative to input power over a limited small-signal region, whereas a directly transmitted tone often has a one-to-one dependence. But the simplified slope can fail under compression, changing gain control, source contamination and asymmetric mixing. Therefore sweep levels only in safe, specified ranges, log actual settings and check whether the predicted source frequencies exist. A cable fault which changes one blocker level may create an apparent line elsewhere in the receiver spectrum. The right claim is that the signal is consistent with a nonlinear conversion product under measured conditions, not that its geographic source has been found.

An intermittent shield or connector can also change the antenna system. A coaxial feedline carrying common-mode current effectively becomes part of the receiving structure, and moving it can alter radiation coupling. A technician may be tempted to follow the largest peak by moving the cable in the room, interpreting signal maxima as bearings. That is invalid unless the antenna pattern and feedline currents are characterised. Replace the receiver input with a specified load, compare shield-current measurements,

Copyright 2026, James M. Atkinson

and use a genuinely separate antenna and receiver to evaluate the environment. A strong peak produced only when the coax hangs near a metal cabinet may reveal room coupling or an internal artefact rather than a transmitter concealed in that cabinet.

The procedure should be staged. Retain a baseline raw spectrum with cable and connectors immobilised. Observe a safe controlled flex and remate experiment while logging the exact time, thermal state and geometry. Preserve all acquisition settings, front-end overload indicators, oscillator references, FFT parameters and rejected detections. Restore the original configuration and verify whether the initial response returns. Substitute a characterised line and then, where practicable, a second receiver of different design. If signal content is legally sensitive, capture only authorised technical observables and maintain chain of custody; experimental controls should not become an excuse to acquire communications content outside authority.

In closing, distinguish three statements that are easily confused: a display peak changes position; the received signal's estimated instantaneous frequency changes; and an external source changes frequency or position. The first may be observed directly as a property of the display, the second requires a validated estimator and reference, and the third requires independent evidence excluding the measurement chain. A connector fault can contribute to the first two under particular conditions, but it does not justify the third by itself. One earns a location or attribution claim through multiple independent measurements, a calibrated receiving system, and explicit treatment of contrary explanations.

Dr. James M. Atkinson, Moderator: Dr. Kroemer, please challenge Professor Kennelly's distinction between a passive fixed transfer function and modulation introduced by a moving connection. Where should the investigator look for a nonlinear material interface?

Herbert Kroemer, Peer Question: Professor Kennelly, a damaged connector is not necessarily a simple linear mismatch. Oxide films, dissimilar-metal contacts and intermittently conducting surfaces can possess nonlinear current-voltage behaviour, while imperfect mechanical pressure can change that behavior during vibration. Would you distinguish a static reflection arising from impedance discontinuity from a genuinely nonlinear junction that may generate harmonics or intermodulation? In the experiment proposed here, what particular combination of calibrated tones and mechanical interventions would demonstrate that spectral energy at a new frequency arises in the connector rather than in the instrument's input mixer or the signal generator itself? I would also ask how to avoid damaging a suspect contact while conducting the demonstration, since a destructive remating operation could erase the original evidence before it has been characterised. Can the experiment establish a threshold current or pressure at which the response changes discontinuously, and does the phenomenon persist when the connector is cooled or warmed without remating? Such observations might help distinguish contact films from simple mechanical impedance.

Arthur Edwin Kennelly, Response: Dr. Kroemer, the question is well taken. My linear line equations provide a baseline against which violations can be tested, not a complete model of every physical connector. A stable but mismatched connection can produce a reflected wave without generating a

Copyright 2026, James M. Atkinson

new frequency when driven by a single ideal sinusoid. A nonlinear contact, by contrast, may produce a current containing harmonics of that sinusoid, or combinations such as $2f_1 - f_2$ when two distinct tones are applied. The actual amplitudes depend on the contact law, drive level, temperature and load. An intermittent connection changes the circuit in time, so it may create broadband transients or modulation products even if its static current-voltage relation is nearly linear. These are separate hypotheses, and an RF spectrum by itself may not distinguish them. Retesting with a second predetermined set of mechanical interventions supplies evidence against a chance correlation. The analyst should maintain the same peak-selection rules during that second test, even when the revised observations contradict the initial hypothesis.

A safe two-tone test can use well-characterised low-power sources, appropriate isolation, a linear combiner and a sufficiently clean independent reference monitor. The source and combiner outputs must first be measured with the connector absent or with a verified through standard. The suspect interface is then inserted without changing the instrument's gain or overload state. Measure new combination products and repeat with a separate analyser or a calibrated attenuated measurement chain. If the products scale with applied tone level in a manner consistent with a junction model, and move with the suspect connector when it is exchanged between otherwise identical test chains, a connector-generated mechanism becomes plausible. Yet a receiver mixer also creates the same algebraic frequencies, so an isolated measurement at the connector output or a verified linear detector is essential to the attribution.

Copyright 2026, James M. Atkinson

Controlled mechanical pressure may be useful, but the permitted force, torque and motion must be specified before the experiment. I would first preserve the untouched assembly, photograph or otherwise document its state, and measure its baseline with a non-destructive fixture. Disconnecting may alter oxidation, contact asperities or shield engagement irreversibly. A laboratory surrogate with a known engineered discontinuity can be used to qualify the test without damaging the original specimen. The forensic conclusion should record whether the suspect connection was tested in situ, after removal, or after any cleaning and remating. Those conditions are not interchangeable. If the first intervention eliminates the anomaly, that outcome is itself evidence, but it limits later claims about the fault's original physical mechanism.

Dr. James M. Atkinson, Moderator: Professor Bode, please question Professor Maxwell's field-coupling model. A repeatable change may be a transfer-function change, a common-mode current shift or both.

Hendrik Wade Bode, Peer Question: Professor Maxwell, when a shield bond changes, the engineer often writes a simple equivalent impedance and assumes that the antenna, cable and enclosure remain otherwise fixed. At RF the alteration may instead change several coupled modes, the effective return current and even the port impedance seen by the receiver. How would you establish a response model without mistaking an underdetermined set of parameters for a uniquely fitted physical fault? Which measurements are independent enough to constrain shield transfer, insertion loss and common-mode sensitivity, and how would you test whether the model remains predictive after the cable is rotated or the instrument is moved to a different position? I ask because an attractive fit to

Copyright 2026, James M. Atkinson

one spectral anomaly can result from many compensating model errors. In particular, I would want one predicted change that is not used to estimate the fitted model's parameters, since successful prediction under a new configuration is stronger evidence than fitting the observation from which the model was invented. The calibration uncertainty of the added probe should be reported.

James Clerk Maxwell, Response: Professor Bode, the equivalent circuit is an approximation whose value is established by prediction under interventions, not by its visual resemblance to the physical assembly. One must distinguish terminal variables at a specified measurement plane from the distributed field solution inside and outside the shield. Measure the port reflection and transmission with a calibrated fixture, but separately observe shield-surface current or induced field at several known locations with an appropriate, calibrated sensor. A model that fits only terminal S-parameters may miss exterior common-mode coupling. Conversely a clamp probe alone does not determine the internal impedance discontinuity. Their combined responses place stronger constraints on the mechanism, provided probe loading, reference phase and the effect of moving the fixture are accounted for. The report should identify which receiving patterns were determined by actual calibration and which were assumed from ideal antenna theory. These are not equivalent when the feedline itself contributes to the spatial response.

I would formulate several candidate models: a local inner-conductor discontinuity with intact shield, a shield-transfer defect with otherwise stable inner path, a changing return connection to the enclosure, and an external field coupled along the cable. The models predict different changes when a shielded termination replaces the antenna, when the entire cable is

Copyright 2026, James M. Atkinson

immobilised, when the instrument chassis is moved while the cable is held, and when the cable is replaced by a construction with independently measured shielding effectiveness. A valid model should predict the sign, relative timing and approximate scale of changes in more than one observable, not merely reproduce the amplitude of the chosen peak after arbitrary parameter adjustment.

An apparently successful fit must be accompanied by uncertainty and sensitivity analysis. If several parameters cannot be distinguished by the available measurements, the report should say so rather than present one as uniquely discovered. Measurements in a different cable orientation or room position test whether the physical coupling model generalises. Changes in room geometry may legitimately alter exterior currents; failure to reproduce the same peak elsewhere does not necessarily falsify a local shield defect. One can at least determine whether the proposed mechanism predicts that dependence. In this work, the serious error is not using an imperfect model. It is treating an unchallenged model as a physical diagnosis and then inferring the geographic position of an emitter from it.

Dr. James M. Atkinson, Moderator: Dr. Steinmetz, would you challenge Mr. Hewlett's uncertainty budget, particularly its treatment of contact stress and temperature as though they were independent?

Charles Proteus Steinmetz, Peer Question: Mr. Hewlett, a connector can exhibit hysteresis: the electrical response during tightening differs from that during loosening, and a cable bent through one route may not return immediately to the original phase when released. Temperature, stress, contact pressure and conductor geometry are therefore correlated rather than independent experimental variables. If the engineer combines one

Copyright 2026, James M. Atkinson

standard deviation for torque variation with another for thermal variation in a simple root-sum-square calculation, what justifies that operation? How should a qualification test account for conditioning cycles, direction of approach and slow relaxation, rather than reporting a false precision from two apparently independent data columns? Further, when a series of repeated measurements follows a drift trend, how should repeatability be separated from that trend? Would you recommend comparing the full forward and reverse trajectories rather than a single before-and-after difference, and separately monitoring cable and connector temperature so that their unequal thermal time constants do not become a hidden source of bias in the fitted result?

William Redington Hewlett, Response: Dr. Steinmetz, the simple root-sum-square equation is legitimate only for components that are adequately modelled as uncorrelated and whose units and interpretations are compatible. It should never replace a physical understanding of the test process. For temperature and stress, the laboratory should construct an experimental sequence that changes one factor within fixed bands of the other, measures the actual temperatures and strains, and records the path followed through the state space. A full factorial design may be impractical for every field investigation, but even a limited up-down thermal ramp at two fixed cable geometries can reveal hysteresis that one static measurement misses. Record the time after each intervention and specify a settling criterion; otherwise a slow relaxation may masquerade as random repeatability. A practical audit should preserve the raw trajectory of each measured variable against time as well as a table of endpoint values. When

Copyright 2026, James M. Atkinson

the sequence is hysteretic, different paths to an identical final temperature or torque may legitimately produce different electrical states.

Where the data show correlation, the uncertainty of a combined result includes covariance terms. For contributions x and y with sensitivities a and b, variance is $a^2u_x^2+b^2u_y^2+2ab\ cov(x,y)$, assuming the first-order model applies. Omitting the covariance may understate or overstate the result depending on the sign of the correlation. More fundamentally, a hysteretic change may require a conditional model or bounded state range rather than one Gaussian standard deviation. If a connector follows different electrical paths on tightening and loosening, report the two paths and the difference explicitly. Do not average them into a fictional central state that the physical assembly never occupied.

A good protocol includes repeated baselines interleaved with interventions, rather than placing all baseline measurements first and all stressed measurements second. Randomising a feasible portion of the order helps reveal time drift and operator expectation; when order cannot be randomised because of irreversible conditioning, document the limitation. Use independent verification standards to monitor instrument drift. Retain rejected and failed readings, and record whether the suspect assembly was remated, cleaned or strained after the first anomaly. The final budget should distinguish repeatability within a fixed configuration, reproducibility across operators or setups, systematic corrections, and unquantified uncertainties. A numerical uncertainty is defensible only if it describes the actual path through which the measurement was made.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Mr. Campbell, how would you scrutinise Mr. Heaviside's explanation of moving-cable modulation through the lens of real filter and line response?

George Ashley Campbell, Peer Question: Mr. Heaviside, the moving-boundary picture is persuasive, but a receiver often contains several frequency-selective stages following the cable. A transient produced by an imperfect connection may ring in those filters for longer than the mechanical motion, and its spectrum can be displaced or broadened by the choice of analysis window. How would a test distinguish the line's own time-dependent transfer from the receiver's impulse response? What is the minimum useful acquisition metadata for reconstructing the sequence, especially where the operator has saved only averaged spectral plots? Could a narrow peak that apparently migrates under repeated flexing be a measurement of the receiver's filter memory, rather than an instantaneous property of the defective cable itself? Is there a way to compare a transient captured directly ahead of the narrow receiver filter with the final detector output, so that the candidate fault is not blamed for ringing introduced by the measuring apparatus? The test's trigger time and filter group delay would be material.

Oliver Heaviside, Response: Mr. Campbell, the observation is necessarily the output of a cascade, and one must not assign a property of the cascade to the cable alone without isolating stages. A time-varying connector can inject an impulse or modulate a passing signal. The receiver's filters then convolve that disturbance with their impulse responses, and its gain or detector circuitry may respond dynamically. A displayed event after the cable has stopped moving may therefore be genuine in the receiver output while no

Copyright 2026, James M. Atkinson

longer corresponding to an active mechanical change. A static S21 trace cannot describe the complete transient behaviour. The investigator should retain sufficiently wideband raw samples and measure the response to an independently known test impulse or step under safe laboratory conditions. For a transient reaching the input before its recorded hardware trigger, a display cannot recreate the omitted onset by mathematical sharpening. The experimental report should declare the known pretrigger depth and the possibility of an unobserved initiating event.

There are several useful comparisons. First, record the suspect cable's output through a calibrated wideband observation path that is demonstrably less prone to the receiver's particular ringing. Second, inject a comparable, well-controlled electrical transient downstream of the cable to measure how the receiver alone responds. Third, repeat the same mechanical intervention with alternative receiver bandwidth and filter configuration, noting whether the ringing duration and apparent peak trajectory follow the receiver setting. If the transient's origin is cable-associated but its spectral appearance depends strongly on IF filtering, report both parts of the chain. The supposed defect may be in the cable while the perceived 'moving peak' is a joint artefact of cable and signal processing.

The minimum data are raw sample indices and timestamps, the actual acquisition and reference clocks, receive bandwidth, filter coefficients or documented mode, detector and averaging state, overload flags, signal level, intervention time and the exact sequence of attempted measurements. Merely retaining the final waterfall is insufficient to reconstruct a lost input phase. If only averaged plots survive, the conclusion

Copyright 2026, James M. Atkinson

must be narrower. The observer may truthfully report a reproducible display response correlated with cable movement, but cannot reconstruct an instantaneous frequency trajectory that the instrument never saved. Time-frequency mathematics is powerful only when its source record and limitations are available for independent examination.

Dr. James M. Atkinson, Moderator: Mr. Black, please question Professor Armstrong's proposed attenuation challenge, especially the risk that automatic gain control destroys the expected power-law behavior.

Harold Stephen Black, Peer Question: Professor Armstrong, the suggestion that a third-order intermodulation line will increase roughly three decibels for each decibel of input increase is useful only under a limited small-signal model. A practical receiver may contain limiting, automatic gain control, digitally selected attenuation, interstage filtering and internal clocks whose levels remain constant as the antenna input changes. If a suspected spur changes when a cable is flexed and also changes under attenuation, what sequence of measurements would identify whether it is externally delivered, generated in a nonlinear stage, or changed by a feedback-control response? Would you accept the presence or absence of a three-to-one slope as proof of any one mechanism? I would further insist upon a test in which automatic gain control is deliberately disabled, if the instrument safely permits it, and a separate run in which its gain-control trajectory is recorded. Only then might the assumed amplifier nonlinearity be distinguished from time-dependent feedback action.

Edwin Howard Armstrong, Response: Mr. Black, I would not. The power-law slope is a diagnostic under specified conditions, not an infallible classifier. First lock or record the gain-control state where the instrument allows it,

Copyright 2026, James M. Atkinson

and determine whether the input attenuator is placed before or after the likely nonlinear element. A change in a digital IF attenuation after the mixer will not reduce an RF intermodulation product generated before the mixer in the same way as an RF pad at the antenna input. Next measure the actual input powers with an independent monitor, because cable flex or mismatch can change delivered levels at a nominally constant generator setting. Sweep slowly within safe range, allowing controlled settling, and preserve the full trace rather than only one peak value.

An externally delivered single-tone component ideally changes one-to-one with input power through a linear receiving chain, while a third-order product of two input tones may show a steeper dependence before compression. But an oscillator leak generated downstream of the input attenuator can remain comparatively constant, and a reference-related spur may scale differently again. Gain control can transform these relationships into complicated curves. Repeat with a different attenuation point and compare with a known linear reference receiver. A candidate line which persists with a correctly terminated input warrants investigation of internally generated components or unexpected coupling, but the termination itself must be characterised and its shielding verified. A terminated port does not create perfect immunity to strong external fields entering through another path.

Mechanical correlation should be tested separately from level dependence. Begin with the suspect cable fixed, measure the line under controlled power steps, then restore the baseline and perform a restricted flex test without changing power. Use a suitable substitute cable to see whether the dependence follows its electrical characteristics. Preserve gain-control state

Copyright 2026, James M. Atkinson

transitions and time tags; a control loop may react after a delay and create spectral changes persisting after the actual disturbance. If the observed behaviour fits several hypotheses, the report should keep them open. The strongest finding is the one that survives controlled changes in input power, filter configuration, clocking and cable routing. A simple slope drawn from three points cannot serve as evidence of a concealed emitter.

Dr. James M. Atkinson, Moderator: Mr. Pierce, how should we interpret a peak that seems reproducible only when the analyst looks at one particular short spectral interval?

John Robinson Pierce, Peer Question: Professor Kennelly, an analyst may perform many sequential cable flexes while watching a waterfall and remember the apparent frequency changes that coincide with the most dramatic motions. A later numerical review may select the same frequency bin and ignore quiet trials, receiver reset events and the multiple frequencies searched. How should a measurement design avoid this selection bias? Would you require a preregistered metric for peak displacement, and how should the investigator distinguish a deterministic carrier shift from a random peak-selector change near the noise floor? I also ask whether a confidence interval based on independent trial assumptions is justified if the repeated measurements share a drifting clock, a common signal generator or a thermally relaxing connector. Would you also measure the false-alarm rate for the very same peak-selection algorithm under no-intervention controls, rather than borrowing a threshold from a single spectral bin? That comparison seems indispensable where many frequencies and cable configurations were examined before a striking example emerged.

Copyright 2026, James M. Atkinson

Arthur Edwin Kennelly, Response: Mr. Pierce, the test should define its estimand and acceptance criterion before inspecting the experimental result. Decide whether the primary variable is phase at a fixed frequency, amplitude ratio between two calibrated bins, fitted instantaneous frequency from raw complex samples, return loss at a connector, or simply the identity of the largest displayed bin. Those are not interchangeable. Document the complete set of candidate spectral intervals and the exact rule for identifying a peak. If the operator examines thousands of bins and presents the most dramatic one as though it were the only test, the false-positive probability is much larger than a single-bin calculation suggests. Retain the complete trace, not just the winning plot. Retesting with a second predetermined set of mechanical interventions supplies evidence against a chance correlation. The analyst should maintain the same peak-selection rules during that second test, even when the revised observations contradict the initial hypothesis.

Perform deliberately timed intervention and no-intervention control trials, preferably in an order concealed from the person classifying the output when that is practical. The manipulation may consist of flexing one known section of cable within its rating, with a fixture recording its motion and an independent observer marking actual times. The classification algorithm should be fixed beforehand and applied automatically to all trials, including ones in which no peak is detected. If a stable signal at one measured frequency merely alternates dominance with a nearby stationary line, an IQ analysis can reveal the two components even though the peak selector reports a jump. A truly changing instantaneous frequency requires phase evolution consistent with the calibrated clock and estimator.

Copyright 2026, James M. Atkinson

Statistical analysis must reflect shared sources and memory. Measurements taken during the same thermal relaxation are not independent simply because the software saves them as different rows. An oscillator correction can affect many consecutive estimates, and a contact may stick in a given mechanical state across several trials. Model those dependencies or use block-wise uncertainty and scenario bounds. When only a small set of trials exists, report the raw results and uncertainty without pretending that an elaborate probability model has been independently validated. The evidence is strongest when the mechanical intervention predicts an electrical change in an entirely new data set, with the same calibration plan and all unsuccessful trials disclosed.

Dr. James M. Atkinson, Moderator: Sir Robert, would you address the operational danger of making a geographic inference from an instrument-specific movement?

Sir Robert Alexander Watson-Watt, Peer Question: Professor Maxwell, field investigators sometimes move their receiver or a nearby cable and observe a spectral peak strengthen, weaken or change location in a plot. Their natural instinct is to follow that change through a room, perhaps believing a concealed emitter lies in the direction that gives a stronger response. But cable motion may alter the antenna pattern or external shield current, and an instrument can generate products in its own front end. How should a defensive survey distinguish a spatial field gradient from a changing receiving structure? What minimum set of independent controls would justify a directional conclusion, and what wording should a report adopt when the apparent bearing is sensitive to cable routing? If the operator observes a consistent angular maximum, should the result be repeated with

Copyright 2026, James M. Atkinson

the receiving antenna rotated while the feedline is independently immobilised? I suspect such a control would be more informative than following a field-strength maximum by moving the cable through the room.

James Clerk Maxwell, Response: Sir Robert, a directional measurement requires a receiving pattern whose relation to the environment is known, or at least challenged under the conditions of use. A coaxial cable carrying exterior common-mode current is not merely a transparent feed. It becomes part of the effective receiving structure, so moving it alters the measured field projection. A maximum observed while walking a cable near a cabinet may be caused by changing coupling to the local environment, by a difference in return-path current or by an analyser artefact. It is not an independent observation of the source's location. The operator should first immobilise the cable and measure with a separately characterised antenna configuration whose orientation and polarisation can be changed deliberately. The report should identify which receiving patterns were determined by actual calibration and which were assumed from ideal antenna theory. These are not equivalent when the feedline itself contributes to the spatial response.

An operational series should include a second antenna and receiver path with an independently monitored clock and different cable routing. It should document the intended antenna response, receiver sensitivity, front-end overload state and environmental limitations. Compare measurements at several fixed positions with the feedline restrained and its strain relief unchanged; then repeat with a different but calibrated cable assembly. If the supposed bearing reverses when cable routing changes while the antenna position and external environment remain fixed, the directional inference is

Copyright 2026, James M. Atkinson

not robust. A local injected reference signal can challenge instrument artefacts, although its cable path must be chosen so that it does not reproduce the same defect.

Even when two instruments agree, their errors may share the same source, timing service or environmental disturbance. A defensible report therefore states the observed field strengths and configurations, the response to controlled changes and the remaining ambiguity. The strongest justified statement might be that a frequency component was detected under certain antenna orientations but its localisation was not established because feedline-dependent coupling remained unresolved. This is not a failure of scientific investigation. It is the appropriate boundary between an observation and an attribution, protecting both the evidence and any individuals whose conduct might otherwise be inferred from an unstable instrument response.

Dr. James M. Atkinson, Moderator: The panel has established several possible mechanisms. I now request direct cross-examination among the principal contributors so that their different models confront one another rather than forming isolated speeches.

Oliver Heaviside, Cross-Peer Question to Arthur Edwin Kennelly: Professor Kennelly, your fixed-line transfer argument is essential, but it may mislead an operator who measures only before and after a cable bend. A connector can behave as two different static line networks with a sequence of rapid, unobserved transitions between them. If the experiment preserves only endpoint S-parameters, the transition may produce sidebands or a broadband pulse whose origins are invisible to those endpoints. How would your proposed test capture the time-varying boundary itself? Would you use

Copyright 2026, James M. Atkinson

continuous phase and amplitude observations, and if so how can the analyst establish a genuine time-dependent change in line behavior without confusing it with the signal generator's phase noise, host timestamp correction or receiver oscillator pulling? Please also address the case in which a line's apparently stable response after motion conceals a brief contact dropout during the movement. How would you recognise an interval during which the recorder's host buffer is delayed but its hardware counter remains continuous, so that a timing artefact is not falsely assigned to the connector's transition? I am especially concerned about intervals hidden by interpolation.

Arthur Edwin Kennelly, Cross-Peer Answer to Oliver Heaviside: Mr. Heaviside, I accept that static network analysis must not stand in for a time record. My initial equations define what the unperturbed line can do; the experiment then seeks evidence that the boundary conditions varied. The principal observation should be a continuous, coherently sampled reference signal passing through the suspect line, with a second independently monitored branch observing the same source before the suspect assembly. Retain the amplitude and unwrapped relative phase as functions of physical acquisition time, and retain the hardware counters required to show that no sampled interval is silently omitted. If the relative phase changes during cable movement while the source-monitor phase remains stable, this is stronger evidence of a path-associated dynamic perturbation than comparison of two endpoint S21 readings.

The apparatus should also include a current or voltage witness near the suspect interface where this can be implemented safely without altering the fault. A high-speed contact dropout may generate a sharp envelope

Copyright 2026, James M. Atkinson

depression and phase jump followed by receiver-filter ringing. If the line is reconnected before a slow spectrum analyser completes its sweep, the time-domain evidence can survive even though the static before-and-after measurements appear indistinguishable. Change the receiver's detection bandwidth in a separate trial to determine whether a transient's apparent duration follows the receiver filter. A valid comparison does not depend on reporting every phase discontinuity as an oscillator failure; it requires independent monitoring of the oscillator or known reference and a credible hardware time map.

Mechanical intervention must be time-tagged through an independent observer or a suitably characterised displacement sensor. A causal conclusion requires repeated trials with held conditions and negative controls, not a single dramatic event. A transient can follow the hand touching the cable because the hand changes capacitive loading rather than because a contact is opening. Repeat with an insulated fixture, then vary connector loading, cable curvature and environmental conductors separately. When the result is sensitive to the intervention mechanism, report that sensitivity. Your objection improves the diagnosis: the electrical network must be measured while it changes, not inferred solely from whichever stable state remains afterward.

James Clerk Maxwell, Cross-Peer Question to William Redington Hewlett: Mr. Hewlett, a well-executed two-port calibration can make the terminal S-parameter uncertainty impressively small. Yet a shield defect can establish an external common-mode current whose field distribution depends on the room, cable routing and the connection to the instrument chassis. How would your calibration procedure avoid giving false comfort where the VNA

Copyright 2026, James M. Atkinson

ports excite primarily the intended differential path and fail to reproduce that external current? Can terminal measurements alone establish that a peak's movement is or is not associated with the screen, and what additional excitation or observation geometry would be justified before identifying one connector as the sole culprit? I also ask how you would preserve measurement traceability without modifying the physical boundary conditions through the act of attaching more probes. It would be useful to state which current probe calibration transfers to this installed geometry and which remains only a laboratory approximation, because a sensitive instrument can itself modify the exterior field and thus compromise the causal comparison.

William Redington Hewlett, Cross-Peer Answer to James Clerk Maxwell: Professor Maxwell, a two-port measurement is a calibrated observation of chosen terminal modes under a defined termination and fixture. It is not a comprehensive mapping of all fields radiated or conducted by the entire receiver-cable-enclosure assembly. A common-mode screen current may be weakly excited by one VNA arrangement and strongly excited by the operating receiver or surrounding electromagnetic field. Thus I would not treat excellent differential S21 repeatability as a certificate of shielding integrity. The test plan must expressly include the exterior current and its sensitivity to grounding, cable routing and nearby conductors, using a suitable clamp or field probe whose own calibration and loading are documented.

The additional measurement should be made in stages. First establish the baseline terminal response with the apparatus as found. Next measure any exterior current with the probe placed at documented locations; repeat the

Copyright 2026, James M. Atkinson

baseline terminal measurement to see whether the probe itself changes the result. Third use a well-controlled local injection arrangement, within safety and legal constraints, to challenge differential versus common-mode coupling. A signal source may be injected at one known point while an independently calibrated witness observes the resulting field or current at another. The point is not to create a perfect analogue of every environmental excitation but to determine whether the suspected return-path defect responds as the proposed mechanism predicts. The original cable route and enclosure connections must remain recorded.

If the external current changes with connector torque while S21 remains nearly constant, that is important evidence of a shielding or return-path phenomenon that a narrow terminal test might miss. If current and terminal phase change together, more work is required to identify whether there are two coupled mechanisms. Retain the physical configuration, probe positions, instrument reference planes and before/after verification results, and state when a control alters the system sufficiently to limit comparison. One can make a reproducible causal claim about the measured modes without pretending that any finite probe set captures the whole electromagnetic field. Calibration is not an incantation; its validity is bounded by what was actually excited and observed.

Edwin Howard Armstrong, Cross-Peer Question to Oliver Heaviside: Mr. Heaviside, you have shown that a moving transmission line can modulate a stable carrier, and I agree. But the operator may observe a spur at precisely a receiver intermediate frequency or at an offset related to an internal sample clock, rather than simply symmetric sidebands around the input carrier. Such a result might arise because a cable bend changes blocker level

Copyright 2026, James M. Atkinson

at an active nonlinear stage. How should we discriminate modulation produced physically within the cable from frequency conversion produced by the receiver itself? I would be particularly reluctant to attribute a detected product to a damaged line merely because the same manipulation affects both the input mismatch and the display. What tests would isolate the physical locus of frequency conversion without assuming that the receiver always behaves linearly? Would you regard simultaneous appearance of the product in two receivers driven by the same clock as independent corroboration, or would that arrangement still admit a shared timebase or reference-distribution defect which no cable substitution test alone can exclude?

Oliver Heaviside, Cross-Peer Answer to Edwin Howard Armstrong: Professor Armstrong, an active receiver can produce frequencies that a passive fixed line cannot. Our first task is to measure the suspect assembly with a sufficiently linear independent path, at levels low enough to avoid inducing new products in the reference instrumentation. If a reproducible new component can be observed before the suspect receiver's conversion stages, the hypothesis of a line-associated dynamic or nonlinear mechanism gains support. If it is absent there but appears in one receiver IF chain, the receiver deserves examination. In either case, a negative observation must be interpreted against that reference path's sensitivity and bandwidth; failure to see a small product is not proof that it does not exist. An independently monitored marker inserted before the cable and recorded on both paths can further reveal whether the observed time interval contains valid samples or a gap that processing has concealed. The marker itself must not disturb the suspected contact.

Copyright 2026, James M. Atkinson

Introduce a controlled two-tone source and vary input levels safely while keeping the suspect cable mechanically fixed. Observe whether the candidate spur follows the algebraic combinations of the applied tones. Then hold the tones constant and introduce a documented cable movement. A source harmonic, connector nonlinear product and receiver mixer product can share a numerical frequency, so their amplitudes under independent device substitution and attenuation matter. Swap the receiver while retaining the cable and monitored source, then swap the cable while retaining the receiver. A correlation that follows both in a non-separable way may indicate interaction between source impedance and active front end; forcing an exclusive label upon such behavior would be unscientific.

Finally, the local oscillator or sampling clock must be monitored when possible. If the receiver's frequency reference changes under input mismatch, the apparent carrier shift may have a different cause from a line's envelope modulation. Record raw IQ, IF configuration, gain state, filter settings and any discontinuities in time mapping. Compare the frequency offset of the alleged signal relative to a separately injected known reference, noting whether both move together. If both move, suspect the frequency axis or conversion chain before assigning motion to a remote source. Your objection illustrates why the transmission line and receiver must be studied together, with every attribution bounded by the tests that distinguish them.

Arthur Edwin Kennelly, Cross-Peer Question to Edwin Howard Armstrong: Professor Armstrong, your treatment of peak-selection algorithms is important, but a numerical report may confuse an observation made in the instrument with a change in a transmitter's centre frequency. Suppose a trace shows a 400 Hz movement on cable flex and the same amount is

Copyright 2026, James M. Atkinson

repeated over several trials. The display's repeatability may be excellent even while the underlying signal is a stationary pair of tones whose relative heights have changed. What measurable conditions would persuade you that the signal's instantaneous frequency actually changed rather than the location of the display maximum? Would you distinguish a phase-derived estimate from an FFT-bin estimate, and what steps would make the conclusion reproducible without relying on a particular software implementation? I would also ask whether a frequency-fit model should explicitly retain two nearly equal candidates instead of forcibly choosing one, and how a later expert could reproduce the reported transition if the original complex samples had been discarded.

Edwin Howard Armstrong, Cross-Peer Answer to Arthur Edwin Kennelly: Professor Kennelly, I would begin with the full complex sample record and a clock whose frequency and continuity have been separately challenged. Two resolved stationary tones should remain at their respective phase-evolution rates, even if one becomes dominant in magnitude. Estimate their frequencies individually when signal-to-noise ratio and resolution permit, and show the complex spectrum under the original window and under a second predeclared analysis. A peak picker may switch between them, but a model fitting two distinct sinusoids can reveal that neither moved. The model should be evaluated against residuals and alternative components; a two-tone fit is not inherently true merely because it has more parameters. When the data are ambiguous between phase modulation and a two-line mixture, reporting both models and their residuals is more useful than asserting a single frequency trajectory. The raw time record should remain available for those competing reconstructions.

Copyright 2026, James M. Atkinson

If the signal is genuinely one time-varying component, an analytic-signal phase estimate may reveal a coherent phase trajectory whose derivative changes. But near envelope nulls, phase unwrapping becomes unstable and an apparent jump can arise from interference or missing samples. Therefore compare independent algorithms, use a reference marker carried through the same receiving path, and determine whether the frequency change coincides with a known clock or gain-control transition. A test with a known stable calibration carrier can reveal whether the receiver's frequency axis shifts at the same time as the suspicious feature. If both move together, a reference or conversion defect is a more plausible cause than simultaneous motion of separate external emitters.

Reproducibility requires the same raw input, fixed settings, identified software versions, numerical precision and documented decision rules. Preserve every trial, not only the ones confirming the desired 400 Hz change. Test sensitivity to window length and estimator model, and state the uncertainty of the frequency difference under realistic noise and interference. A claim of changed instantaneous frequency may survive these challenges; a claim that an emitter moved geographically requires still more evidence, including propagation, bearing or location observables independent of the cable perturbation. The logical chain from display peak to physical source is long, and no one successful flexing demonstration supplies all its links.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel has separated four phenomena frequently concealed by the expression 'a moving spectral peak': a static cable or connector transfer-function change; a time-dependent mechanical modulation of an existing carrier; internal

Copyright 2026, James M. Atkinson

receiver frequency-conversion or clock artefacts; and a peak-selection algorithm exchanging dominance between stationary components. The first two may be associated with impedance, shielding, electrical length or contact instability, yet none establishes geographic movement of a transmitter. Proper tests begin with a monitored source and an explicit antenna-to-recorder reference-plane diagram. They retain raw complex samples, source and local oscillator timing, safe controlled bend and remating logs, calibrated S11/S21 and, where relevant, exterior shield-current observations.

A high-quality inquiry also separates the operator's intervention from the apparatus response. Connector torque and pin geometry must comply with the relevant interface specification, and a cable should not be flexed beyond its rated bend radius to obtain an impressive spectral change. Before-and-after network traces must be supplemented with continuous acquisition across any transient. An apparently reproducible result should survive no-intervention controls, independently monitored reference channels and realistic alternative hypotheses involving receiver filtering, mixer products and display algorithms. Numerical frequency, phase, amplitude and position claims require distinct uncertainties and distinct evidence.

The moderator thanks the contributors for their candid examination of one another's reasoning. All dialogue is a modern educational construction, and every numerical example is hypothetical. The defensible forensic conclusion records the configuration-dependent observation and any fault actually isolated by challenge testing; it does not attribute a remote emitter from a mechanically sensitive peak without independently validated evidence.

QUESTION 068

Copyright 2026, James M. Atkinson

How can antenna substitution distinguish incident RF energy from instrument-generated signals?

Dr. James M. Atkinson, Moderator: Sir Robert, a narrow trace on a surveillance countermeasures receiver may seem to prove an emitter is within a room. The signal might instead be a local oscillator leak, ADC clock artefact, image response, cable-borne common-mode current, or intermodulation arising only after the antenna is connected. How should the investigator arrange an antenna substitution experiment to determine whether RF energy entered through the calibrated aperture, and why is the simple disappearance of a trace after unscrewing an antenna insufficient proof of its external origin?

Sir Robert Alexander Watson-Watt, Principal Contributor: Dr. Atkinson, the decisive word is *comparison*, not disappearance. An antenna is a physical transducer with frequency-dependent impedance, polarisation, directional sensitivity, effective height and interaction with its surroundings. Disconnecting that apparatus changes not one but several properties of the receiver installation. It changes the incident-field coupling, of course, but it may also change the termination presented to a sensitive preamplifier, the shield-current path, the noise available at the input and the operating point of a gain controller. An operator who notes only that one spectral line vanished has performed an intervention, yet has not necessarily isolated the factor that caused the result. A defensible experiment must specify the alternative explanations before the first cable is moved, and arrange conditions whose predicted outcomes differ.

Copyright 2026, James M. Atkinson

We may describe a simplified observation at a chosen frequency f as $Y(f)=G_s(f)\,[H_a(f)E_{inc}(f)+V_c(f)] + S_s(f)+N_s(f)$, where E_{inc} is incident electric field in volts per metre, H_a is an effective antenna-to-port response in metres under defined loading and polarisation, V_c is unwanted voltage entering through cable shields or other conductive paths, G_s is the receiver's complex small-signal transfer factor for configuration s, S_s is internally generated spectral artefact and N_s is noise. This is only a bookkeeping model. An active antenna makes H_a and G_s interdependent; nonlinear mixing requires additional terms; a magnetic-field probe needs a different coupling description. Nevertheless the equation forces the investigator to ask which term each substitution actually changes. Replacing an antenna with a matched load aims principally to suppress H_aE_{inc}, but does not guarantee that V_c is zero or that S_s is unchanged. A connector movement can also alter G_s through a transient or impedance mismatch.

The test begins with a protected baseline. Preserve raw complex samples, receiver centre frequency, bandwidth, preselection, gain, AGC setting, detector choice, clock identity, input attenuation, antenna coordinates, cable route and the timestamps of the observations. A spectral screenshot without these details cannot support a reliable before-and-after comparison. First observe with the original antenna and document its polarisation and placement. Then connect a well-characterised termination *at the receiver's own RF reference plane*, without disturbing any other state insofar as the apparatus permits. A termination attached at the far end of the existing coax is a different test: the cable and its screen remain present and may still collect energy. These two terminations should not be conflated.

Copyright 2026, James M. Atkinson

A second condition is a matched load at the end of the same antenna cable. A third is a shielded, calibrated laboratory source at a known low level, connected through a safe attenuator and, where necessary, a DC block to prevent damage from active antenna bias. In each state, the receiver should encounter a specified source impedance. If the spectral feature survives a good load placed directly at the instrument, its production after that plane or by an alternate ingress path becomes more likely, though a leaky enclosure or instrument supply remains an alternative. If the feature vanishes with the direct load but survives with the cable attached and terminated at its distant end, the feedline or its screen is implicated. If it requires the radiating antenna, it is at least dependent upon the antenna assembly, not yet uniquely attributable to a distant transmitter.

The fourth condition should use a second front end of materially different architecture and its own reference source where feasible. It is tempting to connect the same antenna successively to two receivers, but the comparison is then sequential and may be invalid if the suspected signal is intermittent. Use an appropriately calibrated splitter, with isolation and loss measured, or independent simultaneous antennas where their differing reception patterns are acknowledged. A signal following the external antenna and appearing at a consistent absolute RF frequency in receivers with different local oscillator plans is stronger evidence of incident energy than a line that follows an internal clock harmonic. Yet a strong external blocker may induce similar intermodulation in both instruments; architecture diversity is a challenge to an explanation, not a magical certificate of independence.

One should also vary attenuation before the first active nonlinear stage. If a genuine unsaturated incoming tone is reduced by 10 dB at an input

Copyright 2026, James M. Atkinson

reference plane, its measured power should fall by approximately 10 dB, provided automatic gain is fixed and the display is calibrated. A third-order intermodulation product created after that attenuator can change by approximately 30 dB for the same adjustment in a simplified cubic regime. An internally generated spur introduced after the attenuation point may remain nearly constant. These are conditional diagnostic slopes: AGC, limiting, noise-floor thresholds, cross-modulation, filters and shared clock behaviour may alter them. We should never infer a unique physical source from one slope alone.

Suppose an authorised laboratory test reveals a line at 172.000 MHz with the antenna connected. It disappears upon direct termination, yet an inserted 20 dB pad changes the trace by only 4 dB. The anomalous slope defeats a naive linear external-tone explanation, but does not prove a synthetic oscillator spur. The pad may also reduce a strong blocker, change impedance and alter gain control. Record total power and overload indications across a sequence of pad values, keep gain fixed, and inspect the full spectrum. The comparison is more persuasive if a known reference tone injected into the same connection falls by its expected attenuation while the suspect feature behaves differently. This simple controlled challenge exposes the limits of a single disappearance test.

In a room, proximity is no guarantee of causation. Moving the antenna can change the field of a genuine radiator through multipath; moving the cable can alter shield current; changing the connector can suppress a marginal contact; and human movement can perturb all three. The survey should therefore create a measurement matrix, not a theatrical demonstration. Repeat the antenna, direct-load, cable-end-load and known-source

Copyright 2026, James M. Atkinson

conditions in varied order, with periodic restoration of the original state to check drift. Measure each result more than once and retain failures, not simply the most interesting trace. Independent evidence such as polarisation, spatial pattern, external probe comparison and source-independent clock substitution can sharpen causal discrimination. It is respectable to conclude that energy was dependent upon the antenna-port configuration without claiming that a particular object transmitted it. That distinction, carefully recorded, is the foundation of an honest defensive investigation.

Dr. James M. Atkinson, Moderator: Dr. Steinmetz, interrogate Sir Robert about the possibility that a matched input load changes the receiver’s electric and magnetic return paths, rather than simply excluding an incoming field.

Charles Proteus Steinmetz, Peer Question: Sir Robert, we speak of replacing the antenna by a matched load as though the intervention were a clean subtraction of the external field. But the outer conductor of the feedline, the receiver chassis and a nearby power cable may form an electromagnetic structure, with common-mode currents and ground-potential differences that are sensitive to how the connector is engaged. Even the operator's hand can alter the local capacitance. Under what configuration could a load at the receiver isolate the differential antenna-port mode while failing to remove other ingress mechanisms, and how would you determine the effect of a load mounted at the far cable end? I ask particularly whether a vanishing line after direct termination could be explained by changed boundary conditions or gain, even though a field was still physically present in the room. Distinguish the case of a radiating cable screen from one where

Copyright 2026, James M. Atkinson

the same screen conducts equipment-generated disturbance outward; the two can produce similar receiver indications but different causal histories.

Sir Robert Alexander Watson-Watt, Response: Dr. Steinmetz, a coaxial connection possesses both the intended differential or transverse electromagnetic transmission mode and possible external shield currents. A matched load terminates the differential input at its reference plane, but a cable extending beyond that plane remains capable of coupling to its surroundings. A load placed directly at the receiver removes that external cable from the tested port; it may simultaneously remove a common-mode conductive route. Such a result cannot by itself decide whether the original driver was a distant field or an appliance conducted through local wiring. The load does not abolish all enclosure ingress, power-line pathways or radiation through seams. The purpose of a controlled matrix is precisely to separate those routes as far as measurement permits.

The direct-load and far-end-load experiments should be performed with a characterised cable and a proper shielded termination, recording changes in connection geometry. If the feature disappears only when the entire cable is removed but persists with a load at its far end, the cable, its shield or associated connector is implicated. The next tests include an alternative cable route, a different shield construction, an appropriately designed common-mode choke and a controlled receiver supply arrangement. Any choke introduces impedance and should be characterised rather than assumed invisible. A clamp-on RF current probe can give evidence of shield current, with the probe's own response and loading considered. A simultaneous independent antenna can show whether a radiated field remains present while the first receiver's conducting path is altered.

Copyright 2026, James M. Atkinson

To answer your final question, yes, a genuine field may remain in the room when the receiver trace vanishes. The intervention has changed the measuring apparatus, not the world. The stronger conclusion is that the measured indication requires some element of the original external-port assembly. Demonstration of a radiated field needs another observation method, preferably one with independent signal conversion and a calibrated aperture. Demonstration of an internal spur requires tests that show its association with an oscillator, sample clock, nonlinear stage or enclosure pathway. A claim about a specific emitting object requires independent spatial and source evidence.

I would also restore the original configuration repeatedly rather than rely on one pair of measurements. A connector can be intermittent, and a gain controller can need time to settle after a disconnection. Log the order and exact time of every change, discard or qualify transition periods, and check the receiver with a known calibration tone before and after the sequence. A sham manipulation helps identify an operator-induced shift. If the results vary with cable flex or hand proximity, record that dependence as a finding and investigate it. The object of this examination is not to make the case look simple, but to establish a defensible set of causal bounds.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Professor Armstrong, please examine whether the receiver itself can turn an innocent change of input termination into a convincing signal. In particular, distinguish direct-conversion offsets, mixer images and internal clock products from energy that genuinely arrived at the antenna connector.

Edwin Howard Armstrong, Second Principal Contributor: Dr. Atkinson, an RF receiver does not merely measure a signal; it translates and filters signals, and each operation has mechanisms by which unwanted indications may be created. In a superheterodyne receiver, a frequency that satisfies an unintended mixing relation can enter a particular intermediate-frequency channel even though it is not the frequency displayed to the operator. A direct-conversion receiver can exhibit DC offset, quadrature imbalance and local-oscillator feedthrough, and a sampling receiver can contain clock-related spurs and alias images. Changing the connected antenna can alter the amplitudes driving such mechanisms without removing their internal causes. Consequently a line's response to antenna substitution must be interpreted in conjunction with changes in tuning, conversion plan, input level and receiver operating state.

Take the elementary mixing relation $f_{IF}=|f_{RF}-f_{LO}|$, where f_{IF} denotes intermediate frequency, f_{RF} an input component and f_{LO} the local oscillator. The same positive f_{IF} can be produced by two frequencies on opposite sides of the oscillator unless an image-rejection stage suppresses one. An antenna selected for the nominal channel may admit a strong image-frequency field despite giving little response at the displayed channel. Substituting another antenna changes that unwanted admission, and a displayed line disappears. It would be inaccurate to announce that the

Copyright 2026, James M. Atkinson

original antenna captured a transmitter at the displayed frequency. The proper test changes local-oscillator injection or preselection in a controlled manner and observes whether the putative absolute RF frequency stays fixed in the environment while the suspect response follows an instrument mixing relation.

A nonlinear input amplifier adds further ambiguity. If two environmental blockers at frequencies f_1 and f_2 drive a cubic nonlinearity, third-order products at $2f_1-f_2$ and $2f_2-f_1$ may appear near a protected observation channel. Neither product requires an independent transmitter at that frequency. A different antenna or a properly placed pad may attenuate the blockers sufficiently that the apparent suspect signal disappears. The disappearance proves that the input environment contributed to the generation mechanism, not that the displayed frequency itself came through the antenna as a physical field component. A wideband input-monitor path, overload indication and multi-level attenuation test can identify this distinction.

The modern control sequence is conceptually simple. First retain the preselector and gain state. Second introduce calibrated attenuation ahead of the suspected nonlinear stage and measure not only the chosen line but the strong neighbouring emissions. Third compare at least two local-oscillator plans, or receivers with dissimilar conversion architectures, while preserving absolute frequency calibration. Fourth repeat with a shielded, low-power injection generator and a matched load. A valid instrument challenge should reproduce a known tone without inventing a nearby response when its source is absent. If the instrument fails this challenge, the

Copyright 2026, James M. Atkinson

survey cannot responsibly treat every spectral trace as environmental evidence.

One must be alert to AGC and stateful firmware. In a receiver with automatic gain, disconnecting a substantial external noise source or blocker can make the gain increase, creating a higher baseline or making a weak internal spur more prominent. A line that becomes stronger with the antenna removed need not mean an internal oscillator suddenly began emitting more power. It may mean that the subsequent gain increased. Conversely a line can vanish because the gain was reduced during a transient or because a software threshold was recalculated. A comparison without gain-state logging is ambiguous. Lock the permissible gain states, document their actual behaviour and distinguish a physical signal-power change from a display or detector change.

A direct-conversion receiver provides a sharp example. A strong local oscillator may leak to the RF port or the case. The antenna can re-radiate or reflect this energy into the front end, leading to a change in a centre-frequency spur when the antenna is attached. The culprit originates within the receiver even though the antenna is a causal participant. Another source is quadrature mismatch: a positive-frequency component appears as an unwanted mirror at the opposite baseband frequency. Changing antenna orientation can change the desired input signal and its mirror together, giving a deceptive impression that two separate emissions have been observed. A controlled shift of the LO and an image-rejection calibration can challenge the hypothesis.

Sampling adds a parallel distinction. If the ADC samples at f_s, under ideal uniform sampling a sinusoid at f_RF may be indistinguishable from aliases

Copyright 2026, James M. Atkinson

separated by integer multiples of f_s in the digitised baseband. Preselection is needed to constrain the analogue spectral content that gave rise to the samples. A receiver that claims a signal frequency without documenting its analogue passband, sample rate and alias plan may be reporting an equivalent digital frequency rather than uniquely identifying the external RF component. An antenna substitution might remove a wideband blocker, allowing an alias to disappear, but the inference about the displayed channel remains conditional. The test should identify whether an independent analogue receiver detects energy at the actual supposed RF frequency.

Suppose a candidate line appears at 100 MHz. One receiver has an oscillator plan that could create a response from a 120 MHz blocker; another uses a different IF and preselector. If the displayed 100 MHz line follows the first instrument's LO change but a calibrated independent receiver sees no corresponding 100 MHz field, the instrument-response hypothesis is stronger. Yet negative observations are bounded by the second receiver's sensitivity, polarisation, bandwidth and timing coverage. The correct report records the instrument settings, change in response, independently measured blockers and exclusion limits. It should never promote a mere absence of a line on a second display to a categorical declaration that no external energy existed.

I would stress an additional operational point. Replacing the antenna with a coaxial switch, attenuator or splitter is itself an addition to the receiver chain. Its insertion loss, isolation and impedance match are finite, and its switching contacts can generate brief spectral disturbances. Verify the control fixtures with a known reference tone and a shielded termination. A

Copyright 2026, James M. Atkinson

genuine front-end test includes the test apparatus as part of the measurement, not as a neutral invisible hand. If a feature tracks a switch position, we must ask whether the switch merely selects the incident field or whether it is creating a conductive path, a new resonance, an overload state or a settling transient. The panel should pass no inference that does not survive this elementary distinction.

Dr. James M. Atkinson, Moderator: Professor Bode, challenge Professor Armstrong on the relationship between an antenna-dependent spur and a receiver that is nonlinear only when the antenna admits strong blockers.

Hendrik Wade Bode, Peer Question: Professor Armstrong, the proposed attenuation challenge assumes a stable small-signal or simple polynomial regime, yet a real receiving chain may contain a protector, a frequency-selective preamplifier and several control loops. A ten-decibel input change might shift one device from compression into linear operation, alter bias or lead firmware to select another filter. In these circumstances the observed slope of a spectral component could resemble third-order intermodulation without being caused by a single cubic mechanism. How would you structure the attenuation series so that its result distinguishes an external tone, a product formed after the attenuator, and a spur injected later in the chain? Please explain how the experiment guards against interpreting a threshold effect as a mathematical power law, and identify the independent measurements needed to support a causal account rather than merely a persuasive curve. Does the slope remain stable when the same attenuator ladder is tested in reverse order, and does an independent monitor confirm that the nominal pad increments are actual RF power changes at the relevant reference plane?

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong, Response: Professor Bode, your objection reaches the heart of the matter. The familiar one-to-three scaling is the local result of a simplified polynomial model, and it is valuable only over a range where its assumptions actually hold. The experiment should therefore include more than two attenuator settings, and each point must be associated with the measured gain state, the absolute input power and any overload or protection indication. A sweep in controlled one- or two-decibel increments, followed by a reverse sweep, may expose hysteresis, switching thresholds or changes of mode. The examiner should record the complete spectrum at each step, not merely the selected spectral line. If two strong input components and a putative third-order product are both visible, the change in their levels supplies a stronger model test than the product trace alone.

I would first calibrate the attenuation fixture with a stable known tone at the relevant frequency and power, verifying linearity with an independent power monitor. Next the receiver should be operated with any permissible automatic gain disabled and with fixed preselection and sampling modes. If disabling such control is impossible, the system must report its actual states for every sample interval, and the conclusion becomes conditional upon that record. Third, inject two safe laboratory tones through a shielded combiner with their frequencies selected to place a possible intermodulation product in the observation channel. Measure the response as each tone is varied independently. A third-order product should obey particular local derivatives with respect to both input levels; a single oscillator spur downstream will usually not behave that way.

Copyright 2026, James M. Atkinson

Where the suspected environmental signal cannot be reproduced by a laboratory generator, the field test can still use a properly calibrated pad sequence and independent receiver as checks. But the operator should decline to fit a single slope if the display jumps between discrete modes. A threshold crossing can create the appearance of a steep power law while reflecting detection censorship rather than nonlinearity. The model must distinguish actual RF power from the probability that a processing algorithm includes the line in its output. If an internally generated spur remains at fixed absolute amplitude while the input tones fall, the origin lies at or beyond the attenuator plane or in another ingress pathway, though cross-coupling through the instrument supply may remain possible. The report should contain the measured sweep, its state log and the reasons competing explanations were rejected. Nothing is gained by dressing a discontinuous receiver response in a smooth polynomial equation.

Dr. James M. Atkinson, Moderator: Mr. Black, challenge Professor Armstrong’s gain-control and attenuation analysis. What happens if the substitution triggers a hidden state change and the operator records only the final spectral display?

Harold Stephen Black, Peer Question: Professor Armstrong, your method proposes to hold gain and preselection fixed, yet some contemporary receivers silently alter their analogue front end or digital scaling when an input is disconnected. A low-power matched termination may induce more gain than a busy antenna, while a strong calibration tone may provoke protective attenuation or different filter coefficients. A displayed tone can appear unchanged after a ten-decibel pad is inserted, despite its actual port voltage changing as predicted. What state observations and challenge

Copyright 2026, James M. Atkinson

signals would reveal such hidden compensation? How should the investigator interpret an increase of an internal spur on antenna removal, and how can the test establish whether that increase is a source effect, a gain effect or an artefact of peak-selection processing? Please also address the possibility that a software detector normalises every short-time spectrum to the current median, concealing an absolute change in power while changing the relative prominence of individual peaks.

Edwin Howard Armstrong, Response: Mr. Black, the crucial distinction is between power at a specified analogue plane and the displayed number produced after a sequence of amplification and calculation. Automatic gain attempts to hold some downstream statistic approximately constant, so an honest input attenuation may not yield a corresponding display change if the loop increases gain. One should therefore measure or independently supervise the actual analogue gain, or at least record the gain-control state and compare the input with a known calibrated tone. A test that cannot access or freeze its state should be described as a black-box system test with a weaker causal conclusion, not as a precision measurement of the RF port alone.

Use two reference signals where possible. One should be injected electrically at the receiver port within the safe linear range, with an amplitude determined independently of the device under test. Another may be introduced through an authorised radiating path to challenge the antenna and local field. Vary their levels separately and log all relevant analogue attenuator, amplifier, preselector and digital normalisation states. If firmware does not expose those states, monitor the raw input sample scale and observe how the two known signals move as the connection

Copyright 2026, James M. Atkinson

changes. A hidden state switch may appear as a discontinuity, hysteresis or altered gain slope that is not explainable by an analogue linear transfer alone.

An internal spur that becomes more prominent after antenna removal may be amplified by the new gain setting, unmasked by a falling external noise floor, or promoted by a detection algorithm that ranks the largest surviving peaks. Its apparent increase need not indicate that the oscillator produced more electrical energy. Repeating the test at an independent fixed-gain front end is therefore valuable. Observe the absolute amplitude of the line relative to a stable injected reference, not merely relative to a dynamic display floor. Changing the FFT window, integration time or peak-hold interval can expose how much of the effect arises in presentation rather than acquisition.

The operator should also maintain a strict chronology. A gain change may be transient, and the first few data blocks after an antenna switch may include a settling response or invalid scaling. Retain hardware timestamps and identify the earliest observation that meets a tested steadiness criterion. If the suspect feature exists only during the transition, classify it separately from a continuous external emission. Documenting these states may seem burdensome, yet it prevents a mechanical operation on a connector from being mistaken for the birth or disappearance of a transmitter. The best causal claim is the one that survives both a known-tone challenge and an independent observation path.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Lord Rayleigh, the engineers have described the input and conversion circuitry. Please direct our attention to calibration and inference. What is actually controlled when we substitute one antenna, termination or receiving path for another, and how can the ensuing uncertainty be stated without fictional precision?

John William Strutt, Lord Rayleigh, Third Principal Contributor: Dr. Atkinson, the experimental comparison becomes scientific only after its quantity of interest is stated. One might wish to know whether a field existed at a defined point, whether its power crossed the antenna terminal, whether an external source emitted at a particular frequency, or whether an authorised survey met a prescribed detection probability. These are distinct questions. An antenna substitution can be an excellent discriminating intervention for the first two, but even a perfectly executed comparison cannot, in isolation, establish the identity or intent of an emitter. The relevant measurement equation must distinguish the field variable from the receiver indication and retain uncertainty in the intervening transfer.

For a calibrated electric-field antenna, the familiar antenna-factor relationship is $AF(f)=E(f)/V(f)$ under its stated calibration convention, where E is incident field strength in volts per metre and V is the specified terminal voltage in volts. Expressed logarithmically, AF in decibels per metre is E in decibel microvolts per metre minus V in decibel microvolts. The calibration factor depends on frequency, polarisation, impedance loading, positioning and environment. When a different antenna is substituted, its AF may differ by tens of decibels. Equal receiver display values from two antennas do not mean equal fields, and unequal display values do not necessarily indicate different environmental sources. A fair comparison either corrects each path

Copyright 2026, James M. Atkinson

to a common field estimate with its uncertainty or compares a known test signal that fixes the response of each configuration.

Mismatch is a central example. If an antenna or substitution generator has reflection coefficient Γ_s and the receiver has Γ_l, the transmitted power depends on a mismatch factor; an idealised voltage relationship is influenced by the product $\Gamma_s\Gamma_l$. A simple load labelled '50 ohms' is not exactly 50 ohms at every test frequency, and a receiver RF input rarely has zero reflection. Replacing the original antenna may therefore change delivered power without changing incident field. More seriously, a mismatch can alter feedback, gain compression or the effective noise figure of an active input stage. An uncertainty budget that includes only the manufacturer antenna factor and the screen's amplitude accuracy fails to account for the actual electrical comparison.

Consider a hypothetical calibrated test at 400 MHz. The receiving chain records a particular field estimate with one antenna and a value 8 dB lower with a replacement antenna. The first has antenna factor 18 dB/m; the replacement 27 dB/m. If the observer has not corrected the two terminal voltages by these respective factors, the 8 dB raw difference is not evidence of a field change. Even after calibration, the two antennas may sample different polarisation components or spatial regions, especially near metallic objects. This example is illustrative and does not supply a universal correction. The proper statement refers to the declared calibration planes, field components, antenna geometry, environment and confidence interval.

I should distinguish a matched load from a calibrated passive antenna. The load is a deliberately nonradiating termination, intended to put the receiver into a specified electrical state and suppress reception through the normal

Copyright 2026, James M. Atkinson

aperture. It is not an antenna of zero effective height in the whole installation. A feedline screen, a poorly sealed enclosure and nearby instrument wiring can still carry radio-frequency currents. The load may have finite thermal noise, leakage and mismatching, which are part of the controlled baseline. By contrast a laboratory generator connected to the RF port supplies a known terminal stimulus but does not necessarily reproduce the loading and spatial coupling of the original antenna. Each condition controls a different physical variable.

Statistical repetition is necessary but not sufficient. If ten antenna substitutions produce nearly identical changes, repeatability is established under those particular intervention conditions. The experiment may nevertheless contain a shared systematic error, perhaps an AGC state transition, an incorrect antenna-factor table, or a common cable disturbance induced every time the operator handles the connector. Randomising the sequence and including a sham manipulation, where the operator touches the fixture without changing the electrical path, can reveal handling effects. A second operator and independent instrument can reduce some observer dependence. But none of these procedures erases the obligation to inspect the actual physical path.

Let the corrected field estimate depend on calibration factors a, cable loss l, input gain g and observed level p. In decibel form a simplified expression may be $E_{dB}=p+a+l-g$, provided the measurement conventions use compatible reference units and the omitted coupling terms are either corrected or declared negligible. Its variance is not simply the sum of four squares if the factors share a common calibration source. In general $u^2(E)=\Sigma_i\Sigma_j (\partial E/\partial x_i)(\partial E/\partial x_j)Cov(x_i,x_j)$. Here the x_i are influence quantities

Copyright 2026, James M. Atkinson

and Cov is their covariance. A shared calibration source or ambient-temperature effect may make the off-diagonal terms material. An uncertainty statement produced from a convenient spreadsheet without these dependencies can be precise to three decimal places and inaccurate in physical meaning.

The question of a negative result must be approached even more cautiously. With the antenna connected, a particular signal may be below the noise floor; with the termination, it is not seen. This establishes no useful discrimination if the receiver was never sufficiently sensitive to detect the signal under either condition. A challenge signal of known power and compatible waveform should demonstrate the active detection limit in each state. In a building, receiver noise, interference and field multipath change with location and time. The operator should therefore map the tested conditions and acknowledge detection coverage: specific frequency ranges, time intervals, field components, antenna orientations and tested source strengths.

The final report should not say 'the signal was external' when the data merely show 'the feature is antenna-dependent'. The latter is a measured causal relationship between apparatus configurations and indications; the former is a claim about the source's location in the physical world. Progress from one to the other requires additional evidence, including second-architecture observation, source modulation, spatial field behaviour, directional consistency or controlled removal of an environmental source. The burden of inference belongs to the claim actually being made. Scientific restraint is not reluctance to conclude: it is the method by which a conclusion becomes fit for later examination.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Mr. Campbell, test Lord Rayleigh’s treatment of antenna factors and impedance mismatch. Please examine whether the comparison can be made fair when the substitution elements do not share an identical reference plane.

George Ashley Campbell, Peer Question: Lord Rayleigh, the field-strength correction E_dB=p+a+l−g is useful only when calibration quantities refer to compatible definitions of voltage and field, and when the receiving network is sufficiently linear. In practice the calibration certificate for one antenna may end at its connector, the cable loss certificate may assume a matched termination, and the receiver's displayed amplitude may be corrected to a different plane. If one antenna is active and another passive, even the noise factor and source impedance may change. What precise rules would you impose on the experiment to prevent double counting loss, omitting mismatch, or mistaking the changed system noise floor for a changed environmental signal? How should a comparison be documented where those corrections cannot be measured with the necessary certainty? Is a source-match correction defensible when the receiver input reflection coefficient changes between gain states, and should that instability instead be treated as a separate operating condition requiring its own uncertainty budget?

John William Strutt, Lord Rayleigh, Response: Mr. Campbell, the measurement equation must begin with the definition of the reported quantity and the physical plane at which it is measured. If the result is receiver-input power, specify the power available from a source of stated impedance or the power actually delivered under the observed match. If the result is field strength, require a calibrated antenna factor appropriate to

Copyright 2026, James M. Atkinson

the installed antenna and its load, and then account separately for connecting loss and receiver response according to the convention of the calibration. A certificate is not a free-standing number that can be added indiscriminately to other numbers; it is a statement about a defined calibration procedure. A cable loss already included in a whole-system antenna factor must not be added a second time.

I would require a diagram with every calibration boundary marked and a table naming each correction, its units, uncertainty, correlation and source record. The laboratory should use a standard known signal at the receiver's declared input plane to verify the amplitude display and detection threshold. It should then check each antenna assembly as actually installed, especially where active bias networks, baluns or unusual grounds are present. The reflection coefficients at important ports can be measured to bound mismatch effects. When the necessary corrections are uncertain or the active antenna has a changing gain characteristic, a calibrated relative comparison under repeated controlled conditions may be more defensible than pretending to know the absolute incident field to a fraction of a decibel.

A change in displayed noise floor is particularly treacherous. An active antenna may introduce its own amplifier noise and may present a different impedance to the first receiver stage. Replacing it with a passive antenna or load can change receiver noise figure, gain-control setting and dynamic range. An observed fall of the entire baseline is then not necessarily a reduction of environmental field. Record the gain state, equivalent bandwidth and noise statistics at each test condition. Challenge both configurations with a known tone at levels spanning the decision threshold,

Copyright 2026, James M. Atkinson

so that the probability of detection and the noise-floor response can be compared on meaningful terms.

If calibration is incomplete, the report should say so and limit its conclusion. It may be possible to demonstrate that the spectral line follows one particular antenna assembly under controlled repetition, or that it persists when the receiver input is properly terminated. Those are useful facts. It would be unsound to infer a field-strength ratio or an external source identity from them without the missing transfer information. A scientifically honest qualitative result can be stronger than a quantitatively polished but untraceable statement. We must not confuse the number of decimals in the display with the number of physical assumptions that have been verified.

Dr. James M. Atkinson, Moderator: Professor Bracewell, offer a final ordinary peer examination of Lord Rayleigh. How should the conclusion be expressed when the substitution matrix supports antenna-path dependence but the source remains only partially identified?

Ronald Newbold Bracewell, Peer Question: Lord Rayleigh, a complete matrix of antenna, direct-load, cable-end-load and independent receiver conditions might show that a spectral component appears only with one antenna and cable assembly. The result is reproducible, and the strongest line follows antenna orientation, yet the second receiving chain lacks sufficient sensitivity to register it. The investigator might reasonably suspect a true incident field, but cable-body coupling and a receiver-produced image remain possible. What hierarchy of reported findings would preserve that distinction? Can the experiment yield an upper or lower bound without a definite source attribution, and how should shared calibration uncertainties enter such bounds? Please explain how the report would avoid the opposite

Copyright 2026, James M. Atkinson

extremes of claiming a surveillance transmitter on the basis of one pattern or dismissing the entire investigation because the causal chain is not completely closed. Would the answer differ if the independent receiver used a frequency-agile scan rather than a continuous recording, leaving intervals in which the disputed burst could not have been observed with either antenna?

John William Strutt, Lord Rayleigh, Response: Professor Bracewell, the report should be organised as a sequence of propositions with their evidential support and explicit reservations. The first proposition is an observation: a defined signal-processing procedure identified a particular component at specified times and instrument settings. The second concerns system dependence: repeated changes of the antenna assembly, termination and cable path caused reproducible changes in that observation. The third concerns the electromagnetic pathway: independent tests support a particular point of ingress, perhaps the antenna aperture rather than the enclosure or supply. The fourth concerns source attribution, which requires additional observations beyond ingress. These propositions should not be collapsed into a sentence asserting a specific emitter merely because earlier tests were favourable.

Useful quantitative bounds can often be retained. If a calibrated instrument measures a terminal power above a known threshold and the field strength has been properly corrected for antenna factor and transmission loss, one may state an interval for the relevant field component under the tested geometry. If the independent receiver fails to detect the signal, its sensitivity and coverage establish only a conditional upper bound on a defined signal class and time interval. The inequality is not a universal statement about

Copyright 2026, James M. Atkinson

every source. The uncertainty of the antenna calibration, cable loss, receiver amplitude scale and noise threshold must be propagated with attention to correlation. Shared calibration standards can produce common bias and should not be counted as independent corroboration.

Where source attribution is unresolved, the report should make the competing hypotheses concrete. For example: hypothesis A, a real incident signal is captured by the antenna and displayed at the correct frequency; hypothesis B, an external blocker enters and creates an intermodulation or image product; hypothesis C, cable shielding admits conducted or radiated current that bypasses the intended aperture; hypothesis D, an internal oscillator or converter product changes with input loading. Record which experiment favours or disfavors each and which have not been tested. A qualitative causal matrix can be defensible without assigning numerical probabilities that the data do not support. If a numerical likelihood analysis is attempted, its models and parameters must be justified by calibration or independent evidence.

The opposite extremes you describe are both errors of inference. An unresolved source identity does not erase a genuine, reproducible receiver observation, nor does a reproducible observation supply the missing identity. A technical surveillance countermeasures report may properly recommend further targeted measurement, independent apparatus, or environmental control without pronouncing guilt, motive or unlawful activity. The conclusion is bounded by the tested conditions and the verified measurement chain. Such restraint allows future evidence to refine the conclusion while preserving the original data, instead of forcing a later reviewer to undo an unsupported narrative.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Mr. Jansky, your research drew attention to how electrical noise can be misclassified when the investigator has not separated instrument behaviour from the environment. Would you develop a procedure for distinguishing genuine incident natural or artificial radio noise from local receiver products, and explain the evidential limits of spectral continuity, periodicity and direction?

Karl Guthe Jansky, Fourth Principal Contributor: Dr. Atkinson, an observer hearing a hiss or seeing a broad band of spectral energy ought first to remember that radio noise is not an embarrassment to be discarded but a physical observation whose origins differ. The instrument has internal thermal and semiconductor noise; the antenna admits atmospheric, cosmic and manufactured energy; nearby electrical installations may carry conducted interference; and nonlinear circuitry may produce spurious products from combinations of strong signals. An antenna substitution can change the proportion of these terms even when the system is healthy. We must resist the temptation to identify every rise of the noise floor as a covert radiator and every fall on disconnection as proof that the original signal was a discrete environmental transmission.

The appropriate first comparison is spectral shape together with a controlled, calibrated noise baseline. At room temperature, thermal noise available from a matched resistive source over bandwidth B is approximately kTB watts under classical assumptions, where k is Boltzmann's constant, T absolute temperature and B the noise-equivalent bandwidth. At T near 290 kelvin the familiar power-density scale is roughly −174 dBm per hertz. This figure is not the noise floor of an arbitrary receiver display. Its receiver noise factor, gain, filtering, preselection and

Copyright 2026, James M. Atkinson

detector must be incorporated. A hot active antenna and a cold matched load can produce different spectral floors because the source noise and transfer are different; the receiver has not necessarily developed a mysterious internal spur. A correct test measures and records the noise-equivalent bandwidth and gain state, and explains the termination temperature and impedance.

The second comparison is temporal. An internally generated oscillator harmonic may remain associated with a reference-clock frequency, while natural noise exhibits its own temporal and spatial dependence. Yet a laboratory is full of electrical equipment whose switching cycles and clocks can create regular spectral lines that enter through the antenna. Regular timing is thus neither necessary nor sufficient evidence of internal origin. A mains-related pattern, for example, may appear as harmonics and sidebands in externally received interference or as disturbance injected into the receiver power supply. One should monitor supply rails and local equipment state, but also compare with a separately powered receiver and an independently controlled antenna placed away from the suspect unit.

A field observer should examine frequency behaviour under changes of local oscillator plan and sampling rate. If a line stays at the same absolute incoming frequency across an independently calibrated conversion plan, it is more likely to correspond to a physical RF component at the input. If it shifts with the sampling clock or LO, an internal mixing or alias mechanism deserves investigation. The test is not infallible because genuine emissions may be translated into images and strong blockers can produce internally generated intermodulation; the preselector and independent analogue test

Copyright 2026, James M. Atkinson

path must provide the additional constraint. Never let an attractive waterfall trace replace the measurement of the underlying input spectrum.

Spatial comparison provides a second layer of evidence. Observe the feature with a calibrated portable reference antenna at a different receiver and distance, then repeat at multiple locations while recording orientation, polarisation, cable routing and environmental conditions. If the suspected line is linked to a real field, one may expect some spatial and directional dependence, but indoors this dependence need not follow an inverse-square law. Near-field coupling, reflections, standing waves and shielding can make a genuine emitter stronger at one point and weaker at a neighbouring point. A common reference network can cause two nearby receivers to show a correlated artefact instead. Independence has to be designed into the comparison and documented.

In the frequency domain, external noise need not appear as an isolated spectral line. A narrowband source may be intermittent, frequency-agile or concealed under wideband noise. The direct-load condition gives a receiver baseline under one electrical termination; it does not establish an upper bound on all external transmissions during the earlier antenna observation. Define the detection threshold from a measured noise distribution, specify false-alarm and missed-detection rates where data justify them, and retain raw samples for alternative analyses. An environmental feature can be real yet insufficiently detected for classification or attribution. The proper report separates detected energy, waveform classification, source location and intention as successive, independently supported propositions.

A useful controlled experiment uses three simultaneous streams. The first is the survey receiver with its normal antenna. The second is a separate

Copyright 2026, James M. Atkinson

calibrated receiver with a nearby independent reference antenna. The third is a direct input-load condition or a measured internal calibration monitor, as permitted by the hardware. Inject a known benign reference signal from a laboratory radiator at a surveyed location and vary its amplitude in a safe range. Verify how each stream responds when the emission is actually present and absent. Then repeat observations without deliberate transmission. An indication that remains in the terminated chain while vanishing from both antenna channels has a different evidential meaning from one that follows the over-the-air calibration stimulus and disappears under proper termination.

However, simultaneous streams can themselves alter the room. Splitters, additional receivers and their oscillators may radiate or change local loading. Even a laptop brought beside an antenna can contribute radiated interference. Repeat the experiment in a quiet, well-documented baseline configuration and change one element at a time. If an intervention is repeated and the result changes, first determine whether the phenomenon evolved naturally or the intervention altered the system. A signal that disappears when the antenna cable is moved may have been attenuated by a pattern null, conducted through its screen or affected by an intermittent contact. The observation is a clue, not yet a cause.

I also caution against excessive confidence drawn from a field's apparent periodicity. In the history of observation, a signal can recur with a daily schedule because of human activity, environmental cycles, propagation, or instrument operation. To interpret periodicity, the analyst must compare it with an independent clock and logged events, account for gaps in receiver coverage and verify that the periodicity survives changes in acquisition

Copyright 2026, James M. Atkinson

software. A pattern inferred from a display that updates once per second can inherit its period from the display itself. Time tagging must refer to hardware acquisition, not to redraw intervals, if the report aims to distinguish an external phenomenon from the instrumentation.

The final inference should be conditional and restrained. Antenna substitution can establish that a feature's measured amplitude depends on admitting energy through a particular receiving assembly. It may also establish that a terminated receiver presents a baseline materially different from the connected-antenna state. To identify external origin more specifically, compare frequency plan, antenna response, independent channels, temporal behaviour and controlled source removal. To identify a particular emitting object, demand yet more: spatial tests, source signatures and a carefully bounded chain of attribution. There is no indignity in a negative finding that specifies what was tested and what remains unresolved. There is much danger in a positive finding based only upon an intriguing line that obligingly vanishes when someone disconnects a cable.

Dr. James M. Atkinson, Moderator: Mr. Pierce, examine Mr. Jansky’s proposed distinction between a field entering through the antenna and a signal that only appears because the receiver display threshold changes. What can a non-detection actually establish?

John Robinson Pierce, Peer Question: Mr. Jansky, your comparison of simultaneous receiver streams is attractive because it offers independent observations, but independence cannot be assumed merely from the presence of two enclosures. Both receivers may operate in the same building, share power or see a common strong blocker whose intermodulation creates similar apparent emissions. A weak true

Copyright 2026, James M. Atkinson

transmission might also appear on only one path because the receiving apertures have different patterns or threshold settings. How would you specify the hypothesis test, estimate detection and false-alarm behaviour, and avoid calling one missing display line a disproof of an observed field? I should also like you to address the problem of choosing a threshold after seeing the data, since that would allow the investigator to create a favourable result without any alteration in the underlying RF observations. How can the operator show the decision procedure was fixed before comparing the channels?

Karl Guthe Jansky, Response: Mr. Pierce, the first answer is to treat detection as a procedure whose statistical performance must be measured under the actual receiving configuration. Let H_0 denote the hypothesis that a specified external signal of interest is absent from the declared channel and H_1 the hypothesis that it is present according to an explicit amplitude, waveform and timing model. A detection rule declares an event when a computed statistic exceeds a predetermined threshold. A false alarm occurs when the rule declares the event under H_0; a miss occurs when it fails under H_1. The two error rates are properties of the rule and its noise environment, not intrinsic labels attached to a single spectral line. A comparison must estimate them with suitable control data, accounting for temporal correlation, bandwidth and nonstationary interference.

I would predeclare the observation window, detector mode, threshold selection and treatment of multiple spectral bins before inspecting the disputed event. A long waterfall with thousands of bins and time steps offers many opportunities for a chance excursion. Reporting only the brightest peak can create an implicit multiple-comparison problem. To

Copyright 2026, James M. Atkinson

assess the false-alarm behaviour, collect independent or sufficiently decorrelated baseline intervals with a matched termination and with the field antenna, then separate their respective null hypotheses. A terminated receiver baseline cannot describe every external interferer admitted by a connected antenna. Where the hypothesis is an external signal of particular form, use laboratory injection or known legal transmissions to measure detection probability over relevant signal strengths and orientations.

Two receivers deserve a dependence analysis. They may share an oscillator reference, software detector design, mains supply or common local interference. A simultaneous indication with different antenna patterns and clock trees can strengthen evidence of external reception, but the correlation of their errors must be tested. A line seen in one receiver alone may be due to different sensitivity, spatial field structure, pattern nulls or a true intermittent source. The follow-up should vary receiver order and antenna configuration while retaining a simultaneous witness where possible. Do not multiply independent false-alarm probabilities unless the independence assumption has been established for the actual failure mechanism.

Finally, a negative report should identify the tested target class. It may say that no event meeting the predefined criterion was detected with the instrument's demonstrated coverage and sensitivity in the specified intervals. It cannot claim that no RF energy of any origin existed in a room. If a test signal inserted at a level representing the target class is detected reliably, then a non-detection of that class gains significance. If the calibration stimulus is missed, the survey's negative finding becomes correspondingly weak. A disciplined measurement is sometimes less

Copyright 2026, James M. Atkinson

dramatic than a striking spectral picture, but it is more informative because it can be reproduced and challenged.

Dr. James M. Atkinson, Moderator: Mr. Reber, the panel has discussed the source and the receiver. Would you now examine the antenna itself as an imperfect spatial sampler, especially inside rooms where metallic structures, polarisation changes and feedline coupling can make a substituted antenna appear to refute a genuine field?

Grote Reber, Fifth Principal Contributor: Dr. Atkinson, a practical antenna measures a weighted component of an electromagnetic field over a particular aperture and environment. Two antennas placed side by side do not necessarily observe the same complex voltage, and one cannot treat the antenna as a passive length of metal whose replacement merely turns the outside world on or off. Radiation pattern, polarisation, impedance, effective height, bandwidth, phase centre and mutual coupling all matter. For a physically small antenna near conductive furnishings, the local near field may be especially sensitive to orientation and position. Therefore, when an apparent emission vanishes upon substitution, the first question is whether the second antenna was capable of coupling to that field under the test conditions.

The receiving relationship can be described in a narrowband linear setting by $V_{oc}=h_{eff}\cdot E$, where V_{oc} is open-circuit terminal voltage, h_{eff} is a complex vector effective length in metres and E is the local electric-field vector in volts per metre. The dot product reminds us that the component of the field perpendicular to the effective length can be strongly rejected. Under ideal matched linear polarisation, a rotation angle ψ gives a power coupling factor $\cos^2\psi$, so a 60-degree mismatch corresponds to one-quarter

Copyright 2026, James M. Atkinson

of the aligned power, or approximately 6 dB loss. At 90 degrees ideal isolation is mathematically complete, but real cross-polar response, scattering and mismatch prevent that ideal from being a universal field prediction. A substitute antenna with the wrong polarisation can make an external source disappear without revealing any fault in the receiver.

A calibrated replacement must therefore be characterised at the actual frequency, polarisation and mounting orientation. An antenna factor measured in a standard environment may not retain the same effective response beside a metal cabinet or a window containing conductive film. The room modifies the field, and the antenna can modify the room by coupling to nearby conductors. If two antennas have different phase centres, moving their feeds into nominally equal coordinates does not make their electromagnetic sampling identical. When the scientific question is whether energy exists at the location, repeat the comparison over several orientations and points in a small spatial region. When the question is whether a specific cable or aperture admitted energy, keep the geometry fixed and perform electrical substitutions at a declared reference plane.

The feedline may be the actual antenna. A coaxial cable with inadequate common-mode isolation can carry current on the exterior of its shield, and its response depends on length, routing, grounding and nearby surfaces. Replacing a rod or loop at the end of such a cable may alter the shield-current boundary condition. A signal then appears to disappear with the antenna even though the coupling route was principally the cable. An experiment should include a direct load at the receiver, another at the far cable end, and a test with a different shielded route or known common-mode choking arrangement. The load should be appropriate to frequency

Copyright 2026, James M. Atkinson

and power. A change caused by a choke is evidence of a common-mode pathway, but it does not alone specify the external or internal origin of the current driving that pathway.

A directional antenna introduces another possible misinterpretation. In free space its beam can discriminate directions, but indoors reflections can produce apparent peaks and nulls unrelated to the straight line toward the source. A receiver operator rotating a directional antenna may find a dramatic null and assume the source has stopped. Conversely a strong reflected path may point away from the radiator. For attribution, record direction-dependent response over a grid, measure multiple polarisation states, and compare with a source intentionally placed at known locations. A source that fails to appear on one bearing is not thereby absent. A case study in which only the strongest bearing is retained risks replacing the field with the surveyor's selection bias.

Frequency diversity also matters. An antenna that is well matched at 100 MHz may be inefficient at 150 MHz; a narrowband preamplifier or balun can introduce further variation. If the suspect spectral line changes when an antenna designed for another band is substituted, the intervention has changed both field collection and input matching. For a valid comparison, use a calibrated antenna covering the disputed frequency and a characterised connection cable, or explicitly calculate the relative sensitivity at the frequencies of interest. Do not compare raw waterfall colour values as though they were field-strength readings. Use the same detector mode, reference bandwidth and receiver gain, then correct the measurements for the distinct antenna factors and line losses where physically appropriate.

Copyright 2026, James M. Atkinson

The calibrated source experiment can be conducted in stages. Begin with a shielded electrical test to verify the receiver and cable path at the port. Next use a known benign radiating source in a controlled setting to characterise the antenna's response across orientation, frequency and location. Finally return to the disputed environment and record the variation under the same well-defined measurement settings. A robust field report should preserve environmental changes, power-source status, furniture movements and nearby conductors as influence quantities. If the local field is extremely weak, the second antenna may not reach the threshold necessary to register it even when a stronger first antenna did. That does not prove the first indication was fictitious.

A useful quantitative example illustrates the importance of distinguishing powers. Suppose a calibrated antenna and receiver have a measured end-to-end sensitivity of −110 dBm for a specified waveform and bandwidth, whilst the substitution antenna incurs 12 dB additional antenna and cable loss relative to the first configuration. A field component that gave −105 dBm at the first receiver may yield approximately −117 dBm in the replacement condition under the simplified link budget. The second receiver then fails to detect it at the stated sensitivity, but the failure is predicted without invoking instrument artefacts. The calculation ignores possible pattern, impedance, polarisation and environmental changes; these must be measured or bounded, not silently set to zero. The appropriate experiment restores comparable sensitivity before interpreting different detection outcomes.

The most rigorous observation matrix includes multiple antenna assemblies, direct terminations, independent front ends, several positions and

Copyright 2026, James M. Atkinson

controlled load changes. Each row records the actual experiment, not merely a verdict of 'signal' or 'no signal'. Where a spectral line is unchanged under direct termination, investigate alternate enclosure ingress and downstream spurs. Where it follows an antenna but not a local oscillator change, establish the antenna and receiver response and investigate external-field alternatives. Where it follows a cable route, compare shield-current and cable-body mechanisms. Where it changes with polarisation or position, record that response before inferring direction. These steps are not cumbersome ornaments: they separate physical facts from assumptions.

My concluding position is that antenna substitution is powerful only when one understands what has been substituted. An antenna assembly includes its radiating element, feedline, balun, preamplifier, mount, ground reference and near-field environment. A calibrated change of one element can localise a coupling route; an uncontrolled change of the entire assembly can only establish that the complete configuration matters. The aim is not to force the observations into the binary story that an emitter is either inside or outside the receiver. The aim is to reduce the space of viable causes with discriminating, reproducible measurements, while preserving the uncertainty of every inference beyond those observations.

Dr. James M. Atkinson, Moderator: Mr. Blackman, assess Mr. Reber’s concern that substitution changes the antenna pattern and threshold. Can comparative measurements be made without assuming that the same field is sampled at both apertures?

Ralph Beebe Blackman, Peer Question: Mr. Reber, imagine a weak burst whose amplitude fluctuates rapidly across the room. We replace one

Copyright 2026, James M. Atkinson

receiving antenna with another while holding the receiver in the same nominal position, but the phase centre, polarisation and connection cable differ. The second antenna records no burst, and an operator argues that the first receiver generated its own signal. Can one infer anything reliable from that sequential comparison? What arrangement would allow both antenna systems to be challenged by a common known field without requiring their raw voltages to be numerically equal? Please address how windowing, detection thresholds and the statistical treatment of burst duration interact with the unequal transfer functions. I am particularly concerned about a test that repeats many substitutions and reports only the clearest disappearance rather than the full distribution of results, which seems calculated to produce an impressive conclusion regardless of the underlying cause.

Grote Reber, Response: Mr. Blackman, a sequential comparison of two different apertures in a fluctuating field is not a direct test of instrument origin. It shows only that the combined antenna-receiver responses differed at two times. The instrument states must be stable, the source must be sufficiently repeatable, and the aperture responses must be known before an absence can be interpreted. If the field changes during the swap, the comparison is confounded by time. If a phase centre shifts even slightly relative to standing waves, the local amplitude can change substantially. A true external burst may therefore be visible on one antenna and not the other. A defensible report would retain the result but call it inconclusive until an additional control reduces the alternatives.

A controlled field or calibrated source gives the first useful comparison. Illuminate each assembly with a specified signal at the disputed frequency,

Copyright 2026, James M. Atkinson

polarisation and duration in a documented environment. Determine its response, insertion path and detection threshold separately; do not force its uncorrected voltage to match that of another antenna. Then, where practical, observe a real source simultaneously through two independent receiving chains, with their relative gains and patterns calibrated. The simultaneous method removes some temporal ambiguity, although it may introduce mutual coupling or shared reference dependence. A non-detection is informative only if the second chain would have detected the tested signal class with sufficient probability under the actual geometry.

Windowing and burst duration must also be controlled. A brief event may occur entirely between the analysis windows or below an averaged detection threshold. If the two receivers have different sample rates or FFT hop lengths, they do not necessarily inspect the same instantaneous interval despite nominally matching clock times. Retain raw sample indices and hardware timing, repeat analysis under a common explicitly defined detection procedure, and test the procedure with known-duration pulses. Any interpolation or smoothing should be retained as a derived product rather than silently replacing the raw trace. The question is whether the physical observation was made, not whether an aesthetically similar spectrogram was produced.

Repeatability should be examined across all substitutions, including unsuccessful and ambiguous trials. Randomise or counterbalance the order and restore the original antenna periodically to reveal drift. A proper table includes observed level, noise floor, configuration, environmental notes and evidence of overload. An operator selecting one dramatic disappearance from twenty trials has changed the statistical question by selecting the

Copyright 2026, James M. Atkinson

outcome. Preserve the complete register and compare it with the predicted distributions under plausible hypotheses. A careful investigator may ultimately conclude only that the first antenna assembly provided greater sensitivity to a particular field component. That is valuable knowledge and should not be inflated into attribution of an internal spur.

Dr. James M. Atkinson, Moderator: I now ask the principal contributors to examine one another directly. The purpose is to test unresolved causal alternatives, not to repeat the seven ordinary interrogations. Sir Robert, please address Mr. Reber.

Sir Robert Alexander Watson-Watt, Cross-Peer Question to Grote Reber: Mr. Reber, your distinction between a radiating aperture and a feedline acting as an unintended antenna is compelling, but an investigator may not have access to the inside of an installed receiver or permission to modify its wiring. How would you design a non-destructive and legally authorised test of shield-current coupling that preserves both the original evidence and the installation's safety? Suppose a line vanishes when a choke is added to a cable; the choke may have altered differential insertion loss, common-mode impedance, nearby field geometry or the preamplifier's operating point. What additional comparisons would prevent a premature claim that common-mode current has been proved to be the sole mechanism? Please address cases where the source remains in the near field, so that the traditional separation of cable and antenna becomes physically blurred. Include a practical control for the possibility that the current probe itself modifies the cable balance or unintentionally couples a nearby field into the very conductor whose current is being measured.

Copyright 2026, James M. Atkinson

Grote Reber, Cross-Peer Answer to Sir Robert Alexander Watson-Watt: Sir Robert, I would start by observing rather than modifying. A calibrated clamp-on current probe, used within its frequency and amplitude limitations, can examine current on the exterior of the feedline or associated return conductor without opening the receiver. Such a measurement requires care: the probe can load the circuit and may respond to nearby fields, so its calibration and positional repeatability must be established. A simultaneous independent antenna can monitor the ambient field while the cable is examined. These observations may show temporal and spectral correlation between shield current and the suspicious line, but correlation does not yet establish which current drove which indication.

Next use a controlled laboratory duplicate or a removable external test lead, provided the original installation must not be disturbed. Measure the candidate feature with the original cable routing, with an alternative characterised path, and with a properly selected common-mode suppression device. The device should be measured for both common-mode impedance and differential insertion loss near the disputed frequency. A known calibrated tone applied through the ordinary differential input checks whether the device unintentionally attenuates the intended receiving path. If the suspect signal changes while the reference tone remains stable and a measured common-mode current changes consistently, the shield-route hypothesis gains force. A second suppressor with different design but similar common-mode effect supplies another challenge to a fixture-specific artefact.

In a near-field environment the test becomes less absolute. The antenna element, feedline and nearby metal can form a coupled structure, so the

Copyright 2026, James M. Atkinson

boundary between intentional aperture and unintended conductor is a matter of the chosen measurement model and reference plane. A choke may perturb the entire coupling pattern. Therefore, I would not write that the choke 'proved' the sole cause. I would write that the observation is sensitive to a measured change in common-mode impedance, that the independent differential reference tone did not show a comparable change within its uncertainty, and that alternative physical explanations remain possible. A controlled source at known positions can help map the coupled system, but its findings belong to those test geometries.

For a lawful defensive survey, preservation is part of the science. Retain original instrument data before the intervention, photograph or describe the unaltered connection, and record time, cable position and each test fixture. Avoid leaving a modified system in operation when the change has not been authorised or safety assessed. If the original environment cannot be perturbed safely, the correct outcome is a limited causal conclusion and a proposal for a controlled bench comparison. Uncertainty does not justify invasive testing, and a non-destructive result is useful when its limitations are reported accurately.

Dr. James M. Atkinson, Moderator: Lord Rayleigh, examine Professor Armstrong directly on the numerical evidence that can be extracted from a receiver with imperfectly characterised automatic gain and attenuation.

John William Strutt, Lord Rayleigh, Cross-Peer Question to Edwin Howard Armstrong: Professor Armstrong, attenuation slopes may distinguish a linear signal from intermodulation, but they are usually plotted in logarithmic units while the gain and noise statistics change with frequency and instrument state. What uncertainty should attach to a slope estimated

Copyright 2026, James M. Atkinson

from only a handful of attenuator settings, especially if their calibration errors are correlated? Could a two-tone result under controlled laboratory conditions fail to predict a multi-signal field environment in which the antenna pattern and source impedances differ? I ask also whether one ought to privilege a direct independent receiver measurement over a beautiful cubic fit where both instruments share the same antenna splitter and oscillator reference. Please explain what would constitute adequate model validation rather than a merely plausible regression. Should the predictive test be performed at two independent carrier frequencies so that a mechanism tied to a single receiver image or calibration accident is less easily mistaken for a general law?

Edwin Howard Armstrong, Cross-Peer Answer to John William Strutt, Lord Rayleigh: Lord Rayleigh, I would never promote the nominal slope of an intermodulation product into an isolated fact about the field without examining the statistical and physical conditions under which it was measured. If P_out in logarithmic power units is plotted against P_in, the derivative dP_out/dP_in has an interpretation only where gain, frequency selection and the set of interacting signals remain constant. A regression from three points spanning an AGC threshold is not an estimate of the local cubic response. Measurement uncertainty attaches both to input attenuation and output level, and the same pad calibration can introduce correlated errors in several points. A fit that assumes independent error in its horizontal variable will understate uncertainty if the attenuation scale itself is poorly known.

One sensible experiment samples a larger set of safe power levels in both increasing and decreasing order, retains repeated measurements and state

Copyright 2026, James M. Atkinson

logs, and checks for stable residuals under the proposed model. The instrument can be challenged with controlled single-tone and two-tone inputs that vary independently, using an external power monitor to verify levels. The predicted third-order products should appear at the appropriate calculated frequencies and change under independent adjustments in the manner expected for the model's valid region. Where they do not, I would not rescue the hypothesis with an arbitrary curve; I would investigate clipping, gain switching, receiver protection and the possibility of more than two interacting signals.

The field case may differ sharply from the laboratory because its blocker powers, phases and source impedances are unknown. A two-tone test demonstrates an instrument capability and a possible mechanism, but does not prove that the mechanism actually produced a particular line during the survey. A wideband capture, controlled preselection and another receiver architecture should therefore be used to identify candidate driving components. If a splitter is shared, the receivers may share both the same incoming disturbances and a feedline-generated artefact. Independent receiving apertures and clocks add value when their response limits are characterised. Any comparison should document that independence as a physical property rather than an administrative label.

I would count model validation as agreement across predictions not used to fit the model. Suppose the initial data suggest a third-order mechanism. The operator may predict how the candidate product will move when one input tone is changed by a known frequency increment, how its amplitude will respond to a small independent power change and how the signal will behave under a different preselector state. If those predictions are

Copyright 2026, James M. Atkinson

confirmed by blinded or predeclared tests, the explanation gains credibility. If only the selected line fits while the expected partner products or blocker relations do not, the model remains weak. The final statement should include the tested power range, uncertainties, control states and alternative explanations that survive. Elegant logarithmic arithmetic cannot replace a discriminating experiment.

Dr. James M. Atkinson, Moderator: Professor Armstrong, please put a reciprocal challenge to Mr. Jansky. The distinction between environmental noise and receiver-state artefact has major consequences for defensive survey claims.

Edwin Howard Armstrong, Cross-Peer Question to Karl Guthe Jansky: Mr. Jansky, you properly insist that externally admitted noise may be genuine without belonging to any discrete transmitter. But a survey receiver can generate an elevated noise floor from gain compression, reciprocal mixing under a strong blocker, digital clipping or internal clock phase noise. Disconnecting the antenna can improve the floor dramatically. How do you prevent the observer from describing that improvement as the physical disappearance of external noise, when the original noise floor partly arose from receiver-created effects triggered by strong input energy? What controlled tests separate actual incident noise power, source-dependent desensitisation and reference-clock-related spectral spreading? I would also ask how one could preserve a useful negative finding when the receiver is demonstrably unable to detect a weak test signal in the presence of the environmental blocker. What control would reveal a reference-oscillator spur appearing within the same analysis bandwidth when the blocker is

Copyright 2026, James M. Atkinson

removed, thereby preventing the operator from misinterpreting a changing noise-floor estimate as a newly transmitted field?

Karl Guthe Jansky, Cross-Peer Answer to Edwin Howard Armstrong: Professor Armstrong, the correct interpretation starts with the distinction between available noise power at the receiver port and noise-equivalent response at the receiver output. A large external blocker may raise the apparent noise floor through reciprocal mixing against local-oscillator phase noise, while a preamplifier in compression may lose sensitivity to a weak desired signal. The broad spectral elevation then depends upon incident energy and instrument defects together. Disconnecting the antenna removes the blocker, but the fall of the displayed floor cannot be assigned wholly to a reduction in physical environmental noise. The report should state that the coupled system showed a reduced output-noise indication under the new input condition, then test the mechanism.

A suitable experiment adds a calibrated weak probe tone at a fixed safe level while independently varying a stronger blocker. Measure the weak tone's recovered signal-to-noise ratio, the displayed broadband floor and any overload or gain-state indicators as blocker level changes. Perform the series with a high-quality external source, a characterised input pad and at least two preselector states. If the weak probe becomes less detectable as the blocker grows, the system displays desensitisation. If the floor rises in an offset pattern that depends on oscillator phase-noise characteristics and blocker frequency, reciprocal mixing deserves examination. A receiver with a different LO or reference plan offers a stronger challenge than another copy of the same architecture.

Copyright 2026, James M. Atkinson

To distinguish incident noise from instrument noise, compare a calibrated matched termination, a known noise source and the receiving antenna under consistent bandwidth and gain conditions. A noise-figure or Y-factor procedure can inform receiver contributions in a suitable laboratory configuration, but an antenna-dependent active front end and variable environment complicate transfer of that calibration. Record the noise-equivalent bandwidth, input impedance, preamplifier state, thermal conditions and uncertainty. A source with high external noise may mask an internally generated spur; a quiet load may unmask it. Neither appearance proves that the spur was newly created by the act of substitution.

Your last question concerns the integrity of a negative search. If a calibrated test tone representing the minimum target signal is not reliably detected in the presence of the blocker, the system has not demonstrated the sensitivity needed to support a negative finding for that condition. The correct action is to change the measurement method within lawful and safe limits, perhaps using preselection, attenuation and an independent front end, and then repeat the challenge. If those measures do not restore detection capability, disclose the untested interval or frequency as a coverage limitation. The duty is to describe the instrument's effective observation space, not to declare a room free of emissions merely because an overloaded receiver remained silent.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Mr. Jansky, close the reciprocal examination by testing Sir Robert’s causal inference. Please ask whether a line that follows the antenna assembly is sufficient to establish an external transmitter.

Karl Guthe Jansky, Cross-Peer Question to Sir Robert Alexander Watson-Watt: Sir Robert, the four-state substitution matrix is valuable, yet it may produce a strong-looking result: a narrow line is present with the antenna, absent under direct termination, present again when the original antenna is restored, and visible on a second receiver whose sensitivity is similar. The investigators may be satisfied and begin a search for a nearby concealed transmitter. But both receivers could be responding to a legal external broadcaster by an image or intermodulation route, or to common-mode current from a building cable, while an apparent spatial maximum could be caused by standing waves. What further evidence is necessary before the team can move from 'antenna dependent' to 'incident field at the displayed frequency', and thence to a particular source? How should the language of a forensic report distinguish these stages without becoming so vague that the technical findings are unusable?

Sir Robert Alexander Watson-Watt, Cross-Peer Answer to Karl Guthe Jansky: Mr. Jansky, I would begin by treating the four-state matrix as a successful experiment establishing an association with a defined reception configuration. It is an important finding precisely because it is reproducible, but it is not yet a complete account of energy origin. To show incident field at the displayed frequency, the investigator should use an independent receiving chain with a different conversion architecture, a calibrated antenna that can respond at that frequency, and appropriate preselection to

Copyright 2026, James M. Atkinson

reject possible images and strong blockers. A swept analogue monitor or a second SDR with a different oscillator plan may provide useful independence if its sensitivity and calibration have been demonstrated. The team should record the absolute RF frequency and confirm that it does not follow the first receiver's local oscillator or ADC clock.

To exclude common-mode cable routes, test direct and far-end terminations, controlled cable routing, shield-current observations and a change of receiving aperture with its own known feed. The aim is not to prove that every conductor in the room is irrelevant, which may be impossible, but to demonstrate a pathway consistent with the claimed field observation and inconsistent with the most plausible instrument alternatives. If the feature follows a local test generator at a known frequency, the instrument's frequency assignment is strengthened; if it follows a strong off-channel blocker, the image or intermodulation hypothesis becomes stronger. Controlled source removal where lawful can provide especially persuasive causation, but it must not be attempted by disrupting unrelated communications or equipment.

The step to identifying a particular emitter demands still more evidence. Directional response, distance trends, modulation characteristics, timestamps, known equipment activity and independent inspection may contribute. Indoor multipath and near-field coupling make a single bearing or apparent field maximum inadequate. Measurements should be taken over multiple positions and polarisation states, with environmental controls and uncertainty bounds. A source can be genuine without being malicious, intentional or even within the premises. A legal and evidential conclusion must not outrun the technical record.

Copyright 2026, James M. Atkinson

The report could therefore say: 'A repeatable spectral feature at the reported frequency was observed with the specified antenna assembly; the feature was not observed under the direct-load control; independent testing with a differently configured receiver corroborated an incident component within stated sensitivity and uncertainty. Several receiver-image and cable-coupling alternatives were challenged as described. The emitting equipment has not been established.' If later evidence identifies a source, the earlier record remains useful. If it does not, the report has not accused an object or person without grounds. Technical precision and professional restraint are compatible; in this discipline they are inseparable.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel distinguishes four evidential propositions. First, a spectral indication exists under recorded settings. Secondly, its amplitude or detection depends on a specified antenna or input configuration. Thirdly, calibrated and independent measurements support incident RF energy at a declared antenna reference plane and frequency, rather than an image, overload product, clock spur, cable-body current or display artefact. Fourthly, further spatial and source-specific evidence may identify the emitting apparatus. These propositions do not automatically follow from one another. Antenna substitution is a discriminating experiment only when loading, gain, noise, cable routing, timing and sensitivity are controlled, the alternative explanations are stated in advance, and the complete result register is preserved. Disappearance after disconnecting an antenna is evidence of configuration dependence; attribution requires more. All the dialogue here is fictional educational reconstruction, and all numerical illustrations are hypothetical.

QUESTION 069

Copyright 2026, James M. Atkinson

When do resolution and video bandwidth settings cause a swept analyser to miss brief pulses?

Dr. James M. Atkinson, Moderator: Professor Blackman, consider a surveillance receiver showing a clean baseline throughout a broad swept span while a laboratory pulse source is known to be active. The operator has narrowed the resolution bandwidth to distinguish small adjacent tones and lowered the video bandwidth until the displayed noise looks quiet. Under what circumstances do those sensible-looking adjustments make the measurement blind to short RF bursts? Please distinguish the act of acquiring energy from the later business of depicting it on a screen, and explain what a negative trace actually establishes.

Ralph Beebe Blackman, Principal Contributor: Dr. Atkinson, a spectrum analyser is a chain of causal operations rather than a transparent window onto electromagnetic events. We must distinguish the signal present at its input connector, the output of its tuned intermediate-frequency or digital resolution filter, the detector statistic, the subsequent video smoothing and the representation of those values as finite trace points. A short pulse may reach the input during the observation yet fail to create a discernible output because the analyser is tuned elsewhere. Alternatively, the instrument may be tuned correctly but present a heavily attenuated response because the intermediate-frequency filter has insufficient time to rise. A third case occurs when the filter responds but the detector or video processing conceals the excursion. These are different mechanisms. They demand different corrective experiments, and cannot be inferred merely from an empty display.

Copyright 2026, James M. Atkinson

Let the transmitted waveform be $x(t)=A\,p(t)\cos(2\pi f_c t+\varphi)$, where A is the radio-frequency carrier amplitude, f_c the carrier frequency, φ a constant phase, and $p(t)$ an envelope that equals unity during the pulse and zero otherwise. The pulse duration is τ seconds. In a conventional swept receiver the centre frequency of the resolution filter is $f_s(t)$, itself a function of time. A pulse is favourably observed only when $f_s(t)$ is sufficiently close to f_c for the passband response to be appreciable, and when that overlap lasts long enough for filter settling and data formation. Both a time condition and a frequency condition must hold. A spectral peak is not the pulse itself, but a statistic extracted from this doubly conditioned process.

A useful idealisation of the filter is a first-order linear response with characteristic time T_R; for a step in input envelope its output grows as $y(t)=A[1-\exp(-t/T_R)]$. This is a teaching model, not a manufacturer's calibration law for a particular resolution filter. If $T_R=20$ microseconds and the pulse lasts $\tau=5$ microseconds, the output at the end of the pulse reaches only $1-\exp(-0.25)=0.221$ of its eventual amplitude. Expressed as a voltage ratio this is $20\log10(0.221)=-13.1$ dB. A narrow bandwidth can thus convert an otherwise strong burst into a smaller transient. Different analogue filter poles, digital FFT acquisition windows, detector definitions and centre-frequency motion modify this result, so the investigator must validate it with a known source rather than apply one universal correction factor.

Do not mistake the familiar inverse relation between bandwidth and response time for a precise universal equality. One may write $T_R\approx\kappa/B_R$, where B_R is effective resolution bandwidth in hertz and κ is a dimensionless coefficient tied to the filter impulse response and the selected settling criterion. The value of κ differs for Gaussian-like filters, synchronously tuned

Copyright 2026, James M. Atkinson

filters and FFT-derived bins. A tenfold reduction in B_R increases a representative settling time approximately tenfold if the architecture remains comparable. It may also change noise power in the filter, which complicates attempts to interpret an apparent rise in sensitivity. A reduced noise floor does not necessarily imply an improved probability of detecting brief signals.

There is a further sampling problem. Suppose a 100 MHz span is swept in one second, with a nominal 10 kHz frequency-resolution region of interest. An elementary linear-frequency model gives an overlap duration of approximately 1 s×(10 kHz/100 MHz)=100 microseconds for a fixed carrier, before allowing for filter shape and instrument-specific step acquisition. If a random 2 microsecond pulse occurs once every 100 milliseconds, only a minority of independent pulse opportunities will coincide with that region. It would be technically indefensible to turn this rough time-frequency coverage into an exact instrument probability without measuring blanking, IF dwell, retrace, firmware behaviour and correlations. The rough calculation does, however, expose why several apparently excellent sweeps may provide little assurance.

The detector introduces a distinct question about what statistic is retained. An appropriately implemented positive-peak detector is well suited to maintaining the largest response actually captured within its observation bucket, but it cannot recover a pulse absent from the underlying sample sequence. An RMS detector reports an energy-related quantity over its integration interval; a sample detector can miss extrema; a negative-peak detector is inappropriate for finding rare maxima. Trace maximum-hold may record the strongest observed peaks across many revisits, but does not

Copyright 2026, James M. Atkinson

repair radio-frequency blind time. A max-hold trace which remains quiet after five minutes supports only a finding about the events and frequency-time conditions actually visited during those minutes.

Finally consider video bandwidth B_V. In many traditional analysers a video low-pass filter acts on the detected envelope after frequency selection. Excessively narrow B_V suppresses short excursions and makes the display attractively placid. With a first-order example $T_V=1/(2\pi B_V)$, a B_V of 1 kHz corresponds to approximately 159 microseconds. A 5 microsecond positive excursion yields an output fraction of roughly $1-\exp(-5/159)=0.0309$, or about −30.2 dB in amplitude before other loss mechanisms. This is not an assertion that all analyzers perform identical exponential smoothing, nor that all digital trace averaging uses this transfer function. It demonstrates the hazard of applying long time averaging to short signals.

My concluding procedure is therefore a matrix rather than a single setting: vary resolution bandwidth, video bandwidth, sweep duration, detector type and acquisition mode independently while injecting controlled pulses of measured duration, amplitude and repetition. Keep input attenuation, preamplification, frequency span and reference level fixed when isolating each effect, and capture the original trace metadata. Compare the complete detector outputs, not only the final screenshot. An empty trace is a conditional observation about the chosen instrument. It is not proof of a silent room, and certainly not evidence that an emitter could never have radiated there.

Dr. James M. Atkinson, Moderator: Dr. Harold Black, scrutinise the distinction between noise visibility and pulse capture. A very narrow resolution filter may make a weak continuous signal visible while making

Copyright 2026, James M. Atkinson

brief emissions substantially less visible. What exactly would be measured to separate those two effects?

Harold Stephen Black, Peer Question: Professor Blackman, I accept the mathematical distinction but challenge the practical inference that broadening the resolution bandwidth is a simple cure. Increasing the bandwidth necessarily admits more receiver noise power, and a modest pulse in a dense field of adjacent transmissions may become less distinguishable even though its filter envelope rises more promptly. If the input preamplifier is nonlinear, a wider filter and altered preselection can also admit products which were previously outside the analysis window. How do you construct a controlled test where the same incoming physical pulse is represented on equal terms by narrow- and wide-bandwidth configurations? Would you measure maximum voltage, integrated energy, or probability of declaring an event at a specified false-alarm rate? I should also like a rule for documenting a pulse whose centre frequency falls between nominal trace bins, particularly when the synthesised sweep changes the effective dwell at each bin. Without such discipline the investigator can declare success by selecting whichever display appears most dramatic.

Ralph Beebe Blackman, Response: Dr. Black, your objection is well founded because bandwidth is not a free improvement in sensitivity. For a receiver whose input noise has approximately flat one-sided power spectral density N_0 over the relevant passband, the noise power is proportional to its equivalent noise bandwidth B_e, so $P_n \approx N_0 B_e$. A tenfold increase in B_e therefore increases integrated white-noise power by ten decibels, all else equal. A continuous narrow tone may become less conspicuous against that

Copyright 2026, James M. Atkinson

background even while a five-microsecond pulse attains a more faithful temporal response. We must not compare the visibility of two differently processed pictures without preserving the detection criterion.

I would use a calibrated pulse generator and record three outcomes for each configuration: recovered peak at a specified detector and reference plane, integrated response over a documented observation interval, and empirical detection probability at an independently chosen false-alarm constraint. Define an event decision threshold before running the final trial. Estimate a noise-only distribution using a source-matched termination, but do not suppose that a cable termination reproduces real environmental noise or common-mode currents. Repeat the experiment with genuine antenna-connected background. If the question is whether a short burst can be detected at all, empirical recovery and false alarm should dominate a visually appealing peak measurement.

The instrument must disclose actual sweep points, filter equivalent noise bandwidth where known, detector bucket statistics, any digital resampling and the frequency step between adjacent observations. If the pulse carrier is deliberately offset by half a nominal bin, the test can expose passband scalloping or under-sampling of the filter shape. A second offset near the edge of the filter's defined passband tests a different ambiguity. The operator should vary pulse onset against sweep phase through controlled delay rather than accepting naturally favourable coincidences.

An elevated noise floor may conceal a weak pulse even when the input energy reaches the filter, so the report should explicitly distinguish failure of acquisition, attenuation by finite response, and failure of statistical declaration. A defensible result might say that a 2 microsecond, −70 dBm

Copyright 2026, James M. Atkinson

laboratory burst was recovered in 87 of 100 trials with one configuration and 28 of 100 with another at their respective precommitted thresholds. Such numbers would be empirical results if actually observed, not the hypothetical figures in this explanation. The essential point is that the comparison retains both miss rate and false-alarm rate, rather than placing judgement on a single colourful spectral picture.

Dr. James M. Atkinson, Moderator: Dr. Pierce, the same trace often contains a thousand frequency buckets but few details about what happened between them. Please press the point about the mathematical difference between a frequency bin and a genuine opportunity to observe a rare event.

John Robinson Pierce, Peer Question: Professor Blackman, when we say that a display contains 1,001 bins we may unconsciously treat them as 1,001 simultaneously observed channels. A swept heterodyne receiver does not ordinarily provide that parallel coverage. Its local oscillator visits places in sequence, perhaps pausing, retracing or changing filter states, while digital firmware later composes a line that resembles one instantaneous spectrum. In a field survey the operator may leave the instrument sweeping for many minutes and falsely believe that every displayed frequency has enjoyed the same temporal protection. How would you represent the coverage as an exposure function of both time and frequency? If pulse arrivals are periodic, does repeating the same sweep schedule guarantee an increasing probability of observation, or can coherent synchronisation create permanent blind spots? I also ask whether shortening the sweep can merely substitute inadequate filter settling for inadequate temporal overlap, which might leave the probability of a correct detection unchanged even when the number of displayed sweeps rises.

Copyright 2026, James M. Atkinson

Ralph Beebe Blackman, Response: Dr. Pierce, it is better to model the receiver as a time-dependent measurement kernel K(f,t) than as a permanently open collection of frequency bins. A simple binary coverage map C(f,t) may equal one when the receiver provides a validated sensitivity at frequency f and time t, and zero during tuning, blanking, retrace, inaccessible filter states or other known blind intervals. A more informative map records the measured recovered response to a standard pulse as a function of its onset, duration and carrier offset. It includes the imperfect shoulder of the resolution filter rather than asserting that the band is either entirely open or entirely shut.

The probability of detecting a randomly timed event is then associated with the proportion of event-onset positions for which the pulse and the receiver's observation kernel produce a sufficient statistic. The naive independent approximation P(at least one recovery)=1−(1−p)^n is appropriate only when the n observation opportunities really have independent capture probabilities p. A periodic transmitter and a repetitive sweep can be locked into the same unfavourable relative phase. Then n can increase without supplying new, independent information. The correct response is to randomise or deliberately dither the sweep start, introduce independent continuous observation at the frequency of concern, or prove that phase coverage has genuinely varied.

Your second point is equally important. A very fast sweep can traverse the frequency of interest before the resolution filter settles; the transient's peak is then attenuated or displaced. Manufacturers may compensate some sweep-induced amplitude errors in calibrated modes, but this must be demonstrated for the instrument, filter, amplitude and signal class being

Copyright 2026, James M. Atkinson

tested. A larger sweep counter does not transform defective measurements into valid ones. Accordingly the coverage record should log valid dwell, filter-settling qualification, detector integration and effective retrace time. Merely recording elapsed wall-clock time is inadequate.

For an audit, I would present a two-dimensional heat map of verified pulse recovery over onset phase and carrier frequency, with uncertainty limits from repeated injections. A sparse region becomes visibly distinguishable from a truly negative measurement. Where an external transmitter cannot be controlled, characterise the instrument with an authorised local source, then state the assumptions under which that characterisation bears on the disputed event. The most honest report may identify a lower bound on useful surveillance coverage rather than invent a universal probability of having seen all possible bursts.

Dr. James M. Atkinson, Moderator: Professor Gabor, take the issue beyond the sweep mechanism. Explain how duration and frequency concentration constrain the very meaning of a pulse spectrum, and why a highly resolved display can be a misleading representation of an ephemeral emission.

Dennis Gabor, Second Principal Contributor: Dr. Atkinson, the relevant difficulty is not simply that an analyser is sometimes looking in the wrong place. It is that the analyst may demand a sharp answer in frequency while refusing the observation time required to justify it. A brief electromagnetic pulse has temporal localisation. Its spectrum necessarily spreads across frequencies according to its envelope; a rectangular carrier burst is accompanied by a sinc-shaped spectral envelope, not a solitary infinitely thin line. A spectrum analyser that resolves narrow continuous-wave carriers admirably can be a poor instrument for estimating the time and amplitude

Copyright 2026, James M. Atkinson

of a very brief burst when the acquisition method is incompatible with the burst length.

For an envelope p(t) equal to one from time zero to τ, the continuous Fourier transform of the baseband envelope has magnitude proportional to τ|sinc(πfτ)| under the normalised sinc convention. The first zeros occur at frequencies f=±1/τ relative to the carrier, so their separation is 2/τ. A 10 microsecond rectangular envelope has first baseband nulls at ±100 kHz, while a 1 microsecond envelope has nulls at ±1 MHz. These figures describe the ideal envelope, not every modulation, rise time or real pulse-shaping circuit. If a narrow 1 kHz resolution filter is applied to the shorter burst, its passband captures only a small part of the broadband pulse energy and its temporal response may dominate the display.

The familiar time-frequency concentration principle may be written in a particular statistical convention as $\sigma_t \sigma_f \geq 1/(4\pi)$, with σ_t the root-mean-square time spread and σ_f the root-mean-square frequency spread of a properly normalised signal, both measured about their respective means. This inequality is not an instruction to set RBW to a single number for all pulse measurements. Nor does it predict the detailed behaviour of an analogue swept filter. It is a conceptual guard against claiming arbitrary precision in both domains without appropriate data. Gaussian signals attain the relevant lower bound under the chosen convention, whereas a hard-edged rectangular pulse has different spectral tails and may not possess finite second moment in the same straightforward manner.

The instrument may supply more than one kind of spectral representation. A conventional swept trace assembles frequency-selective responses at successive instants. A zero-span view fixes the centre frequency and reports

Copyright 2026, James M. Atkinson

detected amplitude versus time through the selected passband. A short-time Fourier transform partitions continuously acquired complex samples into overlapping windows, with choices of window length, shape and hop size. A triggered capture can retain the raw waveform for retrospective reprocessing. These displays are not interchangeable evidence. Each has its own response to a short pulse, and each can conceal a transient if its acquisition contains gaps or if its window is poorly chosen.

Consider a 100 microsecond burst followed by one second of silence. A long FFT window provides fine frequency-bin spacing but includes mostly silence; a peak amplitude normalised as though a continuous tone occupied the whole window can appear markedly reduced. A very short window provides better localisation of onset but blurs narrow spectral structure. An appropriate spectrogram should disclose its window definition, sample rate, overlap, scaling convention, trigger logic and any dropped samples. Otherwise two spectrograms with different brightness are incommensurable. Colours are persuasive to the eye but do not supply a calibrated reference plane.

The post-detection video filter adds a second loss of temporal detail. If the analyser first converts the filtered carrier to a scalar envelope, phase information may already be lost. Smoothing that envelope with a low-pass filter cannot recreate the original pulse shape afterwards. In digital systems the phrase video bandwidth sometimes names a specified trace-smoothing operation rather than a literal analogue RC network. For that reason I favour measurement of its impulse or step response using a pulsed calibration source, not supposition based on a front-panel value. We should record

Copyright 2026, James M. Atkinson

whether the signal was sampled as complex RF or IF data, detected as power, or reduced to display ordinates before any data were exported.

A special difficulty arises with multiple pulses. Coherent repetition produces a line spectrum whose spacing is the pulse repetition frequency, while pulse timing jitter and random burst amplitude modify or broaden that structure. A sweeping instrument may catch different pulses at different frequencies and unintentionally join them into what resembles a stable single event. Conversely, its max-hold function may accumulate a plausible pulse spectral envelope over many sweeps without ever observing a complete pulse in one interval. Such a constructed envelope may help characterise a stable repeating source, but it does not prove that all displayed spectral points were present simultaneously.

In a forensic interpretation I would separate at least three questions. Was energy present in the receiver input passband? Did the apparatus acquire that energy with adequate temporal response? Does the displayed representation preserve the parameter at issue, whether peak field, pulse duration, repetition period or occupied bandwidth? Each requires its own evidence. I would describe a negative finding in terms of bounded observation windows and validated detector performance, never as an unqualified proof that an instrument could not have missed a source.

Dr. James M. Atkinson, Moderator: Sir Robert, please challenge Professor Gabor on the practical temptation to reconstruct a complete spectrum from a sequence of pulses that may not be identical. How might a survey distinguish a persistent physical pattern from a display assembled from several inconsistent episodes?

Copyright 2026, James M. Atkinson

Sir Robert Alexander Watson-Watt, Peer Question: Professor Gabor, consider the common case of a surveillance instrument whose emissions are not under the investigator's control. It may change carrier frequency, pulse interval, modulation and output power in response to its own sensors or to surrounding traffic. The operator may collect a max-hold sweep over an hour and then describe the resulting outline as though it were the spectrum of one stable emission. Yet the narrow ridge at one frequency may have been created by a brief episode at midday, while a broad lobe represents a different mode much later. What acquisition and review protocol would make it possible to tell whether the composite is representative? Is there a legitimate use for max-hold in discovering rare transients, provided the limitations are explicitly recorded? Finally, if the operator is restricted to a swept receiver with no continuous I/Q recording, how should the evidence be graded rather than dismissed entirely?

Dennis Gabor, Response: Sir Robert, maximum hold has a proper but limited use as a search aid. It accumulates the maximum detector statistic at each frequency bin over successive visits. It can reveal that the instrument once registered energy at a particular bin, subject to artefacts, overload and correct calibration. It does not establish simultaneity between maxima in different bins, nor does it preserve the time sequence that distinguishes modes of operation. If the apparatus lacks an event log associated with each changed bin, the operator should resist writing a continuous waveform history from the appearance of a continuous trace.

The improved protocol retains at least the timestamp of each meaningful peak update, the sweep configuration and an independent event counter or trigger trace where feasible. If the instrument can save successive raw

Copyright 2026, James M. Atkinson

traces with their acquisition times, build a time-indexed record and identify clusters corresponding to distinct episodes. A source that changes frequency can then appear as a series of conditional observations rather than one mythical wideband emission. A triggered zero-span capture at selected frequencies, simultaneous wideband I/Q acquisition or a separate tuned receiver can supply the missing relationship between time and frequency. These are complementary methods, not interchangeable guarantees.

One must also test whether apparent spectral changes originate in the receiver. Frequency-dependent gain corrections, preselector switching, local-oscillator settling, detector transitions and automatic rescaling can produce changes that follow the scan programme rather than an external emitter. Inject a stable laboratory pulse source at the antenna reference plane, repeat the actual survey settings and observe whether the instrument generates similar features. That test does not exclude every environmental effect, but it measures one important class of alternative explanation.

If only a conventional sweep is available, evidence may still be useful when expressed conditionally. A sequence of narrow peaks recorded at separate documented times supports observations of discrete receiver indications. A repeating peak at one setting over independent sessions can motivate more careful tests. The report should give the observed and unobserved intervals, calibration confidence and the risk that the indications represent different pulses or instrument products. As long as a composite is labelled a composite, and no conclusion exceeds the available timing information,

Copyright 2026, James M. Atkinson

max-hold can be an honest discovery instrument rather than an unwarranted historical reconstruction.

Dr. James M. Atkinson, Moderator: Professor Nyquist, direct the discussion to discrete observation and detection decisions. A trace composed of digital samples may appear continuous on the screen even if important RF events fell between acquisition intervals. Explain how to establish a meaningful lower bound on the observation coverage.

Harry Nyquist, Third Principal Contributor: Dr. Atkinson, there is a dangerous ambiguity in the word sample. A receiver may sample an intermediate-frequency waveform at a particular clock rate, compute a sequence of power estimates, display one selected maximum per trace bucket, and then sample that screen for archiving. Each step is different. The familiar sampling theorem concerns a band-limited continuous signal and its reconstruction from appropriately spaced uniform samples under stipulated conditions. It does not imply that a swept receiver continuously monitors every frequency printed on its display, nor does it guarantee the capture of an unannounced brief burst during intervals when the relevant front end was elsewhere.

Let f_s be an analogue-to-digital sampling rate in samples per second and B the highest frequency in a baseband representation after proper anti-alias filtering. For a real-valued signal band-limited to B hertz, a familiar sufficient ideal condition for reconstruction is $f_s>2B$. Complex baseband has a different two-sided spectral bookkeeping convention and can cover a band approximately commensurate with the complex sampling rate when correctly filtered. Neither statement certifies continuous processing, absence of memory overrun, suitable analogue bandwidth, or adequate

Copyright 2026, James M. Atkinson

trigger selection. A digitiser operating at 100 megasamples per second can still miss a five microsecond event if its input is disconnected, its tuning is elsewhere, or its buffer discards that interval.

For a periodic swept instrument, define T_s as the interval between effective visits to a given narrow frequency, and let d denote the duration for which that frequency is observed with validated sensitivity during each visit. The simplest duty fraction is $q=d/T_s$, provided $0 \leq d \leq T_s$. If pulse onset times are uniformly distributed relative to the visit cycle and a pulse is so short that partial overlaps can be neglected, q is an approximate fraction of onsets leading to observation. A more careful overlap model for a pulse of duration τ, valid dwell d and revisit T_s gives $p_{overlap} \approx \min[1,(d+\tau)/T_s]$ when the relevant periods are non-overlapping and the arrival phase is uniform. Overlap does not guarantee detection because filter settling, threshold and signal-to-noise remain.

For example, suppose an analyser revisits a channel every 250 milliseconds and provides 0.5 milliseconds of effective sensitivity per visit. A randomly timed 20 microsecond pulse has an idealised overlap probability of approximately $(0.50+0.020)/250=0.00208$, or 0.208 percent. That is roughly one opportunity in 481 under the stated uniform-onset model; it is not an observed performance rating. For ten genuinely independent pulses the chance of one or more temporal overlaps is $1-(1-0.00208)^{10} \approx 2.06$ percent. If all ten pulses are phase-locked to the same external cycle relative to the sweep, treating them as independent would be mathematically wrong. The operator must distinguish a probabilistic assumption from a physical observation.

Copyright 2026, James M. Atkinson

There is also the problem of detector aggregation. A display point may summarise many internal time samples. A positive peak detector preserves an extreme in its sample bucket, while an average or RMS detector may dilute the contribution of a rare strong event among a long interval of noise or silence. If a pulse of power P occupies fraction δ of a detector's integration time, and background power is negligible, an ideal mean-power statistic is approximately δP. In decibels relative to pulse peak power the reduction is 10log10δ. With a 10 microsecond pulse integrated over 10 milliseconds, δ=0.001 and the ideal mean-power reduction is 30 dB. This simple result concerns linear power averaging, not the response of every log detector or trace-averaging algorithm.

When firmware records only final display values, the reviewer cannot necessarily reconstruct the intermediate time samples. That is why raw sample capture, timestamps and a record of dropped acquisition intervals are so valuable. In a modern receiver an apparently uninterrupted waterfall may contain packet loss, processing latency, FFT hop gaps or discarded blocks. If timestamps are generated by the host after buffering, they may refer to processing completion rather than antenna arrival. Characterise the timebase, queue depth and block indices, then verify with an injected sequence whose onset schedule is independently recorded.

False-alarm and detection probabilities must be tied to a defined class of pulses. One cannot assign one number to all possible emitters when their carrier offsets, durations, bandwidths, powers and modulation differ. The correct performance statement might define a bounded range of frequency offsets, pulse lengths and powers under known noise, together with the proportion of known injections recovered at a predeclared threshold. If

Copyright 2026, James M. Atkinson

interference or occupancy conditions change, the probability must be reevaluated. A single scalar sensitivity figure quoted from a manufacturer's continuous-wave specification is insufficient to predict capture of rare bursts.

A defensible instrument record would include the sampling frequency and anti-alias filter, the real or complex representation, the acquisition duty cycle, each frequency visit, any handover time, FFT window and overlap, detector definition, trigger condition and whether full data were retained. A screen that paints every pixel during a slow sweep is not a contract that every incident photon or radio-frequency oscillation was observed. It is a representation of an acquisition policy. The burden of proof lies with whoever turns that policy into a negative physical claim.

Dr. James M. Atkinson, Moderator: Mr. Weston, pursue the practical question of calibrating a continuously running detector against an intermittently acquired swept trace. How should one compare the same pulse sequence without imposing a misleading common scale?

Edward Weston, Peer Question: Professor Nyquist, the figures for observation duty are compelling, but laboratory comparisons can be easily spoilt by differences in where and how voltage is measured. One instrument may state a peak in decibels relative to a milliwatt at a nominal fifty-ohm port, another may report RMS voltage in a digitised channel, and a third may display a trace normalised to the noise-floor gain chosen by automatic scaling. At the same time, a supposedly stable pulsed source may vary amplitude with pulse width, load mismatch or repetition rate. What reference-plane discipline would you impose so that a capture probability measured on a continuous I/Q path can be compared fairly with a swept

Copyright 2026, James M. Atkinson

analyser? Would you insist upon a physical power detector as arbiter, and how would you prevent that detector's own finite bandwidth from becoming another source of undercount? Please distinguish a physical delivery of pulse energy at the input connector from subsequent detector thresholding, so that a failure at one layer is not mistaken for a failure at another. I also want the impedance mismatch correction recorded separately from the timing correction.

Harry Nyquist, Response: Mr. Weston, the comparison must start with a defined source and an agreed physical quantity. For a fifty-ohm matched reference plane, average power and RMS voltage are related by $P=V_{rms}^2/R$, where R is the reference resistance. The peak envelope of a burst is not identical to its long-term average power, particularly when its duty cycle is small. Specify whether a stated −60 dBm refers to power during the pulse's active plateau, time-averaged power over many cycles, or an analyser-derived spectral-bin estimate. Without that distinction two instruments can appear to disagree while each is correctly reporting a different quantity. Place the source at a characterised tee or splitter whose loss and isolation are measured across the relevant bandwidth. Keep the attenuator, cable routing, terminations, source pulse settings and triggering reference constant. Measure the pulse waveform with an independently bandwidth-qualified oscilloscope or envelope detector, but treat that device as another measurement system with finite rise time, noise and possible loading. If the pulse is 500 nanoseconds wide, a slow power sensor is unsuitable as the arbiter of its peak. A faster instrument whose bandwidth has been established can verify amplitude and timing, while an average power meter can provide an independent energy-related constraint for stable repetition.

Copyright 2026, James M. Atkinson

The comparator should not be forced onto an inappropriate output scale. Report recovered pulse plateau power when that quantity is well defined, event detection rate at a declared threshold, and time-frequency coverage separately. If the swept analyser never tuned to the carrier during most injections, its low recovery probability is not necessarily a failure of its amplitude calibration. Conversely, if a continuous receiver acquired all sample blocks but the wrong detector discarded short maxima, its failure belongs to downstream processing. Classification matters when deciding what should be repaired.

To control the timebase, use a common reference trigger where feasible and document its physical path, jitter and latency. Record both instrument-side timestamps and an independent source-onset log, then calculate their offsets rather than aligning graphs by eye. Repeat with at least two pulse powers, more than one carrier offset, and onset phases distributed across the sweep. State the uncertainty of the reference measurements and the number of trials. An impartial comparison may properly find that an old swept receiver measures continuous-wave amplitude accurately yet gives sparse coverage of brief events. That is not a contradiction, but an expression of different measurement capabilities.

Dr. James M. Atkinson, Moderator: Sir Harold Jeffreys, challenge the use of the word probability. Explain why a string of blank sweeps cannot be converted into strong evidence of absence without a defensible model for the source and the acquisition process.

Sir Harold Jeffreys, Peer Question: Professor Nyquist, you have appropriately qualified independence, yet an expert witness may still present a clean succession of sweeps as if statistical confidence rose automatically with each

Copyright 2026, James M. Atkinson

additional trace. What if the relevant emitter transmits only after a person enters the room, after a network packet arrives, or on the occurrence of a specific environmental stimulus that the survey never reproduced? What if the frequency and duration of transmission are unknown rather than randomly drawn from the conveniently specified model? I ask you to distinguish the probability of detecting a fixed, known laboratory pulse from the probability that an undiscovered device exists. How would you report a negative result so that the court or investigator understands what was actually challenged, without attaching numerical confidence to hypotheses the experiment never tested? If an estimate is based on repeated trials, should its uncertainty interval reflect clustering and common triggering rather than a fictitious binomial sequence of independent pulses? Please distinguish repeatability of a test rig from representativeness of the unknown transmitter behaviour.

Harry Nyquist, Response: Sir Harold, the probability of detecting an injected test waveform is conditional on the waveform, the observation schedule, the receiver configuration, the noise environment and the detection rule. It is not the probability that an unknown device exists or does not exist. A laboratory can estimate P(detection | pulse class and conditions) from controlled injections. Turning that into P(no device | negative survey) requires prior information about possible devices, their behaviours and how they were sampled. If none of these populations is characterised, a definitive posterior probability is a pretence, however tidy the algebra.

The report should make that distinction in plain terms. For example: 'With the receiver configured as specified, 100 of 100 test pulses lasting 200 microseconds at the stated frequency and level were detected under the

Copyright 2026, James M. Atkinson

recorded background. The survey did not test condition-dependent transmission outside those observation windows.' That sentence would be justified only by actual data matching the description. It does not imply that shorter or weaker bursts would be detected, nor that an emitter requiring a trigger absent from the survey was challenged. We should not silently transfer results from convenient test pulses to an unknown signal class.

A negative surveillance exercise can still be substantial evidence about a restricted physical proposition. If a particular channel was observed continuously at a calibrated sensitivity for a documented interval, the absence of a specified class of emissions during that interval may be supported. The proposition becomes weaker as the allowed alternatives expand to include arbitrarily short, rare or contingent transmissions. A useful evidential map lists each tested class and each exclusion. One may write 'not observed within the validated measurement envelope' and describe that envelope quantitatively rather than claiming a perfect search.

Nor should multiple traces be counted as independent evidence without inspecting the measurement programme. Ten identical sweeps phase-locked to a five-second transmission cycle may revisit the same blind phase ten times. They then add remarkably little new information. Randomised start times, deliberate changes of sweep duration, continuous monitoring of priority frequencies and triggered environmental stimuli provide distinct tests of the hypothesis. The statistical apparatus should account for them explicitly. In the absence of such evidence, the correct conclusion is uncertainty, not either assurance or alarm.

Dr. James M. Atkinson, Moderator: Mr. Hewlett, your historical work in the design of stable signal sources affords a particularly instructive perspective

Copyright 2026, James M. Atkinson

on instrumentation. Explain how one could construct a reproducible calibration experiment that exposes pulse erasure by resolution and video bandwidth, without confusing it with generator error or receiver overload.
William Reddington Hewlett, Fourth Principal Contributor: Dr. Atkinson, the experiment must begin with the source, not with the analyzer's front panel. A calibrated continuous-wave signal is inadequate to validate the detection of microsecond bursts because it never tests the instrument's transient path. The laboratory requires a pulsed radio-frequency source whose carrier, envelope, on-state amplitude, off-state leakage, width, rise and fall times, repetition interval and trigger timing are themselves measured. It is possible for a pulse generator to have an excellent nominal timing specification yet exhibit droop across the plateau, overshoot on transitions or carrier leakage during its quiet interval. These imperfections must be described before the analyser's reported response is judged.
I would construct two paths from a source whose output is protected by measured attenuation. One path reaches the analyser through a characterised splitter, with suitable impedance matching and overload margins. The second path reaches a bandwidth-qualified independent time-domain monitor that retains the actual envelope of each pulse. The monitor's own bandwidth and sampling cadence must comfortably resolve the fastest transitions under test; its calibration and loading are part of the uncertainty budget. The two paths must have measured delay, and the source and receiving instruments should share a traceable timing reference or at least a measurable common trigger. An oscilloscope trace drawn without trigger discipline is not a definitive standard for simultaneity.

Copyright 2026, James M. Atkinson

The test matrix should include at least three duration classes. Begin with pulses long compared with the measured resolution-filter settling time, so there is a baseline in which steady-state amplitude can be approached. Move to pulses near that settling time, where shape distortion is expected. Finish with pulses much shorter than that time, where attenuation may be substantial. In each class use multiple pulse powers sufficiently below the receiver's compression threshold, repeat at several carrier offsets within the displayed bin, and place pulses at varying phases of the sweep. This isolates duration, frequency, amplitude and timing without making the factorial design unmanageable.

A teaching sequence might use pulse widths of 1 millisecond, 50 microseconds and 2 microseconds, with a stable carrier at 100 MHz. First compare 1 MHz, 100 kHz and 10 kHz nominal resolution bandwidth settings while keeping VBW wider than the fastest relevant detected envelope, where the instrument permits that choice. Measure actual observed peak and event capture. Then hold RBW constant and reduce VBW through a series such as 1 MHz, 100 kHz, 10 kHz and 1 kHz, noting whether that control changes physical video filtering, digital averaging, or both on the particular model. The numerical settings are an experimental example rather than an assertion that every analyser offers precisely those ranges or uses equivalent filters.

The experiment should not rely on trace maximum-hold alone. Preserve raw or minimally processed detector data where the instrument permits it, and obtain a time-aligned zero-span capture at each bandwidth. Compare the measured pulse envelope and the detector response in the same time coordinate. If a pulsed source is repeated every 100 milliseconds, an

Copyright 2026, James M. Atkinson

arbitrarily timed sweep that misses nine out of ten opportunities must not have its missing values silently replaced by maximum-hold from a fortunate tenth sweep. Record counts of injections and counts of actual recoveries, and distinguish physical input delivery from successful on-screen declaration.

The analyser's linearity also needs qualification. A high crest-factor input can produce momentary compression even when its long-term average power is modest. An instrument with automatic gain control may recover differently after a large pulse than after a weak one. Set input attenuation, reference level and preamplifier state deliberately, verify against a known linear source and repeat selected tests with additional attenuation. A genuine linear power change should follow the added pad to within the known measurement uncertainty, while overload products or internal settling may behave otherwise. This is not merely a courtesy check. An overloaded front end could imitate either an exaggerated peak or the disappearance of a following pulse.

A well-designed source can also reveal video-filter attenuation by keeping the IF filter effectively settled. Choose a long enough burst to permit the RF selectivity chain to reach the expected plateau, then vary B_V independently and observe the video rise time and displayed peak. Reverse the procedure by holding B_V wide and reducing burst width while changing B_R. The order of experiments matters because changing two controls at once makes causal attribution difficult. If automatic coupling changes sweep time when RBW or VBW is altered, preserve that change in the log and, where possible, run a second matched-sweep comparison.

Copyright 2026, James M. Atkinson

The final record should include the pulse-source settings and their independently measured values; the full analyser setup; swept and zero-span traces; detector type; overload indicators; frequency-reference information; equipment identifiers; cable and attenuator calibrations; trial counts and rejection rules; and the exact meaning of each plotted amplitude. The purpose is not to construct an impressive demonstration but to test a precise proposition: whether the instrument, at a specified configuration, could have detected a particular class of brief emission with a known probability and amplitude error. That result can then inform the design of a surveillance survey without being inflated into a universal certificate of absence.

Dr. James M. Atkinson, Moderator: Dr. Bracewell, examine how the laboratory should control the relation between pulse length and receiver bandwidth when a finite-duration signal has a broad spectrum. Can a power meter, a zero-span trace and a swept spectrum legitimately report different values without any of them being defective?

Ronald Newbold Bracewell, Peer Question: Mr. Hewlett, the proposed reference path is persuasive, but I am concerned about the phrase 'same amplitude'. A finite pulse sends energy across a band, and a narrow resolution filter accepts only a portion of it. A broadband power sensor integrating over the entire signal spectrum may yield an entirely different number from a frequency-selective instrument receiving a single small slice. A zero-span trace may report the detected envelope after a nontrivial IF transient; a swept trace may report a statistical maximum at one selected frequency. How would you choose a common measurement definition that does not prejudge one instrument as right and the others as wrong? Would

Copyright 2026, James M. Atkinson

you calibrate the total RF energy, the carrier-referenced peak voltage, or the spectral density? Please also explain how changing the pulse's rise time can alter the result even if the nominal width and crest amplitude remain constant.

William Reddington Hewlett, Response: Dr. Bracewell, the first obligation is to identify the measurand. Total pulse energy, in joules, is the time integral of instantaneous delivered power across the complete occupied spectrum. A correctly specified broadband sensor may estimate that energy after calibration for its response. The peak RF envelope power, by contrast, refers to the maximum power during the active portion of the waveform at a reference plane. A resolution-filtered spectral bin reports an instrument-dependent measure of the waveform's power within a finite passband. None should be labelled simply 'amplitude' without qualification, and none is automatically a substitute for another.

For a well-matched load R and a known voltage waveform v(t), the delivered energy during the observation interval is $E=\int v^2(t)/R\, dt$. If an ideal pulse delivers 1 milliwatt of power for 10 microseconds, its energy is 10 nanojoules. If that pulse repeats once every 10 milliseconds, its ideal duty cycle is 0.001 and its long-time average power is 1 microwatt, or −30 dBm, whereas the on-state power is 0 dBm. Those figures are internally consistent but measure different properties. A narrow frequency filter does not capture all ten nanojoules unless its frequency weighting and integration permit it. Rise and fall times complicate the simple rectangular model. A raised-cosine envelope, for example, reduces high-frequency sidelobes compared with abrupt switching at the same plateau, while modifying total energy if the duration definition is not adjusted. The correct comparison saves the

Copyright 2026, James M. Atkinson

measured envelope, rather than merely the generator's setting. When one instrument is broadband and another frequency-selective, compare both against a waveform model convolved with each instrument's characterised transfer function. This permits an expected difference to be computed without describing it as error.

I would specify distinct tests for each measurand. Use the broadband path for waveform and energy characterisation, with appropriate bandwidth and dynamic range. Use zero span to assess the analyser's amplitude-versus-time response in a nominated frequency passband. Use a calibrated swept or FFT spectrum with documented windows to estimate spectral distribution. The three data sets can be cross-checked for energy consistency after allowing for bandwidth, windowing, mismatch, leakage and uncertainty. If an apparent discrepancy persists, investigate the reference plane, detector definition and calibration before calling the source or analyser faulty. Clear nomenclature is an instrument of forensic fairness.

Dr. James M. Atkinson, Moderator: Dr. Townes, inquire about the possibility that nominally identical pulses produce different observed peaks because of frequency and phase changes during the pulse. We need a procedure which is robust to unintended chirp and source modulation.

Charles Hard Townes, Peer Question: Mr. Hewlett, an oscillator may be exquisitely stable over a long period while a pulsed output exhibits frequency pulling during its leading edge, thermal changes within a burst, or transient phase modulation from the switch. A spectrum analyser set to a very narrow resolution bandwidth could then show a small peak, not because the event was absent, but because instantaneous frequency moved through and beyond the passband while its filter was still settling. How

Copyright 2026, James M. Atkinson

would you separate pulse-duration attenuation from chirp, drift or phase transients? I am particularly concerned about an investigator who broadens RBW and finds a large new peak, then claims that the original narrow-band measurement was simply 'incorrect'. Should the proper explanation instead distinguish the two filters' responses to a genuinely broadband or time-varying waveform? Could a deliberately measured frequency trajectory, rather than the generator's nominal tuning label, serve as the reference when comparing these instrument settings? Please explain how phase noise in a low-amplitude leading edge should be excluded from a spurious chirp estimate.

William Reddington Hewlett, Response: Dr. Townes, yes. A short burst is not guaranteed to be a perfectly gated stationary sinusoid. Its frequency may change during turn-on, and those changes need not be defects when the source is intentionally agile. A narrow frequency-selective path can report only the portion of energy and time lying within its transfer function. If a frequency trajectory crosses the IF passband while the filter settles, the observed transient depends on both frequency history and filter dynamics. Broadening RBW may increase the recovered peak for physically intelligible reasons without proving that the original instrument was operating outside specification.

An appropriate experiment begins by recording complex I/Q samples with enough instantaneous bandwidth to capture the entire pulse spectrum. From those data estimate instantaneous phase after appropriate amplitude thresholding and unwrap the phase carefully. The derivative of phase divided by 2π gives instantaneous frequency where the signal has sufficient amplitude and the model is meaningful. At a rising edge, where amplitude

Copyright 2026, James M. Atkinson

approaches zero, phase becomes ill conditioned; an apparent enormous chirp can be merely noise. Compare frequency trajectories across repeated pulses and record the confidence of each estimate rather than relying on a single colourful spectrogram.

Next feed the same observed waveform, or a source reproducing its well-characterised envelope and frequency trajectory, through characterised filter responses. A long constant-frequency pulse serves as the settling control; a short constant-frequency pulse isolates temporal response; a deliberately chirped pulse tests tracking or filtering loss. Preserve the amplitude scale of the source and distinguish simulations from physical measurements. If the narrow-band path differs from the broad-band path by the amount predicted from the characterised transfer functions, the difference is expected. If it differs materially more, look for sweep mistiming, overload or calibration faults.

The report can therefore state three facts separately: the physical pulse duration, the occupied frequency-time trajectory, and the analyser's recovered detector statistic under a named configuration. This avoids the false binary judgement that one filter tells the truth and the other lies. In surveillance work the broad-band record helps establish that an emission occurred, while a narrow-band path may help resolve close interference once sufficient observation time exists. Their respective strengths are complementary, and neither can vindicate a conclusion about unobserved signals outside the validated acquisition envelope.

Dr. James M. Atkinson, Moderator: Professor Armstrong, attend to the receiver itself. Explain how mixing stages, resolution-filter transients,

Copyright 2026, James M. Atkinson

detector choices and automatic sweep coupling can turn a real pulsed input into either an attenuated trace or an apparently spurious one.

Edwin Howard Armstrong, Fifth Principal Contributor: Dr. Atkinson, a frequency-converting receiver is an active electronic experiment. Its mixer does not simply transport an incoming signal from radio frequency to an intermediate frequency in a lossless manner. Local-oscillator energy, preselection, gain distribution, nonlinear products, filter shape and detector response all influence the indication. These effects become especially visible with pulses, because switching the RF envelope imposes rapid time variation while the receiver's internal circuits may have slower settling and recovery. One should never infer from a smooth displayed trace that the front end enjoyed continuous, linear sensitivity throughout every burst.

A conventional swept spectrum analyser places a local oscillator at a succession of frequencies so that a narrow IF resolution filter samples each corresponding input region. Where the RF input is present for a shorter interval than the IF filter needs to settle, the output does not reach the value obtained for a continuous carrier of equal on-state amplitude. The precise response depends on filter implementation and on where the sweep begins relative to the pulse. A later video low-pass filter can further attenuate the detector excursion. Thus two distinct time responses may compound. But because logarithmic detectors and digital processing can be nonlinear, one must not simply add two estimated decibel losses without verifying the processing order and dynamic regime.

Suppose an IF filter has an experimentally established 10 to 90 percent envelope rise time of 30 microseconds. A two microsecond carrier burst begins just as the sweep approaches the correct frequency. The filter may

Copyright 2026, James M. Atkinson

produce a short ringing response whose maximum occurs after the external pulse ends. A screen timestamp tied to that maximum is not necessarily the emission onset. The analyser can also shift the apparent spectral peak if its local oscillator moves during the filter transient. If the displayed peak appears later or at a nearby frequency, the investigator must first test whether the instrument itself creates such displacement from a stable laboratory pulse.

There are additional deceptive mechanisms. A strong pulse may compress an RF amplifier for its first microseconds and cause slower recovery, concealing a weaker pulse immediately afterwards. Automatic level control may lower gain following a burst and make the next event appear absent. A pulsed blocker outside the nominal displayed channel may mix with other energy to produce a transient within the IF; an image response can be mistaken for a direct emission unless preselection is adequate. Noise blankers, overload-protection circuits and adaptive digital suppression can deliberately remove impulsive energy. Each mechanism calls for a different calibration and cannot be resolved by tuning RBW alone.

The display detector matters greatly. An averaging detector may be appropriate for mean noise or mean channel power, but it can understate isolated high-amplitude pulses. Positive-peak detection better preserves captured extrema, provided the dwell and bucket formation actually include the event. A quasi-peak detector has weighting that intentionally distinguishes repetition rate and is not a general peak-power estimator. Video smoothing can make noise look less restless, but a smooth video trace is not proof of a small RF peak. The instrument should disclose its detector

Copyright 2026, James M. Atkinson

algorithm, any logarithmic averaging and whether the video-filter control is applied before or after the selected statistic.

Consider a pulse repeated every 10 milliseconds, an analyser sweep with 1,001 display points, and a frequency of interest visited for an effective fraction of the repetition interval. If pulses are periodic and sweep phase is stable, some frequencies may be observed reliably while neighbouring points consistently miss. Increasing trace accumulation without changing relative timing can preserve those blind positions. A triggered zero-span measurement at the frequency of interest can characterise pulse width and interval, while an appropriately bandwidth-qualified simultaneous receiver can establish whether events occurred during skipped sweep regions. A careful test distributes pulse onset relative to sweep timing and documents the resulting collection of responses rather than presenting the most striking trace.

A simple frequency-conversion calculation illustrates another ambiguity. A local oscillator at 900 MHz and a desired RF signal at 910 MHz produce a 10 MHz difference-frequency IF in a first-order mixing model. An unwanted component at 890 MHz produces the same absolute difference if image rejection is imperfect. Pulsing either signal can create a brief 10 MHz response. The fact that the detector traces a pulse at the IF does not by itself establish which RF input frequency caused it. Direct input-path substitution, suitable preselection and a second independently characterised receiver architecture may be needed. The numeric example teaches mixer symmetry rather than describing a particular commercial instrument.

The field procedure should begin with an instrument self-test and a calibrated source through a known attenuation path. Check the receiver at

Copyright 2026, James M. Atkinson

more than one power to expose gain compression and at more than one pulse width to reveal settling loss. Record both narrow and broad RBW with a video bandwidth that is demonstrably adequate for the relevant envelope, then change VBW separately. Include positive-peak and RMS or average detector measurements, using the proper interpretation for each. If available, retain a synchronous I/Q record so that the swept trace can be compared with actual incident energy. Conduct a source-off control and repeat the source-on sequence to test reproducibility.

The forensic conclusion is deliberately restricted. A quiet swept trace does not exclude an external pulsed transmission unless the specific transmission class lay within valid time-frequency coverage at demonstrable sensitivity. A spectacular peak does not alone identify an external emitter because overload, images, internal clock products and transient filter behaviour can imitate it. The strength of a survey lies not in the polish of a screen but in verified measurement conditions and adversarial alternative explanations. I would pass that doctrine to the final panel exchange: no technical witness should be permitted to trade an instrument display for a stronger proposition than its acquisition chain actually supports.

Dr. James M. Atkinson, Moderator: Dr. Steinmetz, investigate why the operator might change a bandwidth setting and thereby alter automatic sweep time, input gain or other coupled parameters without appreciating that the measurement is no longer controlled.

Charles Proteus Steinmetz, Peer Question: Professor Armstrong, an instrument may offer automatic coupling between resolution bandwidth, video bandwidth, sweep duration and sometimes detector behaviour or preamplification. If the operator adjusts RBW from 100 kilohertz to 1

Copyright 2026, James M. Atkinson

kilohertz, the device may silently lengthen the sweep so that its IF response remains calibrated. The analyst then attributes a disappearing pulse to the narrow filter while the chief cause might instead be changed temporal sampling of a periodic event. Conversely, forcing manual sweep time may cause the instrument to over-sweep the filter and generate an inaccurate amplitude. How would a technician distinguish these interacting causes with a compact but rigorous set of experiments? Would you also regard instrument alarms, such as an uncalibrated sweep warning, as evidence that a completed trace is unsuitable for quantitative interpretation, even if the picture resembles the expected spectrum? The frequency sweep may also contain hidden retrace intervals and preselector transitions. Should these be represented as unavailable observation time rather than folded into an apparently continuous sweep duration? How would a technician document the validity of those transitions?

Edwin Howard Armstrong, Response: Dr. Steinmetz, the front panel must be treated as a set of coupled control variables, not a row of independent knobs. I would first capture the complete instrument state before and after every user-initiated change, using the device's configuration export or a carefully checked manual register. The change log should include not only the selected RBW, but also actual sweep time, sweep points, VBW, detector, trace averaging, attenuation, reference level, gain and any automatic corrections. Where the firmware exposes real filter dwell or acquisition mode, those should be recorded. An uncalibrated or overload warning must be preserved as a qualification even if the trace looks persuasive.

The experiment proceeds in two passes. In the first, use normal automatic coupling and document the complete resulting state for each RBW setting.

Copyright 2026, James M. Atkinson

This establishes how an ordinary operator would encounter the instrument. In the second, hold those other parameters fixed where safe and calibrated, changing only the particular bandwidth being investigated. If the instrument cannot provide a valid calibrated manual configuration, the second pass must not be represented as an accurate amplitude comparison. It may instead illustrate the degree of algorithmic dependence under a deliberately diagnostic, nonquantitative setting.

The source should supply pulses whose onset is swept through the entire relative timing cycle. One may use a trigger delay that changes by known increments on successive trials, or a measured pseudo-random onset sequence. A stable pulse generator alone does not reveal time-coverage failure if it repeatedly occupies a favourable phase. Compare the resulting detection surfaces as functions of onset and carrier offset. The effects of changing sweep time will then appear separately from the filter's characteristic attenuation, at least to the extent that the experimental variables can be isolated.

Finally, any instrument alarm is substantive evidence about metrological validity. A trace can remain attractive while a manufacturer-defined amplitude calibration condition is violated. An alarm does not necessarily mean that no qualitative information exists, but it forbids an unqualified amplitude claim. The review should say whether each trace was obtained in calibrated operation, in a known diagnostic exception or in an uncharacterised state. A report can then attribute the observed omission to narrower bandwidth, changed coverage or an unresolved combination, rather than inventing a single tidy cause.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Dr. Jeffreys has raised the interpretive burden; Professor Gabor and Professor Nyquist should now interrogate one another directly. Cross-peer exchanges must identify the respondent, and the response must immediately follow its question rather than be deferred to an unspecified general discussion.

Dennis Gabor, Cross-Peer Question to Harry Nyquist: Professor Nyquist, your expression for the chance of overlap has the merit of revealing the large blind intervals, but it becomes deceptive if a pulse has complex frequency structure or if a filter's response continues after the physical envelope ends. The event might overlap a nominal dwell only through a weak sidelobe, while an appropriately sensitive detector could register a later filter response after the scan has moved. How would you generalise a binary time-coverage map into a measurable event-detection kernel without multiplying unknowable probabilities? I am especially interested in whether the investigator should define 'capture' as any energy above the noise, the first threshold crossing, an amplitude estimate within tolerance, or a reconstructable pulse. Please clarify how these definitions change the quoted coverage and how a report should prevent a favourable detection rate from being mistaken for accurate parameter estimation. In particular, should a delayed output caused by IF ringing count as a detected emission if its frequency and onset labels are both outside the allowed reconstruction error? I want the response to distinguish simple alarm sensitivity from reliable forensic localisation.

Harry Nyquist, Cross-Peer Answer to Dennis Gabor: Professor Gabor, the proper generalisation is a response surface based on explicit test waveforms and decision rules, not an imagined universal detector probability. Let θ

Copyright 2026, James M. Atkinson

denote the pulse parameters, including onset, carrier offset, duration, power and waveform shape. Let s denote the receiver state and observation schedule. The instrument produces a statistic Z through its physical and digital chain. We can estimate $P[Z>\gamma \mid \theta,s]$ for a declared threshold γ from repeated injections under specified background conditions. That quantity does not presume a binary filter passband. It permits the real impulse response, sidelobes, scan motion and processing artefacts to influence the result as observed.

But we should preserve several success criteria. First, 'indication' means that a predeclared detection threshold was crossed during a valid record. Second, 'localisation' means that the reported time and frequency lie within specified errors of the injected event. Third, 'amplitude recovery' means that the reported pulse parameter lies within a declared tolerance. Fourth, 'waveform recovery' might require enough samples and bandwidth to reconstruct selected details with bounded error. These criteria form nested or overlapping claims depending on the instrument; a detector can flag energy without reconstructing the waveform or finding onset precisely.

The test matrix should report separate recovery fractions for each criterion, with trial counts and uncertainty intervals, rather than one undifferentiated 'detection probability'. We can also retain the raw measured response surface as a function of event onset and carrier offset. Only after establishing a credible distribution of possible source behaviours should we average those conditional results into a broader operational prediction. The latter distribution is often unknown in a surveillance case, and that uncertainty must not be hidden.

Copyright 2026, James M. Atkinson

A delayed filter ring may cross threshold after the physical pulse ceases. It may still be a valid indication under the first criterion, but not a correct onset estimate. The record should therefore distinguish the time of emission, the time of first receiver response and the time of screen update. Those quantities can differ because of group delay, buffer latency and detector aggregation. This is why I prefer separate evidence categories rather than allowing one successful display to certify every aspect of the incident waveform.

Harry Nyquist, Cross-Peer Question to William Reddington Hewlett: Mr. Hewlett, your pulsed source is the backbone of the calibration programme, but the apparatus may contain two correlated imperfections: the pulse timing generator and the receiver sweep may share an oscillator reference, and the reference monitor may derive its trigger from that same generator. A beautifully repeatable result can then arise because both systems are synchronised to the same rhythm rather than because the receiver has general competence at detecting unsynchronised bursts. How would you expose this common-clock bias without sacrificing the traceability of frequency and time measurements? Is true randomisation of pulse onset necessary, or would a deterministic set of controlled phase offsets suffice? I also ask how you would prevent a 'known good' calibration instrument from becoming a source of common-mode coupling that the survey receiver mistakes for an RF input event. Would a second set of trials with intentionally uncorrelated timebases expose false confidence that survives deterministic phase stepping? Please specify the evidence needed to show that the randomisation procedure did not itself change pulse amplitude, spectral shape or reference-plane power.

Copyright 2026, James M. Atkinson

William Reddington Hewlett, Cross-Peer Answer to Harry Nyquist: Professor Nyquist, a shared reference may be desirable for measuring frequency and time precisely, but it must not be allowed to dictate the event phases sampled by the experiment. I would deliberately vary the relative timing between the pulse source and the sweep, using a programmable delay whose actual increments are checked with an independent time-domain recorder. A deterministic sequence covering the full phase cycle can be adequate when the receiver is stable and the schedule is known. Randomised order is particularly useful when instrument temperature, gain or environmental interference drifts during the test. Neither approach requires abandoning traceability. It requires separating a common timebase from a common phase of event occurrence.

A second pass could use a free-running pulse generator with an independent, recorded timing reference. Compare its relative phases and capture statistics with the synchronised trials. If coverage is highly sensitive to phase, the divergence will be apparent. The operator should not average the two regimes into one indistinct success rate. A useful audit includes both the phase-conditioned response and a marginal performance estimate under a specified phase distribution, making explicit the source of that distribution.

To exclude coupling through the laboratory apparatus, first substitute a matched termination at the receiver's input while the timing and trigger cables remain connected. Then change trigger routing, isolation and physical separation without altering the intended RF power path. Observe whether the supposed event persists or follows the trigger wiring. Use properly screened attenuators and verified isolation in the source splitter;

Copyright 2026, James M. Atkinson

check for emissions from the pulse generator itself with an independent probe. A calibration tone that leaks by a cable shield or power lead can produce exactly the kind of false certainty this experiment seeks to avoid. The whole exercise therefore contains a source-verification experiment, a receiver-coverage experiment and a coupling-control experiment. Their results should be reported separately. Shared-clock coherence is a feature when studying one phase precisely, and a trap when generalising that phase to arbitrary events. We can preserve the former and expose the latter through controlled phase sweeps, independent observation and honest uncertainty statements.

William Reddington Hewlett, Cross-Peer Question to Edwin Howard Armstrong: Professor Armstrong, suppose the analyser shows no pulse at narrow RBW but displays a striking peak when RBW is broadened. An investigator may have controlled sweep time and VBW and may still conclude too quickly that the narrow filter itself is solely responsible. Yet source power can drive the mixer into compression, the front-end response may vary with frequency, and a pulse may cause local-oscillator or IF transient effects not present for a steady tone. What sequence of receiver tests should separate genuine filter settling from gain compression, image responses and AGC recovery? I ask for a procedure that retains both qualitative diagnostic value and credible quantitative limits, without making the report a collection of unrelated screen pictures. Please also distinguish an input-stage saturation effect from a recovery transient generated by a preceding pulse, since the second burst might be lost even though an isolated burst at the same nominal peak level passes perfectly. How would inter-pulse interval changes reveal this history dependence?

Copyright 2026, James M. Atkinson

Edwin Howard Armstrong, Cross-Peer Answer to William Reddington Hewlett: Mr. Hewlett, first establish that the source's active-pulse amplitude is within the linear operating region of the entire signal path. Repeat the pulse experiment with known input attenuation in several steps while preserving the pulse generator's settings and recording the actual power at the receiver reference plane. In a linear chain, recovered voltage and power should track the expected attenuation according to the selected detector and calibration. If a broadband configuration changes by an unexpectedly small amount, or produces new spectral components, compression or mixing products merit investigation. Automatic gain control should be disabled where possible, with the state explicitly recorded. If it cannot be disabled, test the recovery after different inter-pulse intervals.

Second, hold the signal frequency fixed and vary pulse duration from much longer than the RBW settling time to much shorter. A characteristic duration dependence consistent with a measured impulse response supports the filter hypothesis. Then use a stable continuous-wave tone at the same carrier power to check frequency calibration and steady-state gain. A receiver with correct continuous-wave amplitude but deficient short-pulse response has a different fault or limitation from one whose steady-state calibration is already wrong. Neither condition is repaired by a new screenshot.

Third, test alternative input frequencies capable of producing the same IF through images or intermodulation. Vary the local oscillator or preselector, if the instrument permits safe diagnostic control, and observe whether the suspect response follows the expected mixing relation. A second front end with different architecture and independently characterised clocks can help.

Copyright 2026, James M. Atkinson

If a line appears only under a certain overload condition or input mixture, do not interpret it as an external transmitter at the displayed frequency without independent evidence.

Finally combine the observations in a test table: attenuation slope, continuous-wave calibration, pulse-width response, onset phase, RBW/VBW setting, receiver alarm state and independent reference waveform. State which mechanisms the tests exclude and which remain. Where no unique mechanism is demonstrated, conclude that a response is instrument-dependent and give its measured bounds. Proper engineering does not require every ambiguity to be resolved; it requires the record not to disguise unresolved alternatives as established facts.

Edwin Howard Armstrong, Cross-Peer Question to Ralph Beebe Blackman: Professor Blackman, we have distinguished a filter's failure to settle from a sweep's failure to visit the carrier, yet a legal or security reader may struggle to see how those mechanisms combine in one negative-survey statement. Consider an instrument for which an injected pulse class is found in 60 percent of trials at one frequency and 95 percent at a second, while false alarms differ because the local interference is stronger at the second. If the investigator also lacks a justified model of how an unknown device chooses when to transmit, what is a principled way to state the limits of exclusion? Would you propose a bounded performance envelope, a worst-case statement, or a sensitivity map? Please explain how you would avoid averaging incomparable frequencies and pulse classes into one attractive but misleading percentage. A reviewer might also be tempted to infer that four good results compensate for one entirely uncharacterised frequency band. Please address whether any aggregate measure may be reported

Copyright 2026, James M. Atkinson

without explicitly declaring its frequency weighting and the decision significance of the blind region.

Ralph Beebe Blackman, Cross-Peer Answer to Edwin Howard Armstrong: Professor Armstrong, I would begin with a conditional performance map, indexed by tested frequency, pulse duration, level, carrier offset, onset phase and background condition. Each entry should distinguish detection probability at a specified false-alarm rate from the accuracy of any amplitude or timing estimate. The figures 60 percent and 95 percent in your example tell us about the tested classes and thresholds. They cannot be averaged to 77.5 percent merely because two frequencies are available; that average would silently assume equal relevance and equal opportunity for each condition. If one channel has severe persistent interference, its apparently larger hit rate may be accompanied by a very different false-alarm burden.

A worst-case figure can be useful only when its domain is explicit. 'At least 60 percent of the tested pulses were detected' may describe the two demonstrated frequencies, but it says nothing about untested carrier offsets, weaker powers, shorter durations or phase-locked periods of receiver blindness. A sensitivity map shows where the apparatus has established competence; outside that region the correct label is uncharacterised, not zero sensitivity and not guaranteed absence. I would also preserve the underlying trial counts and confidence intervals, because a reported 95 percent based on twenty trials carries a different precision from the same fraction based on thousands.

The survey conclusion should then identify the exact surveillance claim. A defensible statement is that no qualifying event was observed during the

Copyright 2026, James M. Atkinson

recorded coverage at validated sensitivities, and that the detection programme would be expected to recover the tested pulse classes at the measured conditional rates. The inference remains weaker for emitters with unknown activation, shorter pulses, atypical modulation or frequency agility. If a security decision must be made despite that uncertainty, it should be framed as a risk-management judgement informed by the measurements, rather than dressed as a scientific proof of a completely silent environment. I would retain the maps, source waveforms, receiver configurations, calibration records and negative-control data in the evidential package, together with a short plain-language statement of the untested conditions. That approach allows a future reviewer to reproduce the comparison and revise the conclusion when better information emerges. The integrity of the examination lies in preserving the distinction between observed absence, validated test sensitivity and the larger unobserved world.

Dr. James M. Atkinson, Moderator: The discussion will close on a common evidential formulation. A swept analyser reports the behaviour of an acquisition system under stated settings. Narrow resolution bandwidth, restrictive video bandwidth, sweep scheduling, detector aggregation and nonlinear receiver behaviour may all suppress or misrepresent brief emissions. Every negative conclusion must be constrained to validated pulse classes and actual time-frequency coverage. The moderator thanks the contributors and formally passes the token to the independent publication reviewers for source-to-claim checking, mathematical review and integrated pagination, none of which is certified by this fictional reconstruction.

QUESTION 070

Copyright 2026, James M. Atkinson

How should antenna, cable, preamplifier and receiver uncertainties be combined without double counting?

SCHOLARLY RECONSTRUCTION. Every speaker is a deceased historical specialist. The modern dialogue is entirely fictional educational speech; contemporary RF applications and worked figures are editorial calculations, not historical quotation.

Dr. James M. Atkinson, Moderator: Sir Harold Jeffreys, imagine that a field-strength survey presents a numerical result corrected for an antenna factor, a cable loss, a preamplifier gain and a receiver reading. Every component arrives with a calibration certificate, and one laboratory has used the same power standard and temperature reference to produce several certificates. If we place each uncertainty in a column and calculate a root-sum-of-squares total, have we established the uncertainty of the reported field? Or have we counted one underlying reference error several times while omitting the dependence introduced by installation, mismatch and temperature? Explain what should be measured, which correlations enter, and how an expert report can defend its combined uncertainty without inventing precision.

Sir Harold Jeffreys, Principal Contributor: Dr. Atkinson, an uncertainty budget is a quantitative description of a measurement model, not a shopping list of certificates. The first question is what the reported number means. If it is the electric field strength at an explicitly identified position and frequency, its measurand differs from the voltage at a receiver connector. If it is the available power at an antenna port, an antenna factor may not belong in the equation at all. These choices determine which

Copyright 2026, James M. Atkinson

corrections and uncertainty contributors are relevant. An analyst should establish the physical quantity, reference plane, installation, measurement bandwidth, polarisation, detector statistic and observation interval before adding a number from any calibration record.

For a conventional narrowband field-strength measurement with consistent logarithmic units, one may write $E_{dB} = V_{rx,dB} + AF_{dB} + L_{cable,dB} - G_{preamp,dB} + C_{misc,dB}$. Here E_{dB} is a field-strength level expressed, for example, in dB microvolts per metre; $V_{rx,dB}$ is the calibrated input-referred receiver level in dB microvolts; AF_{dB} is the antenna factor in dB per metre for the specified geometry and polarisation; $L_{cable,dB}$ is the insertion loss of the designated cable path in decibels; $G_{preamp,dB}$ is the net amplifier gain in decibels referred to the same measurement planes; and $C_{misc,dB}$ represents explicitly defined corrections such as mismatch or known instrumental offsets. This model is local to the declared frequency, load and conditions. A correction must never be inserted solely because a certificate prints a tolerance beside it.

The corresponding first-order uncertainty law is $u^2(E)=\text{sum over } i \text{ and } j \text{ of } c_i c_j \operatorname{cov}(x_i,x_j)$, where c_i is the partial derivative of the measurement model with respect to input x_i, expressed in compatible units. For the four explicitly displayed logarithmic terms the sensitivities are $+1,+1,+1,-1$. A positive covariance between antenna factor and cable loss therefore adds variance, whereas a positive covariance between measured receiver level and the subtracted amplifier gain enters with a negative sign. In a more general nonlinear model c_i need not equal unity. If the input vector has covariance matrix Σ and sensitivity vector c, the calculation is $u^2(E)=c^T\Sigma c$. The matrix should be physically plausible, symmetric and positive semidefinite.

Copyright 2026, James M. Atkinson

An arbitrary collection of guessed correlation coefficients that violates those properties is not a defensible uncertainty estimate.

Consider a hypothetical observation with V_rx=42 dB microvolts, antenna factor AF=18 dB per metre, cable loss L=2 dB and amplifier gain G=20 dB. The inferred field level is 42 dB microvolts per metre before any separately justified extra correction. Let the associated standard uncertainties be 0.5, 1.0, 0.2 and 0.6 dB, assumed initially independent. The combined standard uncertainty is sqrt(0.5^2+1.0^2+0.2^2+0.6^2)=sqrt(1.65)=approximately 1.28 dB. This number is not a coverage interval and is not justified if the certificates share a significant reference or if the physical installation introduces effects absent from the model.

Now suppose an experimentally supported correlation of +0.6 exists between the antenna-factor and cable-loss estimates. Their covariance contribution, given identical positive model sensitivities, is 2(1.0)(0.2)(0.6)=0.24 square decibels. The revised variance is 1.89 square decibels, giving u(E)=1.37 dB. If a different pair has opposing signs in the measurement equation, the covariance term may reduce the result. One cannot therefore say that correlation always raises the combined uncertainty. Nor can one safely omit it merely because root-sum-of-squares is familiar. The sign and magnitude follow from the causal measurement model and evidence about the input estimates.

The deeper mistake is to enter the same systematic source once as the uncertainty of the calibrated receiver reading and again as a free-standing uncertainty of the shared power standard, when the receiver certificate already includes it. If the calibrator contributes a latent quantity r to two measured corrections, we should express each correction in terms of r and

Copyright 2026, James M. Atkinson

independent residuals, then propagate r only once. Alternatively, retain the covariance that follows from the shared r, without adding another separate r term. These are mathematically equivalent routes when applied consistently. Mixing them double-counts the reference. The same warning applies to room temperature if several device corrections were determined with the same thermometer and thermal model.

Type A evaluations use the statistical behaviour of repeated observations under specified conditions. Type B evaluations use documented information such as calibrations, physical limits, engineering data or justified probability models. Neither type automatically determines whether two inputs are independent. Two laboratories can produce statistically precise results with a shared national standard; several observations from one field chain can be correlated by an unrecorded cable temperature. The distinction between random and systematic is also not synonymous with Type A and Type B. A corrected effect can retain uncertainty, and a repeated uncorrected bias can remain systematic without appearing in the scatter of trials.

I would therefore require an uncertainty register which gives every input's provenance, correction, standard uncertainty, assumed distribution, coverage factor where relevant, common reference identifiers, covariance evidence and sensitivity coefficient. The register should show which uncertainty sources have been absorbed into certificate results and which remain additional. It should be versioned so that later changes to antenna position, preamplifier bias or receiver firmware do not silently inherit the old numbers. The final claim should identify its confidence interpretation and the operating conditions to which it applies, while preserving the distinction between a calibrated measurement and an attribution of a transmitter. For

Copyright 2026, James M. Atkinson

our next speaker, I pass the token to Professor Neyman: experimental design is needed to determine whether the covariance terms are supported by the data.

Ralph Beebe Blackman, Peer Question: Sir Harold Jeffreys, your covariance expression assumes that the same error has been traced through each calibration without confusing a statistical correlation with a repeated document entry. Suppose a laboratory calibrates an antenna factor using a reference source, and then uses that same source to establish the receiver level scale. The first certificate may include uncertainty of the reference standard, and the second may also contain it. An operator is tempted to enter both complete certificate values, their stated uncertainties and a separate line for the calibrator. How would you decide whether the calibrator uncertainty has already been counted once, twice or three times? Please show the correct treatment where its effects have equal signs, and explain what evidence would justify a covariance rather than merely assuming that the certificates' shared letterhead proves perfect correlation. Finally, should the final reported uncertainty always be larger whenever certificates are declared correlated, or can physical sensitivity coefficients produce cancellation?

Sir Harold Jeffreys, Response: Mr. Blackman, identify the elementary uncertainty sources before combining the derived certificate quantities. A calibration certificate may provide a result and combined standard uncertainty but not its full covariance with another result. If both certificates include one known reference contribution r and the measurement model uses them with coefficients a and b, the common contribution to the output error is (a+b)r when both derive from the same physical r with the same sign

Copyright 2026, James M. Atkinson

convention. Its variance is $(a+b)^2u^2(r)$. Calculating $a^2u^2(r)+b^2u^2(r)$ omits the covariance $2ab\ u^2(r)$; adding an independent extra $u^2(r)$ line after that may double-count the source in a third way. Conversely, if the two coefficients are opposite and equal, their shared reference error cancels in the derived contrast, even though each individual certificate includes it.

Take a hypothetical calibrator error with standard uncertainty 0.4 dB appearing in two calibration corrections that both add to the field model with coefficient +1. The common contribution to the final standard uncertainty is $|1+1|\times0.4=0.8$ dB. If falsely assumed independent, the corresponding contribution would be $\mathrm{sqrt}(0.4^2+0.4^2)=0.566$ dB, an understatement. If one correction adds and the other subtracts the same calibrator error, the shared contribution is zero in the ideal common-mode model, whereas an independent calculation again gives 0.566 dB, an overstatement. Neither result proves any given real calibration behaves in this ideal fashion. The actual coefficients depend on how the calibrations were computed and how the reference enters the model.

To establish the covariance, obtain the laboratories' calibration equations, identify the traceable reference instruments and relevant calibration dates, and determine whether the common reference errors are indeed the same variable. An error from an instrument whose value changed between calibration dates is not necessarily perfectly correlated. A certificate that lists only an expanded uncertainty cannot be casually decomposed into a shared component and an independent remainder. The proper response is to request covariance information, reanalyse the underlying calibrations if possible, or present bounds obtained from plausible dependence models. A document issued under the same accreditation scheme may have entirely

Copyright 2026, James M. Atkinson

different traceability routes, while documents issued at separate facilities may still derive from one common standard.

I would ask the examiner to retain a dependency diagram with the reference standard as a single node and arrows to every affected correction. Then either perform propagation at the elementary node level or propagate certificate-level estimates with an explicit covariance matrix, but not both at once. The field result may have a wider, narrower or unchanged uncertainty after correlation is included. The sign and magnitude are conclusions of the measurement equation, not attributes of the word 'correlated'.

Ronald Newbold Bracewell, Peer Question: Sir Harold, antennas introduce uncertainties that do not resemble scalar calibration errors. The field at a survey position may be polarised elliptically; the laboratory antenna factor may have been measured in a specified plane-wave field; and a cable or amplifier can alter the terminating impedance. Would it be appropriate to add one manufacturer's antenna-factor tolerance, another generic mismatch allowance and a third polarisation tolerance as independent normal errors? Or would that produce a number with no meaningful relation to the actual uncertainty of the physical field? Please explain how the measurand, the antenna orientation and the spatial field distribution affect the uncertainty model. If the investigation is specifically about detecting a possible hidden emission rather than reporting an absolute field level, should one use the same uncertainty budget without modification? I would also require the report to distinguish uncertainty in a calibrated field component from the unknown component orthogonal to the receiving antenna, since no covariance calculation can reconstruct a component the measurement never observed.

Copyright 2026, James M. Atkinson

Sir Harold Jeffreys, Response: Professor Bracewell, the specified field component is central. A calibrated antenna factor generally applies under stated frequency, polarisation, termination and geometry conditions. If the incoming field is not a known plane wave and the antenna sits within a reactive or strongly reflecting environment, a scalar antenna factor may not describe the desired measurand. The defensible response is to define what is actually estimated: a component along the antenna's effective polarisation, a received terminal voltage, a power-equivalent indication under an explicit reference model, or a bounded search result. These are not interchangeable. The uncertainty budget must follow the selected quantity rather than convert every environmental complication into an arbitrary standard deviation.

For a simple far-field linear-polarisation example, the received voltage can contain a factor cos θ, where θ is the angular mismatch between the field polarisation and the antenna response. At θ=60 degrees, cos θ=0.5 and the voltage loss relative to alignment is 20log10(0.5)=−6.02 dB, under the idealised assumptions. If θ is unknown, the correction may be ill-defined, particularly near a polarisation null where a small angular change causes a large relative change in received level. It is inappropriate to take a tidy normal error around an unknown large attenuation and announce a tight uncertainty for the total field. Instead perform orientation sweeps, suitable orthogonal-polarisation checks and spatial substitutions, and state the scope of the detectable component.

Mismatch similarly requires interface-specific modelling. If a calibration certificate includes uncertainty from mismatch between antenna and standard load, while the field installation adds an adapter and different

Copyright 2026, James M. Atkinson

preamplifier input, the original and new interfaces must be distinguished. The same physical reflection contribution should not be listed independently in several categories merely because both an antenna certificate and cable certificate refer to mismatch. A frequency-dependent network model or an empirically measured mismatch envelope is superior to stacking generic allowances. Where the model lacks a valid correction, present alternative calibrated configurations or limits.

A detection search has another statistical question. Negative findings depend upon observation coverage, sensitivity, false-alarm control, polarisation coverage and the class of emissions the method can detect. Standard uncertainty in a field estimate conditional on successfully detecting a steady test carrier cannot establish the probability of detecting an unknown brief transmission. The report should therefore give separate calibration uncertainty and validated search-coverage limitations. Neither a highly accurate antenna factor nor multiple readings from one orientation alone prove that a concealed source was absent.

Jerzy Neyman, Cross-Peer Question to Sir Harold Jeffreys: Sir Harold, your covariance expression is rigorous when the dependency structure is known, but in practice a laboratory may supply only expanded uncertainties with coverage factors and no detailed common-reference decomposition. If the examiner fills in missing correlations by adopting zero, the resulting confidence statement can be much too narrow, while treating every input as perfectly correlated may create a needlessly pessimistic bound. What defensible procedure should govern the interval between full evidence and total ignorance? I would particularly challenge the temptation to add the same standard's uncertainty both as a common latent term and as part of

Copyright 2026, James M. Atkinson

the complete certificate-level variances. How can the manuscript show alternative dependence scenarios without presenting them as probabilities verified by experiment? And under what conditions could a partial re-calibration against an independent standard reduce rather than merely rearrange the uncertainty? Does the proposed sensitivity analysis remain valid if the certificates quote coverage intervals with different distributions or different coverage factors, rather than standard uncertainties that can legitimately enter one covariance matrix?

Sir Harold Jeffreys, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, the first principle is disclosure of what the laboratory knows. A certificate's expanded uncertainty U may equal a coverage factor k multiplied by a combined standard uncertainty u under its stated convention; one must examine the certificate rather than assume all k values are two or all distributions normal. Where the calibration provider cannot supply common-reference components, an examiner should not manufacture them. Instead identify which inputs plausibly share sources and calculate a defensible family of covariance scenarios, explicitly distinguishing measured coefficients, reasoned bounds and unverified assumptions.

For a pair of standard uncertainties u_1 and u_2 with sensitivities c_1 and c_2, the variance contribution is $c_1^2u_1^2+c_2^2u_2^2+2c_1c_2\rho u_1u_2$. If only the constraint $-1\leq\rho\leq1$ is known for that pair, one can compute endpoint values, provided those values are physically and jointly possible. For example, for two positive sensitivities and $u_1=0.5$ dB, $u_2=0.3$ dB, the combined standard uncertainty ranges from $|0.5-0.3|=0.2$ dB at $\rho=-1$ to 0.8 dB at $\rho=+1$; at $\rho=0$ it is sqrt(0.34)=0.583 dB. This interval is a sensitivity illustration, not a probability interval for ρ and not a permission to pick its

Copyright 2026, James M. Atkinson

most convenient endpoint. For several inputs, a candidate covariance matrix must remain positive semidefinite, so independently choosing every pair's extreme correlation may be inconsistent.

A partial independent calibration can narrow this uncertainty when it is designed to observe the relevant common source. For instance, compare the complete receiver-path response using a separately traceable level reference against a result obtained from the original standard. Retain the uncertainty of both transfer paths. If the difference agrees within a sufficiently small uncertainty bound, some candidate large common biases may become less plausible. But agreement does not prove the sources have no remaining shared traceability dependency or no drift under other conditions. It constrains a specific hypothesis and range.

To prevent double-counting, the analyst should choose one of two consistent parameterisations. At the elemental level, model individual reference errors and residuals as separate inputs and propagate them once. At the certificate level, retain the complete variances and add covariance between certificate estimates, but do not insert the same original reference as another independent line. A dependency diagram with source identifiers, dates and transformations is essential. When covariance remains unidentifiable, report the alternative uncertainty outcomes and their effect on the final decision. A bounded finding with honest sensitivity analysis is more persuasive than a falsely precise number generated by an arbitrary independence convention.

Dr. James M. Atkinson, Moderator: Professor Neyman, Sir Harold has written the measurement equation, but its covariance must not be filled from intuition alone. How should the survey team design repeatable tests that

Copyright 2026, James M. Atkinson

distinguish common reference drift from the independent behaviour of each component?

Jerzy Neyman, Second Principal Contributor: Dr. Atkinson, the choice of design precedes the arithmetic. If an investigator changes every antenna cable, amplifier and receiver setting in one trial, no observed change can be assigned uniquely to a given mechanism. Conversely, holding the entire chain untouched for a hundred measurements may produce deceptively low scatter because it never samples the configuration or environmental influences responsible for field error. A meaningful uncertainty experiment must state the population or ensemble to which the reported inference is meant to apply: one fixed instrument chain over one afternoon, a particular receiver over its calibration interval, or an ensemble of possible installations. Different estimands call for different designs.

A useful study begins with a stable laboratory signal injected through an explicitly documented RF path and monitored by an independent reference. Measure the receiver display as a function of generator level at several frequencies and levels to reveal linearity and gain dependence. Calibrate or verify the cable loss with a network-analyser arrangement under a defined termination. Measure preamplifier gain at its operating bias, temperature and loading, rather than assuming a catalogue figure. The antenna factor requires the relevant antenna calibration method and its geometry; an electrical substitution at the receiver input cannot establish an installed antenna's absolute field response. Keeping these distinct measurements prevents a reference substitution from being treated as a universal replacement for all physical corrections.

Copyright 2026, James M. Atkinson

To estimate common temperature influence, one could vary ambient temperature in a controlled chamber over a safe range while logging the antenna or representative network, cable, preamplifier and receiver responses. If the actual antenna cannot be chamber-tested, the limitation should be described rather than hidden. A repeated set of temperature plateaus with both rising and falling sequences can reveal hysteresis and thermal lag, which would be missed by a single linear regression. Each device may have a different response time. A multivariate analysis should distinguish a temperature effect in a shared calibration signal from individual physical temperature coefficients. Where the same thermometer measures all components, its calibration uncertainty is a common input, not independent added noise for each component.

For a simple model let measurement residual z_{ij} denote the corrected field result at temperature condition i and device configuration j. One may posit $z_{ij}=\mu+\alpha_i+\beta_j+\gamma_{ij}+\varepsilon_{ij}$, where μ is a declared baseline, α_i the temperature effect, β_j the configuration effect, γ_{ij} their interaction and ε_{ij} residual variation under the design. This is a descriptive model until the experimental sampling and error structure justify a particular inferential method. When repeated measurements are collected serially, ε_{ij} may itself be autocorrelated. Treating a long correlated trace as hundreds of independent trials would understate uncertainty. A block design with randomised order where practicable and recorded environmental history helps expose this weakness.

Cross-calibrator work is especially useful. If the receiver, preamplifier and cable corrections were all measured against one power standard, repeat selected tests with an independent standard whose traceability and

Copyright 2026, James M. Atkinson

uncertainty are separately documented. The discrepancy between those two calibration chains contains information about possible shared bias, but does not automatically identify the bias in either chain. A third comparison, or an interlaboratory procedure with stated transfer uncertainties, may be needed. A cable substitution can isolate cable-specific variation only if its connectors, bending, impedance and temperature are controlled. A receiver substitution changes receiver noise, matching and detector response; it is therefore a designed intervention, not a pure test of one coefficient unless the other consequences are measured.

Consider two observations of the same nominal field taken with separate receiver boxes but one antenna and one cable. Their noise floors may differ independently, yet the antenna factor and cable loss uncertainties are shared. Let a be the common correction error with standard deviation 0.9 dB and let independent receiver errors have 0.4 dB standard deviation each. Each result's error variance is $0.9^2+0.4^2=0.97$ square decibels. The difference between the two errors cancels a, giving standard deviation $\mathrm{sqrt}(0.4^2+0.4^2)=0.566$ dB. It would be a mistake to infer from that good differential agreement that the absolute field result has only 0.566 dB uncertainty. The shared error has simply become invisible in the comparison. This experiment diagnoses receiver agreement, not antenna traceability.

A complementary design employs crossed substitutions. Use two independently characterised cables and two preamplifiers in a small matrix, so that each cable operates with each amplifier. The raw result can reveal interactions such as amplifier input mismatch changing when a different cable is attached. Without these crossed trials, an observed gain difference

Copyright 2026, James M. Atkinson

might be falsely assigned to amplifier drift when part came from source mismatch. The experiment should also contain a complete-chain verification in which a known external field, or an appropriately traceable transfer arrangement, is observed with the installed antenna. A bench test at the receiver port tests only the electrical subsections downstream of that port.

The important output is not merely an estimated covariance table but an auditable description of how it was acquired, including sample size, trial sequence, environmental range, measurement repeatability and any selective exclusions. Statistical confidence must not be claimed merely because software reports a covariance matrix. Positive-semidefinite checks, residual diagnostics and sensitivity analysis should be applied. If the design cannot identify a correlation, provide a bounded scenario and evaluate its impact on the final conclusion rather than inventing a convenient coefficient of zero. Finally, the quantity being measured is not the source identity; a low-uncertainty field estimate does not by itself identify an emitter. I would pass the discussion to Professor Box, whose work on models should challenge whether our appealing linear relation is sufficiently faithful to reality.

Edward Weston, Peer Question: Professor Neyman, a survey team has one temperature chamber and one reference generator. They perform many measurements at three temperatures and report small standard errors for antenna, cable and preamplifier corrections. All three components were tested sequentially while the generator warmed, and only one thermometer observed the chamber. The team then claims that the corrections are independent because a statistical package reports a separate standard error for each regression. How would you design the study to expose correlated

Copyright 2026, James M. Atkinson

drift and avoid mistaking serial repetitions for independent evidence? Please describe which randomisations and cross-over tests are useful, how long-term ageing or hysteresis can confound the thermal response, and how you would handle an experiment that cannot directly characterise the installed antenna. I should also like to know what information must be retained so a second laboratory can reproduce your covariance estimates. Please identify the control that would demonstrate a change in the common generator rather than a simultaneous genuine temperature effect in all three pieces of hardware, and how its uncertainty enters the comparison.

Jerzy Neyman, Response: Mr. Weston, a regression programme describes the observations supplied to it; it cannot certify their experimental independence. I would divide the investigation into traceable reference changes, temperature changes and configuration substitutions. First, characterise the generator and its power standard independently, noting warm-up, drift and the times of each measurement. Repeat calibration observations in an order that changes the device sequence rather than always measuring antenna, then cable, then preamplifier. Where randomisation is physically possible it reduces confounding between elapsed time and component identity. Where equipment warm-up prevents arbitrary order, employ planned balanced blocks with explicit time effects in the model.

At each controlled temperature plateau, allow sufficient equilibration for the slowest relevant component and record actual component temperatures, not merely the chamber controller setpoint. Follow both rising and falling trajectories to reveal hysteresis. Duplicate some settings at the end of a sequence to measure reference drift during the experiment. Introduce a

Copyright 2026, James M. Atkinson

second independently monitored thermometer or calibrated local sensor to distinguish thermal gradients from one shared sensor bias. A single thermometer's uncertainty must appear as a common latent input to the temperature corrections. Independent random errors in separate fitting routines do not make that shared uncertainty disappear.

For the installed antenna, one cannot infer complete in-situ field sensitivity from a cable-and-amplifier chamber exercise. A traceable known-field or appropriate site-based substitution test is required, with its own geometry and uncertainty. If that cannot be performed, state a limitation and consider separate plausible scenarios. A covariance matrix estimated under laboratory conditions may not transfer to an enclosure with strong multipath, unknown antenna loading or temperature gradients. The ensemble of operating conditions must match the stated purpose of the reported result.

Retain the raw time series, calibration-source identity, device serials, full trial order, excluded observations with reasons, temperature-control history, chamber maps and the analysis code or equations. State whether the covariance is across repeated readings, calibration factors, device substitutions or operating conditions. Use confidence intervals or uncertainty estimates appropriate to the actual number of independent blocks, rather than to the total number of rapid data points. When one physical component is measured repeatedly under nearly identical conditions, successive readings are often temporally correlated; their apparent count overstates the effective independent sample size. An explicit dependency graph, crossed experimental design and independent

Copyright 2026, James M. Atkinson

reference challenge offer more useful evidence than a narrow regression confidence band produced by an untested independence assumption.

Harry Nyquist, Peer Question: Professor Neyman, consider repeated frequency-domain measurements obtained from a spectrum analyser using overlapping FFT windows. The operator has one thousand numerical readings and treats them as one thousand independent indications of amplifier gain. Yet their overlapping records share many samples, and a stable reference source imposes a common amplitude drift. How would you compute a meaningful uncertainty for the mean response without turning correlation into an arbitrary penalty? Is there a defensible role for effective sample size, block methods or separate calibration controls? Please also distinguish the statistical uncertainty of the estimated average noise power from the uncertainty in converting a receiver display into field strength. I am concerned that the same stochastic fluctuations might be included once in the empirical standard deviation and again in a manufacturer's stated receiver-noise allowance, thereby double-counting the actual variability. In particular, should the covariance be estimated separately for adjacent FFT bins and separated frequencies where filter overlap and common local-oscillator behaviour create different dependence patterns?

Jerzy Neyman, Response: Mr. Nyquist, overlapping estimates must be analysed through their covariance, not their nominal count. For observations Z_1 through Z_n with covariance matrix C, the variance of their arithmetic mean is $(1/n^2)1^TC1$, where 1 is the n-component vector of ones. If all observations had equal variance σ^2 and were independent, that expression reduces to σ^2/n. With positive autocorrelation it is generally larger. A long sequence of overlapping FFT estimates may contain much less

Copyright 2026, James M. Atkinson

independent information than its thousand entries suggest. The relevant covariance can be estimated from a sufficiently stable and representative series, using block bootstrap or time-series methods where justified, but no technique removes an unobserved shared calibration bias.

A simple illustrative case helps. Suppose each of ten nominal readings has independent error standard deviation 0.2 dB plus one common gain error of 0.6 dB. The average has variance $0.6^2+0.2^2/10=0.364$ square decibels, hence standard uncertainty approximately 0.603 dB. Treating ten complete readings as independent, each with variance $0.6^2+0.2^2=0.40$, would imply sqrt(0.40/10)=0.200 dB. That is an unjustified threefold improvement. The data may provide excellent evidence of repeatability while remaining dominated by the shared calibration component.

The distinction between field-strength and noise-power uncertainty is likewise essential. A receiver's noise estimate may affect the variance of a detector statistic and thereby the uncertainty of a field estimate near threshold, but it does not necessarily constitute an additive field correction. If the empirical standard deviation includes the receiver's relevant noise under the actual bandwidth and averaging scheme, adding the same noise variance again merely because a manufacturer lists noise performance is double-counting. Conversely, laboratory repeatability with a strong injected tone may exclude the additional uncertainty caused by field interference or detector thresholding. The model should distinguish what each experimental term represents and whether the observation regime matches the intended use.

I would organise the budget by causal origin: reference calibration, analogue path corrections, sample or detector noise, configuration effects

Copyright 2026, James M. Atkinson

and environmental influences. Each causal source should be included once, then propagated through all affected quantities with appropriate sensitivities. The trial ledger should identify overlapping blocks, window weights, detector settings and source-off conditions. An effective sample size can be a useful diagnostic but should not conceal changes in variance or correlation across frequency and time. Where correlation is uncertain, present sensitivity scenarios and qualified confidence intervals. A large spreadsheet is not itself evidence that a measurement's independent information content is large.

George Edward Pelham Box, Cross-Peer Question to Jerzy Neyman: Professor Neyman, your controlled temperature and source-substitution design seeks covariance across repeated trials, but the measurement can involve changes that are not random draws from any stable distribution. An operator may bend a cable once, tighten a connector, replace an amplifier or move an antenna in a reverberant room. The resulting change can be a switch between distinct measurement regimes, not a new sample from one population. How will your experiment detect when the model's error structure is changing rather than merely estimating an ordinary covariance more accurately? I would ask you to separate repeatability under unchanged conditions from reproducibility under installation changes, and to specify when a small pooled standard deviation conceals a systematic difference between groups. Finally, should the laboratory claim one universal uncertainty when frequency, signal power and temperature jointly affect the transfer function? What specific check would distinguish a genuinely random installation effect from a deterministic calibration shift that should be corrected before any residual variance is combined?

Copyright 2026, James M. Atkinson

Jerzy Neyman, Cross-Peer Answer to George Edward Pelham Box: Professor Box, a designed experiment must include explicit factors for the regimes whose transfer is being claimed. If bending a cable or retorquing a connector changes the physical measurement equation, the operation should be recorded as an experimental treatment, not silently pooled into a single residual. Compare trials within each configuration and between configurations. A hierarchical or fixed-effects model may describe separate groups, but the model must be justified by the intended population of future use. If the instrument is to operate only with one fixed cable routing, variation among arbitrary routings may be a stress test rather than a direct contribution to its standard uncertainty; if routine deployment includes changes of routing, the uncertainty model must reflect those possibilities or require recalibration after each change.

An illustrative two-group result demonstrates the danger. Suppose ten repeated readings before a connector change average 40.0 dB with within-group standard deviation 0.1 dB, while ten readings after the change average 41.0 dB with the same within-group standard deviation. Each group's repeatability is excellent, but the one-decibel between-group shift cannot be dismissed as ordinary short-term noise. A pooled standard error calculated without representing the configuration distinction might describe neither operational case correctly. The measurement engineer must determine whether that shift is a correction to be applied, an instability that prevents quantitative use, or evidence of a different physical coupling mechanism.

I would pre-register the relevant factors and monitor interactions: frequency, signal level, temperature, cable position, termination, amplifier

Copyright 2026, James M. Atkinson

bias and receiver attenuation state. Rather than exhausting every mathematically possible combination, use a justified factorial or response-surface design in the region where the equipment is expected to operate. Maintain controls for source drift and independent checks of the reference standards. A sudden transition or nonrepeatable response triggers investigation of model adequacy rather than automatic enlargement of a normal error distribution.

Where the response is frequency-dependent, report an uncertainty function over frequency or a set of verified bands, not one universal scalar copied to every line in the survey. The same applies to level dependence and temperature. If the user wants a single conservative summary, its derivation should state the operating envelope and the worst-case or coverage rationale. It should not pretend that different operating regimes are identically distributed. The experiment should ultimately test predictive adequacy on held-out configurations or an independent path substitution. A small fit residual within one training regime is not enough; the model must anticipate data under the conditions to which the report applies.

Dr. James M. Atkinson, Moderator: Professor Box, examine the situation where the model is tidy but the receiver is near overload, or where logarithmic units, mismatch and detector statistics produce nonlinearity. What is the practical limit of a linear uncertainty budget?

George Edward Pelham Box, Third Principal Contributor: Dr. Atkinson, a model should be judged by the decisions it supports and the observations it fails to explain. The equation for field strength in decibels is convenient because gains and losses become additive, but its convenience is not proof that the actual chain behaves linearly in the relevant signal range. A

Copyright 2026, James M. Atkinson

preamplifier near compression, a receiver showing intermodulation, an antenna subjected to a changed termination or an automatic gain-control stage may no longer respond according to the calibration factors used. No adjustment of covariance can rescue a measurement equation that has omitted a dominant physical mechanism.

Begin with the transformation between linear voltage and logarithmic units. A change of one decibel represents a multiplicative voltage ratio of 10^(1/20), approximately 1.122, when voltage and impedance conventions are consistent. Uncertainty stated as a symmetric interval in decibels is not symmetric in linear voltage. If a field reading is close to a detection threshold, one should consider whether the natural estimand is an amplitude, an energy, a logarithmic level, a probability of detection or a limit of observation. A first-order propagation of uncertainty in decibels may be perfectly adequate for a small, well-behaved calibration region, but it can mislead when the measurement distribution is strongly skewed or censored by a detection threshold.

Receiver nonlinearity is diagnosed by varying the lawful injected signal over a specified range and checking whether the reported level advances in the expected proportion. If an input is increased by 10 dB, a linear, properly configured chain should report a compatible 10 dB change after accounting for its response and measurement convention. A departure may indicate compression, automatic attenuation switching, a change in detector response or input mismatch. A data set that includes such behaviour should not be 'fixed' by increasing an uncertainty term without first determining whether a different model or operating condition is required. The safe

Copyright 2026, James M. Atkinson

output may be an inequality, a qualified lower limit or a rejection of that measurement configuration.

Mismatch is a useful example of structural dependence. The power delivered from one RF device to another depends on their complex reflection coefficients and the interconnecting network; a cable insertion-loss measurement obtained between matched reference ports is not automatically the in-situ loss between mismatched devices. The antenna factor can also be defined for a specified load and configuration. If a modeller adds a separate mismatch uncertainty to both the antenna correction and cable loss, and each calibration certificate already includes a mismatch term for the same interface, the physical effect has been counted twice. The audit should identify each interface exactly once, with a model that exposes how its reflection coefficients affect the measured voltage. A general-purpose percentage added at the end is not a substitute for defined interfaces.

An explicit example can expose the fallacy. Suppose two separate certificate entries each carry 0.4 dB standard uncertainty attributed to the same reference-level calibration. If that one common source enters the final field estimate with one net sensitivity coefficient of unity, its contribution to combined variance is $0.4^2=0.16$ square decibels, not $0.4^2+0.4^2=0.32$. But if that reference enters the receiver and amplifier corrections with opposite signed sensitivities and identical magnitude, the shared reference may cancel in the final contrast. Whether it contributes once, twice or not at all follows the underlying measurement equation. It cannot be decided from how many times the certificate printer wrote 'reference uncertainty'.

Copyright 2026, James M. Atkinson

When the linear approximation is questionable, propagate distributions through a physically validated model, as described in the supplements to the Guide to the Expression of Uncertainty in Measurement. In a Monte Carlo calculation one samples the joint distribution of input quantities, including correlations, and evaluates the measurement equation repeatedly. The resulting distribution may be asymmetric or multimodal and should be reported as such. Yet simulation does not create evidence: a million samples from unjustified input distributions merely compute the consequences of unjustified assumptions more precisely. The sources, covariances, limits, and nonlinear response must first be characterised and stress-tested.

We should also distinguish uncertainty due to a measured correction from epistemic uncertainty about whether the model contains the correct physical factors. A covariance budget cannot automatically include a hitherto unidentified intermittent connector, a frequency-selective preamplifier spur or an antenna-pattern null. These require challenge tests, receiver substitution and a limitation on inference. The investigator ought to keep a model-adequacy register: which hypotheses were tested, which remain and which were not observable with the apparatus. When a replacement antenna yields a different indication, ask whether the difference arises from external field sensitivity, input impedance, cable current or an instrument artefact. The difference does not identify a transmitter by itself.

For publication, I would separate the measurement equation, input estimates, statistical uncertainty budget, alternative-model analysis and evidential conclusion. A small uncertainty value should not be framed as the probability that a particular defendant, device or location generated the

Copyright 2026, James M. Atkinson

emission. That inference demands a different statistical and physical model. The objective of uncertainty propagation is to quantify how well one specified measurand has been measured under specified conditions. I invite Charles Proteus Steinmetz to examine the physical circuit mechanisms capable of connecting nominally independent budget entries.

Charles Hard Townes, Peer Question: Professor Box, a report presents a neat uncertainty budget in logarithmic field-strength units even though the preamplifier may have compressed on occasional strong pulses and the receiver has employed automatic attenuation. The analyst's mean level and standard deviation are nevertheless stable because the highest events were clipped or removed as outliers. Does enlarging the uncertainties for the amplifier, receiver and detector produce a defensible field estimate, or has the measurement model changed category? Would you require a separate bounded result or a rejection of the observation? Please discuss the consequences of converting a censored distribution into decibels, and the danger of treating a receiver overload warning as a minor nuisance term. Finally, explain how a model challenge test differs from merely fitting additional residual variance until the apparent goodness of fit becomes satisfactory. What experimental observation would make you refuse to compute a conventional combined standard uncertainty at all, even if each individual certificate remains within its printed date of validity?

George Edward Pelham Box, Response: Professor Townes, unobserved or clipped events cannot be restored by enlarging an error bar around their surviving mean. A calibration relation built for linear amplitude response is invalid in compression, and an instrument that changes attenuation without a reliable state record may be applying a different transfer function to

Copyright 2026, James M. Atkinson

different parts of the record. First establish what values were actually observed, which were discarded and whether the measurement response remains identifiable. Where the high values are censored by a known threshold, a censored-data model might be appropriate if its assumptions and threshold are measured. Where overload produces unknown nonlinear distortion, a bounded statement or explicit rejection may be more defensible than a formally precise estimate.

Logarithmic transformation complicates the distribution. A symmetrical normal model in decibels corresponds to an asymmetric multiplicative distribution in linear amplitude. That may be acceptable for modest uncertainties, but not if half the signal population is below threshold or the upper tail is clipped. A source capable of producing short peaks may have an average level that is not an adequate summary of the risk or phenomenon under investigation. Define whether the measurand is mean power, peak amplitude, maximum observed level, occupancy or presence of a signal class. The detector should be tested for that quantity.

A model challenge injects a known, traceable signal at several amplitudes and waveform durations and compares the observed response with the predicted measurement function. If a 6 dB increase of input power produces only 3 dB of reported increase, a nonlinear response or state change must be investigated. Merely raising the residual variance until the fit looks acceptable does not restore the missing sensitivity. Perform an independent instrument substitution, inspect gain-control and overload logs, and repeat under reduced signal levels that place the chain in its calibrated range. State when a laboratory calibration does not apply to the field environment.

Copyright 2026, James M. Atkinson

The proper uncertainty budget also depends on whether discarded data were missing at random. Removing extreme values because they appear inconvenient destroys the evidence needed to evaluate censoring and may artificially lower sample variance. Every rejected reading should have an auditable reason grounded in instrument validity rather than in the result's magnitude. If the source-off baseline remains stable but the source-on peaks trigger overload, the relevant inference is conditional on that nonlinearity. A small uncertainty for the ordinary low-level samples may still be valid within the low-level regime, but should not be presented as uncertainty for all possible transmissions.

Thus model adequacy precedes distribution propagation. Compare a linear calibration model, an explicitly measured nonlinear one and a conservative bounded statement. Present their operational differences rather than choose whichever produces the narrowest error interval. A carefully qualified absence of a quantitative result may be more scientifically responsible than a confident figure which no controlled instrument challenge can reproduce.

Charles Proteus Steinmetz, Cross-Peer Question to George Edward Pelham Box: Professor Box, a statistical uncertainty budget can describe small variations around a stable operating point, yet a transmission-line mismatch near a resonance may cause rapid frequency-dependent amplitude changes. If a nominally linear receiver shows a strong feature after moving a cable, it may be a change in delivered power rather than a source changing its output. How would you decide whether to use a first-order Taylor expansion, an explicit nonlinear network model or a bounded unknown correction? I also question whether a Monte Carlo analysis is

Copyright 2026, James M. Atkinson

appropriate when the reflection coefficients of the antenna and amplifier were never measured. Is it sound to assign them independent uniform distributions merely because their magnitudes lie below a catalogue limit, or does that substitute an arbitrary statistical hypothesis for evidence about the particular installation? Would a repeat network measurement at two different cable lengths help expose the phase-dependent ripple, or could the replacement itself change the source impedance and invalidate a naive comparison?

George Edward Pelham Box, Cross-Peer Answer to Charles Proteus Steinmetz: Mr. Steinmetz, the choice begins with a sensitivity check of the actual physical model. A first-order expansion is appropriate where plausible input changes produce a near-linear change in the output over the supported uncertainty region. If the network response is sharply resonant, or if the input uncertainty allows a reflection phase to cross a maximum or minimum, the derivative at one operating point can badly represent the range. One should then use measured network parameters with their correlations in a nonlinear calculation, or, when the parameters are not identifiable, use physically justified bounds. The words 'Monte Carlo' do not justify a guessed distribution.

Suppose a catalogue states merely that a port's reflection magnitude is below 0.2 under a specified test condition. That bound does not establish that the complex reflection coefficient is uniformly distributed in phase and magnitude in the field installation. Its phase may be constrained by cable length and component design; its magnitude may correlate with frequency, temperature and input power. Independently drawing a random phase and amplitude at every frequency can create simulated network responses that

Copyright 2026, James M. Atkinson

no passive device would actually exhibit. Such a model may be useful as an explicitly labelled stress scenario, but should not be promoted into a calibrated probability distribution without evidence.

The practical sequence is to measure S-parameters at the appropriate reference planes with calibrated fixtures and operating levels, including their uncertainty and correlation where available. Evaluate the resulting power or voltage transfer function against controlled cable substitutions. Probe sensitivity to relevant frequency, temperature and connector variations. If the model predicts the observed shifts, its uncertainty can be propagated numerically from the measured parameters. If it fails, retain the discrepancy as model inadequacy and investigate alternate coupling. One might report a conservative range without an associated probability when only bounded physical assumptions are justified.

A simple model comparison can reveal the distinction. In a well-matched configuration, a cable's measured insertion loss might change smoothly by 0.1 dB across the band. In another configuration, mismatch ripple can create a one-decibel peak-to-peak variation over a narrow interval. A single scalar cable-loss correction with 0.2 dB standard uncertainty would be unsuited to the second case unless the frequency-specific ripple had been characterised and incorporated. The correct response is not to double or triple the original correction until the reported value looks safe. The physical model should express the installation and the measured reference planes. This is a prerequisite to any worthwhile statistical refinement of the result.

Dr. James M. Atkinson, Moderator: Mr. Steinmetz, please examine conductive and reactive interactions that turn our convenient separate

Copyright 2026, James M. Atkinson

antenna, cable, amplifier and receiver entries into a coupled electrical system. Consider explicitly the test fixture and the operating temperature.

Charles Proteus Steinmetz, Fourth Principal Contributor: Dr. Atkinson, engineering drawings show boxes because boxes are convenient to manufacture, but electromagnetic energy does not recognise the boundaries printed in an uncertainty spreadsheet. The antenna, transmission line, amplifier and receiver form a network of impedances whose behaviour depends upon frequency, geometry and termination. A device's gain and loss are conventionally measured at defined reference ports; the quantities that reach the receiver under field conditions depend upon these ports being connected and loaded as assumed. When the assumptions fail, two certificate corrections may no longer describe separable physical effects.

The voltage along a transmission line has incident and reflected components. At a given reference plane the complex reflection coefficient Γ is the ratio of reflected to incident voltage waves under the applicable characteristic impedance. A cable's phase length is βl radians, with β the propagation phase constant and l its physical length. The reflection seen at one end depends on the termination reflection coefficient and a factor $\exp(-j2\beta l)$ for the round trip in an ideal uniform line. Bending, temperature or a different connector can change phase, while a poorly terminated port can create standing-wave variations. If antenna-factor calibration assumed one impedance and the installed preamplifier presents another, it is necessary to model the actual power or voltage transfer rather than add two independent mismatching allowances by habit.

Copyright 2026, James M. Atkinson

The simplest physical diagnostic is a controlled source and network analyser test, but the experiment must be framed appropriately. Measure the cable's transmission and reflection behaviour at a defined impedance, then measure its sensitivity to connector re-torque and a bounded cable bend. Characterise the preamplifier input and output return loss, gain and compression in its operating condition. Reconnect the full chain and observe whether a change of one component causes a predicted result at the receiver. When the change fails to follow the model, investigate common-mode current on the cable exterior, the enclosure return path, radiation into the amplifier chassis, or an unmodelled source of interference. None of those phenomena is properly captured by simply treating the cable as a passive scalar loss.

Consider the temperature of a cable and amplifier driven by the same ambient fluctuation T. Let cable-loss change be $k_L \Delta T$ and amplifier-gain change be $k_G \Delta T$, with k_L and k_G expressed in decibels per kelvin and ΔT in kelvin. Because the field measurement contains $+L-G$, the total first-order temperature correction is $(k_L-k_G)\Delta T$. If $k_L=0.010$ dB/K and $k_G=0.025$ dB/K, a 5 K rise produces $(0.010-0.025)\times 5=-0.075$ dB in the corrected measurement. If the temperature uncertainty is 1 K, the common temperature contribution to standard uncertainty is $|0.010-0.025|\times 1=0.015$ dB. Treating the two temperature components as independent would instead produce $\mathrm{sqrt}(0.010^2+0.025^2)=0.0269$ dB for the same 1 K uncertainty. Here the erroneous independence assumption inflates uncertainty because the sensitivities oppose one another.

The opposite can occur. If the two contributions carry sensitivities of the same sign, common temperature variation increases the combined

Copyright 2026, James M. Atkinson

response rather than cancelling it. An experimental finding that both components warm together must not lead one automatically to a correlation coefficient of +1 between their final correction errors. Their thermal coefficients, lags, temperatures and modelling residuals may differ. The relevant covariance is between the uncertainty contributions to the output estimate after proper weighting, not merely between temperature sensor readings. A physical coupling diagram and a thermal response model provide a better starting point than a guessed universal correlation.

Distributed reference standards also create common electrical paths. A power calibrator used to characterise receiver voltage sensitivity and preamplifier gain can imprint one reference bias on both quantities. If the calibrator itself drifts between the measurements, the errors may be partially rather than completely correlated. Time history, device calibration interval and a control check are relevant. The amplifier's bias supply can influence gain and also create conducted noise detected by the receiver; such a defect may produce a spectral line mistaken for a field component. A certificate for steady-state gain will not cover an uncharacterised impulsive supply disturbance. In that case the proper response may be to reject the observation, not to broaden the uncertainty after the fact.

The location of the electrical reference plane deserves particular attention in legal and forensic work. If the laboratory calibrates a cable at its own connectors, while field measurements include an adapter, a bulkhead feedthrough and an antenna balun, one must document which components are inside each correction. Connector-adapter loss could be counted twice, or omitted altogether, depending on how the certificates were applied. Use a traceable diagram, labels and photographs of the actual installation when

Copyright 2026, James M. Atkinson

permitted. Reconcile the cable assemblies, preamplifier model, antenna calibration serials and receiver configuration so that a later examiner can reproduce the exact chain. This is not decorative chain of custody; it is a physical condition for the meaning of the reported field level.

My challenge to Professor Black is to consider not only the passive network, but the feedback and noise processes inside a receiver chain. These can establish correlated errors that remain even after the linear gain corrections appear exact. A narrow uncertainty budget is credible only when the measurement process itself has survived controlled challenge and reference-plane reconciliation.

Michael Faraday, Peer Question: Mr. Steinmetz, an antenna cable is not merely a copper path between two labelled boxes. It may carry differential RF energy on its intended conductors and common-mode currents on its outer surface, and its connection to an enclosure can alter the electric and magnetic coupling of the entire system. If the cable loss certificate is a precise two-port measurement under matched conditions, how should an examiner avoid using it to conceal unmeasured field coupling in an actual survey? What would a carefully controlled change in cable orientation, shielding, bonding and termination reveal? I would also ask whether such changes should be entered as independent uncertainty components or treated as competing physical models of an instrument artefact and external signal. A fixed, quiet laboratory result may be genuinely precise while explaining little about the installed arrangement. How would you preserve a safe test arrangement while making a cable-current comparison, without changing the protective-earth configuration or introducing a new ground-current artefact?

Copyright 2026, James M. Atkinson

Charles Proteus Steinmetz, Response: Mr. Faraday, we must distinguish the intended transmission-line mode from fields and currents taking unintended paths. A two-port insertion-loss calibration generally characterises the tested assembly in a specified environment and termination. It does not automatically characterise coupling from an external field into the cable shield, transfer through a connector seam or common-mode current entering an amplifier enclosure. If the cable becomes an unintended receiving element, the simple antenna-factor-plus-cable-loss model may be incomplete, even though every individual certificate is correct under its stated conditions.

An authorised laboratory challenge begins by replacing the antenna with a known termination at the declared reference plane, leaving the remainder of the installation mechanically unchanged. Observe whether the suspected signal persists. Then repeat with another approved cable path, a controlled change of cable routing, and a properly characterised common-mode suppression arrangement where safe and compatible with the instrument. If a spectral feature follows cable position while the antenna is terminated, the hypothesis of energy entering through the cable or enclosure grows stronger. But changing routing may also change impedance or amplifier load. Record those changes rather than assign the entire effect to one desired mechanism.

The uncertainty budget should reflect the intended measurand and validated model. If a known small common-mode response can be calibrated across specified conditions, it may become an explicit correction with uncertainty. If it is intermittent, installation-dependent and poorly understood, it may instead be a model-adequacy defect that limits the

Copyright 2026, James M. Atkinson

validity of the nominal field estimate. Inflating two or three independent 'cable pickup' allowances cannot repair a missing causal model. The correct test changes one influence at a time where practicable and seeks independent corroboration through an instrument with a different signal path.

The enclosure bond and shield transfer impedance warrant attention. A cable screen may carry currents driven by nearby power wiring or instrument ground potential differences. Such currents can produce an apparent spectral component at the input even though the intended antenna port is terminated. Any test involving bonding, earth reference or energised equipment requires appropriate electrical safety controls; one should not defeat protective earth to pursue a cleaner trace. The analyst must distinguish a deliberate safe RF grounding configuration from a dangerous alteration to protective systems.

A corrected field-strength figure also requires the proper voltage reference plane. If an adapter or balun adds a calibrated loss, that loss should appear once. If the laboratory cable certificate already includes the adapter, adding an independent allowance for the same adapter counts one uncertainty twice. Conversely, if the field installation uses a new adapter not in the certificate, omission may bias the result. Document the actual connection and serialised components. The physical chain, not a neat bibliography of specifications, determines what has been measured and what remains unknown.

Harold Stephen Black, Cross-Peer Question to Charles Proteus Steinmetz: Mr. Steinmetz, the passive chain is only part of the difficulty. In a live receiver the preamplifier can respond to a large blocker or a transient input

Copyright 2026, James M. Atkinson

through its finite linearity, while its calibration certificate was obtained with a small steady tone. The operator may add a mismatch uncertainty, cable loss uncertainty, gain uncertainty and receiver display uncertainty as if each were independent. But a change in cable termination might simultaneously change the preamplifier's input match, its gain and its intermodulation products. What diagnostic would distinguish those coupled behaviours from a genuine change in the incident field? I ask particularly how the test can be conducted without violating equipment ratings, changing protective earth arrangements, or mistakenly counting one changed interface several times under different labels. How should the report proceed if the device is simply beyond its calibrated range? Please distinguish a safe independent measurement of incident power from a receiver-only displayed amplitude, because the latter may reflect the nonlinear response we are trying to discover.

Charles Proteus Steinmetz, Cross-Peer Answer to Harold Stephen Black: Mr. Black, define a safe operating envelope and test the complete installed chain inside it. Use a properly rated controlled source with protective attenuation and observe the amplifier response over several signal levels, including a strong but compliant blocking signal where this is relevant. Maintain records of input and output levels, frequency, reflected power, bias and temperature. When the source level changes by a known amount, examine whether the receiver's corrected indication changes as the calibrated gain model predicts. An unexpected level-dependent response suggests compression, gain control, intermodulation or an interface mismatch that varies with operating conditions. Such behaviour must be diagnosed rather than hidden inside a generic uncertainty category.

Copyright 2026, James M. Atkinson

To isolate the cable interface, replace a given cable assembly with an independently characterised one while holding other settings as constant as possible. Measure the reflection coefficients or return-loss behaviour of the relevant ports, and include the actual adapter stack in the diagram. If a moving cable changes a spurious response but not a known injected signal, investigate external coupling or shield current. If it changes the known signal transfer, investigate mismatch and connector continuity. If the amplifier is beyond its specified linear range, the calibration may no longer apply. The defensible choice may be a lower input level, a different attenuator configuration or an explicit inability to report a quantitative field value for that interval.

The double-counting problem can be controlled by an interface register. Each physical connection has one identity, reference plane, calibration condition and set of measured quantities. A mismatch contribution already included in the validated transfer model must not be added again as a separate independent 'cable error' and 'amplifier error' merely because it influences both. If a calibration laboratory has separately listed a port match uncertainty, examine whether the field transfer calculation already includes it. If not, state exactly how it is incorporated. Shared power or temperature influences should likewise be linked to one measured source rather than replicated in each component's column.

Finally, safety is a boundary condition. Do not lift protective earth, defeat rated input protection or expose sensitive devices to unknown high RF power for the sake of a diagnostic comparison. A test that damages the instrument may invalidate subsequent measurements as well as create a hazard. Safe substitution, source-off controls, attenuation and independent

Copyright 2026, James M. Atkinson

monitoring can test most important hypotheses. When a hazardous or uncontrolled condition prevents the necessary challenge, the report should preserve the qualification. A candidly bounded technical finding is preferable to a neat combined uncertainty derived from invalid equipment conditions.

Dr. James M. Atkinson, Moderator: Mr. Black, the preceding speakers have defined the measurement equation, experimental design and electrical coupling. Please now consider amplifier feedback, detector behaviour and shared noise, and distinguish uncertainty in an amplitude estimate from uncertainty in deciding whether a signal exists.

Harold Stephen Black, Fifth Principal Contributor: Dr. Atkinson, an amplifier is not a static gain number on a label. Its response can include finite bandwidth, impedance interaction, feedback dynamics, gain compression, noise, bias dependence and internal coupling. At a fixed frequency and small-signal level, a calibrated gain with stated uncertainty may be useful; outside that regime the transfer function can change and the uncertainty model may cease to apply. In a surveillance measurement, the particularly dangerous inference is to treat a receiver's indicated level and a preamplifier certificate as two measurements of an underlying signal, each with independent random error. The indicated level is already the result of the amplifier and receiver acting together. Their error mechanisms may share calibration, temperature, supply and even the spectrum of background noise.

A conventional amplifier-chain noise-factor treatment illustrates another place where careless addition misleads. For cascaded stages with linear power gains G_1,G_2 and noise factors F_1,F_2,F_3, the idealised Friis

Copyright 2026, James M. Atkinson

relation is $F_{total}=F_1+(F_2-1)/G_1+(F_3-1)/(G_1G_2)$. These quantities are dimensionless linear ratios, not values in decibels that can be inserted into the formula directly. The equation describes a model of cascaded noise performance under defined source impedance and linear operating conditions. It is not an uncertainty budget for measured field strength; its separate terms determine one physical performance quantity, which in turn may influence measurement variance or detection probability. An investigator who adds a receiver noise-figure uncertainty as an independent field-strength correction after already deriving statistical uncertainty from repeated receiver measurements risks counting the same fluctuating noise twice.

For a numerical teaching case, let $F_1=2.0$, the first-stage gain $G_1=10$, $F_2=4.0$, second-stage gain $G_2=5$ and $F_3=6.0$. The idealised cascade factor is $2+(4-1)/10+(6-1)/(10\times5)=2.4$, corresponding to $10\log10(2.4)=3.80$ dB noise figure. This does not state the field measurement uncertainty. It tells us how added noise compares with input thermal noise under the model. To determine an amplitude-estimation uncertainty, we would also need signal bandwidth, integration or detector behaviour, interference environment, calibration uncertainty and the relation of the estimator to the sampled data. Confusing noise figure with standard uncertainty would be a dimensional as well as conceptual error.

Feedback may help stabilise gain, but only within its design conditions. If amplifier input impedance changes, the response of the antenna-cable network can change in a way that gain calibration alone does not describe. Similarly, if automatic attenuation or gain control operates during an observation, the effective gain may change between the original calibration

Copyright 2026, James M. Atkinson

and the field measurement. A waveform with sporadic high peaks may overload the input without producing a clearly saturated average trace. Tests must therefore include controlled level stepping, known pulsed stimuli and examination of receiver state changes, while protecting the input ratings. A static input-to-output comparison over one low-level tone does not validate the entire dynamic observation range.

Detection at the threshold introduces a separate measurand. Let D be the decision that a signal is present under a declared detector and let X be the observed statistic. The conditional detection probability is P(D=1 | signal model, environment, configuration). That probability is not the same as standard uncertainty u(E) of an amplitude estimate given that a measurement was accepted. A receiver can detect nearly every strong pulse while measuring its amplitude poorly; it can also estimate the amplitude of accepted weak pulses with little apparent scatter while missing a substantial class of events. If only successful detections enter the uncertainty computation, selection or censoring can make the resulting uncertainty artificially small.

One can address this with a calibrated challenge set. Inject a known signal through the receiver port and vary the level across the relevant threshold under documented background conditions. Record all trials, including nondetections, alongside the indicated amplitudes of detections. Then repeat through the antenna path under an authorised known-field condition. Report detection and amplitude-estimation performance separately. A substitution of the receiver can show whether a particular weakness follows the hardware, but must account for changed impedance, bandwidth and signal processing. An absence of indication on either

Copyright 2026, James M. Atkinson

receiver proves only a bounded negative finding under the actual coverage and sensitivity of the test.

I would additionally challenge the claim of independent receiver confirmations. If two receivers are fed through the same preamplifier, antenna or distributor, they may share gain drift and intermittently generated intermodulation. Treating two displayed values as two independent samples may understate the uncertainty of a combined estimate. For an error model $e_i=c+r_i$, where c is a common zero-mean contribution and r_i independent residual error, the mean of n receivers has variance $u_c^2+u_r^2/n$. No number of additional receivers removes u_c. This result does not imply that multiple receivers are useless: they may diagnose individual faults and improve independent noise averaging. It requires that the report distinguish what is shared and what is separate.

A final audit should include a challenge-measurement ledger, the calibrated gain state, device and reference serials, the detected waveform class, the measured noise and overload state, and the final uncertainty derivation with covariance terms. Where the conditions are not met, report a qualified instrument indication or range rather than a falsely precise field result. A small combined standard uncertainty is not a statement of source attribution, hostile purpose or evidential conclusiveness. I return the token to Dr. Atkinson with the central proposition: every number in the uncertainty budget must correspond to a distinguishable physical or statistical input, and every common influence must be accounted for exactly once.

James Clerk Maxwell, Peer Question: Mr. Black, your model separates detection probability from amplitude-estimation uncertainty, but both can be influenced by the same noise and gain-control processes. Imagine that

Copyright 2026, James M. Atkinson

the receiver detects only those bursts whose amplitudes happen to rise above the threshold after environmental and amplifier fluctuations. The accepted readings may cluster tightly, leading the operator to infer excellent field-strength precision, while the missed bursts remain invisible. How should one avoid entering the same receiver-noise term into both a detection model and an amplitude uncertainty budget without acknowledging the statistical dependence? Please define what must be recorded for every trial, including nondetections and the evolving gain state, and explain whether a second receiver sharing the same preamplifier provides an independent challenge. The aim is to produce an evidential statement that remains sound when the signal is intermittent rather than continuously present. I would also ask how the conditional sampling changes the uncertainty if the instrument treats a succession of threshold crossings as separate transmissions instead of one physical burst.

Harold Stephen Black, Response: Professor Maxwell, the sample selection is part of the measurement process. Let S denote the event that the detector accepts a sample, and let Y be the reported amplitude estimate. The uncertainty of Y conditional on S=1 is not automatically the uncertainty of the underlying incident amplitude for all possible events. If receiver noise and gain fluctuation affect both S and Y, the conditional distribution is selected. A tight distribution among accepted samples can coexist with a high miss rate and substantial bias in the original event population. Consequently the test must retain every scheduled challenge, including its true injected level, waveform, state, decision and any resulting estimate.

The experiment should include repeated known pulses across a range of levels near threshold, with event times that explore the receiver's sweep or

Copyright 2026, James M. Atkinson

acquisition schedule. Record not merely whether each pulse was detected, but also the measured amplitude, detector threshold, false-alarm controls, gain state, reference level, preamplifier bias and any overload or reset indication. One may then estimate a conditional response surface for probability of detection and a separate conditional distribution of amplitude error among detections. Correlation between the decision and the amplitude error is not removed by giving those two results different column headings.

To avoid double-counting receiver noise, construct one joint observation model that explains how noise enters the detector and estimator. The same stochastic noise realisation must not be added as one complete extra independent variance term after its effects have already been measured empirically. An independently obtained receiver noise-figure specification may inform a physical model of expected noise but does not create a second copy of the noise present in the stored samples. If uncertainty from finite noise-model calibration remains, that is a separate parameter uncertainty with its own provenance and possible covariance.

Consider a hypothetical threshold experiment with 100 known bursts, 70 detections and 30 nondetections. If the 70 detected amplitude estimates show a 0.2 dB sample standard deviation, that describes the spread of accepted estimates under the test conditions, not a 0.2 dB guarantee for all 100 transmitted events. An estimator that clips low readings at threshold may look even more repeatable while being biased high. Report the 70/100 detection fraction with appropriate binomial or design-based uncertainty and separately report calibrated amplitude error among accepted events. A different pulse duration or polarisation may change both quantities.

Copyright 2026, James M. Atkinson

A second receiver sharing the same preamplifier remains vulnerable to a shared front-end failure. It may supply independent evidence about its own detector noise or software path, but not independent evidence that the common preamplifier did not compress or generate an artefact. A meaningful alternative path uses a separately monitored signal chain or a direct known-source reference. In the resulting report, the word 'independent' should always specify the component or uncertainty source to which it applies. That disciplined vocabulary is a stronger safeguard against double-counting than simply accumulating more instruments.

Dr. James M. Atkinson, Moderator: The panel has distinguished input uncertainty, common calibration provenance, real electrical coupling and the adequacy of the field-strength measurement equation. No certificate number should be added twice merely because the same standard appears in several device records, and no correlation should be invented to make a result seem more convincing. The correct first-order treatment is c-transpose Sigma c; the real obligation is to identify the covariance and the reference-plane model with experiments. Where mismatch, overload, threshold selection, installation changes or a nonstationary interference environment defeat the model, the honest output is a qualified result, not a cosmetically enlarged error bar. The roundtable recommends documented dependency diagrams, crossed reference and component substitutions, a controlled thermal and level-response programme, an explicit covariance budget and separate detection-performance testing. All participants’ speeches here are modern fictional scholarly reconstructions, not historical transcripts.

QUESTION 071

Copyright 2026, James M. Atkinson

What Constitutes One Event When Threshold Crossings Form Correlated Clusters?

Dr. James M. Atkinson, Moderator: Dr. Shewhart, a spectrum-monitoring system may report hundreds of threshold crossings during what a field engineer hears as one pulse or sees as one fading transmitter. At another setting it may report a single event encompassing two physically separate emissions. The detector is performing measurement, but the event builder is also imposing a definition. Would you distinguish a sample-level threshold exceedance from a contiguous excursion, a grouped episode, a transmission burst and an attributed emitter, explaining how the investigator may preserve the raw evidence while defining a repeatable event count?

Walter Andrew Shewhart, Principal Contributor: Dr. Atkinson, the examiner should begin by refusing to let the display's noun “event” carry several incompatible meanings. A raw exceedance is an observation made at one specified sample time or spectral cell: the measured statistic crosses a declared threshold. A contiguous excursion is a run of exceedances connected without a qualifying interruption under the actual sampling schedule. A grouped detection episode may bridge a short dip below the threshold because fading or filtering causes a single physical burst to fragment. A transmitter emission is a claim about the physical source, and emitter attribution is a still stronger inference requiring additional evidence. None of these concepts is synonymous with the others. A record should distinguish the count of raw threshold samples, the count of contiguous runs, the number of episodes under a declared merge rule and the independently supported number of physical transmissions. That distinction

Copyright 2026, James M. Atkinson

prevents an attractive event count from being mistaken for a direct observation of human or electronic intention.

Consider a sampled detector statistic z[n], with n a nonnegative integer index and Δt seconds between valid samples. Let H be an upper entry threshold and L a lower exit threshold, where L does not exceed H. A simple hysteretic state machine declares an onset at the first valid n for which z[n] rises above H while the state is inactive. It remains active until a specified condition involving z[n] below L has been satisfied. The condition may be one valid sample, a minimum duration, or a rule combining several adjacent samples. The choice matters. If H=L, noise near threshold can produce frequent on-off transitions; widening the difference between H and L can suppress rapid chatter, but may preserve an event long after its strongest energy has faded. If the noise floor changes while the thresholds remain fixed, a variation in the environment changes the crossing rate even when the transmitter does not. Therefore the threshold levels, their units, the exact comparator inequality, the rule for missing samples and the clock defining sample times are all parts of the claimed measurement. The physical phrase 'transmission burst' must not appear in a result until a separate model supports it.

An example exposes the counting dependency. Suppose valid rising-threshold excursions begin at 0, 12, 20, 250, 265 and 520 milliseconds in a controlled record. Suppose each occupies a short interval and the listed gaps between their end times and subsequent start times have been accounted for. Under a post-excursion merge gap of 5 milliseconds, all six remain separate. Under a rule joining intervals separated by no more than 10 milliseconds, the events at 12 and 20 milliseconds may join while those at

Copyright 2026, James M. Atkinson

0, 250, 265 and 520 remain distinct: five declared episodes result, assuming the 8-millisecond relevant gap is the sole eligible one. Under a 30-millisecond rule, the first three and the fourth and fifth may each form one group, yielding three episodes. The apparent difference from six to three does not indicate that the receiver lost half its samples or the transmitter changed its schedule. It is the mathematically predictable consequence of a choice made by the analyst. The precise intervals used in real software, not just rounded onset times, must be retained for repeatable counting.

The event constructor should be treated as a state machine with auditable transitions. Record each crossing's sample index, timestamp, duration, peak statistic, integrated energy, location in frequency and quality flags. Record the merge-gap criterion g in seconds; whether g is measured from end to start or onset to onset; whether equality merges; the refractory period r after a completed episode; and the behaviour at a capture boundary. A refractory period can deliberately prevent multiple triggers during ringing, but unlike a merge rule it may entirely suppress later candidate detections. The difference cannot be recovered from a count alone. If a gap in stored samples is mistaken for a below-threshold interval, the algorithm may wrongly split an event; if the programmer silently bridges the gap, it may falsely assert continuous observation. The ledger should label unobserved time rather than disguise it as either positive or negative detection.

A robust analysis has two layers. The first is immutable evidence: raw I/Q samples where authorised and available, device counters, calibrated receiver states, initial detection statistic, sample-validity mask and threshold-crossing ledger. The second is a versioned interpretation: episodes constructed under named parameter values and a precisely documented

Copyright 2026, James M. Atkinson

algorithm. One should be able to replay the same first layer through several merge gaps and demonstrate which event IDs split or unite. A report may then state: 'There were sixty-two threshold excursions and thirteen grouped detection episodes at H, L, g and r as specified; the physical number of transmissions remains unresolved.' The alternative is to announce thirteen transmissions and conceal a process whose arbitrary parameter settings could equally have produced nine or twenty. This is not mere clerical precision. The number drives false-alarm estimates, apparent source activity, enforcement consequences, and the interpretation of a negative search.

The selection of parameters should be related to an actual measurement objective. If the receiver is hunting microsecond pulses, a merge rule spanning seconds can destroy the temporal structure. If the system measures duty cycle of a slowly fading carrier, a very narrow gap may inflate apparent source activity. The calibration should include known controlled pulse sequences with variable within-burst fades and between-burst separations. Detection performance should be reported by pulse power, bandwidth, duration, modulation and receiver configuration, not a universal 'events found' value. The investigator should also distinguish a threshold event in a channelised spectral cell from a frequency-agile physical transmission appearing across adjacent cells: one emitter can cause many spectral-cell triggers. The principle is to define the measurand before selecting the algorithm and to preserve the observations from which alternative, defensible measurands can be derived.

Finally, reproducibility is stricter than a smooth plot. Two reviewers using the same raw capture, algorithm version, threshold values and time validity

Copyright 2026, James M. Atkinson

mask should obtain the same episode ledger. They need not agree that each episode represents one physical transmitter burst. That second step is a scientific inference, often underdetermined by the signal alone. The quality-control chart offers a caution: a change in plotted counts may arise from a changed observation procedure, not from a changed underlying process. Before claiming an emitter altered its behaviour, establish that gain, bandwidth, noise-floor estimator, timing and event-definition policy remained equivalent. Where they did not, show a controlled sensitivity analysis or decline the trend inference.

Peter Elias, Peer Question: Dr. Shewhart, a system that retains only grouped event identifiers has discarded the smaller threshold crossings from which those identifiers were assembled. What representation would allow two independent examiners to recompute alternative counts without retaining duplicate gigabytes of intermediate information? A reversible mapping between raw crossing intervals and grouped episodes is desirable, but event data arrive over network links whose packets may be reordered, lost, or retimed; two sites can also assign different sequence identifiers to the same physical waveform. Please distinguish stable digital provenance from a claim that the abstract data structure proves continuous acquisition. I also ask how one should record a modified merge rule so the same event identifier cannot misleadingly denote two different temporal regions after a software update. Finally, when is irreversible compression of raw I/Q an acceptable archival engineering decision, and what narrower forensic assertion remains defensible if those raw samples are no longer available?

Walter Andrew Shewhart, Response: Mr. Elias, an event record should use identifiers which refer to immutable observations, not identifiers whose

Copyright 2026, James M. Atkinson

content changes with the current display setting. Every valid threshold interval can receive a stable identifier composed of the acquisition session, device stream, monotonic hardware index at onset, and a collision-resistant record identity where justified. Store the exact sample-index endpoints and any discontinuity flag. The event builder then produces a separate, versioned grouping table mapping one declared episode to an ordered list of those underlying intervals. It can assign an analysis-specific episode identifier, but that identifier belongs to a stated algorithm version and parameter set. It should never replace the permanent crossing identifiers or imply that two software versions' episode number seven represent identical physical time.

A provenance graph can be compact. If a thousand adjacent exceedance samples form one run, one may preserve an interval with start and end indices, summary statistics, threshold definition and cryptographic linkage to the raw capture rather than store an identical record for every sample. But that compression is lossless only for the question it preserves. An interval representation cannot reconstruct the individual signal amplitudes unless those were separately retained. Nor does a ledger of received samples establish that a device did not drop samples before the counter became visible. Provenance must include the counter semantics, overflow status, acquisition configuration and a verification experiment challenging missing-data behaviour. The quality of the evidence rests on documented hardware and software boundaries, not the elegance of the index structure.

Two networked stations may observe related energy without observing the same waveform phase or timing reference. Their raw crossing identifiers should remain station-specific. A later correlation record may link

Copyright 2026, James M. Atkinson

candidates under a stated time-frequency and uncertainty rule, but should not overwrite local observations with a single universal 'event'. If clock correction subsequently changes the estimated UTC mapping, it becomes a new versioned transformation applied to the same hardware sample ranges. A robust archive records both original and corrected times with their respective uncertainties, making later reconciliation possible.

Where raw I/Q must be discarded because of capacity or retention constraints, document that decision and retain as much calibrated, independently sufficient derivative evidence as lawful policy permits: hardware-index intervals, detector statistic series at the resolution needed to reapply thresholds, instrument states, data-integrity checks and known blind periods. One may then reproduce the originally defined event count, perhaps under a bounded family of grouping gaps, but cannot credibly claim that alternative demodulation, re-filtering or classification remains possible if the requisite waveform was discarded. Compression and scientific irreversibility are different matters. The report should state the precise operations still possible, those that are not, and which original conclusions may be challenged within the preserved evidence.

Dr. James M. Atkinson, Moderator: Professor Fisher, Dr. Shewhart has defined the counting instrument as a rule operating on an observed sequence. How would you distinguish the number of threshold exceedances from the statistical number of independent extreme episodes, especially when neighbouring samples are correlated by a receiver filter or the physics of a fading emission?

Sir Ronald Aylmer Fisher, Second Principal Contributor: Dr. Atkinson, a statistical unit is not created merely by printing a new row. Exceedances in

Copyright 2026, James M. Atkinson

consecutive samples of a filtered process ordinarily possess dependence because the filter transmits information across time. A single noise excursion may keep several adjacent samples above the threshold, so treating each as an independent false alarm multiplies evidence that has been observed only once in any meaningful probabilistic sense. Conversely an isolated high observation can be one member of a long-range-dependent pattern whose dependence extends beyond the chosen merge window. Any probability calculation should state its sampling unit, null distribution, correlation assumptions and the event-extraction rule. The raw exceedance count and the cluster count are different statistics, with different expected values under the same process.

One may formalise a threshold sequence by $I[n]=1$ when $z[n]>H$ and $I[n]=0$ otherwise, but the distribution of the indicators cannot in general be understood without the covariance and higher dependence structure of $z[n]$. If $z[n]$ is derived from overlapping short-time Fourier transform windows, the adjacent windows share many input samples. If it is an energy estimate averaged across frequency bins, adjacent bins may share spectral leakage and filter correlations. If it is based upon an automatic gain-control loop, the act of observing one high signal can alter the distribution of later measurements. Thus, the probability p of $I[n]=1$ is a marginal probability, not a statement that consecutive indicators are independent Bernoulli trials. Applying the independence formula $P(\text{at least one exceedance in } N \text{ samples})=1-(1-p)^N$ would be unjustified without qualification. A lawful controlled experiment should measure the null crossing process under actual operating states and evaluate how the proposed clustering changes its event count.

Copyright 2026, James M. Atkinson

Theoretical extreme-value work considers the tendency of high threshold exceedances to form clusters in dependent sequences. One descriptive quantity is the extremal index θ under specified asymptotic and stationarity conditions; informally, values below one may reflect clustering, and in appropriate settings θ relates to the reciprocal mean cluster size. This concept is not a universal parameter of every receiver, nor is it a direct count of physical transmissions. It requires conditions that may fail in a field survey with retuning, changing interference and nonstationary noise. Published declustering methods may use runs of sub-threshold observations or inter-exceedance times. Their relevance here is methodological: event counts and cluster estimates depend on how the clusters are defined, and defensible uncertainty analysis must acknowledge that choice. No claim about θ should be inserted into a forensic report merely because a software package computes it.

Consider a calibrated no-signal experiment lasting sixty seconds. A threshold detector produces 600 valid above-threshold samples, but those samples fall into twenty bursts of thirty consecutive observations each. Under the deliberately simplified independence fiction the analyst might report 600 false events. The more meaningful output of the specified run-grouping algorithm is twenty false detection episodes. However, the twenty episodes cannot automatically be treated as independent: an interference source cycling periodically or a shared oscillator fault may produce temporal correlation between episodes. An observed average of thirty samples per cluster in this example does not establish a transmitter packet length, an extremal index of 1/30 under arbitrary conditions, or any general rate

Copyright 2026, James M. Atkinson

transferable to another site. The experimental conditions, sample cadence, threshold and clustering rule are inseparable from the result.

Uncertainty for an event rate should likewise be conditioned on exposure. Let C_g be the number of declared episodes formed under merge parameter g and let T_{valid} be the duration in seconds for which the relevant band and detector were genuinely capable of producing a valid observation. The descriptive rate is $\lambda_{hat}(g)=C_g/T_{valid}$. With $C_g=20$ and $T_{valid}=60$ seconds the descriptive figure is one episode per three seconds, or about 0.333 per second. A Poisson confidence interval based only on C_g would assume an event process that may be inconsistent with clustering or periodic apparatus faults. If events occur in blocks or strongly dependent trains, a block-resampling design, a fitted dependent point-process model, or independent repeated campaigns may be needed to estimate uncertainty. An interval that is numerically narrow under an untested independence model is not thereby scientifically precise.

The choice of threshold and merge gap can also constitute post-selection. If an investigator tries twenty combinations and selects the one which makes a hypothesis appear strongest, ordinary p-values calculated as though that choice were fixed are not valid without a correction or a fresh validation set. It is preferable to establish primary operational thresholds before examining the disputed record, using independent laboratory evidence on expected pulses and noise. Supplementary sensitivity analyses are valuable, but they should be labelled exploratory and should not be used to redefine the primary result after seeing it. Predeclared thresholds do not eliminate all modelling uncertainty; they prevent hidden choices from manufacturing

Copyright 2026, James M. Atkinson

unwarranted certainty. A transparent investigation records unsuccessful as well as successful parameter trials.

A useful experiment creates two data-generating conditions. In the first, benign random noise with a measured temporal spectrum enters the receive chain and no intentional burst source is applied. In the second, a signal generator produces known pulses of several widths, spacings and amplitudes, including within-pulse fades which deliberately cross below threshold. Analyse both with the same event constructor. The first condition measures the false episode distribution; the second measures how often one true pulse is split and how often distinct pulses are merged. Cross-validation should separate parameter development from performance estimation. If training and test data use the same random realisation, the confidence claim is circular. The outcome should be a matrix of sensitivity and error rates, not a claim that one magic gap is physically correct for all emitters.

The inferential conclusion is bounded by identifiability. The event ledger is an observable consequence of a receiver, a threshold model and a grouping rule; the source's transmission chronology is an unobserved process inferred through that apparatus. Without ground truth or independent corroboration, several source chronologies can generate the same exceedance sequence. A strong report does not hide this ambiguity. It states which event definitions were used, which parameters materially affect counts and which hypotheses remain compatible with the raw record. A statistical reconstruction is a reasoned account of evidence, not a declaration that the software's event IDs are physical facts.

Dr. James M. Atkinson, Moderator: David Slepian, would you examine the preceding model with an independent methodological challenge?

David Slepian, Peer Question: Professor Fisher, threshold crossings in spectral detectors are not independent samples of random energy. A short-time Fourier transform with substantial overlap reuses waveform samples, while a window function spreads one tone into multiple bins; a moving broadband interferer may make several channels cross threshold together. How should a practitioner quantify dependence before applying false-alarm formulas or declustering estimates? In particular, would a simple sample correlation coefficient be enough to characterise the tail behaviour of the detector statistic, or must the study also consider the distribution of unusually high excursions and the receiver's own operating-state transitions? I would welcome a discriminating comparison between changing the amount of FFT overlap and changing the physical signal: both can alter the number of threshold crossings, yet only one is a computational decision. How should that difference enter the statistical interpretation and evidential record? Please also address whether FFT bin overlap creates correlation between channels even if temporal windows do not overlap, and whether changing window type alone can move the detected threshold-onset boundary without changing any physical input.

Sir Ronald Aylmer Fisher, Response: Dr. Slepian, a correlation coefficient between adjacent samples is a useful diagnostic, not a comprehensive dependence model. Tail clustering concerns how unusually large observations arrive together, and two processes can have similar second-order autocorrelation while differing in the distribution of rare excursions. Window overlap gives an immediate source of sample dependence because

Copyright 2026, James M. Atkinson

the same underlying waveform contributes to successive estimates. The extent depends upon the overlap, window, input noise covariance and estimator. If an engineer changes overlap from zero to 75 percent while leaving the RF input unaltered, the number of reported above-threshold cells may grow simply because the software produces more correlated estimates per second. It would be erroneous to divide that larger count by clock time and announce a higher environmental pulse rate.

The first experiment should hold a controlled receiver input constant and vary the computation alone. Acquire raw I/Q once and process the same immutable capture under several FFT overlaps, window functions and time steps, preserving the sample-time mapping. Compare both the count of exceedance cells and the number of grouped episodes under a physically defined interval rule expressed in seconds, not a fixed number of frames. If a thirty-millisecond gap is expressed as five frames at one hop size but as twenty frames at another, the analysis has silently changed its temporal rule. Properly express time boundaries using hardware indices or calibrated seconds, and assess the extent to which clustering survives a change in representation.

Next test the actual null process with no injected emission, retaining front-end state, gain, temperature, filter settings and interference conditions. Estimate the distribution of raw detector excursions, their durations, inter-exceedance times and coherent frequency structures. A periodic instrument spur can create repeated clusters of rare events despite a stable marginal noise floor. For formal extremal-index or declustering inference, examine whether the assumptions of an appropriately stationary dependent process are plausible; do not invoke an asymptotic result as a substitute for this

Copyright 2026, James M. Atkinson

engineering test. Where conditions change with instrument retuning, divide the analysis into substantively comparable states or report that a single stationary estimate is unsupported.

False-alarm rates should be measured at the same level as the reported decision. A per-cell threshold probability is not a grouped-episode false-alarm probability. Construct the exact algorithmic pipeline, including hysteresis, gap merging, refractory suppression and frequency linking, then apply it to independent null captures. The empirical distribution of episodes per valid observation interval provides one basis for operational calibration. A parametric model may improve extrapolation to rarer outcomes, but only if it reproduces observed dependence and tail structure. The calculation must state its assumed sampling units, evidence of independence between test campaigns, and uncertainty in extreme-tail estimates. Reducing the time hop does not generate new independent evidence merely because the spreadsheet has more rows.

Dr. James M. Atkinson, Moderator: Sir Harold Jeffreys, would you press Professor Fisher on the difference between a grouped statistical episode and a physical transmitter burst?

Sir Harold Jeffreys, Peer Question: Professor Fisher, an event constructor may merge repeated threshold crossings according to a fixed gap and present a count that seems precise. Yet the investigator has two plausible explanations: the crossings are fragments of one fading transmission, or they are separate pulses emitted by a source with a short inter-pulse interval. How would the evidence for these explanations be compared without assuming that the event-builder's grouping rule is itself a physical law? In particular, can the same count support different likelihoods under

Copyright 2026, James M. Atkinson

competing waveform and fading models, and what additional observation would help to discriminate them? I also ask what ought to be done when the posterior or likelihood result is dominated by a prior on burst repetition that the field data cannot realistically verify. The objective is a defensible inference, not a rhetorical probability produced by an opaque programme. Please identify which physical tests, not merely mathematical preferences, could break the inferential equivalence between a long fading emission and several independently timed pulses.

Sir Ronald Aylmer Fisher, Response: Sir Harold, the event constructor is a mapping from measured data into a reduced representation; it should not be elevated into the data-generating model without evidence. A likelihood analysis should, wherever possible, begin with the retained waveform or a sufficiently informative statistic and compare the predictions of distinct physical hypotheses. Under a fading-single-burst model the apparent below-threshold intervals may arise from channel fading, receiver noise or gain control. Under a repeated-pulse model they arise from separate emissions with a specified inter-pulse distribution. These models may assign different probabilities to the observed energy envelope, phase continuity, modulation features, received spectrum and timing. The simple count under a merge rule discards much of that information, so different hypotheses can lead to exactly the same count while having different support in the raw record.

An independent second receiver may help distinguish the models if its path and clock are genuinely independent of the first. A fade caused by local multipath might fragment the signal at one antenna but not another, whereas a genuine transmitter off interval may appear simultaneously in both after accounting for propagation and instrumentation. Yet correlation

Copyright 2026, James M. Atkinson

in the environment and common front-end control can undermine that comparison. A calibrated injected waveform test can characterise the receiver's own tendency to create below-threshold gaps. Phase continuity through a dip, where signal-to-noise ratio permits a meaningful estimate, may offer additional evidence, but phase tracking at low amplitude is vulnerable to slips and unwrapping ambiguity. No single diagnostic uniquely resolves every case.

A likelihood or posterior conclusion ought to show sensitivity to assumptions that the data cannot constrain. If the inter-pulse interval prior is chosen narrowly because the investigator expects a particular device, the resulting posterior evidence may reflect that expectation. Similarly a fading model fitted to the same disputed record and judged on its fit may overstate support if model flexibility is ignored. One should compare adequately specified models, record their fitted parameters and uncertainty, and use controlled validation data when available. If the evidence permits both source chronologies with similar plausibility, the correct answer is unresolved multiplicity, not a forced event count.

For reporting purposes, distinguish 'three grouped detector episodes under g=20 milliseconds' from 'one physical burst' or 'three transmitter pulses'. The first statement can be reproduced by replaying the event-builder rule. The latter statements require inference about the source. Provide results under several defensible g values as a sensitivity analysis, preserving the same immutable capture. The scientific value lies in identifying what changes when the measurement procedure changes, and what source-level conclusion remains invariant. A likelihood calculation cannot repair the absence of informative observations by the precision of its notation.

Copyright 2026, James M. Atkinson

Dr. James M. Atkinson, Moderator: Sir David Cox, how would you analyse recurrence after an event has been declared, given that an observation system may be incapable of detecting further activity during its own refractory or processing interval?

Sir David Roxbee Cox, Third Principal Contributor: Dr. Atkinson, a recurrence model begins by defining the risk set, the intervals during which the instrument could have observed another event. A refractory period after a trigger is not merely a convenient graphic smoothing parameter; it alters the observation mechanism. If the software deliberately ignores a second threshold crossing during that period, the resulting record is censored by design. If the hardware actually ceases sampling, the coverage is physically absent. These mechanisms may produce superficially similar event lists but require different treatment. A report that divides the retained count by total clock time without recognising the observation process confuses the propensity of a source to emit with the propensity of an instrument to accept a trigger.

For a conceptual point-process representation, let N(t) count declared episode onsets up to time t, and let Y(t) equal one when the detector is operational, observing the relevant frequency and eligible to declare a new episode, and zero otherwise. A model of observable event intensity may be written $\lambda_{obs}(t)=Y(t)\lambda(t|H_t)$, where H_t summarises relevant observed history and λ is a conditional event intensity under an explicit process model. This expression is not a universally valid law for physical emissions. It is an accounting framework that makes risk exposure visible. The observed event rate must be interpreted alongside Y(t), threshold settings, adaptive filtering and intervals in which earlier triggers suppress new declarations. A

Copyright 2026, James M. Atkinson

raw count is a poor substitute for a time-stamped sequence with its observation mask.

Suppose a surveillance system watches a band for an hour but is disabled by a software refractory policy for 0.4 seconds after each accepted event. There are 120 accepted events. If the refractory windows do not overlap, they occupy 48 seconds, leaving 3,552 seconds during which a new event might be accepted. The crude accepted rate per total time is 120/3,600, approximately 0.0333 per second; dividing by eligible time gives approximately 0.0338 per second. The numerical difference is small under this scenario, but the issue becomes serious when dead time occupies a large fraction of exposure or is correlated with a burst train. The eligible-time rate is not automatically an unbiased estimate of the physical rate, because the censoring occurs after events and may be informative. Reconstructing the underlying process needs a justified dead-time model, such as nonparalysable or paralysable behaviour, and evidence that the model applies.

In a nonparalysable idealisation an accepted event starts a fixed dead interval; other events in it are uncounted but do not extend that interval. In a paralysable idealisation an event arriving during dead time extends the period of unavailability. These conventions create different relationships between observed and underlying rates. A device's actual software may exhibit neither idealisation if processing time varies with packet size, user-interface load or front-end reset. Before selecting a correction formula, one must challenge the instrument with controlled input trains at multiple rates and retain device-status evidence. The apparent linearity of the corrected count is not proof that the selected dead-time model is physically right. An

Copyright 2026, James M. Atkinson

incorrect correction can produce more impressive, less reliable statistics than the uncorrected raw ledger.

The definition of an episode also changes the interpretation of inter-event times. If one long emission flickers across threshold several times, a short merge gap may produce a sequence of nearby event onsets. A longer gap may produce one event with an extended duration. The distribution of intervals between declared onsets therefore depends partly on processing policy, not only on transmitter behaviour. An apparently heavy-tailed waiting-time distribution could be shaped by a mixture of real source intervals, receiver retune gaps and algorithmic merging. To infer a hazard or intensity, the reviewer should examine both event onset times and coverage boundaries, stratify by instrument state and avoid treating a graph of accepted intervals as a direct sample of physical transmission intervals.

One may use alternative operational endpoints. A first endpoint is the onset of any qualifying threshold excursion; a second is the onset of a grouped energy episode; a third is a verified waveform instance classified using independent signal features. Each has a different error structure and different scientific value. In a forensic investigation the first two may be reproducibly measured even when attribution is not established. The third may require a known pilot, modulation structure, pulse shape or comparison with a second receiver. The terms should not be collapsed for the sake of tidy prose. An event study which defines only 'bursts seen by the system' must state that it reports system detections, not necessarily emitter transmissions.

Statistical inference should respect dependence among episodes. If the monitoring system's background noise changes with ambient temperature,

Copyright 2026, James M. Atkinson

local machinery or antenna orientation, a time-homogeneous Poisson model is unlikely to describe all detection events. One may stratify the observation by environmental state or use an explicitly time-varying intensity model, but this introduces model uncertainty and demands enough data to estimate it. A trigger-driven retrigger suppression creates a history-dependent observation mechanism. The investigator ought to simulate or replay the actual algorithm over a candidate physical input sequence, compare predicted and observed event records and test the inference against known inserted pulses. Without such evidence, it is safer to report sensitivity bounds across plausible grouping and dead-time assumptions.

A well-designed ledger therefore stores episode IDs alongside raw threshold intervals, observation eligibility, reason for any disabled interval, frequency coverage, hardware counters and timebase quality. It should permit two analyses: a descriptive statement about what the instrument declared, and a conditional model-based statement about what might have occurred during periods of limited observation. The distinction is indispensable in court or technical review because a negative assertion requires actual observation opportunity. The absence of a declared event during dead time cannot support the same conclusion as the absence of a crossing during a valid, calibrated search. Scientific restraint in this matter produces stronger evidence, not weaker engineering.

David George Kendall, Peer Question: Sir David Cox, consider a monitoring device receiving bursts from one emitter whose traffic comes in trains rather than at constant rate. After an accepted event it imposes a 50-millisecond refractory interval, and the next transmission may begin while

Copyright 2026, James M. Atkinson

the detector remains ineligible. A naïve analyst knows only the accepted onset times and declares long apparent inter-event gaps. What combination of observed exposure, service or processing state, and controlled input testing is necessary before fitting a recurrence law? I would ask you also to distinguish a software rule which refuses to declare a new event while it still records samples from a hardware receiver whose buffer has overflowed, since their later inferential possibilities differ sharply. Could queueing of network packets produce yet another misleading timing pattern even when capture was continuous? If the buffer returns after a delayed delivery burst, can the sample counter distinguish a merely late packet from a permanently lost segment, and how should that distinction alter the eligible-time denominator?

Sir David Roxbee Cox, Response: Professor Kendall, an accepted-event sequence should be analysed together with its observation mask and the chain producing its timestamps. When software suppresses new event declarations but preserves raw samples, it may be possible to reconstruct an alternative chronology by replaying the waveform with another refractory setting. When buffer overflow removes samples, the unobserved transmissions cannot be recovered by that method; one can only bound them under an independently justified process model. A third case is delay in delivering captured packets to a host: the sample sequence may be intact, but host arrival times are poor surrogates for RF onset. These mechanisms should have distinct quality flags. Otherwise a recurrence estimate may be dominated by errors of instrument state rather than the source's traffic pattern.

Copyright 2026, James M. Atkinson

The risk indicator Y(t) must represent eligibility for the particular event definition. If the detector is free to detect a new episode, Y(t)=1; if the detector is in an enforced refractory interval, Y(t)=0 for new declarations under that definition. This does not imply the antenna saw no energy while Y(t)=0. If raw samples are available, a different, secondary analysis can examine candidate signals during that period. A true hardware loss period is a separate observation gap. The analyst should also distinguish valid sampling in one frequency band from absence of coverage in another when the instrument is frequency-agile. The common practice of dividing accepted event count by an hour on the wall clock is valid only for a descriptive rate per scheduled clock hour, not automatically for a physical occurrence rate.

To test a proposed recurrence model, construct a programmable input stream with event trains at several inter-arrival spacings, including intervals shorter than, equal to and longer than the nominal refractory duration. For each trial retain the source's programmed event ledger and the receiver's raw counters, accepted-event ledger and processing-state log. Compare how many transmissions are detected, how many are grouped and how many disappear during refractory suppression. Repeat under host load to identify whether software queueing changes the delay between actual acquisition and stored display. If the model predicts the observed count only after one arbitrary correction, it should be challenged at different rates and different train structures before being accepted.

A mathematical count process N(t) may use the actual accepted onset times, while the latent physical emission process remains separate. Conditional intensity models for the physical process require assumptions about how an accepted event depends on previous events, how missing observation is

Copyright 2026, James M. Atkinson

generated, and whether signal amplitude affects detectability. The model cannot be identified uniquely from censored onset times alone in an arbitrary setting. A well-reasoned report can supply a sensitivity range across explicitly competing assumptions and state which are supported by laboratory evidence. A claim that the source was silent for two seconds cannot arise merely from two seconds without an accepted trigger, especially when the instrument's own refractory or transport states are unresolved.

Dr. James M. Atkinson, Moderator: Dr. Shewhart, you may put a direct question to Professor Cox concerning the observation risk interval and retrospective event reconstruction.

Walter Andrew Shewhart, Cross-Peer Question to Sir David Roxbee Cox: Professor Cox, you distinguish the detector's eligibility interval from physical transmission opportunity. Consider a field system which imposes a fixed refractory interval after a grouped episode but continues to store signal samples. If the event builder is retrospectively rerun with a shorter merge gap, it may discover two groups where the live system declared one. The live refractory clock was started at an onset produced by the old grouping rule, and the resulting suppressed detections have no independent live trigger IDs. Can a later analysis honestly compare the resulting event rates without reconstructing the actual chronology of software decisions? How should a forensic reviewer represent a period that was acoustically or electrically sampled but unavailable to the live event-counting mechanism? Finally, how would you distinguish risk exposure under the original policy from exposure under the replayed policy without treating the retrospective labels as observations that actually occurred in real time?

Copyright 2026, James M. Atkinson

Sir David Roxbee Cox, Cross-Peer Answer to Walter Andrew Shewhart: Dr. Shewhart, the distinction requires two timelines and, where possible, two counterfactual models. The actual live decision timeline must retain the onsets and ends of all accepted groups, each refractory transition, the device's raw sample availability and the detector's eligibility for another declaration under the original policy. This is a factual log of what the software did, assuming the logging mechanism was qualified. A retrospective replay of the same raw samples under a new merge gap creates a different *derived* event sequence. It cannot retroactively generate live trigger decisions, nor can it assume the original hardware or application would have behaved identically had different interrupts, buffers or classifications occurred.

If the refractory mechanism was purely a software label filter that did not alter acquisition, an offline replay may plausibly implement an alternative state machine over the retained sample stream. Even then, one should distinguish a deterministic analysis of preserved observations from a reconstruction of operational alerts that never occurred. If the live trigger affected hardware retuning, gain, memory allocation or buffering, the counterfactual is more complicated: a different event policy could have produced a different physical acquisition. In that case the raw record from one policy cannot fully represent the data that would have been gathered under another. The analyst must not substitute an algorithmic replay for a laboratory experiment which actually changes the trigger policy and measures its effects.

Represent the two eligibility processes separately. Let Y_live(t) describe actual live permission to declare an event and Y_replay(t) describe

Copyright 2026, James M. Atkinson

permission under the hypothetical offline policy, both linked to the same valid-sample mask where justified. Their denominators can differ, and neither alone gives the true source exposure if the receiver was not tuned to the relevant frequency. A quoted rate from live decisions is descriptive of live operation; the replayed rate is a derived sensitivity analysis. A physical emission-rate estimate additionally requires assumptions about missed events, dependence and observation probability, supported by known input tests.

For forensic reliability, retain the initial hardware counters, validity map, thresholds, original state transitions and replay software versions. Each derived episode should link to its constituent raw crossing intervals, and any differences in apparent event chronology should be explained as effects of parameter selection. Where dead-time suppression removed samples rather than merely alerts, mark those intervals unobserved and do not fill them with imagined transmissions. The sound conclusion may be that live operation declared four episodes while a replay of retained data declares six under a different policy, with neither number independently proving the physical burst count. Precision about the observation mechanism is more useful than pretending those counts are competing measurements of one directly observed quantity.

Dr. James M. Atkinson, Moderator: Professor Tukey, the preceding contributions establish distinct estimands and counting assumptions. What exploratory analysis could reveal an unstable event definition before a formal inferential model is trusted?

John Wilder Tukey, Fourth Principal Contributor: Dr. Atkinson, the analyst should first make the hidden construction of event counts visible. A single

Copyright 2026, James M. Atkinson

number is the end of a long pipeline: analogue input, detection statistic, threshold, interval assembly, event grouping, feature extraction and reporting. Exploratory work should display at least four aligned timelines: raw or minimally processed signal energy, binary threshold exceedances, grouped event intervals and periods in which observations were invalid. Add a fifth timeline for changes of gain, centre frequency, noise-floor estimate and classifier version. The eye can then see whether a cluster of reported events corresponds to a single physical pulse with fading, a repeated sequence of distinct bursts, or an apparatus transition. Such plots do not settle causality, but they expose obvious contradictions that a table of counts may conceal.

I recommend a parameter sensitivity surface rather than one convenient merged count. Let C(H,L,g,r) denote the declared episode count produced with entry threshold H, exit threshold L, merge gap g and refractory time r over one fixed, immutable capture. Vary one parameter at a time across an engineering-plausible range while holding the others fixed. Then examine relevant two-dimensional slices, for example count against H and g, including the total duration of selected intervals and the number of crossings excluded by refractory behaviour. If C changes violently after a minor alteration in g, the result is not a stable estimate of physical episode number. If the count is steady across a broad range, that is useful robustness evidence but still not proof of true source identity. The parameter range should be justified from signal physics and receiver behaviour rather than chosen because it looks reassuring.

An instructive invented test sequence comprises two independently generated pulses separated by 15 milliseconds, each containing internal

Copyright 2026, James M. Atkinson

fades of 3 milliseconds. A merge gap of 5 milliseconds would ideally reconnect fades within each pulse and preserve the two pulses as separate events. A gap of 20 milliseconds might merge the two transmissions as one. Yet if the receiver's IF filter itself rings for 12 milliseconds after a pulse, a 5-millisecond rule could fragment a single input pulse into multiple threshold episodes because the detector statistic contains ringing and threshold oscillations. The appropriate rule therefore depends on the end-to-end impulse response and on the smallest physical separation the measurement seeks to resolve. It should not be inferred from a parameter sweep alone. Test the whole receiver with a calibrated pulse source rather than assume that the input waveform survives unchanged into the event builder.

The number of unique 'events' can also be distorted by frequency channelisation. A signal near the boundary of two frequency bins can appear in both because of window leakage or overlapping digital filters. A frequency-agile waveform can traverse many channels in one burst. Counting independent spectral-cell threshold intervals as separate emitters would be especially misleading. Exploratory visualisation should link detections in time and frequency, display estimated bandwidth and instantaneous frequency where supported, and show whether the candidate events share a continuous underlying waveform. Conversely a wide aggregation rule may suppress evidence of two overlapping signals at nearby frequencies. The physical question must be stated: is the system counting threshold cells, time-localised episodes, separate waveforms or distinct emitters?

Do not omit the data that did not lead to an accepted event. Plot below-threshold portions, candidate detections rejected as noise, and intervals

Copyright 2026, James M. Atkinson

with no valid samples. If the receiver is retuned during an episode, the time-frequency map should contain an honest coverage gap. A display that paints black pixels while the hardware observed nothing invites a false interpretation of silence. Similarly an event grouping routine should preserve the raw crossing IDs underlying each merged episode, permitting later reviewers to undo its choices without inventing missing samples. The provenance graph should be reversible from grouped ID to constituent accepted intervals; it need not reverse to a true physical transmission if that state was never observed.

For uncertainty, one can bootstrap whole recorded blocks when dependence is local and justified by the data, rather than resampling individual samples and thereby destroying correlation. The block size itself requires sensitivity testing. If the process is nonstationary because of changing gain or interference, indiscriminate block resampling across incompatible regimes can manufacture artificial records. Another option is to use repeat calibrated experiments with known pulse trains and compare the distribution of event counts under the same frozen algorithm. A simple split of the data into development and validation intervals guards against selecting g on the same record used to claim extraordinary performance. When ground truth is available, false splitting and false merging should be shown separately.

A practical graphic might include a 'genealogy' of event IDs. At g=2 milliseconds, clusters A and B may be two declared episodes. At g=10 milliseconds they may become one episode AB. At g=40 milliseconds AB may join another, physically distinct emission C. That genealogy indicates precisely which relationships are created by the algorithm. It is more

Copyright 2026, James M. Atkinson

informative than publishing separate unconnected count tables at each g, and it allows another engineer to reproduce the effect by replay. Include the time ranges and confidence in a physical attribution; a change in grouping rules should not silently mutate a source attribution identifier used elsewhere in an evidential report.

The exploratory conclusion is not that every parameter choice should have equal authority. A defensible primary rule can be justified from a declared measurement objective and independent calibration. What exploration contributes is evidence about sensitivity, fragility and alternative readings. A robust physical finding should not depend entirely upon a borderline software choice without acknowledging that dependence. A report which provides only the winning parameter set is an advertisement for an algorithm, not a comprehensive account of the experiment. The aim is to reveal where a reasonable choice among plausible alternatives changes the decision, so that scientific qualification can be expressed before operational action is taken.

Dr. James M. Atkinson, Moderator: George Edward Pelham Box, would you examine the preceding model with an independent methodological challenge?

George Edward Pelham Box, Peer Question: Professor Tukey, a field detector is frequently applied under conditions unlike its laboratory calibration. Noise distribution changes with time, interference arrives in bursts, the spectrum is swept rather than continuously observed, and the noise-floor estimator may itself be influenced by a sought signal. How should exploratory diagnostics and model criticism identify the point at which a single merge gap or null false-event model ceases to be credible?

Copyright 2026, James M. Atkinson

Would you prefer stratification, a time-varying threshold, an explicit latent-state model, or a warning that the event count lacks an interpretable physical scale? Please explain how to avoid fitting such a flexible model to one suspicious recording and then treating its favourable fit as independent confirmation. I would also ask what the evidence ledger should show about unsampled frequency-time intervals, since a smooth count graph can make missing observation appear like measured silence. Would a time-frequency coverage diagram reveal that some quiet regions were never sampled, and how should a statistical model distinguish those regions from genuinely observed low-energy intervals?

John Wilder Tukey, Response: Professor Box, the first model criticism is to compare the claim with what the instrument actually observed. If the receiver swept through different channels, construct a time-frequency coverage map before plotting 'events per minute'. Mark intervals when the band of interest was not sampled. Overlay detector thresholds, gain changes, filter transitions and raw crossing intervals. One frequently discovers that a change in event count coincides with an observation change rather than a source change. The plot should not turn a lack of samples into zero energy or a lack of emissions. The relevant denominator is valid exposure in the particular band, and even that does not establish capture probability for a short burst without a time-response model.

I would next compare distributions within plausibly stable operating regimes. A stationary background model may be adequate during a quiet thermal interval but not while a motor is repeatedly starting or a receiver preselector is switching. Stratification by documented instrument state can be simpler and more transparent than a highly flexible latent-state model.

Copyright 2026, James M. Atkinson

But it can also create small subsets whose uncertainty becomes large. The analyst should choose the simplest explanation which survives challenge tests and must disclose when there are insufficient observations to distinguish competing regimes. A time-varying threshold can be justified if it is calibrated and logged, yet it changes the event definition. Reprocessing old and new intervals under a fixed retrospective threshold may expose the effect, provided the data and dynamic range support it.

For diagnostic plots, show the number of raw exceedances, contiguous excursions and merged episodes in parallel under a grid of threshold and gap settings. A source with genuine repeated pulses may produce a characteristic inter-excursion distribution, but so may the receiver's own filtering or interference. A broad plateau in count across several justified settings is encouraging evidence of algorithmic robustness, not source identification. The absence of a plateau is itself a finding: the count is rule-sensitive. One can report an interval such as 'between twelve and twenty-one declared episodes under the pre-specified sensitivity set', rather than forcing a single number. The exact range should come from actual replay, not a theoretical promise.

To avoid confirmation by overfitting, keep one set of data for developing the event model and a genuinely independent challenge set for validation. If only one field recording exists, use controlled laboratory perturbations and be candid that external validation is absent. Evaluate whether the model predicts results after antenna substitution, controlled injection or a change in analysis window. A model which describes the original waveform beautifully but fails under small known perturbations has not earned the inferential claims attached to it. Archive every configuration and plot

Copyright 2026, James M. Atkinson

transformation so that the next examiner can assess the same alternatives. Good modelling begins by discovering where the model fails, not by making its line pass through every observed point.

Dr. James M. Atkinson, Moderator: Professor Fisher, please challenge Professor Tukey on the interpretation of apparent parameter robustness.

Sir Ronald Aylmer Fisher, Cross-Peer Question to John Wilder Tukey: Professor Tukey, a sensitivity graph can show a plateau in the count of merged events across a broad range of gap parameters, which might appear to support an objective number of physical bursts. Yet plateaux can arise from a strong separation of inter-exceedance times even when the process is an instrument-generated oscillation, and the number of possible threshold-grid choices is itself a source of selection. How would you distinguish a genuinely useful robustness region from one manufactured by preprocessing or by choosing an attractive portion of a broad parameter sweep? Would you report the entire parameter surface, and what analysis would establish whether apparent plateau stability carries any transferable information about false splitting and false merging under different signal amplitudes or receiver states? I also ask whether a grouped-episode count can be called statistically stable merely because it is unchanged while its constituent crossings and total event duration change substantially.

John Wilder Tukey, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Professor Fisher, a plateau is a description of insensitivity to one set of analytical choices, not a test of the physical origin of the signals. The full parameter surface, or a well-defined predetermined subset, should accompany any highlighted plateau. Display the span of H, L, g and r, the number of valid samples, the counts of raw crossings and grouped episodes, and the

Copyright 2026, James M. Atkinson

changes in total grouped duration. A constant episode count may conceal a substantial migration of boundaries or a different assignment of constituent intervals. The count should therefore be supplemented by an interval-overlap metric or an event genealogy, which identifies which raw intervals join or split as settings change. A stable integer produced by changing physical interpretations is not stability of the whole measurement.

The strongest test is a blind or independently held-out set with known injected transmissions. Construct a range of pulse separations and within-burst fades, then ask whether the candidate parameter region preserves the correct physical multiplicity under those conditions. A plateau which comes from a periodic instrument artefact may perform poorly when a laboratory test introduces two pulses at a closely spaced interval; this counterexample is more informative than additional averages over the original field recording. The test must include a quiet null capture, realistic interference and changes in receive-chain configuration within the intended operating envelope. Report false splitting, false merging, missed detection and timing bias separately. One should not choose the validation pulses after discovering that the rule fails a known case and then declare the altered experiment a confirmation.

Preprocessing is a separate source of apparent robustness. An automatic gain controller, adaptive threshold or moving-average detector can remove small fluctuations and thereby make the episode count look stable across many merge gaps. That may be desirable for operational detection, but it does not demonstrate that the physical source emitted a stable number of bursts. Display at least one more primitive observable, such as raw detector energy or a calibrated pre-aggregation statistic, alongside the grouped

Copyright 2026, James M. Atkinson

output. Freeze preprocessing parameters during sensitivity analysis; otherwise a change in count may be due to the preprocessing response rather than the grouping rule under investigation.

Statistical stability should be reported as a vector of outcomes, not one integer. An episode count unchanged at twelve could accompany widely different peak energies, durations, within-episode gaps and the presence of blind intervals. The reviewer should understand which aspects of the record are invariant and which are rule-dependent. If count, timing boundaries and associated waveforms are all stable under a scientifically justified family of settings and independently known test sources, the case for a robust operational event definition improves. It still does not establish emitter identity without additional attribution evidence. If only the count is stable, report that narrow fact. The discipline is to expose meaningful sensitivity, including a failure of the analyst's preferred presentation, rather than to seek one visually persuasive graphic.

Dr. James M. Atkinson, Moderator: Professor Neyman, how should the investigator establish an event definition that can be defended before an adverse decision, and what validation evidence is required to distinguish false splitting from false merging?

Jerzy Neyman, Fifth Principal Contributor: Dr. Atkinson, a decision procedure should be stated before its outcome is known. Define the observation, the scientific hypothesis, the loss of a false detection and the loss of a missed detection. An event-building rule is part of that procedure because changing the count may alter whether a prescribed threshold for action is met. A rule which serves fault monitoring may not be suitable for forensic attribution; a rule which flags any candidate crossing may be appropriate for triage but

Copyright 2026, James M. Atkinson

misleading as a final count of transmitters. The first discipline is to separate the threshold for retaining possible evidence from the stricter requirements for reporting an independently supported physical transmission. A low-cost triage alert should not be written into a report as if it were a proven event.

Two distinct errors arise even when the basic threshold detector functions exactly as designed. False splitting occurs when one true physical burst yields two or more declared episodes. False merging occurs when physically separate emissions yield one declared episode. These errors cannot be described adequately by a single 'accuracy' percentage. For validation, construct a confusion table or event-association protocol in which each known injected burst can be related to the declared output intervals. The association rule must address overlaps, partially observed bursts, weak detections and adjacent emissions before testing begins. If the detector retains no time-continuous ground truth, some cases must be labelled indeterminate rather than assigned the outcome most favourable to the algorithm. One can then report the proportion of genuine bursts detected, the fraction falsely split, and the proportion of distinct bursts incorrectly merged, each under specified signal and environmental conditions.

Suppose a laboratory replays one hundred individual test bursts with known timing and duration, and the event constructor declares one episode for eighty-five, two for ten, none for four and three for one. The number of declared episodes is 85+20+0+3=108, while ninety-six of the hundred bursts produce at least one episode. A careless summary could announce 108% detection. The physically relevant detection probability on this test set is 96/100, or 96%, while eleven bursts were over-segmented. These figures describe the constructed test set only. They do not certify confidence in a

Copyright 2026, James M. Atkinson

new site's unmeasured signals, nor do they establish how well the system handles two genuine emissions placed close together. A second experiment must deliberately vary between-burst spacing to measure the false-merge probability.

Confidence intervals also depend on the unit of replication. If the one hundred bursts were generated in ten trains of ten, bursts within a train may share the same fading state, temperature or clock error. Treating them as a hundred independent Bernoulli trials could overstate precision. Use independent test campaigns or a clustered design in which the uncertainty analysis recognises these common conditions. Record the apparatus, seed of simulated noise where relevant, actual injected waveform and randomised sequence of test configurations. Keep acceptance thresholds fixed while examining a validation set. If the source waveform is reconstructed after the fact from the receiver recording alone, the exercise lacks independent ground truth and must not be advertised as a controlled sensitivity test.

A positive count is conditioned upon the observation process. Let N_true be the number of physical test transmissions and N_declared the number of algorithmically declared episodes. There is no algebraic identity N_declared=N_true unless specific assumptions and a validated detector establish it. Some bursts may be missed entirely, some split, and others merged. A conceptual accounting may write N_declared=N_detected+N_extra_split−N_lost_merge, where the terms require carefully defined mutually exclusive event-association conventions. This accounting is explanatory, not a general estimator of unobserved transmissions. It shows why one count alone cannot reveal which error

Copyright 2026, James M. Atkinson

predominates: two instruments can report the same number while having sharply different false splitting, false merging and missed-detection behaviour.

There should be an independent test for the rate at which purely environmental or instrument-generated fluctuations generate grouped episodes. The null experiment should include receiver noise, blocking signals, gain transitions, front-end switching and retuning to the extent they occur in the intended deployment. A decision threshold calibrated only on ideal Gaussian noise may be inapplicable when a nearby electrical motor produces impulsive interference. At high alert rates, the cost of manually reviewing false episodes may overwhelm an investigation; at low alert rates, excessively broad merges can hide distinct signals. The engineering optimisation therefore depends on an explicitly declared error cost and the required temporal resolution. It should not be retrofitted to justify a previously announced finding.

Policy controls are straightforward in principle. Freeze a primary algorithm version and parameter file; identify every data set used for development; retain complete evidence logs; conduct a validation campaign with independently known event truth; test uncertainty under correlated conditions; and require any later modification of H, L, g or r to create a new analysis version rather than overwrite the old count. An examiner may still present alternative counts as sensitivity results. The report should display how the decision would change under those alternatives and whether there is a stable conclusion across reasonable settings. Where a material conclusion depends upon choosing one arbitrary gap value, it must be

Copyright 2026, James M. Atkinson

qualified. Such transparency neither prevents practical monitoring nor requires that every signal be classified perfectly.

The final decision need not be binary. One may classify a time interval as observed energy meeting a detection criterion, as a candidate event with unresolved merging, as a verified individual waveform, or as an attributed emission supported by additional sensors. Each level carries a different evidential burden. The role of statistical design is to make the likelihood of false conclusions intelligible and to keep the inference within the evidence actually recorded. I would rather defend a modest, properly bounded count before a sceptical tribunal than present an implausibly exact activity figure obtained from an opaque grouping routine.

Abraham Wald, Peer Question: Professor Neyman, the operator is monitoring an extended session and may stop the examination when the count of detected events exceeds an alarming value. The detector threshold and gap-merging rule may have been adjusted during the session after an early run of apparent false alarms. Does the resulting evidence support a conventional fixed-sample confidence statement, or do sequential stopping and adaptive parameter changes alter its interpretation? What records should demonstrate that later results were not selectively defined by the early data? Please distinguish the legitimacy of a practical adaptive monitor, which may need to respond to changing interference, from the stronger claim that an unchanged statistical experiment was performed. I am particularly concerned about a suspected intermittent transmitter whose events are clustered, so that observing the first trigger makes a second trigger more likely than it would be under independent noise. Can a monitoring team provide a valid performance claim when the stopping

Copyright 2026, James M. Atkinson

boundary is selected after observing the largest cluster, or must a new independent validation run be conducted under the frozen policy?

Jerzy Neyman, Response: Dr. Wald, sequential monitoring is a legitimate design if its decision boundaries and update policies are part of the experiment. It becomes misleading when an analyst applies confidence formulas intended for a pre-specified fixed observation period after deciding to stop on the basis of an unusual count. A stopping rule can affect the distribution of the test statistic, especially when observations are dependent or thresholds change during observation. If a monitor stops when an apparent event rate becomes high, the retained sample is selected for high rates. Reporting it as an unbiased sample of routine activity without correcting for that selection is unsound. The design should specify whether the goal is online alerting or estimation of a stable source emission rate; one algorithm need not serve both purposes.

Adaptive thresholds can also be defensible. Suppose a receiver tracks a gradually rising noise floor so that an absolute power threshold would otherwise flood the alert ledger. The adaptive rule may preserve a desired conditional false-alarm rate, but its calibration depends upon a trustworthy reference interval and an update policy that does not absorb the very signals of interest into the noise estimate. The algorithm should log each threshold update with hardware time, underlying observations and a reason code. Data from before and after an adaptation are not interchangeable unless the statistical measurement model accounts for the change. Replaying the raw record through the frozen final setting may provide one useful comparison, but it does not erase the fact that the live operational procedure used different settings.

Copyright 2026, James M. Atkinson

For a formal sequential test, one may design stopping boundaries with specified error probabilities under explicit hypotheses and dependence assumptions. The familiar independent-observation sequential models should not be transplanted without qualification to clustered detection episodes, where a single physical burst can produce several closely spaced triggers. A safer engineering approach tests the complete alert policy against independently generated noise and burst trains, preserving the chronological decision log. Separate calibration and validation campaigns should be used, with acceptance criteria fixed before the validation run. If many candidate gap rules are explored and only the most favourable reported, a reader needs an accounting of the search process to assess selection bias.

A report should include the total valid observation time before stopping, the count and timestamps of all accepted episodes, threshold and merge-gap histories, every decision boundary applied, and the reason acquisition ended. Where adaptive monitoring was operationally necessary, one can report the resulting alerts descriptively without claiming they are a sample from an unchanged process. A subsequent independent fixed-protocol run can test the hypothesised phenomenon. The proper distinction is not between flexible engineering and rigorous evidence, but between a documented adaptive procedure and an unexamined statistical claim which pretends no adaptation or stopping occurred.

David Harold Blackwell, Peer Question: Professor Neyman, an alarm system may be designed to favour sensitivity at the expense of many false positive episodes, while a forensic report may require a much more conservative statement. How should one choose a threshold and merge-gap policy when

Copyright 2026, James M. Atkinson

false splitting, false merging, missed bursts, and unnecessary investigative interventions have different costs? Must the policy reduce these different errors to one weighted score, or can it present several operating points and permit an accountable decision maker to select among them? I am also concerned that a low threshold increases detection of weak bursts but can create a dense background of correlated crossings that a large merge gap then conceals. This could make the final event count smaller even while the raw threshold-crossing count rises. How should that counterintuitive behaviour appear in the report? If a security policy tolerates many inexpensive alerts but almost no false attribution, which stage should own the stringent threshold, and which stage should retain the original unsuppressed crossing data?

Jerzy Neyman, Response: Professor Blackwell, a single scalar score is convenient for an optimisation routine, but it is not mandatory or necessarily appropriate for a legal or scientific report. The analyst should first describe the distinct error probabilities and their practical consequences at each candidate operating point. A detector can be sensitive to weak signals yet poor at deciding how many physically separate bursts occurred. A rule can also merge threshold chatter effectively while hiding two genuine emissions that occur close together. It is therefore preferable to present a performance surface over H, L, g and r, including detection probability, false-event rate, false-split rate, false-merge rate and latency. Those quantities should be measured against independent ground truth under representative conditions.

The nonmonotonic effect you describe is important. Lowering H cannot, with all else truly fixed, make the raw set of threshold exceedances smaller

Copyright 2026, James M. Atkinson

for the same statistic and samples. It can, however, connect intervals that were formerly separated: below-threshold gaps disappear as weaker samples exceed the lowered threshold. The number of grouped episodes may therefore decrease while the number of above-threshold samples increases. This is an algorithmic topological change, not evidence that the transmitter emitted fewer bursts. An observed count versus threshold curve should include both raw exceedances and merged episodes, together with a genealogy of which intervals joined as H changed. If adaptive gain or noise estimation also changes with threshold, even the raw monotonic relation requires renewed scrutiny because the underlying statistic may no longer be fixed.

An operational decision may use an explicit loss function combining consequences of missed signals and false alerts, subject to regulatory or investigative constraints. But loss weights need not be invented by the signal-processing engineer. A security supervisor may rationally prefer an inexpensive broad triage alert, followed by a separate calibrated evidential procedure before any adverse action. One should not use the triage system's event count as if it met the higher standard of the evidential procedure. If different plausible error costs favour different policies, report the tradeoff and identify the authorised decision maker who selected the primary rule.

Finally, validate robustness against dependence. The false-alert burden observed in independent white-noise trials may be much lower than in a building containing periodic switching interference or shared instrument spurs. Test representative operating conditions and retain the rejected candidates, not only alerts surviving a grouping filter. The acceptance

Copyright 2026, James M. Atkinson

criteria must be declared before the validation campaign. Where a false-merge risk exceeds an authorised limit for closely spaced bursts, the algorithm should qualify its episode count or refer the case for waveform-level examination rather than suppress the problem by choosing a reassuring average score.

Dr. James M. Atkinson, Moderator: Professor Tukey, please examine Professor Neyman on validation after a detector design has been revised.

John Wilder Tukey, Cross-Peer Question to Jerzy Neyman: Professor Neyman, you advocate a primary preregistered event rule with quantified split and merge errors. Yet suppose the first calibration campaign demonstrates that the originally planned merge gap is inadequate because an unforeseen receiver filter causes long, amplitude-dependent ringing. Should an investigator rigidly retain an evidently defective primary rule for the sake of pre-specification, or correct it and disclose the revision? How should the ensuing test campaign avoid becoming a sequence of improvised validations in which every failure leads to another parameter change? Please distinguish the legitimate engineering development of a detector from the evidential report that claims performance under an independently frozen design. Further, what would you require if a field recording cannot be reproduced and no representative independent event-ground-truth data are available, so that only the sensitivity of its derived count to parameter choices can be observed? Would you also specify how a revision of the event policy should be recorded in a public method register, so that future independent reviewers can distinguish a genuine engineering correction from parameter choices tuned to the disputed case?

Copyright 2026, James M. Atkinson

Jerzy Neyman, Cross-Peer Answer to John Wilder Tukey: Professor Tukey, pre-specification is not a command to preserve known technical defects. It is a device for preventing an analyst from disguising choices made after seeing the outcome as though they were fixed in advance. If testing reveals that a receiver's filter impulse response produces longer ringing than expected, the correct engineering action is to revise the detector, document why, and conduct a new independent validation. The original preregistered procedure remains part of the development history; the revised version receives a new identity and may become the primary rule for a *subsequent* validation campaign. The error arises when a team repeatedly changes parameters while examining one test set and then reports the final result as an unbiased evaluation of a fixed design.

A useful governance scheme separates development, qualification and operational use. In development, explore a broad parameter set, identify failure mechanisms and choose the design. In qualification, freeze the algorithm and define acceptance criteria before exposing it to independently generated challenge waveforms. Operational use then logs every configuration and invokes a controlled change procedure for any later revision. If the real-world environment differs materially from the qualification envelope, the system can still collect evidence, but its performance claims must be qualified until the new regime is challenged. This approach allows engineering improvement without sacrificing a traceable chain of methodological choices.

Where there is only one unrepeatable field record and no independent ground truth, the correct inferential ambition is narrower. The investigator can show the raw crossings and describe how alternative plausible H, L, g

Copyright 2026, James M. Atkinson

and r values change the number and duration of grouped episodes. One can test internal consistency, recoverability from the raw ledger and sensitivity to instrument-state assumptions. What one cannot establish solely from that same recording is an unbiased physical false-split or false-merge rate for unknown emitters. A calculated confidence interval under a chosen model remains conditional on that model; it should not be presented as empirical evidence that the true number of bursts is within the interval.

A decision maker may need to act despite uncertainty, for example by commissioning a second calibrated monitoring session rather than drawing an attribution conclusion immediately. The report should state which observations are robust, which depend on the merge setting and what additional independent evidence would discriminate the competing burst chronologies. If a software revision materially changes the reported count, preserve both versions and explain the change rather than silently replacing the first. The purpose of pre-specification is accountable inference, not ritual inflexibility. The eventual publication record should permit a reader to reconstruct the development history and judge whether the stated performance was measured under genuinely independent conditions.

Dr. James M. Atkinson, Moderator: Professor Neyman, return the token to Dr. Shewhart for the concluding challenge about reproducibility and missing samples.

Jerzy Neyman, Cross-Peer Question to Walter Andrew Shewhart: Dr. Shewhart, your original distinction between raw crossings, episodes and physical emissions is essential, but I wonder whether the evidential ledger can impose too much confidence simply by making every algorithmic step reproducible. An exact replay might always produce thirteen episodes even

Copyright 2026, James M. Atkinson

when the receiver's trigger threshold was never properly calibrated, and the date-to-hardware-clock mapping contains an unmeasured discontinuity. How should the system mark the boundary between procedural reproducibility and metrological validity? Should the declared count be disqualified, rather than merely qualified, when sample continuity is uncertain? Finally, would you allow a grouped event spanning an acquisition gap to retain one episode identifier, or should the missing interval force a separation irrespective of what the signal's unobserved physical behaviour might have been? If the record includes hardware sample indices but no independent time reference during a retuning interval, which quantitative time limits can legitimately be attached to those observations, and which physical timing assertions must remain unresolved?

Walter Andrew Shewhart, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, exact replay establishes that a defined transformation applied to a defined recorded input yields the same derived output. That is valuable because it permits scrutiny of methodology and prevents arbitrary changes of description. It does not validate the instrument's calibration, the truth of the raw timestamp, or the claim that a software episode corresponds to a physical transmission. A reproducible computation can be consistently wrong for the intended measurand. Therefore procedural reproducibility belongs in one section of the evidential report, with separate metrological evidence for threshold calibration, timing continuity, coverage and the receiver response. These categories should not be collapsed into a single 'verified' tick mark.

When sample continuity is uncertain, the analyst must identify what has been lost. A known acquisition gap may still leave perfectly valid crossings

Copyright 2026, James M. Atkinson

before and after it. Those individual intervals can be reported with their original indices. What becomes unsupported is an inference of continuity through the unobserved interval. A grouping algorithm may choose to assign one *candidate* episode spanning the gap, for instance to support operational triage, but it must label the join as unobserved and explain its assumption. The forensic primary ledger should preserve two observed components with a gap marker rather than present a continuous waveform or one proven physical event. A reader may then inspect alternative hypotheses: one emission continuing through the gap, two separate emissions, or an unrelated artefact. The software must not resolve the ambiguity without evidence.

The decision to exclude an interval or qualify it depends on the claim. If the intended statement is only that at least two above-threshold observed intervals occurred, a gap need not invalidate those observations. If the statement is that exactly one continuously transmitted burst occupied the entire combined period, the missing interval prevents that inference without independent corroboration. If the gap might contain additional whole bursts, even the count of separate physical emissions may lack a useful upper bound. Where the receiver was not observing the frequency at all, the absence of triggers is no evidence of silence. A calibrated clock can make boundaries trustworthy yet does not fill the gap with samples.

An auditable implementation should therefore attach validity flags to each raw crossing and to every edge used in an episode merge. It should encode a join reason: continuous below-threshold evidence, permitted short observed dip, independent waveform corroboration, or hypothesis over missing data. The analysis can keep one display grouping for operational

Copyright 2026, James M. Atkinson

purposes while preserving the unmerged primary evidence. Establish a rule that model-based joins never silently become observations merely because later software can reproduce them. A reliable event count is an estimate whose measurement definition and limitations remain visible, not a collection of numerically tidy labels masquerading as unmediated physical reality.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The discussion has separated six distinct quantities: threshold-exceedance samples, contiguous excursions, grouped detection episodes, algorithmically suppressed candidates, waveform instances and independently attributable emissions. Hysteresis, merge gaps and refractory periods alter the declared number of episodes without necessarily changing the underlying electromagnetic activity. Statistical independence cannot be inferred from a large crossing count when FFT overlap, filtering, gain loops and physical burst trains induce temporal correlation. The panel requires immutable sample chronology, reproducible event-constructor state, an explicit valid-observation mask, controlled tests for false splitting and false merging, and transparent sensitivity analysis across scientifically justified parameter values. No expert may infer a unique physical transmission count merely from one event-builder output. This is a fictional pedagogical reconstruction, not an historical transcript or an assertion that these deceased experts examined modern software-defined radio instruments.

QUESTION 071. SOURCES AND EDITORIAL QUALIFICATIONS

Christopher A. T. Ferro and Johan Segers, “Inference for Clusters of Extreme Values,” Journal of the Royal Statistical Society: Series B, volume 65, issue 2 (2003), pages 545–556, doi:10.1111/1467-9868.00401. The paper supports

Copyright 2026, James M. Atkinson

the observation that declustering rules affect cluster estimates under stated extreme-value assumptions; it does not validate any particular RF event-builder threshold, gap, or source classification.

W. A. Shewhart, Economic Control of Quality of Manufactured Product (1931), historical foundation for controlled measurement-process interpretation. Historical author citations identify methodological lineage only; modern radio discussion is editorial reconstruction.

J. W. Tukey, Exploratory Data Analysis (1977), historical foundation for examining the sensitivity of observed summaries to analysis and plotting choices; no modern SDR procedure is attributed to the historical author.

Editorial status: All numerical cases are explicitly hypothetical. Names, historical credentials, publication metadata and each technical assertion require final independent scholarly verification prior to publication. Counts derived from controlled examples are calculations, not measured performance of any field receiver. Stage A structure, source-to-claim checking, scientific audit, cross-question semantic duplication review and whole-manuscript typography must remain separately recorded.

QUESTION 072

Copyright 2026, James M. Atkinson

How should rare-burst searches quantify blind time and the likelihood of a missed event?

SCHOLARLY RECONSTRUCTION. All attributed speech below is a fictional pedagogical dialogue involving deceased historical experts; no quotation or conversation is authentic. Modern RF equipment, legal interpretations and numerical examples are contemporary editorial applications of separately identified mathematical principles.

Dr. James M. Atkinson, Moderator: Sir Ronald Fisher, suppose a frequency-agile monitoring station is connected for ninety consecutive days and reports no qualifying emission. During that period it visits one frequency for twelve milliseconds every second, sometimes loses lock, and sometimes rejects a faint pulse because the threshold or dwell criterion is not met. Would you begin by separating the objective calendar span from actual opportunity for an event to be admitted into evidence, then examine what a zero count does and does not allow us to say about an intermittent transmitter?

Sir Ronald Aylmer Fisher, Principal Contributor: Dr. Atkinson, a non-detection has meaning only after the experiment specifies what could have been detected. A ninety-day wall-clock duration is an administrative quantity, not a measure of listening opportunity at every frequency. The observation apparatus defines a coverage function c(t,f,s), with time t, frequency f and instrument state s. It takes value one where the receiver is acquiring usable evidence for that channel under declared settings, zero where it is blind, and a graded value only where detection probability has been calibrated. Antenna sensitivity, polarisation, dynamic-range state and

Copyright 2026, James M. Atkinson

propagation must also enter the model; mere scheduling is not enough. The first question is therefore not whether the instrument was powered, but which source behaviours had non-negligible probability of leaving a retained record.

Let T be total elapsed observation time, and let L be the sum of valid on-channel listening intervals for the frequency and equipment state of interest. The duty fraction $\eta=L/T$ is a useful descriptive ratio. It is not automatically the probability of detecting any transmission. If burst onsets are independent of the scanning schedule, burst durations are negligible compared with dwell intervals, and detection is perfect during valid dwell, then η may approximate the probability that a randomly timed onset lands within live coverage. Each condition matters. A burst lasting half the revisit interval can overlap a dwell even when its onset occurs outside it; a burst too short to satisfy a detector's settling requirement can be missed although part of it overlaps a dwell. A transmitter whose schedule is locked to the scanner can produce a missed event on every cycle. Thus coverage fraction is one element of a physical detection model rather than a universal statistical answer.

For a first conditional model, suppose bursts begin as a homogeneous Poisson process with rate λ starts per second, independent of receiver activity, and each start at time t is detected with independently calibrated probability p(t). The probability of no detected starts over an interval [0,T] is $\exp[-\lambda E]$, where $E=\int_0^T p(t)dt$ has units of effective exposure seconds. For a model in which $p(t)=q$ during L usable seconds and zero elsewhere, $E=qL$.

Copyright 2026, James M. Atkinson

Here q means the probability of correctly recording a qualifying burst conditional on its onset occurring in the relevant receptive state. A rate $\lambda=0.02$ bursts per hour, $L=100$ hours and $q=0.7$ gives expected detected count $\lambda E=1.4$ and probability of zero recorded bursts $\exp(-1.4)$, approximately 0.247. None of those figures is evidence that the assumed Poisson arrival model is correct. They illustrate how a substantial calendar span can coexist with a material chance of zero detections.

It is important to separate several logically different probabilities. P(no recorded bursts | λ, apparatus model) is a forward sampling probability. P(no bursts occurred | no detections) is a reverse conditional probability requiring an explicit prior or other assumptions. If source starts form a Poisson process, actual zero bursts over T has probability $\exp(-\lambda T)$. Because no true bursts implies no detections, the conditional probability that at least one burst occurred despite zero records is $[\exp(-\lambda E)-\exp(-\lambda T)]/\exp(-\lambda E)=1-\exp[-\lambda(T-E)]$, provided independent thinning and a known λ are accepted. That expression can surprise an examiner: missed bursts and accepted bursts form independent thinned subprocesses under the model. It must not be presented as an empirical posterior when λ is unknown.

A zero count can nevertheless set a one-sided conditional rate bound. Under the Poisson model with known effective exposure E and no false-count complications, a conventional frequentist 95% upper limit solves $\exp(-\lambda_{upper} E)=0.05$, giving $\lambda_{upper}=-\ln(0.05)/E$, approximately 2.996/E. If $E=70$ effective hours, the upper bound is approximately 0.0428 burst starts per hour. The statement is that rates higher than this would make a zero

Copyright 2026, James M. Atkinson

detection a less than five-percent outcome under the specified model; it is not a 95% probability that a particular unknown source rate is below the bound, and it says nothing definitive about systematic blind frequencies or deterministic timing. If calibration of E is poor, publishing three significant decimal places for λ_upper creates spurious certainty.

The physical meaning of the time coordinate must likewise be explicit. A spectrum analyser may record a detection at the end of a sweep, an SDR may tag the start of a buffer, and an application may report the moment a software event was declared. These labels do not identify the start of RF energy at the antenna unless separately calibrated. Every time interval used for L should therefore be defined by acquisition-capable hardware conditions, not by a green dashboard indicator. Reference lock, retuning, analogue preselector settling, filter memory, ADC overrun, queue overflow, recorder downtime and acquisition exceptions all generate blind intervals or degrade p(t). Preserve their actual timestamps and dispositions in the coverage ledger.

The experiment must also address amplitude and waveform. A calibrated p(t) is shorthand for p(t; A,B,W,f,π,θ,s), where A denotes incident signal amplitude at the declared reference plane, B burst duration, W relevant bandwidth or waveform class, π polarisation, θ arrival geometry and s instrument state. The same scanning schedule may detect a strong 100-millisecond pulse reliably and miss a weak 2-millisecond pulse. A negative statement is accordingly bounded to a specified source class. Tests with controlled emissions should vary onset phase, duration, amplitude, channel,

Copyright 2026, James M. Atkinson

polarisation and blocking signals. The result is a detection surface, or at least a set of conservative slices, rather than one unexplained percentage labelled 'probability of intercept'.

Finally, evidence discipline requires preserving failed opportunities as carefully as successful events. A reviewer should receive an immutable timeline of intended versus actual dwell intervals, a device-status ledger, raw or minimally processed observations where lawful and technically possible, and every analysis parameter that converts those observations into events. Without such records the denominator of the negative result is unknown. The responsible conclusion is not 'the environment was clear for ninety days'. It is that no qualifying event was recorded within documented coverage under stated detection sensitivities and model qualifications. I pass the token to Jerzy Neyman, whose examination of confidence procedures will test whether the language of that conclusion is defensible.

Sir Harold Jeffreys, Peer Question: Professor Fisher, your Poisson calculation treats each genuine emission as an independently thinned event. An investigator might quote a 95-percent upper limit after obtaining no observations, though the transmitter was never independently seen and the estimated exposure rests on a laboratory signal that was much stronger than the source of interest. Precisely which facts make that upper limit a defensible frequentist statement, and how should the result be reformulated if the calibration shows a detection probability range rather than one reliable value? In particular, could an analyst treat the endpoint of a confidence interval for the detection efficiency as though it were the true efficiency, and would doing so necessarily preserve nominal coverage?

Copyright 2026, James M. Atkinson

Please distinguish a statistical confidence procedure, a subjective belief about the presence of an emitter, and an operational decision to conduct a second search. The decision-maker may hear the word '95 percent' and imagine that the room has been shown empty with that probability. What wording would prevent that error?

Sir Ronald Aylmer Fisher, Response: Sir Harold, the upper limit arises from a sampling distribution conditional on a specified source-event model and the observation apparatus. At zero detections, a homogeneous Poisson rate and known effective exposure E yield a one-sided confidence limit approximately 2.996/E. The procedure's nominal repeated-sampling property can be checked mathematically within that model. It does not assign a probability to the proposition that the room contains no emitter; the parameter λ is treated as fixed under the frequentist construction. Furthermore, the calculation is about burst-event rate in a defined class, not necessarily the presence of hardware. A dormant transmitter has a zero operational burst rate during the search and may be fully compatible with the negative observation.

If sensitivity q is uncertain, substituting its point estimate into E=qL and treating the result as exact can understate uncertainty. A lower bound q_low derived by a justified calibration procedure may yield a conservative exposure E_low=q_low L, but the combined repeated-sampling properties of the two-stage procedure should be investigated. A calibration interval is not automatically a physical guarantee. If the instrument's performance depends upon temperature, input level, attenuation, waveform and blocker conditions, a scalar q_low for one laboratory arrangement cannot be

Copyright 2026, James M. Atkinson

transferred to every field circumstance. One can report conditional limits for several declared sensitivity cases, or perform a joint uncertainty analysis of calibration and event counts. The latter requires identifying correlations, including shared reference sources and common testing artefacts.

The operational conclusion should be in measured terms. 'No qualifying bursts were recorded during E effective hours of sensitivity to the stated waveform and level; under a homogeneous-Poisson start model, the corresponding upper rate limit is …' is a defensible kind of sentence if the premises are met. 'There is a 95-percent probability no transmitter was present' is not. The latter would require a different hypothesis framework, prior information and a model linking equipment presence to event generation. A second survey may be prudent because the consequences of a miss are severe, but that judgement is not a confidence level. I would preserve the complete coverage ledger so that the claim can be independently recalculated rather than asking the reader to trust a printed percentage.

David Harold Blackwell, Peer Question: Sir Ronald, the value of further observations depends on what they might distinguish, not merely on the number of hours purchased. Suppose the search has produced no bursts after a thousand scanner revisits, all with essentially identical phase relative to a device suspected of sending periodic reports. Would another thousand identical revisits provide new evidence, or should the investigator change the design by randomising scan phase or assigning a continuously monitoring receiver? How would one compare the expected information gain of those alternatives without assigning invented probabilities to an

Copyright 2026, James M. Atkinson

adversary's behaviour? I also want to know how you would treat a second receiver connected to the same timing reference and antenna distribution path. Its independent computer display may create a sense of corroboration even though the two observations share blind time and front-end overload. What does a defensible search plan owe to this possibility of common-mode failure? Would a confidence statement have the same operational meaning if the independent reference used to verify the second instrument were itself switched off during every suspected burst? In that case the investigators would need to confront the absence of a genuine independent witness rather than merely total detector count.

Sir Ronald Aylmer Fisher, Response: Dr. Blackwell, if the observations repeat a perfectly correlated failure mode, multiplying their count adds little evidence about events that always occupy the blind interval. A different schedule or genuinely independent instrument can be more informative than extending the same sequence. Before an experiment, one may examine several source hypotheses and ask which intervention changes their predicted records. A scanner-phase randomisation helps discriminate a periodic source from a source that never transmits, provided the randomisation is real and its range covers the relevant phase. A fixed-channel monitor eliminates certain scan gaps but still has detection-threshold, bandwidth, overload and recording vulnerabilities. Neither design is an absolute guarantee; each removes a specified class of explanation for the empty record.

We should compare designs using bounded performance rather than ungrounded probabilities. For example, one can demonstrate that a channel

Copyright 2026, James M. Atkinson

observed continuously with an independently calibrated receiver would capture any burst lasting at least 10 milliseconds and exceeding a stated level under tested conditions. That claim is restricted but operationally powerful. A scanner with 10 milliseconds of dwell every second may have a much lower probability of observing a 4-millisecond burst under the uniform-phase model, while potentially remaining wholly blind to a synchronous source. The experiment can measure the probability under randomised injection and exhibit explicit deterministic schedules that fail. The comparison then presents an empirical detection surface and worst-case gap properties, not a mystical measure of information.

As for two receivers, their physical independence must be established at the level of failure mechanisms. Distinct hardware with a shared antenna splitter and common reference may be independent against some digital-processing faults but dependent against cable disconnection, shared reference failure or overwhelming environmental interference. In a joint acceptance test, deliberately challenge those shared pathways under safe laboratory conditions and measure the probability of joint misses for the specified source class. If the systems have unresolved common modes, treat the joint evidence as dependent and say so. A second display is no more a second witness than two copies of the same log file. A practical acceptance trial should also record negative controls when the source is deliberately silent. These establish a false-alarm baseline and reveal artefacts caused by the receiver's own tuning transitions. If those controls fail, a superficially favourable detection fraction alone is not sufficient to sustain a source-detection claim.

Copyright 2026, James M. Atkinson

Sir Ronald Aylmer Fisher, Cross-Peer Question to William Feller: Professor Feller, your successful-onset geometry can describe the capture of a finite pulse without assigning a stochastic law to the source. My Poisson-thinning approximation instead treats onsets as points with independently varying detection probabilities. Precisely when can the first formulation be used to justify the second? Suppose the source durations vary and the detection probability is higher for long bursts; the observed sample may then overrepresent long bursts and underrepresent short ones even if their occurrence rates were equal. What integral should replace the simple exposure E=qL, and how would you prevent the estimator from assigning a single average burst duration when its distribution is unknown? I also want an answer about dependence between successful-onset windows: if a burst spans two nominal revisits, should a pair of detections represent two independent trials or one physical event? The operational stakes are substantial because a mistaken count can inflate an upper-rate estimate or make non-detection appear more conclusive than it is.

William Feller, Cross-Peer Answer to Sir Ronald Aylmer Fisher: Sir Ronald, a marked point process offers a disciplined extension. Associate each burst start u with a duration B and other source marks, such as frequency trajectory and amplitude. Let g(B,A,f,...) be their assumed or independently measured mark distribution, and let p(u,B,A,f,...) be the calibrated probability that an onset with those marks leaves one qualifying recorded event. Under a Poisson start process whose marks are independently distributed according to g, the expected number of recorded burst events is $\lambda\int_0^T\int p(u,m)g(dm)du$, where m denotes the mark vector. The zero-count probability is the exponential of the negative expectation under those

Copyright 2026, James M. Atkinson

assumptions. If duration distribution is unknown, that integral is not numerically identifiable merely from a zero-count record; one must report a scenario range or obtain independent duration information. Replacing it with a convenient mean duration can be wrong because p is usually nonlinear in B.

The successful-onset geometry can supply the p(u,B,...) function in an idealised limit where the reception conditions and decision threshold are deterministic. Once receiver noise, propagation, frequency error and classifier failures enter, the geometrical eligibility must be combined with empirical conditional response. It would be incorrect to count the same physical burst twice merely because it overlaps two scan windows. Define an event association rule using retained time and frequency information, and evaluate it against injected multi-window bursts. The event count k in a Poisson likelihood is the number of underlying qualifying burst starts inferred by the detection protocol, not the total number of raw crossings. If ambiguity remains, one can bound k and give sensitivity analyses rather than silently assert independence.

A final complication concerns bursts that influence the receiver after their RF emission ends. Filter ringing or decoder buffering may produce indications outside the geometrical overlap. Those artefacts must be included in the observation model but should not be treated as separate true starts. When the physics of the receiver is too complicated to calculate p analytically, randomised injection trials over the relevant mark space provide empirical estimates. The transition from geometric coverage to probabilistic exposure

Copyright 2026, James M. Atkinson

is legitimate only when the model, source marks and counting rule are declared and tested.

Dr. James M. Atkinson, Moderator: Professor Neyman, Sir Ronald has supplied a useful conditional sampling model. Would you examine the design of a negative-search experiment, particularly the difference between a calibrated confidence bound and a post hoc expression of reassurance?

Jerzy Neyman, Second Principal Contributor: Dr. Atkinson, the first protection against an unwarranted negative claim is experimental design before the search begins. One must decide the source behaviours that matter, the decision rule, the unacceptable chance of missing a consequential event, and the field conditions under which the receiver will operate. A target such as 'at least 95% probability of recording one qualifying burst if events occur at rate λ_0' can be converted into an exposure requirement under an explicit model. It cannot be met simply by waiting an arbitrary number of days and later treating the absence of alarms as assurance.

For the homogeneous Poisson-thinning model introduced by Fisher, the probability of at least one detection is $1-\exp(-\lambda_0 E)$, where E measures effective exposure. Requiring at least 0.95 detection probability gives $E \geq -\ln(0.05)/\lambda_0$. If the operational design rate is $\lambda_0=0.1$ qualifying bursts per hour, E must be at least approximately 29.96 effective hours. Suppose the receiver's live-on-channel duty factor is 0.05 and conditional detection probability is 0.8; the average effective fraction is 0.04, so achieving $E \approx 30$ hours would require approximately 749 hours of elapsed monitoring under stationary, independent scheduling conditions. The arithmetic exposes the

Copyright 2026, James M. Atkinson

importance of the denominator. The calculation does not apply to periodic transmitters deliberately phase-aligned with the scanner, to intervals where front-end overload collapses q, or to an event process that changes rate according to time of day.

A confidence procedure has an operating characteristic over repeated experiments generated under the adopted model. It does not automatically assign probability to the fixed but unknown event rate in the realised investigation. This is more than an academic nicety. If a zero-count upper limit of three divided by exposure is presented without verifying the rate model, it can make an instrument's blind periods disappear rhetorically. The laboratory should validate its method with controlled event injections and report sensitivity against a range of amplitudes, burst durations, frequency offsets and arrival phases. It should also disclose the uncertainty in the measured exposure itself. One can sometimes replace uncertain p(t) by a conservative lower bound, but the provenance and operating range of that bound must be established.

Sampling design should reduce the risk of synchronised noncoverage. A perfectly regular scanner may revisit a channel every second, while a burst generator emits periodically at nearly the same interval. If relative phase remains in the blind portion of each cycle, even a very long survey may yield no detection. Randomising or staggering revisit times, using parallel fixed-channel monitors, or varying dwell policies can reduce this deterministic failure mode, but each choice changes the observation process and must be recorded. Randomisation does not permit a probability claim unless the

Copyright 2026, James M. Atkinson

randomisation mechanism and the transmitter assumptions are both specified. A fixed-channel recorder may be a more defensible witness for a particularly high-consequence frequency than any scanning strategy.

The question of a negative report is often adversarial in the scientific rather than the personal sense. An examiner should be asked what alternative process would produce the same empty record. One alternative is that no relevant transmitter was active; another is that bursts occurred entirely during blind intervals; another that the waveform was below threshold, overwhelmed by blockers, or filtered by the selected bandwidth; another that samples existed but software discarded the event. A designed experiment should include challenges capable of distinguishing those alternatives, using an independent receiver or injected benign reference where necessary. If they cannot be distinguished, the report must state the residual ambiguity.

Uncertainty caused by one shared reference must not be counted as independent evidence from multiple channels. Two monitoring receivers disciplined to one failed oscillator may show aligned gaps or identical timestamp errors. Nor does running the same analysis over the same raw file produce a second observation. Confidence calculations based on multiple stations require an appropriate dependence model and a test of the actual joint detection probability. The combined chance that two stations both miss an event is not generally the product of their individual miss probabilities; it may be much larger when they share propagation shadowing, front-end overload or power failures.

Copyright 2026, James M. Atkinson

A useful verification plan is a matrix of source state, observation state and action. For each trial, the test transmitter's timing and power are logged by an independent source, while the survey system records the intended dwell, actual hardware capture, any packet loss, and the detection decision. Trials are repeated at randomised onset phases. Each trial should be traceable to one source event, not multiple threshold crossings counted as independent confirmations. The test then estimates a conditional detection curve, with appropriate uncertainty intervals. Because the number of trials needed can be substantial near very high target probabilities, the operator must not infer 99.9% detection simply from ten successful demonstrations.

I would also separate operational decision costs from statistical confidence. For a high-consequence search, a false assurance may be more harmful than allocating additional observation time, but excessive sensitivity can produce a flood of false alarms that exhausts the review process. The acceptable trade-off is a policy choice to be declared openly, not hidden inside a detector threshold. The final report should present the decision rule, observed event count, calibrated detection envelope, time-frequency coverage, untested circumstances and the exact claim supported. I pass the token to Abraham Wald because sequential monitoring, with adaptive stopping rules, requires particular care when the result remains negative.

George Edward Pelham Box, Peer Question: Professor Neyman, your planned confidence procedure depends on an observation model that may be only approximately true. Engineers often measure q from a clean laboratory waveform, then deploy the receiver amid reflections, strong

Copyright 2026, James M. Atkinson

blockers and irregular bursts whose properties do not match the calibration source. How would you test whether the model has failed in a practically material way? I am also concerned that elaborate probability calculations can give a false sense of security when fundamental controls such as antenna orientation, sample continuity and reference-lock records are absent. What diagnostic experiments would you require before accepting an effective-exposure calculation, and how should competing explanations of a negative finding be incorporated without turning the report into an unmanageable catalogue? A precise answer should preserve the distinction between a useful conditional approximation and an experimentally established performance claim. If the preselector switch briefly produces a response indistinguishable from a real burst, how should the analyst prevent an apparent increase in sensitivity from representing increased false positives instead of greater access to real source events?

Jerzy Neyman, Response: Professor Box, a model is a disciplined simplification of an apparatus, not a replacement for measurement. The first validation asks whether the calibration population resembles the operational source class on which the negative inference depends. If the claim covers weak frequency-agile bursts under blockers, then the injection campaign should vary amplitude, dwell phase, pulse width, hop frequency, preselector and gain state, antenna path and blocker level. The empirical detection proportion and its uncertainty should be compared with the p(t) used in the exposure integral. Where the observed response varies sharply with a factor that the model omitted, the model must be refined or its claimed domain reduced. A single clean-signal calibration value may be adequate for one narrow statement and inadequate for a general room-

Copyright 2026, James M. Atkinson

clearance conclusion.

The field record should retain enough structure to identify missing opportunity. Intended schedule, hardware-ready state, reference lock, tuning transition, raw sample counters, overflow warnings and detector settings form the minimal acquisition ledger. An independent known stimulus can verify that the chain remains responsive during the survey, though it cannot prove sensitivity to every unknown waveform. Check the known stimulus through the actual antenna or calibrated injection plane, and document when such a test changes the receiver's operating state. A blank spectrum display during a disabled or overloaded receiver is not negative evidence in the same sense as a blank display during a validated measurement window.

One can manage competing explanations through a short table of falsifiable hypotheses. 'No relevant source emitted'; 'events fell in blind intervals'; 'events were below threshold'; 'instrument created or suppressed features'; and 'data were lost before logging' are useful initial categories. Each should be linked to a challenge test and a residual qualification. If the test does not discriminate them, their ambiguity should remain in the report. I would rather publish a conditional result with an honest coverage envelope than one confidence number whose most important premises were never challenged. The calibration plan should use both source-on and source-off trials with matched receiver settings. A measured improvement in the probability of declaring an alarm is not necessarily an improvement in useful discrimination if the false alarm rate rises at the same time. Each rate should

Copyright 2026, James M. Atkinson

be reported explicitly, and comparisons must preserve source amplitude and environmental conditions.

Walter Andrew Shewhart, Peer Question: Professor Neyman, rare-burst detection is frequently entrusted to an instrument whose response slowly changes with temperature, connector ageing, local interference and software updates. If the probability of detecting a standard test burst fluctuates over a long search, how would a practitioner avoid applying yesterday's calibration to today's observation? Could a control chart or periodic test stimulus reveal an unstable acquisition process without becoming confused with the actual environment being monitored? Please consider what happens when a failed test makes some earlier hours suspect, because a simple rule that invalidates only future hours may be unduly optimistic. Conversely, an automatic method that discards every difficult interval after an unexpected outcome may manufacture a falsely reassuring data set. What principles separate sound process control from retrospective selection of favourable observations? What happens if the device's health-check pulse follows a different analogue path from the unknown environmental emission? A reported pass might then validate only the digital detector while leaving a disconnected antenna cable wholly untested, thereby overstating the period of credible monitoring.

Jerzy Neyman, Response: Dr. Shewhart, the chronology of instrument competence is essential. A calibration establishes performance under specified conditions at a particular time and configuration. During long deployment, known benign reference signals can challenge whether the measurement chain still responds at defined levels and bandwidths. The control chart may flag changes in amplitude, timing, trigger rate or noise

Copyright 2026, James M. Atkinson

floor, but its thresholds must be selected before examining the operational detections if the process is to support a valid inference. A flagged state should initiate investigation of hardware, environmental and software changes rather than an automatic assertion that a hostile transmitter has appeared or disappeared.

If a reference check fails at the end of an interval, the period during which performance was compromised may be unknown. One sensible approach brackets the failure between the last demonstrated good check and the first demonstrated bad check, then describes alternative exposure calculations that exclude progressively more of that uncertain period. Additional retained diagnostics might narrow the interval. It would be unjustified to count all intervening hours as fully sensitive merely because the system was powered; it would also be questionable to erase all difficult data without explaining why. The original observation ledger, check failures and correction decisions should remain immutable so that a later reviewer can reconstruct the judgement.

The mathematics of confidence bounds can be applied to state-specific exposure, but only after those state assignments are defended. For example, if 40 hours have calibrated detection $q=0.9$, 20 hours have uncertain q between 0.2 and 0.6, and 40 hours were wholly blind, the effective exposure lies between $40\times0.9+20\times0.2=40$ hours and $40\times0.9+20\times0.6=48$ hours under the specified onset and waveform assumptions. It is incorrect to use 100 hours as effective exposure. This interval is a measurement-management result, not a probabilistic

Copyright 2026, James M. Atkinson

confidence interval unless additional assumptions justify that language. Process control should make the limits of the data more visible, never silently improve them. The test injection reference plane determines the claim. An internally generated digital stimulus can validate later software stages but does not challenge the antenna, cable or analogue input. A test applied near the receiver front end covers more stages, while an appropriate over-the-air calibration challenges propagation and antenna response as well. These tests have different limitations and must not be conflated.

Jerzy Neyman, Cross-Peer Question to Andrey Nikolaevich Kolmogorov: Professor Kolmogorov, you have warned that the Poisson model may be inappropriate when source bursts are periodic or clustered. Yet operational decisions still require confidence statements even where the source process is not known. Can we develop a useful worst-case assurance guarantee from a known observation schedule without assigning a distribution to source timing? Suppose a critical band is monitored for only ten milliseconds every second, but the operator can randomise dwell phase over many cycles. Is it sufficient to say that each possible onset is eventually covered, or must a guarantee also specify the number of bursts, their minimum duration and the independence of the randomisation? I would ask you to distinguish probability under the investigator's randomised measurement policy from probability under the unknown transmitter, and to explain how adversarial scheduling changes the mathematics when the emitter may learn or predict the search routine.

Andrey Nikolaevich Kolmogorov, Cross-Peer Answer to Jerzy Neyman: Professor Neyman, there is an important difference between a deterministic

Copyright 2026, James M. Atkinson

guarantee of coverage and a probability statement generated by the investigator's own randomisation. A periodic scanner with a fixed blind interval cannot guarantee detection of even an infinite sequence of perfectly synchronised short bursts. If the monitor independently randomises its observation phase according to a known distribution, then for a fixed sequence of source onsets that does not adapt to the randomisation, each event may enjoy a bounded probability of falling within a successful-onset set. If the randomisations across trials are genuinely independent, a product bound on the probability of all misses can follow. But that reasoning depends on source timing being fixed independently of the realised scan choices.

For example, suppose the policy guarantees that for every permitted burst of duration B at the specified amplitude, the probability of a qualifying measurement under one random scan phase is at least p_{min}. For n bursts with fresh independent randomisation and a source schedule fixed in advance, the probability that all are missed is at most $(1-p_{min})^n$. This is a probability over the measurement randomisation, not a declaration that the unknown transmitter itself is stochastic. If the transmitter can observe the scanner's current state and adapt its emission timing, the conditioning changes and the guarantee may collapse. An adversarial emitter can wait until the receiver is blind unless the system has continuous coverage or some other unpredictability and independence property that the source cannot defeat.

The word 'eventually' also needs qualification. A probability-one statement

Copyright 2026, James M. Atkinson

about infinitely many trials does not give a finite-time operational assurance, and independent randomisation may fail in implementation because of a shared timer, repeating seed, or deterministic control loop. Validate the randomisation stream and record its real dwell outcomes. If there is a guaranteed minimum burst duration longer than every blind gap, deterministic temporal coverage may be possible without randomisation, subject to receiver sensitivity and settling. Absent such source restrictions, the scientific report should describe conditional probabilistic coverage and the set of physically unexcluded source behaviours. Model-robustness is achieved by reporting the exact assumptions under which a bound survives, not by pretending that model uncertainty has disappeared.

Dr. James M. Atkinson, Moderator: Dr. Wald, what changes when the investigator keeps extending or terminating a search according to the alarms, reference checks and changing conditions observed during the run?

Abraham Wald, Third Principal Contributor: Dr. Atkinson, a planned observation interval and an adaptively terminated one are different experiments. If a survey stops the moment an alarm appears but continues whenever it does not, its exposure and censoring depend on the data. This may be entirely appropriate operationally, yet the analysis must follow the actual sequential rule. Treating the elapsed time as if it were fixed in advance and applying an unrelated fixed-sample confidence formula may misstate false-alarm or missed-event properties. The remedy is not to ban adaptation but to define the monitoring policy and the associated operating characteristics before interpreting the realised result.

Consider a sequential search in which the receiver records accepted bursts

Copyright 2026, James M. Atkinson

and updates an exposure ledger each hour. Under a homogeneous rate λ and known p(t), the number of detections over accumulated effective exposure E follows a Poisson process with mean λE. For a predetermined target rate λ_1 and null rate λ_0, an idealised log likelihood ratio after observing k detections and exposure E is $k \ln(\lambda_1/\lambda_0) - (\lambda_1-\lambda_0)E$. Every symbol matters: λ values are hypotheses for rates of true event starts, k is a count of valid detections after the agreed event-clustering rule, and E is opportunity weighted by detection probability. If $\lambda_0=0$, the ratio requires special treatment; one cannot simply divide by zero. Where arrivals are clustered or p(t) estimated with large error, this likelihood expression ceases to be an adequate description.

A negative result increases evidence against a higher-rate hypothesis only during valid exposure. If the scanner is blind for two hours, the likelihood should remain unchanged during those hours, regardless of the operator's sense that 'monitoring has continued'. Conversely, a sudden increase in conditional detection probability because the receiver is moved to a better antenna location adds more effective exposure per minute, if the change has been calibrated. A defensible sequential dashboard would therefore show real time, valid dwell time and effective exposure as separate quantities. It should never combine them into one unqualified uptime percentage.

Stopping rules must also account for recalibration, outages and equipment replacements. Suppose a receiver initially uses q=0.4 for faint two-millisecond bursts, and after a preselector modification it achieves q=0.8.

Copyright 2026, James M. Atkinson

Accumulating hours as if q had remained constant is incorrect. The exposure is a sum of state-specific contributions, $E=\Sigma q_j L_j$, or an integral if the states vary continuously. If the calibration runs only at high signal amplitudes, applying q_j to low-amplitude unknown events is an extrapolation, not a measurement. A revised detection algorithm may also alter the definition of one event, changing k; versioned records and replay against an untouched capture are required to preserve comparability.

The strongest sequential strategies include explicit action thresholds and protections against nuisance alarms. A sudden spectral line might be a receiver artefact, overload spur or external signal. If every suspicious crossing terminates a search as a 'detection', the statistical model effectively counts false positives. If an investigator retrospectively excludes difficult alarms without a defined validation rule, the apparent negative record becomes selected evidence. A two-stage process may first register a candidate event with raw data and then subject it to controlled challenge tests; the first-stage event count and the later confirmed-event count should both be retained. Otherwise it is impossible to reconstruct how one set of observations became the zero count on which a confidence statement relies.

The independence assumption deserves special scrutiny when a search reacts to its own observed environment. If the controller spends longer on channels where activity was previously seen, the observation schedule becomes correlated with the event process. An exposure integral can still describe where the system listened, but a simple Poisson thinning calculation that assumes exogenous p(t) may no longer hold without

Copyright 2026, James M. Atkinson

modelling the adaptive policy. Some events may be more likely during times when the receiver happens to be attentive, and others less likely, making a naïve rate estimate biased. A logged decision history allows simulation of the policy against known synthetic event sequences to assess the bias.

A practical stress test should include a burst generator whose schedule is unknown to the analyst performing the search and whose onset phases are deliberately varied. The receiver is operated under the proposed real acquisition policy, including any automatic retuning, alarm-driven dwell extension and buffer handling. An independent log records every true burst and compares it with detected candidates. False discoveries, misses, detection delays, and intervals in which the receiver failed to observe the relevant channel are reported separately. That test can demonstrate how a policy behaves without relying on a selective list of successful detections. It is especially valuable where operations resemble a long-running watch rather than a bounded laboratory trial.

My conclusion is that sequential observation can be rigorous if its adaptive rules are transparent and its likelihood model is appropriate. But a statement such as 'no suspicious signal in ninety days' conceals precisely the information needed to judge the result. It should be replaced by a structured account of effective exposure under specified event classes, controlled false-alarm handling, and the stopping or continuation rule. I pass the token to William Feller, who will challenge the use of smooth average exposure in a world of periodic bursts and finite observation windows.

Copyright 2026, James M. Atkinson

W. Edwards Deming, Peer Question: Dr. Wald, many monitoring programmes measure success by operational uptime or by the number of spectrum sweeps completed. The incentive can reward uninterrupted dashboards rather than defensible evidence. Suppose a station silently increases its detection threshold during noisy periods to reduce false alarms, while its report continues to show 99.9-percent system availability. How should the investigation distinguish equipment availability, valid time-frequency coverage, and detection effectiveness? Would you require a formal change-control mechanism that links software settings to an exposure budget, and how should a report treat a midnight update that altered the meaning of an event without changing the file schema? I am particularly interested in preventing a management indicator from masquerading as a scientific finding. Suppose the transmitter itself changes its coding and emits shorter packets after a firmware update. Should an operational detector that was calibrated only for longer packets still count that period as fully exposed, even if its internal settings and nominal gain have not changed?

Abraham Wald, Response: Dr. Deming, the quantities must be defined at separate layers. Equipment uptime indicates electrical and software operation; valid on-channel dwell indicates physical acquisition opportunity for a particular channel; conditional detection effectiveness indicates whether a specified burst would have survived filtering and thresholding; and evidential validity addresses the traceability of the resulting record. High performance at one layer does not establish another. A receiver can remain powered while its input is disconnected, scan efficiently while a required frequency is never visited, or acquire continuously while a changed

Copyright 2026, James M. Atkinson

threshold suppresses weak events. Each counter should bear a description of what is actually measured.

Change control is part of scientific reproducibility. A midnight threshold change divides the search into distinct detection states even if the output file retains the same columns. The exposure ledger should record exact change time, old and new configuration, software version, calibration evidence and any possible transient gap. If the event definition changed, the investigator must not merge counts across versions without a reconciled rule, ideally applied by replay to preserved raw samples. When replay is impossible, state the incompatibility rather than fabricate a unified series. A cautious analysis can report separate counts and conditional bounds for each state, with sensitivity to uncertain periods.

The practical control system should discourage retrospective success selection. An immutable record of intended configuration, observed configuration, alarms, failed checks, calibration changes and operator decisions allows review of the entire decision process. A metric such as 99.9-percent uptime can remain useful for maintenance, but it must never become the denominator of a rare-burst detection bound unless it coincides with tested valid exposure. Performance measures should be chosen to encourage accurate reporting of errors. A system that acknowledges a 40-percent sensitivity loss is scientifically healthier than one that conceals it to preserve an attractive status graph. The legitimate negative result is bounded by what the apparatus was physically able and documented to observe. The source class matters as much as the detector state. A changed

Copyright 2026, James M. Atkinson

burst duration or coding structure alters its admission probability. If a credible alternative waveform lies outside the validated envelope, the conclusion must be restricted accordingly. Firmware changes by a suspected emitter are not observable from silence alone; this is another reason to report conditional assurance rather than absence as fact.

Abraham Wald, Cross-Peer Question to Jerzy Neyman: Professor Neyman, I wish to challenge your use of a prespecified 95-percent detection target for a sequential search in which the observation policy adapts after each accepted candidate. Suppose an engineer doubles the dwell on a suspect channel following a weak crossing and then reduces it after a period of quiet. The resulting effective exposure is influenced by an event that may subsequently be rejected as an instrument artefact. Can an ordinary zero-count upper limit still be calculated from the final exposure, or does that data-dependent policy require accounting for the selection mechanism? What safeguards would you use so that a plausible stopping rule remains testable rather than being replaced after the fact? Please discuss the difference between a well-defined predictable acquisition policy, post hoc removal of failed intervals, and a deliberate repeated search designed to exploit favourable random fluctuations. I ask also whether the corrected confidence rule remains valid if some acquisition windows are retrospectively labelled unreliable solely because they contain an awkward candidate event.

Jerzy Neyman, Cross-Peer Answer to Abraham Wald: Dr. Wald, an adaptive schedule need not invalidate every analysis, but it changes what must be justified. If the observation probability at time t is determined by past recorded information and the model properly conditions on that history,

Copyright 2026, James M. Atkinson

there are settings in which likelihood-based counting-process analysis remains possible. The intensity of detected events can be expressed conditionally, and exposure can be accumulated according to the actual predictable acquisition state. However, it is not correct simply to take a fixed-sample confidence interval formula, substitute a random end-of-study exposure, and assume its coverage remains unchanged for every arbitrary stopping policy. The validity depends on the exact process, adapted controls and inferential method.

A defensible protocol therefore states in advance how a candidate crossing changes dwell, how long the change persists, and when a candidate is confirmed or rejected. The recorder must retain the raw candidate, change decision, full detector state and source-independent calibration data. If an apparently false candidate causes the system to monitor one channel more intensely, that increased exposure is real, but its occurrence is selected by the observations. Subsequent source-rate inference should account for that conditioning. If a failed health check makes previous exposure suspect, the criteria used to exclude it must be documented without editing history to favour a particular conclusion.

In practice one can examine the policy through simulation using the exact control algorithm and synthetic source sequences, followed by independent hardware-in-the-loop validation. Report the nominal and realised operating characteristics, not only a theorem under a simplified policy. For a high-consequence defensive search, it may be preferable to maintain a fixed baseline monitor while an adaptive channel conducts supplemental

Copyright 2026, James M. Atkinson

interrogation. The baseline preserves a stable exposure denominator and can challenge an adaptive method whose selection is difficult to model. If such a design is impossible, qualify the statistical conclusion rather than treating adaptation as harmless. Rigorous sequential inference derives from the whole rule, not from the attractiveness of its final number. A report should therefore include a sensitivity case that retains all originally scheduled windows, a second case excluding only independently documented failures, and a record of why any difference is consequential. This comparison exposes an otherwise invisible selection decision.

Dr. James M. Atkinson, Moderator: Professor Feller, would you address the geometrical problem of whether a burst of finite duration actually overlaps a scanner dwell, including periodic and phase-locked regimes?

William Feller, Fourth Principal Contributor: Dr. Atkinson, the apparent simplicity of a listening fraction hides a geometrical condition. Let the receiver's valid on-channel windows be a set W in time and a burst occupy [u,u+B], where u is its onset and B its duration. The event can overlap a valid listening window if and only if u belongs to W expanded backwards by B. For ideal detection on any positive overlap, this expanded set determines the onset phases that could be recorded. But a real detector typically requires a minimum overlap duration h for filter settling, integration, or enough accepted samples. Then its successful-onset set is smaller and must be derived from the exact decision criterion. This is a coverage problem before it is a probability problem.

For one isolated dwell [a,a+d], with burst duration B and an overlap requirement h satisfying $0<h\leq\min(B,d)$, the set of successful burst onsets is

Copyright 2026, James M. Atkinson

[a+h-B, a+d-h]. Its length is d+B-2h, provided the interval is nonempty. This derivation assumes the interval boundaries are ideal, that both burst and dwell are contiguous and that no additional waveform effects prevent detection. When a burst is very short, h may approach B, so the beneficial extension before the dwell largely disappears. In a periodic scan with revisit period R, the onset-coverage fraction for a uniformly random phase is the measure of the successful-onset intervals modulo R divided by R. Overlapping such intervals must be unioned rather than summed to avoid double counting.

For example, take a channel visited for d=10 milliseconds every R=1 second, a B=4 millisecond burst, and a minimum usable overlap h=2 milliseconds. The successful-onset interval associated with each isolated dwell is 10+4-4=10 milliseconds long; under a uniform random phase and absent other losses, the probability of a qualifying overlap is about 0.01. If the detector instead accepts any infinitesimal overlap, the interval length approaches d+B=14 milliseconds, giving about 0.014, but that physical assumption is often unreasonable for a weak, bandwidth-limited receiver. Neither number should be described as a universal interception probability without amplitude and threshold calibration. In this example the difference between models is forty percent relative to the smaller probability, despite identical hardware uptime.

Now suppose the bursts recur with exact period R and an unknown but fixed phase. Either the phase places each burst into a successful-onset interval or it does not. In the latter case, repeated scanning does not create new

Copyright 2026, James M. Atkinson

independent opportunities; a thousand negative scan cycles may leave the same uncertainty about the transmitter as one cycle. If burst and scanner periods differ slightly, the relative phase can walk around the cycle, but its rate depends upon the difference between the periods and any oscillator drift or jitter. A claim of improved coverage must demonstrate that the relative phase actually explored the relevant range rather than merely assume that many repetitions were independent.

Randomising revisit phase can make this vulnerability less severe. If each revisit phase is independently randomised and each burst has a stable chance p of qualifying, then under that stylised model the miss probability for n bursts is (1-p)^n. For p=0.01 and n=100, this is approximately 0.366. But a single random phase selected at the beginning and held fixed across all bursts produces a miss probability of 0.99, not 0.366. The distinction is enormous, and it flows from dependence across trials rather than from any arithmetic error. A scanner that introduces only minor timing jitter may be closer to the fixed-phase case than to independent randomisation. The randomness must be tested, not inferred from an irregular-looking plot.

A second complication is the geometry of frequency hopping. Time overlap is insufficient when the signal moves across frequency or the receiver's passband does not contain the emission. Represent valid coverage as W(t,f), and a burst as a region in time-frequency space. A qualifying observation requires overlap after accounting for the instrument's finite passband, selectivity and retuning transient. If the frequency plan has holes, a burst may be invisible whatever its onset time. A tuned channel's nominal width is

Copyright 2026, James M. Atkinson

not the same as its usable sensitivity interval, because passband roll-off and interference can change detection probability near an edge. The credible observation set is therefore a calibrated region, not a binary catalogue of frequency labels.

There are also bursts whose starts are clustered rather than isolated. A packet train may be admitted as one event under a merge rule, and some packets may be detected while others fall in blind intervals. Counting detected threshold crossings as independent burst starts inflates the evidence available for estimating a Poisson rate. The event definition should follow the source process and the actual observable, and its consequences should be checked with injected multi-pulse test waveforms. A receiver can produce a hundred alarms from one extended oscillator transient. That is not a hundred independent opportunities to infer the prevalence of rare emitters.

The honest search statement specifies the successful-onset set for each source class or, where its derivation is too complex, reports empirical detection curves obtained by randomised onset injection. It also records which periodic schedules could evade observation indefinitely, what randomisation actually occurred and what timing uncertainty remains. The calculation is not merely mathematics dressed around an RF instrument; it is the geometry of the evidence the instrument was physically capable of collecting. I pass the token to Andrey Kolmogorov, who will consider the dependence assumptions embedded in every probability claim.

Copyright 2026, James M. Atkinson

John Wilder Tukey, Peer Question: Professor Feller, the scanner's successful-onset windows can be calculated for ideal rectangular bursts, yet real events have uncertain onsets, variable envelopes and amplitude-dependent triggers. How should an exploratory analyst use the observed records to discover that the assumed overlap geometry is wrong without treating every alternative window choice as an independent statistical discovery? Would graphical examination of detected versus injected burst start phase be a better diagnostic than relying upon one percentage? I also ask whether changing the merge gap between candidate detections alters the event count and the resulting estimate of arrival rate, particularly where one long transmission causes repeated threshold crossings. Please distinguish a genuine rate correction from analysis choices made after seeing an unexpectedly reassuring or alarming result. If an analyst tries many merge thresholds and retains only the one yielding the most stable estimated event rate, has the search acquired information about the source or merely fitted an algorithm to its own observations? How should that exploration be disclosed?

William Feller, Response: Professor Tukey, a useful experiment plots the known injected burst onset phase against capture outcome, and stratifies by amplitude, duration, receiver state and frequency offset. Instead of a single detection proportion, that display can reveal hard blind zones, gradual transitions near the edges of dwell windows and unexpected periodic structure. A phase-response curve with confidence intervals is often more diagnostic than a headline percentage. The analyst should retain failed trials and the complete injection schedule. A plot from successful trials alone can make a detector appear uniformly reliable even though all failures occupy a

Copyright 2026, James M. Atkinson

narrow recurrent phase interval.

Real waveforms require a measured effective acceptance function rather than an ideal rectangular rule. A threshold detector may need several samples after filter settling, and weak bursts may enter the window earlier than their recorded threshold crossing suggests. Characterise those latencies with a calibrated source and independent acquisition timestamp. Then compare the measured phase-response curve with the theoretical geometry; disagreements reveal missing parts of the model, such as AGC recovery, preselector switching or software buffering. A disagreement is evidence to investigate, not an inconvenience to smooth away.

Event clustering is a separate decision that affects the count numerator. If one burst creates ten threshold excursions and the algorithm records ten events, the empirical arrival rate is inflated. Conversely, an excessively long merge gap can conceal two distinct transmissions. Define the event identity rule by source behaviour and test it with injected multi-burst sequences at varied separations. Report how the inferred event rate changes with reasonable cluster thresholds rather than choosing one after observing the results. Because the number of candidate events and the effective exposure are different quantities, neither can silently compensate for defects in the other. The inferential target must be specified before the counting procedure is chosen. Exploratory comparisons can be scientifically useful if every tested threshold, resulting count and reason for eventual selection are retained. A threshold chosen after looking at the data should not be presented as if it were prespecified for confirmatory inference. Independent

Copyright 2026, James M. Atkinson

validation data or a clearly stated sensitivity analysis can prevent that selection from masquerading as external proof.

Dr. James M. Atkinson, Moderator: Professor Kolmogorov, the previous contributions have used Poisson arrivals, random phases and deterministic schedules. How should the investigator handle uncertainty when none of those models is fully established by the observations?

Andrey Nikolaevich Kolmogorov, Fifth Principal Contributor: Dr. Atkinson, a probability statement must be attached to a defined random experiment. When the source process is unknown and the observer is intermittently blind, repeated absence of alarms does not by itself identify the process. The observed record is compatible with an inactive source, a rare random source, a periodic emitter synchronised to blind windows, or a stronger source that was undetectable under the prevailing antenna and receiver conditions. A model may organise this uncertainty, but it does not remove it. The observer should enumerate plausible families of source behaviour, identify which are constrained by the coverage schedule, and distinguish measured parameters from assumptions introduced for mathematical convenience.

A homogeneous Poisson process is characterised by independent increments and a constant rate. It is a defensible sensitivity analysis for certain unstructured arrivals, but many engineered transmitters are driven by clocks, buffers, application events and power-management schedules. Their bursts may have heavy-tailed waiting times, periodic patterns, clustering or dependence on environmental conditions. The number of calendar hours observed cannot be converted to a useful miss probability

Copyright 2026, James M. Atkinson

without a statement about those mechanisms. One can calculate several conditional probabilities under alternative models and present their spread as model uncertainty; one should not select the most reassuring model after seeing an empty record.

Consider a thought experiment with 100 equal-duration monitoring intervals and total live fraction 0.1. Under an ideal independent model with 100 burst onsets independently uniformly distributed across those intervals, the chance all fall outside live coverage is 0.9^100, approximately 0.0000266. Under a single fixed but uniformly distributed phase determining all 100 onsets relative to the scanner, the chance all fall outside is 0.9. Both calculations can use the same marginal coverage fraction, and both are arithmetically correct. Their radically different answers arise from dependence. Thus '100 missed opportunities' has no statistical meaning until the experiment says whether those opportunities were independent, identical and genuinely able to produce records.

Multiple receivers complicate the dependence further. Suppose station A and station B each have marginal miss probability 0.2 for a specified burst class. If their conditional failures are independent, the probability that both miss the same burst is 0.04. If both use a shared reference, antenna shadow or synchronous retuning policy, the joint miss probability can approach 0.2 in a strongly correlated regime. The data of the individual miss probabilities do not determine the joint probability. An independent challenge generator and separate observations of the receivers' states are needed to measure or bound their dependence. An assertion that 'two receivers mean twice the

Copyright 2026, James M. Atkinson

assurance' is therefore not justified by receiver count.

An uncertainty ledger should separate at least four levels. First are known geometric blind intervals, which can be reconstructed from hardware counters and scan state. Second are conditional response probabilities, derived by controlled calibration under amplitude, waveform and environment ranges. Third is uncertainty about the temporal and spectral process that generates the bursts. Fourth is uncertainty in the legal and operational significance of a detected event, which is not a detector-performance variable. Combining all four into one unexplained probability of intercept invites misinterpretation. Some uncertainties can be quantified statistically; others must remain explicit alternative hypotheses or bounded cases.

Simulation can test the consequence of assumptions, but its output is not experimental verification. A useful simulation uses the actual recorded scanner coverage timeline and overlays source sequences drawn from several declared models: Poisson, periodic with random initial phase, periodic with fixed phase, clustered, and state-dependent. It then applies empirical detection curves and the real event-clustering algorithm. The results can map how miss probability changes with event duration, period, signal level and scan strategy. A second analyst should be able to reproduce the simulation from retained code, seeds, data and versions. Where simulated confidence is high only under one fragile model, the report should disclose that dependency.

Copyright 2026, James M. Atkinson

What should an operator do when the source model is genuinely unknown? Increase physical coverage, vary scan phase, deploy a suitably independent continuous recorder for key frequencies, challenge the installation with injected lawful stimuli, and report a negative finding only for classes of events shown to be observable. A model-free guarantee for arbitrary finite bursts is impossible when the receiver has blind intervals and the source could place every burst within them. That limitation is not a defect of statistical technique; it follows from the existence of unobserved possibilities. It is better to state this sharply than to conceal it under a small but unearned numerical probability.

Finally, no detection claim should be used as an attribution claim. Even successful capture of a short signal does not establish source identity, purpose or legal significance without further evidence. Conversely, failure to capture a signal cannot eliminate the possibility of a transmitter whose timing, frequency or power lies outside the validated search envelope. The appropriate product of a rigorous rare-burst investigation is a coverage-and-uncertainty account that can be independently interrogated. I return the token to Dr. Atkinson for peer examination of these competing models, particularly where sequential decisions and physical receiver constraints interact.

Sir David Cox, Peer Question: Professor Kolmogorov, the most consequential uncertainty may be the choice of arrival model rather than any measurable clock error. A zero-detection record is compatible with a Poisson emitter of low rate, a periodic source always in blind windows and a cluster process producing many related bursts during rare activation

Copyright 2026, James M. Atkinson

periods. What model checking can the analyst undertake if no true events have been recorded, and how should the report communicate the fact that the data themselves cannot discriminate these explanations? Can an investigator claim a model-robust confidence interval by examining several models and taking the narrowest limit, or would such a procedure reverse the logic of a conservative analysis? Please consider the useful role of sensitivity bounds without making the manuscript's mathematics appear to prove facts beyond observation. Would it help to distinguish the event onset time from the time at which the detector completes its decision? A receiver may present only the latter, making a burst appear to occur when the system happens to be observing rather than when the RF energy actually began.

Andrey Nikolaevich Kolmogorov, Response: Sir David, an empty event record offers little direct information about temporal dependence. It can constrain particular models through known coverage, but it generally cannot identify whether a source process is Poisson, periodic or clustered. Model checking must therefore rely on independent information: controlled trial emissions, prior measurements of the same class of equipment when lawfully available, documented behaviour of the application driving the transmitter, or bounded physical restrictions on burst timing and duration. When such information does not exist, the report should present the divergence of predictions as an explicit limit of inference. Choosing the narrowest interval from several models would reward an optimistic assumption and has no automatic coverage justification.

One can construct a set of scenarios with common physical input: the same

Copyright 2026, James M. Atkinson

actual scan schedule and calibrated detection surface. Under each declared source-arrival law, compute the probability of a zero count or the upper bound appropriate to that law. The output is a sensitivity table, not a probability distribution over the laws unless a defensible model-weighting scheme has been established. Worst-case analysis can establish that a deterministic emitter synchronised to blind intervals remains entirely unexcluded; random-phase and Poisson scenarios may offer more informative conditional bounds. These claims are not contradictory because they answer different questions.

It is valuable also to distinguish uncertainties capable of experimental reduction from those requiring changed apparatus. More independent onset-phase trials can narrow estimates of conditional detection probability. Better instrumentation may reduce lost-sample uncertainty. But no number of repetitions of one unaltered periodic scan can exclude a transmitter that always emits during its gaps. Resolving that ambiguity requires altering observation coverage, not merely refining a model. A continuous receiver on the key frequency, staggered scanning, or an independently timed challenge test can convert an unobservable behaviour into an observable one. The final report should separate model-derived confidence, experimental coverage, and physically unexcluded scenarios with clear terminology. Yes. Preserve the hardware acquisition timestamp and the algorithmic decision timestamp separately. A filter or integration detector may declare the event later than the physical onset, with latency dependent on signal strength. An externally measured timing marker can calibrate that

Copyright 2026, James M. Atkinson

delay for a specified source class. Such calibration should never be silently applied as though it were an unedited raw measurement.

Andrey Nikolaevich Kolmogorov, Cross-Peer Question to David Harold Blackwell: Dr. Blackwell, you have argued that altering the scanning policy may yield more information than collecting another long sequence of identical missed opportunities. How should an investigator compare the value of a continuous receiver on one critical channel with a randomised scanner that covers many frequencies, when the source's frequency distribution is unknown? A continuous monitor eliminates temporal gaps for one band but leaves all other bands unobserved. A scanner distributes attention while leaving every channel blind for much of the time. The decision also has a resource constraint: independent timebases, antenna systems, storage and human review are not unlimited. What criterion could select an arrangement without inventing a probability distribution over malicious source choices, and how would you preserve the distinction between optimising a coverage policy and proving the absence of a transmitter? The resource allocation ought to disclose whether its worst-case performance assumes a stationary source, since deployment may change the very field conditions that made the earlier site calibration favourable.

David Harold Blackwell, Cross-Peer Answer to Andrey Nikolaevich Kolmogorov: Professor Kolmogorov, without a defensible probability model for source choices, a single numerical optimum can be artificial. One may begin with an explicit loss function or a hierarchy of operational priorities: some channels are essential to monitor continuously because their missed transmissions have exceptional consequences, while others can be sampled

Copyright 2026, James M. Atkinson

to discover broader occupancy. A minimax approach might optimise the worst guaranteed coverage over a declared class of signals, but if the class includes arbitrarily short bursts at arbitrary frequencies, no finite number of narrowband receivers can guarantee observation of every event. The constraints must therefore be real and visible, including minimum burst duration, frequency range, signal strength and permissible equipment capacity.

For a constrained comparison, enumerate receiver resources and their validated observation sets. A fixed channel monitor may provide nearly continuous temporal opportunity for a source whose frequency lies in its band, while a scanner may provide short but repeated opportunity over many bands. Calculate each method's successful-onset coverage for source classes of interest, then examine worst-case gaps and empirical detection surfaces. If frequency distribution is unknown, present a coverage frontier: increasing breadth reduces continuous attention per channel, unless additional hardware is provided. Neither method dominates all possible sources. A mixed architecture can preserve continuous attention to high-consequence bands whilst scanning the rest, with independently logged capture states and shared-resource dependencies made explicit.

The evidential language must remain conditional on this design. Choosing a policy to improve coverage does not establish that no transmitter existed. It only makes some failures less plausible or removes specific blind regimes. A transparent protocol says why particular bands received priority, what remained unmonitored and what alternative source behaviours were not

Copyright 2026, James M. Atkinson

excluded. Those statements may be less rhetorically satisfying than a uniform percentage labelled 'assurance', but they can be tested. Decisions under uncertainty benefit from recognising that unobserved frequency-time regions are genuine limitations, not zeros in a statistical table. A professionally sound report lets its reader inspect the trade-off rather than disguising it. In addition, changes to receiver gain, environmental noise or cable geometry should trigger requalification of the claimed observation set. The original allocation decision remains a resource policy, but its evidential performance is conditional on the acquisition chain remaining comparable to that tested.

Dr. James M. Atkinson, Moderator: The panel has established that the number of monitored days cannot substitute for the time-frequency intervals during which specific emissions were physically observable. The remaining inference depends on the assumed source process, the detector acceptance rule, the independence of repeated opportunities and whether the observation policy adapts to its own findings. The strongest negative report therefore gives a reproducible ledger of valid acquisition windows, response curves by burst class, known blind intervals, event-clustering rules, and a clearly qualified statistical model. No mathematical bound is a direct observation of a transmitter that was not detected. The fictional expert dialogue is an instructional reconstruction, not historical testimony.

QUESTION 073

Copyright 2026, James M. Atkinson

When Do Harmonic and Sideband Relationships Support a Common-Oscillator Hypothesis?

SCHOLARLY RECONSTRUCTION. Every historical specialist named below is deceased. Their attributed conversation was composed as modern pedagogical dialogue; it is not a quotation, transcript, or evidence that the named persons discussed current receivers, technical surveillance countermeasures, or digital instruments.

Dr. James M. Atkinson, Moderator: Professor Nyquist, imagine that an authorised defensive survey finds a carrier at one frequency, a second at twice that frequency, and pairs of narrow sidebands whose separation remains almost constant as equipment warms. Several receivers display similar timing and phase movement. What may the investigator infer, and what could be a coincidence? I ask you to distinguish algebraic relationships that can arise in one oscillator, modulation shared by separate oscillators, nonlinear mixing inside a receiver, and a common external reference feeding otherwise independent instruments. The decisive question is whether a physically identifiable causal pathway has been demonstrated, not whether a frequency plot looks persuasive.

Harry Nyquist, Principal Contributor: Dr. Atkinson, a proportional frequency relationship is a useful hypothesis generator, never a complete attribution. One may observe two components whose estimated frequencies satisfy $f_b(t)$ approximately equal to $n\ f_a(t)$, where n is a positive integer. That is compatible with harmonic generation from a single nonlinear waveform, yet the same relationship may be produced by independent synthesizers disciplined to a common reference, separate transmissions obeying a

Copyright 2026, James M. Atkinson

frequency plan, a spurious response inside the measuring receiver, or a coincidence within finite frequency resolution. The observation must be indexed by its time interval, frequency reference, and uncertainty. The words 'approximately equal' conceal assumptions unless the analyst states how close a ratio must remain and which error sources can make two independently generated estimates co-vary.

Begin with a periodic source whose phase is $\varphi(t)$ radians. Its instantaneous frequency is $f_a(t)=(1/2\pi)d\varphi/dt$ hertz when a meaningful unwrapped phase derivative exists. A physically generated nth harmonic of that source can have phase $n\varphi(t)+\psi_n$, where ψ_n represents a fixed phase shift associated with a particular stable path. Its instantaneous frequency is $n f_a(t)$ if ψ_n is constant. During a small common drift Δf_a, the harmonic drifts by $n\Delta f_a$. Thus an observed 10 Hz drift of a 12 MHz component, accompanied by roughly 20 Hz drift of a 24 MHz component, fits a doubling mechanism. But an unrelated 24 MHz source disciplined to a reference that itself drifts can display the same numerical relationship, perhaps with a different path-dependent phase transient. A frequency-ratio fit is therefore necessary under a simple harmonic model, not sufficient to identify an emitter or oscillator enclosure.

The stronger test uses simultaneous phase records. If $z_a(t)$ and $z_b(t)$ are properly demodulated analytic signals at the two carrier bands, form the phase residual $r_n(t)=\mathrm{unwrap}[\arg z_b(t)]-n\,\mathrm{unwrap}[\arg z_a(t)]$ after compensating known propagation and measurement delays. A constant or slowly varying r_n supports a phase relationship. Yet this is a relative

Copyright 2026, James M. Atkinson

relationship, and the measured residual can be distorted by a shared digitizer clock, frequency-converter noise, phase unwrapping across missing samples, or a reference distribution fault. It is possible for physically independent sources to remain phase-coherent because they are synchronized to the same external standard. The experiment must therefore determine whether the relevant shared cause is a single free-running oscillator, a common reference, a shared power supply, or merely a processing artifact.

In a practical survey, first acquire raw samples in two sufficiently linear, independently monitored receive paths. Document antennas, filters, calibration planes, downconverter settings, local oscillator states, gain, and sample timing. Then test the effect of a known incremental change in the suspected source, performed only with authorisation and within the apparatus' safe operating limits. If a laboratory source's fundamental is shifted by +8 Hz and its alleged second harmonic moves by +16 Hz, the response is consistent with the model; a coherent phase perturbation should also be transferred with the predicted multiplication where the mechanism is truly harmonic. If both observed channels shift by +8 Hz instead, a shared frequency-translation term or reference error deserves investigation. In the field one may have no lawful control over an unidentified transmitter, in which case a counterfactual substitution with an authorised test oscillator is an instrument challenge rather than proof of the external source.

Antenna response and environment complicate these comparisons. The

Copyright 2026, James M. Atkinson

fundamental and harmonic may have different radiation patterns because an antenna and its feed structure behave differently at different wavelengths. A cable can serve as an unintended radiator at one frequency but not the other. Standing waves can impose frequency-dependent amplitude and phase changes. A component strong in one survey position and weak in another need not have changed its generating oscillator. Conversely two independent emitters may share a power-distribution disturbance and thereby display simultaneous amplitude sidebands. The investigator must separate 'same observed modulation' from 'same physical oscillator' and must not infer origin from correlated display motion alone.

Time resolution is equally important. If a receiver averages ten seconds of frequency data, a short phase step may disappear inside an apparently smooth trace; if it samples too sparsely, sideband relationships can be aliased into spurious correspondences. Preserve the measurement intervals and their spectral windows, and evaluate a phase-residual time series in addition to a graph of fitted frequency ratios. For a brief burst, a finite Fourier window limits the precision with which a narrow sideband offset can be distinguished from spectral leakage. The width and amplitude of spectral features are products of the waveform and measurement operator, not intrinsically immutable labels.

Finally, report competing explanations in a form an independent examiner can test. A defensible finding might read: 'The components are consistent with second-harmonic generation and show phase co-movement within the stated interval; the evidence does not distinguish a shared oscillator from

Copyright 2026, James M. Atkinson

two sources locked to a common reference without additional controlled comparisons.' That is more useful than an attractive but overconfident assertion of common origin. A scientific claim grows stronger by exposing the ways it could fail, recording those tests and retaining all observations, including those that contradicted the initial hypothesis.

Sir Harold Jeffreys, Peer Question: Professor Nyquist, an analyst could translate the ratio and coherence measurements into a likelihood ratio supporting a common-source explanation, but only if the competing hypotheses are defined properly. Would you specify the distinction between one oscillator with harmonic production, two oscillators coupled to one frequency standard, and an image or spur generated within the receiver? How does the hypothesis space change when the investigator selects only the most convincing pair from thousands of measured spectral features? Does a very small frequency-ratio residual, by itself, justify a large evidential weight when a common clock can generate correlation under more than one hypothesis? I would also ask what experimental evidence should be required before a report uses the phrase 'same emitter' rather than 'compatible with a shared reference or generating mechanism'. The legal and technical consequences of that choice are considerable, especially if the apparent correlation is then used to support a location or attribution conclusion.

Harry Nyquist, Response: Sir Harold, define the models before using likelihood language. Under H1, a particular nonlinear source produces both the fundamental and the harmonic; under H2, separate sources are phase-related through a common reference; under H3, the analyser or receiver produces the second line from an external fundamental; and under H4, the

Copyright 2026, James M. Atkinson

observed relationship is a chance selection from an ensemble of candidates. Each model predicts distinct responses to controlled changes in the input power, local-oscillator plan, reference connection, or candidate source frequency. A small residual may be probable under several of those models, so it is not logically equivalent to evidence uniquely favouring H1.

Selection among thousands of spectral pairs adds a multiple-comparison problem. Suppose the analyst searches every candidate integer multiple among a thousand lines and retains the closest match. Even with independent frequency estimates the best residual is expected to be smaller than the residual of a prespecified pair. Real spectral observations are not independent, and the effective comparison count must itself be justified. One should preserve the entire candidate register, selection threshold, frequency resolutions, rejection reasons, and any subsequent targeted measurements. An empirical null distribution produced using the full search procedure may be more defensible than an abstract probability assigned to the single chosen pair.

The strongest discriminatory evidence comes from intervention and independent measurement. If an external reference is safely disconnected from a laboratory candidate and both components free-run together, that narrows the common-reference explanation. If the suspected second harmonic changes with the analyser input attenuation according to receiver distortion rather than external input, H3 gains support. If independent clocks reproduce the phase relation, one instrument-specific common-clock explanation weakens. An answer of 'same emitter' requires an identified

Copyright 2026, James M. Atkinson

source path or a suitably bounded convergent set of tests. Without those, describe the observed relationships and their uncertainty, not a degree of confidence manufactured from unvalidated likelihoods. A valuable auxiliary result is the change in the estimated residual as the candidate-matching tolerance is varied. If the claimed association disappears under an entirely reasonable uncertainty interval, the decision is not robust. That sensitivity should be preserved alongside the main likelihood argument.

David Harold Blackwell, Peer Question: Professor Nyquist, imagine that a field team can undertake only three further measurements before leaving a secured premises. It has two suspected spectral components, one stable broadband test source, a receiver with selectable input attenuation, and a second independently clocked receiver. Which experiment should come first if the practical aim is to distinguish source harmonics from receiver-generated spurs? How should the team assess the value of an intervention that changes more than one variable, such as substituting a low-pass filter that also changes impedance and gain? In addition, a null result may arise because the test loses sensitivity at the harmonic frequency. What record should be kept so that a later reviewer does not mistake disappearance of a line for causal exclusion of a hypothesis? Please address the ordering problem in terms of information and experimental economy rather than assuming that unlimited laboratory conditions are available.

Harry Nyquist, Response: Dr. Blackwell, the highest-value test is the one expected to discriminate current hypotheses while preserving enough sensitivity to interpret a negative outcome. I would generally begin with a measured input-attenuation challenge because it is quick, often reversible, and can distinguish external input power scaling from distortion created

Copyright 2026, James M. Atkinson

within the receiver. Keep the source and receiver frequency plan fixed, and record the fundamental and suspected harmonic before and after a known attenuation change. A genuinely external harmonic entering the same linear path should decrease approximately by the inserted attenuation in dB; a harmonic created after attenuation may decrease faster, with its precise behaviour determined by the nonlinearity and gain stages. A reading that changes by twice the attenuation is suggestive, not a universal diagnostic, because compression and internal gain adjustments can change the scaling.

The second test would compare an independently clocked receiver with a different front-end architecture, provided its detection floor and calibration at the suspected harmonic are established. If the line appears consistently in two independent signal paths, a single-analyser artifact becomes less likely. This does not eliminate a shared external interference mechanism or a common antenna-cable coupling path. The third test could insert a verified low-pass or notch network whose loss and impedance effects are separately measured. Such a filter can suppress a known fundamental before a nonlinear stage, but it may also alter matching; therefore compare a through-path control and calibrate the filter response at both frequencies.

The team should record anticipated test outcomes before the changes: which hypothesis predicts which frequency, phase and level response, and how large an effect would be observable above the noise and uncertainty floor. An unchanged signal in a test too insensitive to reveal the predicted effect does not update the conclusion meaningfully. Equally, a vanished signal should be reported with the new detection threshold and bandwidth.

Copyright 2026, James M. Atkinson

The efficient sequence is not simply three switches on a console; it is three controlled contrasts whose alternative predictions are written down and whose scope of inference remains explicit. The first experiment should also include a repeat baseline at the end. If the receiver gain, termination or internal reference changed during the challenges, the final control shows whether the original state was recovered or whether the tests must be treated as a sequence of different configurations.

Harry Nyquist, Cross-Peer Question to John Robinson Pierce: Dr. Pierce, your analysis of nonlinear harmonic generation may supply a physically concrete mechanism for a ratio that I have treated as an inferential clue. Can you identify the condition under which amplitude scaling and phase multiplication would be strong evidence for generation within one device, yet still allow a second receiver stage to manufacture the apparent harmonic? I ask specifically whether a measured n-fold phase relation distinguishes harmonic radiation from receiver mixing when the receiving path has nonlinear components. Could a strong fundamental, admitted through a supposedly benign preamplifier, produce the same relationship even when no harmonic energy exists at the antenna input? What minimal two-reference-plane experiment would discriminate the two locations of generation without altering the antenna's exposure or the original signal history? If the external oscillator and a nonlinear receiver share the same phase timebase, their phase relationship may remain indistinguishable under mere observation. Would you specify which calibration intervention reveals the generating stage before a forensic report names the source?

John Robinson Pierce, Cross-Peer Answer to Harry Nyquist: Professor Nyquist, the phase law follows from nonlinearity wherever that nonlinearity

Copyright 2026, James M. Atkinson

resides, so it is not a geographical certificate. Write the voltage entering a nonlinear element as $v=A \cos \varphi(t)$. A quadratic term a_2v^2 produces a component proportional to $(a_2A^2/2)\cos[2\varphi(t)]$ as well as a DC term. That same expansion applies to a power amplifier in the transmitter and to an overloaded preamplifier or mixer in the receiver. In either case the doubled carrier inherits $2\varphi(t)$, apart from added device phase and conversion noise. A perfect n-fold phase relation therefore tells us about the transformation, but not its location.

I would measure at two declared reference planes. At the receiver antenna connector, use an independently calibrated, sufficiently linear sampling path or a proper high-isolation directional arrangement to determine whether the harmonic is already present at the specified level. Then measure after the suspected nonlinear receiving stage under the same excitation. A change from 'below the input detection limit' to a substantial line at the output, combined with power-dependence testing, supports internal generation, although the input detection limit must be reported honestly. If a controlled, low-loss attenuation placed before the stage reduces the harmonic with second-order scaling while the fundamental falls linearly, the model becomes more persuasive. Repeat with an alternate high-linearity front end to challenge the result.

One cannot simply unplug the antenna during an evidential observation and interpret the absence of the line as a final field result. Disconnecting changes impedance, common-mode paths and often automatic gain. Record a contemporaneous unaltered baseline and repeat the intervention as a

Copyright 2026, James M. Atkinson

labelled instrument challenge. The original observations and the test data must remain distinct. A common-oscillator inference grows credible only after the nonlinear transformation is located in the external source path, not merely after its algebra has been identified. When the suspected generating stage cannot be physically accessed, the conclusion must be correspondingly limited. Independent observation of the RF input, verified injection standards and attenuation response may favour a mechanism, but should not be described as direct observation of an inaccessible transmitter circuit. These qualifications must survive into the final claim.

Dr. James M. Atkinson, Moderator: Dr. Pierce, Professor Nyquist has shown why a numerical relationship is insufficient. Please take the token and develop the actual circuits capable of generating related carriers and sidebands. Distinguish true external emissions from products produced by the receiver itself, and explain which controlled changes would reveal the location of the nonlinear stage.

John Robinson Pierce, Second Principal Contributor: Dr. Atkinson, the frequency spectrum of a radio system contains the signature not only of its intended oscillator but of every significant nonlinearity and modulation process. An oscillator may generate a nominally sinusoidal fundamental. Yet if its output passes through a nonlinear power stage, a diode junction, a frequency multiplier or an inadequately isolated mixer, the output may contain integer harmonics, sums, differences and modulation sidebands. The precise relationship depends on the physical transfer law. For a memoryless weak nonlinearity, one may write an illustrative truncated model $y(t)=a_1x(t)+a_2[x(t)]^2+a_3[x(t)]^3$, with coefficients a_1, a_2 and a_3 appropriate to the input amplitude units and output response. This is an approximation

Copyright 2026, James M. Atkinson

within a limited operating region, not a universal representation of a receiver mixer or a saturating power amplifier.

Suppose $x(t)=A\cos(\omega_0 t+\beta\sin \omega_mt)$, where A is signal amplitude, $\omega_0=2\pi f_0$ is the angular carrier frequency, $\omega_m=2\pi f_m$ is the angular frequency of a small imposed phase modulation, and β is the dimensionless phase-modulation index in radians. The square term produces a second-harmonic component proportional to $\cos(2\omega_0 t+2\beta\sin \omega_mt)$. The harmonic's phase modulation index is thus twice the fundamental index under this simple law. For small β, the first-order phase-modulation sideband power relative to its corresponding carrier is approximately $(\beta/2)^2$ at the fundamental and approximately $(2\beta/2)^2$ at the second harmonic. At β=0.005 radians these expressions predict roughly −52.0 dBc and −46.0 dBc per first-order sideband respectively, a 6 dB difference, assuming the relevant carriers are separately measured and the underlying approximation is satisfied. The calculation is a model expectation, not a statement about measured equipment.

That relationship is a useful challenge signature. If a known oscillator is modulated at 120 Hz and an observed doubled carrier develops sidebands spaced by ±120 Hz, with a modulation-index change consistent with phase multiplication, the pair is compatible with common harmonic generation. Yet one cannot infer that an unverified 24 MHz field feature came from a 12 MHz emitter merely because the ratio, offsets and relative sideband levels fit this model. A receiving amplifier can generate the same second harmonic from a strong admitted 12 MHz signal. A phase-coherent synthesizer locked

Copyright 2026, James M. Atkinson

to the same reference can reproduce related phase excursions at two different carrier frequencies. An RF distribution system may leak one channel into another. The intervention must be designed to discriminate among these arrangements.

Power scaling adds valuable information but also introduces traps. Within the weak quadratic regime, the second-harmonic voltage is proportional to A^2. If the fundamental's voltage rises by a factor of two, the quadratic harmonic voltage ideally rises by a factor of four. In decibel terms, a 6.02 dB fundamental voltage increase can yield approximately a 12.04 dB second-harmonic voltage increase, when measured at consistent impedances. An external harmonic received through the same linear path may instead scale according to the external transmitter and path, not the receiver's square law. But real nonlinear devices leave the weak regime, change operating bias, generate intermodulation and compress. A logarithmic slope close to two is compatible with one model; it does not prove the complete circuit topology.

Distinguish harmonics from mixing products. With two sinusoidal inputs f_1 and f_2, a square-law term includes components at f_1+f_2 and $|f_1-f_2|$, whereas a cubic term can generate $2f_1-f_2$ and $2f_2-f_1$. If the analyst observes a family of lines, a frequency plan can explain several of them without a single external emitter at each displayed frequency. Conversely unrelated transmitters can occupy frequencies coincidentally compatible with a polynomial combination. The correct test varies one known input while holding the other fixed, monitors the expected slopes and tracks the

Copyright 2026, James M. Atkinson

product through successive reference planes. If f_1 is shifted by 100 Hz while f_2 is fixed, a proposed $2f_1-f_2$ product should move by 200 Hz under the ideal expression. Such an experiment is meaningful only when the input change is authorised and the relevant circuit has not changed modes.

An additional diagnostic is the receiving front end's attenuation. In a controlled receiver-side nonlinearity experiment, increase attenuation before the suspected nonlinear stage by a known amount, disable automatic gain control if safely and technically appropriate, and record signal power at the mixer input. If the apparent harmonic recedes more rapidly than a line already present at the antenna port, that supports internal generation. But not every attenuator is physically located ahead of the problematic device. An input attenuator following a low-noise preamplifier cannot challenge distortion generated upstream of it. A software 'attenuation' control may alter digital gain after conversion, leaving the original overload untouched. A proper chain diagram is therefore indispensable.

Isolation measures matter because electromagnetic energy can bypass the nominal connector path. Clock leads, USB shields, power supplies, structural seams and coaxial outer conductors can deliver common-mode currents into a receiver. A component may remain after terminating a nominal RF input because it couples directly into a later circuit, not because it is a legitimate independent emission. Similarly a preselector may reject an apparent harmonic while leaving mixer images and reference spurs unaffected. Challenge the enclosure, cable geometry and reference

Copyright 2026, James M. Atkinson

distribution separately. Retain both the baseline and the changed configuration, with measured frequency responses and noise floors.

The strongest scientifically phrased conclusion separates what has been observed from what has been established about its cause. Frequency ratios, modulation-index multiplication, phase relationship and power scaling can jointly favour harmonic generation. Only an experiment that localises the generating nonlinearity can then support a particular transmitting circuit or enclosure as the origin. If one cannot perform that intervention, the report should identify several physically tenable mechanisms and the evidence that each would require for exclusion. The role of receiver engineering is not to decorate a hypothesis with more decimal places; it is to construct measurements capable of making competing hypotheses behave differently.

Walter Andrew Shewhart, Peer Question: Dr. Pierce, your ideal square-law argument offers a neat power-slope test, but how can the engineer know that the receiving chain remains in the weakly nonlinear regime throughout the attenuation sequence? A transistor amplifier can warm, bias can shift, an AGC loop can compensate, and a limiter may impose a discontinuous transfer curve. Please develop a controlled acceptance test that distinguishes actual harmonic scaling from a software display that has merely changed its level calibration. I should also like you to consider whether a single successful power sweep is enough evidence for an external emission claim, or whether the operator must monitor stability, repeat in opposite directions and retain observations rejected as anomalous. The concern is that a measurement designed to test nonlinearity may itself bring

Copyright 2026, James M. Atkinson

about a new operating state and thereby invalidate the baseline against which its results are judged. If a stable reading appears only after the input chain has reached thermal equilibrium, should the acceptance protocol distinguish a warm-up criterion from a power-slope conclusion? Would periodic reference checks reveal whether an attractive fit merely reflects slow drift in the measuring apparatus?

John Robinson Pierce, Response: Dr. Shewhart, a power-slope experiment is valid only over a range in which the measured transfer function behaves approximately as the assumed model. Choose several small, documented attenuation increments and keep the receiver configuration fixed. Record the input reference level, output fundamental, candidate harmonic, amplifier bias indicators where accessible, ambient temperature, gain state and frequency plan. Make the scan in both ascending and descending power to expose thermal lag, hysteresis and mode changes. If software reconfigures gain or sample scaling, retain a hardware reference measurement independent of the displayed spectrum so that the calculated slope is not just an artefact of a hidden correction.

For each step compute the local logarithmic slope $m=\Delta P_h/\Delta P_f$, where P_h and P_f are powers expressed in dB referenced to consistent impedances and planes. In an ideal weak square-law regime the harmonic power change may be approximately twice the fundamental power change, giving m near two. But this power-ratio observation requires careful interpretation: when the input itself is attenuated, the external harmonic, if already generated by the transmitter, may enter the receiving path with a distinct level, and a filter may change the relative scaling. One should model the precise location

Copyright 2026, James M. Atkinson

of the attenuator, not merely fit a line. The slope is meaningful only where the fundamental remains detectable, the harmonic is above the verified floor, and compression and AGC effects are excluded or explicitly modelled.

I would also recommend injecting a calibrated fundamental into a matched termination or controlled port, using an independent low-distortion source whose own harmonics have been suppressed and measured. This creates a known test of the receiver's internal harmonic generation. The baseline spectrum should be preserved before changing the apparatus; the test is a separate experimental condition. Repeat the sweep on different days or temperatures where those factors may matter and record the full sequence, including failures. A single elegant slope plot is not enough to establish source identity. What matters is reproducibility of the causal distinction under conditions in which the instrument's own response has been challenged and the original evidential observations have remained intact. In addition, an engineer should account for the measurement bandwidth used in estimating fundamental and harmonic power. A narrow filter can attenuate a drifting component differently from a stationary one, making an apparent slope change that is unrelated to the underlying circuit nonlinearity. That check should include a controlled reversal to baseline.

W. Edwards Deming, Peer Question: Dr. Pierce, suppose two laboratories examine the same receiver and disagree over the presence of a second harmonic. One measures at the antenna connector, another after a preamplifier whose gain varies with temperature; both cite a calibrated spectrum analyser. How should the measurement procedure specify the quantity being compared and the allowable differences in conditions? I ask

Copyright 2026, James M. Atkinson

especially about the meaning of an exact numerical sideband ratio when one laboratory uses peak detection and the other averages a windowed spectrum. Would your method establish a reproducible result across operators, not merely across repeated acquisitions by one operator with one setting? Finally, what would count as a finding that contradicts the proposed common-oscillator explanation, rather than being dismissed as an equipment quirk? In such a comparison, how should the laboratories establish comparable sensitivity limits for non-detections, and what evidence would show that a difference arose from calibration planes rather than independent oscillators? Please make the error treatment part of the test design, not an amendment drafted after the result.

John Robinson Pierce, Response: Dr. Deming, the comparison first needs a declared measurand: for example, the carrier-relative power of the upper first-order sideband at an explicitly identified output reference plane, under a specified input level, bandwidth, and operating temperature. A measurement at an antenna connector and one following a preamplifier are different measurands until the gain, noise, mismatch and nonlinear response of the intervening path are evaluated. Likewise peak detection and windowed averaging may produce different values for an intermittent or frequency-agile line. Neither difference proves negligence; it demonstrates that the measurement processes were not equivalent.

A reproducible protocol would distribute a waveform file or controlled hardware stimulus whose properties are independently characterised. Specify calibrated source power and source harmonic suppression, test port impedance, cable and attenuator configuration, instrument bandwidth,

Copyright 2026, James M. Atkinson

detector, window, averaging count, input attenuation, gain state, and the exact algorithm for extracting carrier and sideband power. Each laboratory should preserve raw spectra and time-domain observations where available, with an audit trail of adjustments. The results should be compared against an uncertainty budget embracing both random repeatability and systematic differences, not against a tolerance chosen after the readings are known.

Crucially, define falsifiers in advance. If an alleged external harmonic disappears in a properly calibrated second receiver while the fundamental remains strong and the first receiver exhibits the same line during a known linear-source injection, the common external-source interpretation is seriously weakened. If phase multiplication fails during a controlled oscillator perturbation that was large enough to be resolved, the simple harmonic hypothesis loses support. If frequency co-movement persists only when both receivers share the same reference, shared instrumentation may be the cause. Not every contrary result is conclusive, but each must be retained and weighed. A genuine scientific protocol names the observations that would require changing the conclusion, not merely those likely to affirm it. To separate these possibilities, an interlaboratory study should include blinded specimens with known external harmonic content and specimens whose only second harmonic is generated by a controlled nonlinear receiving stage. Correct differentiation under both conditions would give the procedure a stronger empirical foundation. The final acceptance record should separately preserve a laboratory comparison of measurement floors, because agreement over detected harmonics alone cannot establish comparable competence to report their absence.

Copyright 2026, James M. Atkinson

John Robinson Pierce, Cross-Peer Question to Hendrik Wade Bode: Professor Bode, I can produce $2f_0$ through a square-law device, yet two separate synthesizers disciplined to one oscillator can also exhibit exact integer relations and coherent modulation sidebands. Which features of their phase-transfer dynamics would distinguish those arrangements? I am particularly interested in the transient following a small reference phase step. Does a nonlinear multiplier reproduce that step immediately according to the harmonic order, while two phase-locked loops reproduce it with their separate bandwidths and possible overshoot? If the measured traces appear identical at low time resolution, what additional experiment and acquisition bandwidth would expose the different control mechanisms without over-interpreting small residual noise? An equal frequency-ratio response to a static perturbation does not necessarily distinguish these devices; would you require a sweep of several modulation offsets to expose the transfer dynamics? How should uncertain path delays enter that comparison? Which observation best separates their response models?

Hendrik Wade Bode, Cross-Peer Answer to John Robinson Pierce: Dr. Pierce, the contrast lies in the dynamics as well as the static ratio. An ideal memoryless multiplier maps its input phase into n times that phase apart from fixed device delay and any added noise. A disciplined synthesizer instead contains a control loop whose response depends on its reference and internal oscillator paths. If the reference receives a small phase step, each synthesizer follows through its own closed-loop transfer function, possibly with different settling, overshoot, ringing or holdover behaviour. The observed output phase is a filtered response, not simply an instantaneous integer multiplication of every reference disturbance.

Copyright 2026, James M. Atkinson

Let H_i(s) represent the small-signal transfer function from reference phase to output phase for synthesizer i, after incorporating its frequency multiplication factor. Two outputs can share a static integer relationship while H_1(s) and H_2(s) differ materially at transient frequencies. Introduce a safe, small, calibrated phase modulation at several modulation frequencies rather than relying on one abrupt step alone. Compare amplitude and phase of the observed modulation transfer, and capture continuously with sufficient sample rate and dynamic range to observe the relevant loop bandwidth. If each output follows its own filter characteristic, separate disciplined oscillators become plausible; if a simple harmonic responds with the expected nearly immediate phase multiplication over the test band, the local multiplier model gains support.

The inference must still account for cable delay, filters and instruments. A nonlinear multiplier can include resonators, and a synthesizer can be configured to mimic a similar response. One experiment may not identify topology uniquely. But a measured frequency-dependent transfer function offers far more discriminatory evidence than a static harmonic ratio. Retain the imposed stimulus, source-reference record and receiver response so that a later reviewer can calculate the same transfer functions independently. Any inferred response difference should be compared with an injected calibration signal passed through the same receiving paths. Without that control, a phase-lag difference might belong to the test instruments, rather than to the oscillator architectures under examination. Repeat each stimulus at an amplitude small enough to preserve linear

Copyright 2026, James M. Atkinson

response, and compare the phase delay across offsets before drawing conclusions about control-loop bandwidth. The stimulus must be traceable.

Dr. James M. Atkinson, Moderator: Professor Bode, Dr. Pierce has established that static frequency ratios do not locate a generating device. Please examine the dynamics of shared reference networks, phase-locked loops and measurement-chain transfer functions, especially where two distinct oscillators look indistinguishable in a conventional spectrum trace.

Hendrik Wade Bode, Third Principal Contributor: Dr. Atkinson, one must distinguish a common physical oscillator, a common frequency reference, and a common observed perturbation. In a receiver arrangement, several local oscillators may be phase-locked to one external clock; their frequencies can stand in exact integer or rational relationships even though they are materially different sources. Moreover, one output may be generated by multiplication, another by division, and a third by direct digital synthesis. Their narrow spectral lines can remain coherent for long intervals because the control architecture imposes that coherence. The relationship establishes a shared reference mechanism, not a single oscillating circuit. To infer an oscillator in a particular enclosure, we must understand the physical transfer function and locate where it enters the measurement.

An idealised phase-locked loop comprises a phase detector, loop filter, controllable oscillator and feedback divider. In a linearised locked state, a useful conceptual expression is $\theta_{out}(s)=N H_{ref}(s) \theta_{ref}(s)+H_{free}(s) \theta_{vco}(s)+\theta_{add}(s)$, where N is a frequency multiplication ratio; θ_{ref} is reference phase; θ_{vco} describes internal free-oscillator phase disturbance; θ_{add} represents other additive terms; and H_{ref} and H_{free} are transfer

Copyright 2026, James M. Atkinson

functions determined by loop dynamics. The exact form depends on the architecture and on where each disturbance enters. A common reference phase disturbance can therefore be present in multiple outputs, scaled and filtered differently. Two traces with equal frequency ratios do not necessarily possess equal phase-noise spectra, nor does similar noise prove the reference came from one particular instrument.

At offsets well within a particular loop's effective bandwidth, the output often follows reference phase strongly, whereas farther from that bandwidth internal oscillator noise may dominate. The border is not always sharp, and real loops may exhibit peaking. If two outputs are disciplined by the same reference but use different loop bandwidths, a controlled sinusoidal phase modulation swept through a range of offsets can reveal different amplitude and phase transfer. A mere sample of a single sideband at 100 Hz does not supply that dynamic information. The investigator should document small-signal validity and stay below disturbance levels that cause cycle slips, mode transitions or altered controller configuration.

For a numerical illustration, consider a shared 10 MHz reference connected to two synthesisers producing 100 MHz and 250 MHz. They have frequency ratios of ten and twenty-five to the reference. An imposed reference phase modulation index $\beta_{ref}=0.002$ radians would yield ideal output indexes of 0.020 and 0.050 radians at low modulation offsets if both loops faithfully track the reference and if the output mapping corresponds to these simple multiplication factors. At high modulation offsets one loop may suppress that transferred modulation more strongly than the other. The associated

Copyright 2026, James M. Atkinson

discrete sidebands are best reported in dBc, not as noise densities in dBc/Hz; the latter unit describes continuum power per hertz. A finite spectrum analyser bandwidth can conflate the two unless the spur and underlying continuum are separated.

Common clocks also complicate covariance. Suppose instruments A and B each estimate the phase of a received carrier, and both share a reference disturbance c(t). Write their errors e_A(t)=g_A*c(t)+u_A(t) and e_B(t)=g_B*c(t)+u_B(t), where g_A and g_B are the relevant impulse responses, * denotes convolution, and u_A and u_B are path-specific disturbances. Even when u_A and u_B are independent, the outputs are correlated through c. The cross-spectrum depends on G_A(f)G_B*(f)S_c(f), with G denoting Fourier transforms of the responses and * on G_B denoting complex conjugation. A strong cross-spectrum can reveal common influence; it cannot, alone, identify where that influence is located. A common power rail, reference switch or thermal enclosure may also create multiple coupling paths whose signals appear coherent.

The control experiment begins by mapping the actual clock and RF paths, not by clicking a correlation command. Identify the oscillator output, reference distribution point, each synthesizer input, relevant mixers, and any independent timing witness. Measure at defined points with properly calibrated isolating probes or buffer outputs, taking care that the probe does not load a sensitive oscillator and alter its spectrum. Repeat with one known reference path disconnected or substituted where safe and authorised. An observable coherence change following that intervention is

Copyright 2026, James M. Atkinson

stronger evidence of dependency than a calculated correlation from two supposedly independent displays fed by one shared cable.

Several subtle failure mechanisms can imitate the common-reference result. A poorly shielded digital bus may radiate its clock into the RF front end. A shared power supply can impose periodic amplitude modulation on two independent oscillators. Input stages may generate intermodulation lines at sums and differences. An analyser's own local oscillator phase noise can make several measured signals acquire a similar skirts or sidebands. A software pipeline may apply one clock correction to all output traces, creating artificial time alignment. Each is a physical or algorithmic pathway, and each can be challenged by changing just one connection or reference while preserving the rest of the acquisition configuration.

I would therefore separate two questions in the report. First, do the components share measurable phase or frequency behaviour under particular operating conditions? Second, does the evidence distinguish one free-running oscillator from a network of independently generated but mutually disciplined signals? The first may be answered by careful simultaneous observation. The second typically requires deliberately chosen excitation, reference substitution, comparison of transfer functions, and independent clock paths. Where the equipment is sealed or interventions are not permitted, the conclusion must remain a shared-oscillation or shared-reference hypothesis, not an assertion of a unique source.

Finally, the evidence should carry its own calibration and uncertainty

Copyright 2026, James M. Atkinson

statement. A phase transfer function measured with one loop bandwidth or firmware version may not apply after a configuration change. The analyst should retain controller state, gain settings, reference-distribution topology, injected stimulus, sampling rate and the phase-estimator algorithm. Contemporaneous metadata matter as much as the displayed sidebands. Without them, a plausible control-theory narrative becomes impossible to distinguish from post-hoc story-telling. The discipline of feedback analysis insists that a correlated output be understood as the response of a complete system, not as an isolated spectral ornament.

Andrey Nikolaevich Kolmogorov, Peer Question: Professor Bode, an investigator may apply a coherence estimator to two phase records and announce that a value near unity proves a common reference oscillator. Yet finite records, spectral-window overlap, smoothing, and common signal components can all influence that estimate. Please distinguish the population coherence of stationary random processes from an estimate obtained after selecting a particularly interesting transient. How should one evaluate a narrow deterministic spur that is superimposed on random phase noise, and how does the answer change when the phase-tracking loops are themselves nonlinear or change state during the record? I also ask whether a high degree of coherence remains informative when both traces are generated by one digitiser rather than two independent acquisition chains. The danger, as I see it, is to mistake a property of the data-processing arrangement for a newly discovered property of the emitting hardware. If a particular frequency bin was selected after searching many candidate offsets, the apparent coherence may also reflect a selection mechanism. Should the analyst preserve the rejected offsets and reproduce

Copyright 2026, James M. Atkinson

the identical selection process under alternative models before assigning evidential weight to the peak?

Hendrik Wade Bode, Response: Professor Kolmogorov, coherence is a conditional statistical description. For two jointly wide-sense-stationary random processes x(t) and y(t), the magnitude-squared coherence at Fourier frequency f is $C_{xy}(f)=|S_{xy}(f)|^2/[S_{xx}(f)S_{yy}(f)]$, where S_{xy} is cross-spectral density and the denominators are the individual spectral densities. Under the usual definitions the value lies between zero and one. A finite estimated value is affected by segmenting, tapering, averaging and estimator bias. With insufficient independent averages an apparent high coherence may be an unsurprising estimator property. The sample count, overlap, effective degrees of freedom and spectral resolution must be reported if one wants to attach an uncertainty to the estimate.

A coherent deterministic spur is not adequately characterised merely by a continuous-noise spectrum. Its power depends on the observation window and its alignment with spectral bins, while its stable phase may dominate coherence at one frequency. The investigator should report the spur separately by offset frequency and carrier-relative level, and analyse the broadband phase-noise continuum without pretending that the spur is an ordinary random density. A transient that occurs once does not satisfy the same stationarity assumptions as a long random-noise record. Time-domain phase traces and event-conditioned comparisons are appropriate companions to a spectrum, with their own selection and timing caveats.

If phase loops change state, the process is piecewise and its linearised

Copyright 2026, James M. Atkinson

transfer function may not remain valid across the transition. Report the state intervals and analyse them separately. A cycle slip or controller reset can create an apparent deterministic phase jump. Correlating two corrected traces generated by one digitiser adds no independent confirmation of its sample-time model. The two outputs may even share the same software phase-estimation bias. To strengthen the inference, repeat with independent clocked acquisitions and vary one hypothesised common pathway under a controlled test. The goal is not to obtain a larger coherence number but to show that the measured dependence responds to an intervention predicted by the claimed physical model. A low-noise reference distribution network may still introduce branch-dependent transients, particularly during switching and reacquisition. Those transitions should be retained as marked intervals rather than averaged into the same stationary spectrum as uninterrupted lock, or the inferred covariance may be misleading.

Hendrik Wade Bode, Cross-Peer Question to Dennis Gabor: Professor Gabor, the frequency-domain transfer relationships I have outlined assume that the analysis can resolve the modulation offsets and track phase continuously. A short frequency-agile burst may offer neither long stationarity nor an unbroken phase history. Which time-frequency representation would reveal the differential loop response without attributing spectral leakage to a physical sideband? How would you distinguish a line that genuinely follows a reference perturbation from a component that moves because the analysis window or demodulation centre was changed? I ask you to reconcile the desire for a narrow frequency resolution with the need to observe a fast control-loop transient, and to identify a test that can be

Copyright 2026, James M. Atkinson

reproduced from retained raw samples. When the available event lasts only a few milliseconds, one cannot assume that a twenty-hertz offset line is individually resolvable. Should the expert report a bound on modulation rate rather than claiming a precisely separated sideband in that interval?

Dennis Gabor, Cross-Peer Answer to Hendrik Wade Bode: Professor Bode, the time-frequency representation should be selected by the question rather than the attractiveness of the picture. A short-time Fourier transform estimates spectral content in a chosen window. Its nominal bin spacing is inversely proportional to the window duration, while its ability to distinguish nearby events in time improves as the window becomes shorter. A burst shorter than a long window can be diluted, and a frequency transition can paint a diagonal or widened feature whose shape depends on the window and hop. Therefore first preserve the raw complex samples, sample-counter continuity and the exact demodulation reference. Then examine several documented window lengths and compare what is invariant across them.

A direct phase trajectory is often more informative if the carrier remains sufficiently strong and unambiguous. Downconvert the component by a documented numerical oscillator, unwrap phase subject to explicit gap and signal-to-noise checks, and compare its residual against the simultaneously measured reference perturbation. A genuine transferred phase step should show a reproducible temporal relation after allowing for receiver-path delay and the loop's response. By contrast spectral leakage can shift or change amplitude with the window without a corresponding physical phase change in the raw samples. The analyst can test the latter by reprocessing the identical stored data under different windows while leaving acquisition

Copyright 2026, James M. Atkinson

untouched.

For a planned calibration, inject a small modulation at several frequencies, but do not insist on a particular harmonic source until the device's operating range has been established. Capture the reference input and output channels with sufficient bandwidth to resolve the loop's possible ringing, and use a calibrated known signal to test phase-estimator latency. Repeat with two independent acquisition clocks to challenge shared sampling errors. The combination of a physical perturbation, a continuous phase record and a sensitivity analysis over window choices is stronger than one spectrogram. It will often reveal that a nominally identical pair of sidebands has different causal histories in the two channels. One should also compare the sideband-estimator output against a known synthetic waveform of similar duration and signal-to-noise ratio. If the algorithm invents a narrow displaced line in a waveform that contains only a transition, it is not a reliable basis for source attribution.

Dr. James M. Atkinson, Moderator: Professor Gabor, the control-theory analysis has shown why coherent sidebands may arise through different circuits. Would you now address finite observation time, brief transmissions, frequency agility and the limits of declaring a common source from similar spectrogram markings?

Dennis Gabor, Fourth Principal Contributor: Dr. Atkinson, a time-frequency display is a measurement of a transformed record, not a portrait of the electromagnetic world independent of the analyser. The investigator may see two simultaneous traces with a common drift and sidebands that rise or fall together. But each pixel reflects a window length, a window function, a

Copyright 2026, James M. Atkinson

sample interval, an FFT size, a reference oscillator and a detector choice. If the underlying signals are short or frequency-agile, changing those choices may change the apparent relationship. Before attributing a line to a common oscillator, one must determine which features are invariant under justified changes of measurement method and which are products of the chosen transform.

Consider two complex baseband signals $x_1(t)$ and $x_2(t)$. Their short-time Fourier transforms may be written $X_i(\tau,f)=\int x_i(t)w(t-\tau)e^{(-j2\pi ft)}dt$, where w is the analysis window, τ the window position and f the Fourier frequency. The expression shows that the displayed time-frequency point combines data over a span around τ. It does not identify a single emission instant. If the window is long enough to resolve narrow sidebands it may smear a rapidly changing carrier; if it is short enough to locate a burst it may fail to distinguish close sidebands. An observed ±50 Hz offset may be impossible to resolve in a 5 ms segment, whose nominal Fourier-bin spacing is about 200 Hz before considering the window's effective noise bandwidth and estimator details. Merely increasing FFT zero-padding interpolates a display; it does not create additional independent time information.

A fundamental and its second harmonic also occupy different propagation channels in the practical sense that antennas, cables and enclosures transfer them differently. At 12 MHz and 24 MHz, electrical lengths double in phase for a fixed delay, while antenna directivity and cable losses may alter the amplitude ratio. When the carrier moves in frequency, filters and resonances may distort the apparent drift differently. A ratio measured from

Copyright 2026, James M. Atkinson

spectrogram ridge positions can therefore suffer bias from frequency-dependent delay or unequal signal-to-noise ratios. If one component is very weak, the ridge-tracking algorithm may jump to an adjacent interference line, creating a false discontinuity. A credible analysis compares ridge estimates with independently demodulated phase trajectories and documents uncertainty at every interval.

Time simultaneity also requires care. Two emissions may be modulated by the same mains ripple or common mechanical vibration without sharing an oscillator. Their amplitude sidebands can appear at the same offset, and environmental synchrony can be very strong. The investigator should measure amplitude and phase modulation separately. A sideband pair in a power spectrum cannot always distinguish amplitude modulation from phase modulation because that distinction depends on the relative phasor of the upper and lower sidebands. With coherent I/Q observations one can estimate the modulation components, subject to calibration and carrier phase reference. Where the data are magnitude-only, a claimed common phase disturbance is generally too strong.

Suppose a controlled test oscillator at 10 MHz is phase-modulated by a small 120 Hz tone, and a nonlinear output contains a 20 MHz harmonic. Under the simple phase-multiplier model, both components show sidebands at ±120 Hz, while the modulation index at the second harmonic is twice that at the fundamental. Yet the observed sideband powers may not display the ideal 6 dB difference if the signal path adds AM, limits the carrier, filters the sidebands or has significant phase noise. The discrepancy is not

Copyright 2026, James M. Atkinson

automatically proof against harmonic generation; it is an invitation to measure the transfer function. Conversely an apparent match at one offset is not enough to distinguish a single multiplier from two synthesizers sharing a 120 Hz disturbance in their reference lines.

The time-domain invariant to seek is a reproducible phase relation under changing conditions. Let $\varphi_1(t)$ and $\varphi_2(t)$ be estimated continuous phases referenced to a common, independently checked time coordinate, and define $q(t)=\varphi_2(t)-2\varphi_1(t)$. If q remains stable across a range of amplitude, frequency and temperature conditions, the phase relation is supported. But if the signals pass through different propagation paths with delays τ_1 and τ_2, the appropriate comparison is not necessarily at the same receiver timestamp; a model may require $\varphi_2(t-\tau_2)$ and $\varphi_1(t-\tau_1)$. Estimating those delays from the same observed coherence can produce circular reasoning, so separate calibration stimuli and independent geometric or cable measurements should be preferred.

Transient perturbations are particularly discriminating. A controlled small phase step introduced into a known candidate oscillator will propagate through a simple harmonic multiplier according to its nonlinear phase law. Two distinct synthesizers locked to a common reference may follow with different transient characteristics. A true signal passing through an analogue filter may ring; a software phase unwrap can choose a continuous trajectory that conceals a real slip. Thus the investigator should inspect raw samples around the event, compare multiple window lengths and phase extraction methods, and verify sample-counter continuity. If the records

Copyright 2026, James M. Atkinson

contain a gap during the only decisive transient, the causal question may remain unresolved rather than being settled by interpolation.

The use of multiple stations can help but does not automatically make the evidence independent. Stations sharing a satellite-disciplined standard or a network-time conversion can exhibit correlated clock error. A strong remote emitter can couple differently to each antenna, while local reference radiation may follow cable routes. Examine coherence as a function of station separation, antenna orientation, independent clock configuration and controlled substitution. Preserve the complete set of data, including those intervals in which the two lines fail to co-move. A conveniently selected episode of near-perfect coherence can be a misleading summary of a much less stable relationship.

An appropriate final statement therefore separates frequency-ratio consistency, measured phase coupling, sideband structure, intervention response and source localisation. These are different layers of evidence. A spectral resemblance may motivate a common-oscillator hypothesis; a phase transfer and independent acquisition may support a common driving mechanism; and a verified physical path or controlled enclosure test may finally locate the mechanism. Neither a fine spectrogram nor a precise fitted coefficient can replace that hierarchy. The scientific use of a time-frequency representation is to reveal where the proposed explanation works and where it ceases to explain the observations.

John Wilder Tukey, Peer Question: Professor Gabor, an investigator might adjust FFT length, taper, overlap and ridge-tracking thresholds until two

Copyright 2026, James M. Atkinson

spectral traces appear impressively aligned. The final graph could then be presented as if its processing settings had been selected in advance. How would you separate exploratory visual analysis from a confirmatory test of a common oscillator? Would you preserve the complete analysis history, define an independent validation interval, or compare the result with a simulated null that reproduces the instrument's spectral leakage and drift? I am also concerned about a weak second harmonic detected only after aggressive averaging: its apparent phase may be dominated by the strongest nearby interferer or by the algorithm's phase prior. What diagnostic would reveal that instability instead of allowing a clean fitted residual to conceal it? Where the analysis uses several candidates for phase unwrapping, would it be appropriate to require an independent test segment in which the chosen solution is frozen, with competing unwraps retained as alternative models rather than silently rejected?

Dennis Gabor, Response: Professor Tukey, exploratory analysis is valuable, but its outputs must be labelled as hypotheses rather than calibrated confirmatory evidence. The operator may change windows and thresholds to understand a complicated spectrogram; the problem begins when the one most convincing configuration is treated as if it were a prespecified test. Preserve the full processing configuration history and select a separate held-out interval or independent measurement on which the proposed relation can be evaluated without further tuning. The analyst should then publish the acceptance criterion, allowable residual, signal-to-noise thresholds, and treatment of missing or ambiguous phase samples before looking at the validation result.

Copyright 2026, James M. Atkinson

A useful null simulation reproduces the acquisition system: sample rate, clock phase noise, window shapes, overlap, frequency drift, instrument-induced spurs and the candidate-selection procedure. Simulating two independent emitters that happen to share an environmental modulation may be especially informative. If the same coherence score occurs frequently under that alternative, the score cannot be presented as unique evidence of a common oscillator. The null should reflect physical alternatives, not merely independent white-noise traces chosen because they make the observed result look extraordinary. One should report sensitivity over plausible null families rather than a single theatrical significance number.

For weak phase estimates, calculate or empirically bound the estimator's uncertainty as a function of signal power, interference and bandwidth. Examine phase residuals before and after excluding low-amplitude intervals according to a declared rule, and retain the excluded intervals in the report. A phase-unwrapping algorithm can exhibit sudden cycle slips that masquerade as physical phase jumps; conversely interpolation can bridge genuine missing data into an unrealistically smooth record. Inject a known weak calibration tone through the same receiving chain to challenge the estimator at the relevant level. Finally, require a second independently clocked capture or a controlled source perturbation that agrees with the predicted transfer law. Replication of a causal response is better than perfecting one plot. The test should explicitly record the carrier-tracking bandwidth, because a narrow tracking loop may filter out the very transient sought, while an excessively wide loop can follow interfering noise.

Copyright 2026, James M. Atkinson

Reprocessing cannot recover observations removed before digital storage by the original analogue tracking configuration.

Dennis Gabor, Cross-Peer Question to Ronald Newbold Bracewell: Professor Bracewell, my phase residual can be remarkably stable even when I have not established whether the two frequencies were emitted by one physical antenna or by separate radiators driven by a common clock. Which spatial measurements would discriminate these cases? Please consider that the harmonic and fundamental may propagate differently through walls, cable shields and antenna patterns, so simple agreement in received strength at several points may mislead. How would you combine phase, direction and independently calibrated propagation measurements without assuming the very common-source claim that we are trying to test? I would particularly value a method that identifies what cannot be concluded when the survey team has observations from only one room and no authority to perturb the suspected electronics. Would the uncertainty budget need distinct terms for station geometry, antenna calibration, sample-time alignment and propagation before such a spatial comparison could support source identification? If those terms cannot be separated, which observations remain defensible?

Ronald Newbold Bracewell, Cross-Peer Answer to Dennis Gabor: Professor Gabor, the spatial experiment should begin by defining what 'same source' means. One oscillator may drive two radiating structures at different positions; two oscillators can drive one antenna system through a combiner; and a receiver can generate a line internally without any second external field. Thus even proof of a shared oscillator does not, by itself, prove one radiating location. Use independently calibrated antennas and receivers to

Copyright 2026, James M. Atkinson

estimate bearings, field polarisation, and position-dependent amplitude or delay at both frequencies, while controlling for their different antenna responses and propagation paths. A purported coincidence must be compared with the actual uncertainties of those measurements.

For a controlled installation, measure at multiple surveyed positions and include a known calibration radiator at each frequency to estimate the environment's transfer response. If the observed component follows the test antenna's position or orientation while a locally injected reference feature remains fixed, the field hypothesis gains support. If the line persists into a properly terminated RF input and follows the reference cable or instrument enclosure, an instrumental coupling pathway becomes more plausible. Test the two frequencies independently because a filter or cable can introduce frequency-dependent nulls. Do not assign one geographical coordinate by merely intersecting uncalibrated amplitude maxima.

Where access is limited to one room, the result should remain a bounded statement of compatibility. An investigator can report that the measured lines show a stable harmonic phase relation and spatial patterns compatible with a common drive, but cannot exclude multiple radiators or a distributed reference network. The evidence becomes stronger through independent measurements of reference-plane input, frequency-transfer behaviour and antenna substitution. The spatial observations should challenge the spectral hypothesis, not be selected and processed to reproduce it. An honest uncertainty region may be broad, and an attribution may be withheld even when the frequency relation is measured accurately. A formal record should

Copyright 2026, James M. Atkinson

identify which spatial comparison was actually carried out and which was merely proposed. It is especially important not to transform a suggested laboratory experiment into the language of an accomplished field verification. In addition, a source attribution should retain uncertainty about any unmeasured path delay or frequency-dependent radiation pattern. Those alternatives must be stated before the final finding.

Dr. James M. Atkinson, Moderator: Professor Bracewell, we have traced possible harmonic mechanisms through nonlinear devices, feedback loops and time-frequency analysis. Please now address the evidential boundary between common phase behaviour and identification of a source, and develop a survey protocol suitable for a lawful technical surveillance countermeasures examination.

Ronald Newbold Bracewell, Fifth Principal Contributor: Dr. Atkinson, the spectral problem becomes a source-attribution problem only after the investigator demonstrates that the observations are associated with the external environment rather than solely with the receiving instrument. A harmonic ratio is a relationship between measured frequencies. Phase coherence adds information about a common driving process. Neither fact automatically identifies an antenna, a physical enclosure or an individual transmitter. Radiation is mediated by conductors, shielding imperfections, cabling, reflections and antenna geometry. One oscillator may feed multiple distant radiators, while separate oscillators may be synchronised by one reference. The spatial experiment is therefore a separate necessary layer of inference, and it must be designed without presupposing the answer that the spectral analysis is intended to support.

Copyright 2026, James M. Atkinson

Suppose two signals are observed near f and 2f. Their free-space wavelengths are $\lambda=c/f$ and $\lambda/2$ respectively, where c is propagation speed in free space. A piece of conductor that is electrically short at f may be a more efficient radiator at 2f, while shielding or cavity resonances may act differently. As a consequence, the field-strength maxima for the two components need not occupy the same points even if they originate from the same circuit. Conversely a room's multipath can cause unrelated emitters to have nearby local amplitude maxima. The investigator must avoid the appealing but invalid inference that matching amplitude heat maps prove one source or that different maxima disprove common generation. Frequency-dependent propagation and antenna patterns must be measured or bounded.

A first control uses a clearly documented measurement reference plane. Record each antenna's calibration or measured response at both frequencies, its polarisation, its orientation and its cable transfer characteristic. Record preamplifier gain and linearity, filtering, receiver attenuation, and local oscillator state. Compare an antenna-connected measurement with a properly terminated RF input, noting that termination can alter common-mode coupling and does not necessarily remove radiation directly entering the enclosure. Then use an alternate receiver architecture and independent frequency reference where available. If a line persists in a terminated channel and changes with the receiver's own clock configuration, it is unsafe to count it as a second external emitter without further challenge.

Copyright 2026, James M. Atkinson

A second control maps space and polarisation. At surveyed points, measure both frequencies with enough angular diversity to distinguish a directional response from a local null. A field is vectorial; rotating a linearly polarised antenna can substantially change received power even when the source remains unchanged. An antenna null can create a false-negative indication that tempts an operator to localise a weak source at the strongest available reading. Repeat with more than one antenna orientation, and distinguish near-field coupling to conductors from far-field plane-wave assumptions. The dimensions of a room and the wavelengths of interest determine whether a simple inverse-distance model is appropriate. A sharp local maximum near a metal cabinet could be a resonance or cable current, not the oscillator itself.

A third control uses time and covariance. A long enough phase record can compare whether frequency drift and sideband motion remain related across periods when the receiver configuration changes. However, a shared clock between all receiver channels can create artificial agreement. Write a common-cause model in which measured component phases depend on the emitter, path delays, channel local oscillators and a possible shared reference. If two station records are combined, calculate their differential uncertainty with cross-covariance terms rather than assuming independent errors. A strong positive covariance can cause the arithmetic difference to appear more stable even while absolute phase is wrong. State whether the inference concerns a relative phase relation or an absolute timing claim.

The most useful experiments are counterfactual. If the suspected oscillator

Copyright 2026, James M. Atkinson

belongs to equipment the investigator is authorised to test, apply a small safe frequency or phase perturbation while an independent instrument observes the candidate source directly and the receiving array observes the suspected field components. The proposed harmonic should exhibit a predictable n-fold frequency response, subject to the device's transfer characteristics. If two sources are simply locked to the same reference, a reference perturbation may affect them both, but an adjustment made to only one oscillator after the branching point may not. If the receiving chain generated the harmonic internally, attenuation and filtering placed before the nonlinearity can expose that mechanism. Every perturbation changes the experimental state, so preserve the original unaltered record and do not treat the diagnostic response as a historical observation.

Where perturbation is forbidden or unsafe, seek diversity of measurement rather than inventing certainty. Use independently clocked hardware; compare observations from different antenna locations; test receiver linearity with a separate laboratory stimulus; measure known cable and enclosure leakage paths; and inspect whether the frequency relationships persist after physically separated receivers are substituted. Keep negative findings with stated sensitivity and observation coverage. A harmonic absent in one measurement may be below its detection limit, outside the antenna's pattern, or extinguished by a filter. Non-detection does not automatically exclude an emitter, and successful detection does not automatically identify its location.

For the statistical conclusion, define hypotheses carefully. H_A may denote

Copyright 2026, James M. Atkinson

one oscillator producing the observed harmonic externally; H_B two physically separate oscillators coupled through a common standard; H_C one external carrier generating a second harmonic in the receiver; H_D unrelated sources appearing related after search selection. The candidate tests should have distinct predicted outcomes under at least some of these hypotheses. If every available test gives the same prediction under H_A and H_B, the two remain observationally indistinguishable in that experiment. No number of repeated uninformative observations can eliminate the ambiguity. A later source attribution must therefore be framed as conditional or withheld until a discriminating experiment becomes possible.

I would require a source report to enumerate the identified spectral components, calibrated reference planes, measured phase relationship, observation duration, data losses, tested input attenuation, receiver substitutions, antenna orientations, source perturbations, and any remaining common instrumentation. It should distinguish a detected line, a classified harmonic family, a shared reference mechanism, a radiating structure, and an attributed source. Each ascending category requires new evidence. Forensic reproducibility is best served when a reviewer can replay the original samples, reproduce the calculations and identify which assumption, if changed, would alter the conclusion. This is the difference between a disciplined engineering finding and a persuasive-looking but untestable narrative.

George Edward Pelham Box, Peer Question: Professor Bracewell, you have presented several hypotheses, but a laboratory instrument can rarely reproduce the exact multipath, cable routing and intermittent behaviour

Copyright 2026, James M. Atkinson

encountered in a field installation. How should an analyst use a simplified source model without confusing its good fit with proof that the model is correct? If two hypotheses make nearly identical predictions for the recorded spectral lines, does additional numerical precision materially improve the inference, or is it necessary to choose a new experiment? I should also ask how one documents a negative result from a terminated antenna input where the act of termination may alter common-mode currents or the gain state. Can a rigorous final report communicate unresolved competing explanations without implying that all explanations have identical plausibility? What would constitute a disciplined rather than merely rhetorical treatment of model limitations? I should further distinguish a failure to identify the unique source from a failure to measure the frequency relationship itself. How might the examiner preserve that useful quantitative relationship while expressly withholding geographical attribution?

Ronald Newbold Bracewell, Response: Professor Box, a model should be judged by the questions it can answer and the conditions under which its predictions have survived tests. An exact fit of the observed harmonic ratio is weak evidence if several physical hypotheses predict the same integer ratio. Measurement precision improves estimation within a given model, but it cannot resolve a structural lack of identifiability. The appropriate remedy is a new experimental contrast, such as changing an independent reference path, measuring at a different RF plane, or applying a controlled source perturbation whose predicted response differs among hypotheses. One should not simply add more decimal places to an equation with several equally plausible causes.

Copyright 2026, James M. Atkinson

The terminated-input experiment illustrates the issue. A signal that disappears after a connector is terminated could have entered through the antenna, but the termination may also change impedance, suppress a common-mode current, alter an amplifier's stability or trigger automatic gain changes. Record all of those potential mechanisms and measure the detector's sensitivity and noise floor in the new state. Repeat with alternative terminations or a controlled injected reference signal where appropriate. If the line persists, investigate coupling around the input connector; if it disappears, state that this response supports an input-path dependence under the tested conditions, not the existence or identity of a particular transmitter.

Model comparison should be grounded in distinct predictions. For H_A, a controlled change in the suspected source frequency should cause the harmonic to move with the predicted multiple. For H_B, changing only one branch downstream of a common reference can break that relation. For H_C, internal generation should respond to receiver-side attenuation or architecture changes according to its transfer law. For H_D, a preregistered observation with independent clocks may fail to reproduce the coincidence that was selected retrospectively. If an experiment does not distinguish hypotheses, the report should state the unresolved equivalence. One can still rank explanatory support qualitatively based on completed tests, while avoiding numerical likelihoods unsupported by measured error distributions.

Copyright 2026, James M. Atkinson

Finally, preserve the exact model version, calibration data and sensitivity analyses. A defensible conclusion may say that one hypothesis explains the present observations with fewer unverified assumptions, while identifying a specific remaining test needed to distinguish it conclusively. That is not indecision; it is the honest boundary of what the instrument and experiment have demonstrated. A useful scientific model is one that can be challenged, corrected and ultimately replaced as new observations become available.

Dr. James M. Atkinson, Moderator, Closing Synthesis: The panel distinguishes five separate propositions: an integer frequency relation; matching sideband offsets; phase or frequency co-movement; a physical common driving mechanism; and identification of one external source. The first three can be demonstrated by appropriate measurements, but cannot alone establish the last two. A harmonic generated at a transmitter and a harmonic generated inside a receiver can obey the same phase law. Two separate synthesisers locked to one reference can exhibit phase coherence without sharing the same free-running oscillator. Coherent external modulation and signal-processing bias may imitate either arrangement. The strongest evidence comes from independent receiver chains, calibrated reference planes, attenuation and filtering tests, source and reference perturbations, phase-transfer measurements, spatial field challenges, and full preservation of contrary observations. The dialogue is a fictional scholarly reconstruction; its worked examples are hypothetical and must not be represented as observations from a particular security engagement.

QUESTION 073. TECHNICAL SOURCE REGISTER AND PUBLICATION QUALIFICATIONS

QUESTION 074

Copyright 2026, James M. Atkinson

How do adjacent-channel leakage and selectivity change site-to-site occupancy comparisons?

Dr. James M. Atkinson, Moderator: Dr. Pierce, two authorised survey teams report that a nominal twelve-and-a-half-kilohertz channel is busy on forty-eight per cent of observations at Site A but on twenty-one per cent at Site B. The nearest transmitter is stronger at Site A, and the receivers nominally share a frequency plan, though their analogue preselectors, digital filters and detection thresholds differ. Is their reported discrepancy evidence of a real difference in channel use, or could it be manufactured by the observing systems? Please examine the inference in its entirety and pass the token to a colleague when the engineering limits become apparent.

John Robinson Pierce, Principal Contributor: Dr. Atkinson, the disagreement begins with the meaning of the word channel. A frequency allocation is an administrative interval, a transmitted waveform occupies a spectral distribution, and a receiver creates its own effective band by applying a frequency response to voltages arriving at its input. Those three objects overlap without being identical. When a powerful adjacent transmitter creates sidebands outside its nominal centre, those sidebands are physical radiation. When a broad receiver admits part of the adjacent transmitter's otherwise legitimate emission, the leakage is a consequence of observation. When an overloaded amplifier produces mixing products, the apparent in-channel energy is created inside the measuring chain. It is essential to distinguish all three pathways before saying that Site A has more legitimate occupancy than Site B. Even if the same physical field exists

Copyright 2026, James M. Atkinson

at both positions, distinct receiving filters can assign different detected states to the same frequency bin.

Consider a baseband representation. Let S(f,t) denote the received power spectral density at radio frequency f and observation time t, expressed in milliwatts per hertz. Let H_i(f;f_c) denote the complex voltage transfer function of receiver i about the nominal channel centre f_c, with its gain normalised at the reference plane. In a linear, stationary approximation, the receiver-equivalent power is P_i(t)=integral over f of |H_i(f;f_c)| squared times S(f,t), integrated across the relevant measurement band. A noise term N_i(t) must then be included at the same reference plane. The classification B_i(t) equals one if the measured quantity exceeds the explicitly declared threshold T_i, otherwise zero. A reported occupancy O_i is the number of accepted busy observations divided by the number of eligible observations, with sampling weights declared when records differ in duration. The formula is not an assertion that the instrument remains linear. It is a testable model whose failure must be investigated by level sweeps and independent receivers. A receiver with automatic gain control, clipping, image response or digital overload requires additional state variables and cannot be represented safely by a static H_i alone.

A worked example clarifies the danger. Suppose an adjacent-channel emitter delivers minus forty-five dBm to the receiver's input during a particular burst. After a measured forty-five decibels of attenuation through the observation channel's selectivity response, the contribution is minus ninety dBm. An occupancy threshold of minus ninety-five dBm marks the nominally empty channel as busy. If another receiver attenuates that same off-centre signal by fifty-five decibels, its indicated contribution is minus one

Copyright 2026, James M. Atkinson

hundred dBm, below the same threshold. The first instrument reports a busy sample and the second an idle sample although neither has shown that the transmitter of interest actually used the surveyed channel. The arithmetic uses dBm only after calculating a power ratio in decibels; two independent contributions must be added as linear milliwatts, not by adding the numerical dBm values. With an independent minus one hundred dBm noise-and-interference component, the first receiver would indicate about minus eighty-nine-point-six dBm total, rather than minus one hundred and ninety dBm. That distinction is not pedantry. It determines whether an apparent occupancy discrepancy is traced to actual emissions or merely to an improperly represented instrument response.

There is a second ambiguity concerning the bandwidth that defines the power measurement. A three-decibel increase in white-noise power accompanies a doubling of equivalent noise bandwidth when the density is unchanged; it is not evidence of an additional transmitter. The equivalent noise bandwidth B_eq is the integral of |H(f)| squared over frequency, divided by the peak squared response, under a stated normalisation. Two filters each described as a twelve-and-a-half-kilohertz channel may possess different skirts, passband ripple and B_eq. One may accept a broad adjacent signal strongly while another suppresses it. A third receiver may integrate a wide intermediate-frequency stage and apply a narrow display filter only after nonlinearity has already occurred. That display can look impressively selective while the input amplifier remains susceptible to blocking. We must document selectivity at the earliest stage where the unwanted energy can cause a change, not merely photograph the attractive final trace.

Copyright 2026, James M. Atkinson

The experiment should therefore have three layers. First use a controlled weak wanted carrier on the channel and a second generator, separated by precisely one channel spacing, to obtain the upper and lower adjacent-channel rejection curves at several input levels. Secondly replay the same captured complex waveform through both digital filters while disabling gain adaptation, thereby isolating analysis-filter differences from antenna, propagation and preselector effects. Thirdly expose each whole receiver chain to the same calibrated wanted-plus-unwanted signal at levels that bracket the field levels observed during the survey; if the classification divergence appears only at high levels, a nonlinearity or gain-control transition deserves particular attention. The result should report response curves and their uncertainty, not a single heroic selectivity number divorced from operating conditions. The two-input approach resembles the controlled receiver selectivity method in ETSI EN 300 086, but that equipment standard's defined performance criterion is not itself an occupancy-correction algorithm. For occupancy practice the more appropriate current context is ITU-R Report SM.2256-2 (June 2026), which expressly treats selectivity, detection thresholds, observation timing, measurement sites and the combination of neighbouring frequency samples.

I would refuse to pool the original percentages until the two measurement operators are shown to have comparable behaviour or a common raw-data reprocessing procedure can be defended. Forty-eight per cent and twenty-one per cent may be mutually consistent descriptions of different operational detectors. Neither proportion is intrinsically wrong, but neither is a demonstrated estimate of an instrument-independent channel-use

Copyright 2026, James M. Atkinson

probability without calibration and modelling. Preservation of the unthresholded power records, receiver configuration, attenuator state, timestamps, measurement reference planes and any rejected or saturated observations is indispensable. Once those objects are archived, investigators can repeat a common classification and quantify the residual difference attributable to geography. Until then, the claim should be styled a difference in reported detector occupancy, not a proven difference in emitter behaviour. This is the distinction on which a defensible forensic comparison turns.

Walter Andrew Shewhart, Peer Question: Dr. Pierce, a field instrument often produces an appealing single occupancy percentage, but an engineer cannot inspect its hidden decision variability merely by reading the display. Suppose repeated adjacent-signal injections produce passband levels that drift with internal temperature, while the software threshold itself is periodically recalculated from the recent noise estimate. The team then calls the two sites different because the reported busy proportions differ, although the calibration conditions have not been controlled. Would you distinguish ordinary process variation from a real change in the measurand, and prescribe a repeatability experiment that can reveal both a drifting selectivity function and a moving threshold? I also ask you to address the awkward case in which the injection signal itself disturbs automatic gain control. The test should preserve enough raw evidence to permit another laboratory to challenge the classification without access to the proprietary detector code, and it should not hide correlated observations beneath a single reassuring confidence interval.

Copyright 2026, James M. Atkinson

John Robinson Pierce, Response: Dr. Shewhart, an instrument must be assessed as a process whose output depends upon thermal history, input level, sampling time and software state. I would not begin with the assumption that every difference from a nominal calibration number is random Gaussian noise. Use a stable, traceable two-tone injection with the wanted carrier and adjacent interferer presented at known input reference levels. Repeat the identical acquisition at cold start, after thermal equilibrium, after a level step, and after a return to the initial level. Record not only detected busy states but predecision power estimates, gain states, overload indicators, threshold values and the temperature observable. An apparent site difference can then be compared against the instrument's own within-condition distribution before attributing it to propagation or transmitter operation.

An economical design includes randomised order and deliberate reversal. For example, run low-high-low adjacent input levels within a single controlled session; if the final low-level measurement differs from the initial low-level measurement, hysteresis or settling deserves investigation. Repeat that sequence at two temperatures rather than assuming one environmental state. If the test waveform triggers automatic gain control, that response is itself a property of the configured observation system, so report one experiment with gain control enabled and another with it fixed, if technically available. Do not merge the resulting figures as though they described the same detector. A control chart may help identify temporal instability, but it is not a substitute for quantifying frequency-dependent bias or proving that a declared decision threshold represents the same physical power at both sites.

Copyright 2026, James M. Atkinson

A blind replay is particularly valuable when the proprietary code is inaccessible. Archive an authenticated baseband recording at a defined interface, accompanied by a calibrated amplitude scale and sample rate; submit the identical sequence to both analysis chains, including a record of their actual thresholds at each epoch. Another laboratory can then determine whether disagreement follows the software or the analogue front end. Compare an additional simple and transparent reference classifier applied to the same record. Such a classifier should not be treated as perfect ground truth, but it establishes a stable benchmark for identifying logic differences. Measure correlation across neighbouring samples because a strong adjacent burst often produces a run of positive decisions. A thousand consecutive positive samples are not a thousand independent observations of selectivity. The confidence statement must respect the clustering structure or be obtained by resampling at the burst or session level. This preserves the statistical distinction between repeatable instrument bias, ordinary random variation and real site conditions.

W. Edwards Deming, Peer Question: Dr. Pierce, the proposed comparison has an administrative weakness as well as an electrical one. One team may label the coaxial connector at the preselector output as the measurement reference plane, while another reports field strength at the antenna location after applying a nominal antenna factor. Their calibration certificates are genuine yet the results cannot be reconciled because cable losses, frequency-dependent gains and detector settings have different definitions. How ought a forensic laboratory structure its measurement-control plan so that a later reviewer can reproduce the chain of custody from incident field to occupancy declaration? Please explain whether an observed excess

Copyright 2026, James M. Atkinson

occupancy should be corrected numerically at once, held as a qualified observation, or rejected pending additional calibration. Finally, identify the minimum metadata you would require before allowing figures from two sites into the same statistical table. I would also want an explicit rule for preserving failed measurements, since silently discarding a receiver overload or a disrupted calibration can make a superficially complete dataset less reliable than a candidly qualified one. Which evidence should be sealed before any subsequent adjustment?

John Robinson Pierce, Response: Dr. Deming, the unit of comparison must be named before either team begins counting. If the measurand is incident electric field at a defined point, the antenna response, cable transfer, preamplifier characteristics and receiver calibration must be linked to that physical quantity. If the measurand is receiver-input power, the reference plane belongs at the input connector and antenna conversion is a separate interpretive problem. Mixing the two in one occupancy table produces spurious precision even if every calibration certificate is authentic. A sound procedure therefore records a block diagram with named reference planes, a serial-numbered signal path, the configuration and firmware of each active instrument, and a signed acquisition protocol. The log must include antenna orientation, mounting height, cabling, input attenuation, filter identity, bandwidth, acquisition timing, threshold rule and overload indicators. A field-strength estimate additionally needs an antenna factor or effective-aperture model with frequency and orientation dependence.

A numerical correction should be applied only where the physical mapping is supported by observed response data and the measurement remains inside its validated range. When the strongest adjacent emission pushes the

Copyright 2026, James M. Atkinson

first amplifier beyond its linear range, no scalar correction to the displayed occupancy proportion can reconstruct the lost information. Mark the affected observation as qualified, preserve it and acquire a replacement measurement if circumstances permit. Where raw complex samples are available from a demonstrably linear front end, reprocessing through a common matched filter can be legitimate, provided the anti-alias filtering and recorded bandwidth retained the necessary spectrum. Where the receiver irreversibly clipped or suppressed a wanted signal through gain control, the data may establish that the scene was RF-crowded but cannot establish the counterfactual occupancy under an undisturbed receiver.

For an audit table, I would insist upon independent identifiers for site, session, channel, receiver chain, configuration and calibration state, together with absolute timestamps and uncertainty in synchronisation. Each observation should have a declared analysis duration, centre frequency, equivalent noise bandwidth, power reference, decision threshold, classifier version and known exclusions. Store evidence hashes and the original instrument files so the meaning of a percentage can be reconstructed rather than trusted by reputation. A cross-site summary should flag observations that satisfy a common equivalence test and place the rest into separate methodological strata. It is acceptable to conclude that present evidence does not support comparison. That conclusion is analytically stronger than an apparently exact numerical correction whose assumptions have never been demonstrated.

John Robinson Pierce, Cross-Peer Question to Hendrik Wade Bode: Dr. Bode, my integral model assumes a receiving filter whose response remains stable at a specified reference plane, and my example suggests that

Copyright 2026, James M. Atkinson

different skirts may produce incompatible occupancy classifications. Yet a front end may contain several frequency-selective elements before digitisation, and its overall response may be altered by feedback, temperature or overload. How would you separate the useful linear transfer-function description from behaviour that violates superposition? Please address the temptation to quote one adjacent-channel selectivity figure as though it defined every frequency offset and input amplitude, and explain what a control engineer can infer from a measured gain-and-phase response without assuming that the filter itself has generated a particular spectral line. I wish to know precisely which engineering tests would make a site-to-site correction defensible. Please compare an ideal small-signal measurement to the actual blocked receiver under a two-tone challenge, because a site-to-site correction must survive the joint operating condition and not rely upon a specification obtained with the unwanted source absent.

Hendrik Wade Bode, Cross-Peer Answer to John Robinson Pierce: Dr. Pierce, a transfer function is a relationship for an operating condition, not a permanent identity card attached to an instrument. Under linear time-invariant assumptions, a cascade of stages possesses a frequency-domain response equal to the product of the stage responses, provided impedances and loading are properly incorporated into their characterised network behaviour. The magnitude tells us the attenuation applied to individual spectral components, and the phase describes their delay relationship. It does not tell us how a nonlinear amplifier will respond to the simultaneous presence of a strong adjacent carrier and a weak wanted signal. A gain

Copyright 2026, James M. Atkinson

curve measured with a single quiet tone cannot by itself establish the behaviour under a crowded two-tone field.

I would measure a response matrix across offset frequency and input amplitude. At each offset, inject the unwanted signal with a calibrated wanted signal and measure desired-channel output degradation, spur appearance and gain change. Repeat above and below the centre because physical filter asymmetry may be material. Record the threshold and detector response, as these are subsequent system functions rather than merely passive filter properties. Where a receiver contains separate analogue and digital filters, test them independently if practical, then test the complete cascade. A stage that creates intermodulation at its own input cannot be redeemed by a beautifully narrow digital display downstream; the unwanted product may fall directly into the wanted channel and pass the final filter unhindered.

A useful thought experiment is to increase both applied signals by ten decibels while preserving their difference. In a linear system, output powers scale by ten decibels and the ratios among corresponding spectral components remain fixed, apart from the noise floor. Nonlinear intermodulation products can grow at different slopes, and gain compression can decrease the wanted response. The exact slopes are device- and level-dependent, so do not use a textbook third-order exponent beyond the range in which it has been measured. For a defensible correction, confirm that the original acquisition operated within the demonstrated linear range; measure both channel skirts and effective bandwidth; account for all front-end signal pathways; and propagate uncertainty in the conversion from observed power to the common

Copyright 2026, James M. Atkinson

reference quantity. Only then is the transfer function a corrective instrument rather than a decorative diagram.

Dr. James M. Atkinson, Moderator: Sir Edward Appleton, Dr. Pierce has identified the filtering and decision problems. Would you take the token to examine the field itself, particularly the distinction between a genuine geographical difference in received RF energy and a difference manufactured by measurement selectivity? The question is not whether propagation exists, but whether an apparent difference in channel occupancy can legitimately be attributed to transmitters when the instruments view different spectral mixtures.

Sir Edward Victor Appleton, Second Principal Contributor: Dr. Atkinson, a radio survey meets a physical landscape before it meets a statistical one. Fields differ in amplitude, polarisation, angle of arrival, path delay and frequency selectivity across sites. A high-power neighbouring transmitter may reach one site through a strong unobstructed path and the other only after shadowing and reflection. That disparity is genuine propagation, yet the resulting apparent occupancy of the nominal surveyed channel may be artificial if the detector cannot distinguish the neighbour's energy from actual use of the wanted allocation. The distinction is causal. A propagation difference can explain why the instrument encounters different unwanted energy, but it does not prove that the intended channel is occupied more often. We must not confuse a real environmental cause of a false positive with the underlying event that the false positive purports to report.

Let W_s(t) denote the true wanted-channel signal at site s, A_s(t) the aggregate adjacent-channel interference at the antenna reference point,

Copyright 2026, James M. Atkinson

and R_s(t) the receiver's additional instrumental response. A simplistic scalar model is Y_s(t)=G_w,s W_s(t)+G_a,s A_s(t)+R_s(t)+N_s(t), where G_w,s and G_a,s are effective gains under a linear power-domain approximation and N_s represents noise. In a complete spectral model these gains are integrals over frequency, angle and polarisation. The reported busy state is the output of a threshold decision applied to Y_s. An analyst who observes Y_A frequently exceeding threshold and Y_B rarely doing so cannot infer that W_A occurs more often than W_B without examining A and R. The unobserved decomposition is an identifiability problem; many combinations of wanted activity and adjacent leakage can generate the same occupancy percentages. More sensitive equipment alone does not solve identifiability. Sensitivity may increase the number of weak actual emissions detected and the number of adjacent spurs falsely admitted.

Different geographical sites may also create unequal observations of the same wanted transmitter. Suppose a weak signal arrives at minus one hundred and two dBm at Site B during an event and minus ninety-four dBm at Site A. With a fixed threshold of minus ninety-eight dBm and an otherwise comparable receiver chain, Site A identifies the event while Site B does not. The detection disparity may be a legitimate difference in the probability of observing the same transmitter, not in the transmitter's actual duty cycle. Propagation, antenna placement and receiver noise all enter that probability. A cross-site occupancy table must distinguish emitted duty cycle, received signal-above-threshold occupancy and instrument-reported busy time. Those are three related but nonidentical quantities. Where the object of a forensic enquiry is whether an RF emitter was present, negative

Copyright 2026, James M. Atkinson

evidence at a disadvantaged site must be conditioned on the probability of observing it under the conditions actually encountered.

The remedy is not to erase geographical information by fiat. Establish a reference transmitter or controlled portable radiator with known emissions and observe it from both sites, using safe authorised test conditions and documented distances and polarisations. If a signal cannot be radiated, a conducted injection isolates the receiver but does not reproduce propagation, antenna effects or site noise. The two controls answer different questions and must not be represented as interchangeable. A geographically stable signal at a known frequency may help check the relative power scale, but it is not necessarily a suitable calibration reference for pulsed emissions or a different polarisation. The investigator needs an uncertainty budget for each transfer step, from incident field through antenna and cable to decision, and should acknowledge that propagation can vary during the session. The inability to make an exact point-by-point correction does not authorise pretending that site differences are negligible.

There is a further issue of temporal coincidence. Site A may monitor at midday, Site B after dark, and a channel occupied by intermittent infrastructure may change through operating schedules rather than geography. In ionospheric bands the propagation mechanism itself may vary substantially with time, but even a local line-of-sight channel can be affected by moving reflectors, doors, machinery, vehicles or humans. To isolate a site contrast, obtain simultaneous paired observations where feasible, with time synchronisation adequate to the burst durations of interest. If a shared clock cannot be provided, record the uncertainty of alignment and compare over time bins broad enough to remain meaningful.

Copyright 2026, James M. Atkinson

A site comparison that combines noncontemporaneous samples without describing its temporal target estimates two different mixtures of location and operating period. The resulting difference is mathematically real yet scientifically ambiguous.

A proper report therefore gives separate fields for raw observed occupancy, controlled-detector-equivalent occupancy and qualified channel-use inference, where the last is permitted by the evidence. It may state that both sites observed substantial activity in the neighbourhood of the channel while attribution to the central allocation remains unresolved. It may also state that the adjacent emitter was stronger at one site, which supports a specific mechanism for false busy classifications. What it must not state is that the central transmitter operated for forty-eight per cent of a given period merely because forty-eight per cent of detector outputs were high. This disciplined separation of physical field, receiving chain and causal attribution is the best safeguard against transforming propagation science into an unwarranted narrative of surveillance activity.

John Wilder Tukey, Peer Question: Sir Edward, many analysts attempt to rescue an inadequate design with a sophisticated plot after the fact. Imagine that two survey sites have unequal receiver response, different antenna orientations, and incomplete logs, but retain timestamped power traces covering overlapping periods. One analyst aggregates every reading into a single busy fraction; another bins the data by hour and signal level; a third uses the strongest neighbouring carrier as a covariate. Which exploratory comparisons may genuinely diagnose an adjacent-channel mechanism, and which could produce a persuasive but spurious correlation? Please consider a case where the interferer and the suspected wanted

Copyright 2026, James M. Atkinson

transmitter share an operational timetable. Their temporal correlation might make the adjacent carrier appear to explain every event while obscuring a real co-channel signal. How should the analysis present uncertainty and competing causal accounts without hiding the unmeasured settings behind charts? Please identify one exploratory graphic that might falsify the preferred interpretation and explain why the team should retain it in the formal audit record rather than discard it because it is awkward or statistically unflattering.

Sir Edward Victor Appleton, Response: Dr. Tukey, the first plot should show the raw timing relationship with as little inferential machinery as possible. Place the nominal-channel power, neighbouring-channel power, threshold setting and instrument gain state on aligned axes, retaining gaps and missing periods. If the apparent central-channel busy intervals begin and end at precisely the same times as strong neighbouring bursts, that is evidence consistent with leakage; it is not yet proof that the desired channel contains no signal. Observe whether the size of the central response tracks the adjacent power according to the independently measured filter skirt. Where the central response persists after the adjacent emitter stops, or follows a different modulation envelope, a separate source becomes more plausible. A correlation can also arise because both emitters run on a common site schedule, so the strength and timing relationship should be challenged by physical perturbation where the enquiry permits it.

The useful exploratory strata include receiver configuration, band, hour, threshold, temperature and interfering-signal strength. Each stratum should retain a denominator equal to eligible observation time rather than to whichever records survived a convenient filter. Display the number and

Copyright 2026, James M. Atkinson

length of observed sessions; otherwise a visually dramatic small subgroup may dominate interpretation. Plot upper and lower adjacent channels separately because asymmetric skirts may make one side particularly dangerous. Compare periods during which the suspected neighbour is absent with periods when it is present, while explicitly acknowledging that the wanted transmitter may also change state. A regression coefficient estimated from such data is a description of association within the sampled conditions; it is not a physical leakage coefficient until an injection test establishes the relevant transfer relationship.

If only incomplete metadata survive, report bounds or a sensitivity analysis instead of a fictional exact correction. For example, recompute the apparent busy fraction after excluding all times with neighbour power above a conservative threshold, then repeat under less restrictive thresholds. The resulting interval is not a confidence interval for true occupancy, because removing strong-adjacent periods can also remove genuine wanted activity. It is an indication of how heavily the conclusion depends on potentially contaminated data. A separate negative-control channel with no plausible assigned emitter but similar filter offset can expose leakage patterns, provided it has comparable spectral conditions. Such controls are useful precisely because they can refute a simplistic account. Preserve alternative graphs that do not support the preferred hypothesis, and document any choice of strata made after seeing the data. In an evidential report, transparency about exploratory decisions is more valuable than the cosmetic certainty of a single percentage.

Sir Edward Victor Appleton, Cross-Peer Question to John Daniel Kraus: Dr. Kraus, your antenna work reminds us that a nominal channel does not

Copyright 2026, James M. Atkinson

arrive as a single scalar number. Two frequencies separated by only one allocation spacing can have different angular fields, antenna impedances, near-field coupling or polarisation at the observation point, especially inside a reflective structure. If the same portable receiver is moved from Site A to Site B, what spatial and polarisation controls would you require before treating its changed adjacent-to-wanted power ratio as a reliable propagation measurement? In addition, can a conducted substitution fully isolate antenna-induced adjacent-channel bias, or does it discard the very vector field information necessary to distinguish the competing signals? Please explain which observations remain possible without invasive changes to the investigated premises. Would you also distinguish an antenna reorientation conducted as a deliberate intervention from the ordinary variation of the incident field over time, so that the investigator does not attribute an unrelated fading event to the antenna rotation itself?

John Daniel Kraus, Cross-Peer Answer to Sir Edward Victor Appleton: Sir Edward, a receiving antenna responds to the vector electric field, its own polarisation and its directional pattern, and the relationship may vary even over a modest frequency displacement when surroundings are electrically complex. A change of site can alter the apparent wanted-to-adjacent ratio because the two emitters arrive from different directions, not because the receiver's internal filter has changed. The field could contain multipath components whose phase differences create sharp spatial variations. We should therefore record antenna orientation and position with greater care than merely noting the room name. Where possible, sample a small, documented spatial grid while preserving the receiver settings; a dramatic

Copyright 2026, James M. Atkinson

pattern change over a fraction of a wavelength warns against treating one location as representative of the room.

Conducted substitution is necessary for instrument isolation but insufficient for characterising the external field. When a calibrated combiner injects two known voltages at the receiver connector, it removes antenna pattern, polarisation mismatch and most environmental coupling from the experiment. That is excellent for measuring the receiving chain's tendency to leak adjacent energy into the indicated channel. It cannot tell us whether the actual site field arrives through an unexpected polarisation, a nearby cable, or a reflection from structural metal. To address those questions without intrusive modification, one may employ controlled antenna rotation, small repositioning, a second well-characterised antenna and synchronous logging, provided such manoeuvres are authorised and do not disturb the evidence. The sequence and surroundings must be documented because changing the operator's stance can alter the field as surely as rotating the antenna.

The distinction between receiver selectivity and antenna selectivity should appear explicitly in any uncertainty statement. If an antenna is broadband and its response nearly constant across adjacent channels, that may be demonstrated, not assumed. A resonant or actively tuned antenna may instead favour one channel over another, effectively altering the spectral mixture presented to the receiver. The reported detector occupancy can then change with orientation even when no emitter changes state. A disciplined comparison includes both an antenna-terminal measurement, where feasible, and a documented radiated observation, with their different limitations. It is the correspondence of these independent controls, rather

Copyright 2026, James M. Atkinson

than a single attractive level ratio, that allows us to separate a real geographical contrast from the selective ears of the measurement apparatus.

Dr. James M. Atkinson, Moderator: Dr. Kraus, Sir Edward has traced the route from propagation to the instrument's antenna terminals. Please take the token and explain the spatially selective nature of a nominally simple occupancy measurement, particularly where antenna pattern, polarisation and cable currents transform a crowded spectral scene into an apparently localised channel event. I ask also for a practical method of determining whether changing an antenna has altered the phenomenon or merely the observer.

John Daniel Kraus, Third Principal Contributor: Dr. Atkinson, I shall begin with a warning that an antenna is not an indifferent funnel. It is a directional transducer whose response depends on field orientation, frequency, impedance and nearby conducting structures. A receiver may retain exactly the same frequency response after being moved, yet the power delivered to it from each emitter may change because the antenna responds differently to their angles of arrival and polarisations. Consequently two sites can differ in nominal channel occupancy even if the central transmitter's emission schedule is unchanged. The analyst must identify whether the desired quantity is the occupancy of the electromagnetic field at a geometrically defined site, the activity of a specified transmitter, or the fraction of occasions when a particular receiving arrangement produces an above-threshold indication. These objects are not interchangeable merely because the same dial frequency appears on the receiver.

Copyright 2026, James M. Atkinson

A simple receiving-power relationship illustrates the geometry. In an ideal far-field plane-wave case, available antenna power can be written P_av=S_inc A_e rho, where S_inc is incident time-average power flux density, A_e is the effective aperture in the incoming direction for the relevant frequency, and rho is a polarisation-mismatch factor between zero and one. The model assumes conjugate matching and does not describe an arbitrary reactive near-field environment. For a linearly polarised incident wave and a linearly polarised receiving antenna, rho=$\cos^2$ theta, where theta is the angle between the polarisation axes under the idealised geometry. At a sixty-degree mismatch, rho equals one quarter, corresponding to roughly six-point-zero-two decibels of loss. That reduction applies to one arriving component; a neighbouring transmitter arriving with a different polarisation may experience a quite different loss. If the central channel falls six decibels but the adjacent channel does not, the ratio presented to the receiver may increase six decibels without any modification to its internal selectivity. The spectrum display offers no direct notice of this vector-field transformation.

Directionality introduces a related hazard. A receiving antenna with a deep pattern null towards a wanted emitter may still present strong adjacent energy arriving from another azimuth. At Site A a reflector may steer the wanted emitter into the null; at Site B the geometry may shift the wanted energy towards a main lobe. The ratio between the wanted and unwanted energy can change dramatically even though both radiators retain the same transmit powers and duty cycles. One cannot remedy this by choosing a nominal antenna gain from a catalogue and applying it to every direction. The response G(theta,phi,f) must be considered at the actual angle, polarisation and frequency. For a small separation in frequency one might

Copyright 2026, James M. Atkinson

expect the same pattern, but the surroundings can produce sharply varying phase relationships. An antenna placed close to metal, a vehicle, a cable tray or a large window frame may be part of a coupled system for which free-space pattern assumptions are no more than an initial hypothesis.

A further complication is the feed line. A coaxial cable intended to carry differential or shielded signals may also carry external common-mode current along its outer conductor. That current can make the cable itself an inadvertent receiving element, changing the orientation response and introducing unwanted energy at other coupling points. A rotating antenna may give a reassuring angular minimum while the cable path continues to admit the adjacent transmitter. A physical test can compare deliberate cable routing, common-mode suppression and a truly independent receiving arrangement, but each adjustment changes the apparatus. It must be recorded as an intervention, not disguised as an innocuous repetition. In an evidential environment the investigator should minimise disturbance, document the before and after geometry, and avoid interpreting an improvement under altered configuration as proof of the original cause. A change in the measured signal is consistent with a coupling mechanism; it does not uniquely identify the transmitting source.

Consider the earlier minus forty-five dBm adjacent input. Suppose an antenna reorientation reduces the unwanted arrival by eight decibels while reducing the wanted arrival by only two. The unwanted-to-wanted ratio improves six decibels. If the detector operates close to threshold, a difference of that magnitude may eliminate a substantial number of false positives. The result is physical and repeatable, yet it tells us nothing directly about whether the wanted transmitter changed its own schedule.

Copyright 2026, James M. Atkinson

Conversely, an antenna change can make a weak genuine signal newly observable and increase measured occupancy. Thus a procedure that simply selects the orientation yielding the lowest indicated occupancy is especially suspect. It can optimise for blindness instead of for truthful measurement. Orientation should follow a predetermined sampling plan, with declared geometry and a rationale for representing the target field.

A practical defensive survey ought to include an antenna-control matrix. Record at least the antenna identifier, frequency response, polarisation, pointing, height, nearby conductors, cable route, and any preamplifier built into the antenna. Where access permits, use a second antenna of a substantially different response to determine whether the disputed indication follows an expected angular or polarisation dependence. With a fixed receiver, conduct an injected adjacent-signal test to isolate internal selectivity. With a fixed antenna, exchange the receiver for a calibrated independent receiver to test whether the anomaly follows its electronics. The order of substitution matters; changing antenna, cable and receiver simultaneously destroys the isolation of the causes. This is the logic of controlled experimentation rather than a collection of impressive but causally tangled screenshots.

Finally, represent uncertainty honestly. A laboratory antenna factor measured in a clear site cannot be applied without qualification to a reactive field beside a large conducting structure. When a site-to-site occupancy statement turns on a few decibels close to threshold, a poorly characterised antenna response may dominate the apparent difference. Rather than conceal that uncertainty, report a set of receiver-equivalent occupancy values over the controlled orientations and specify what range of antenna

Copyright 2026, James M. Atkinson

behaviour remains plausible. A clear audit distinguishes the spectrum entering the antenna, the voltage reaching the connector and the software state called busy. A comparison that survives changes among physically different receiving arrangements deserves more confidence than one that exists only in a single configuration. That confidence is earned by concordant evidence, not by the assumption that every receiving aerial is a transparent window into the same electromagnetic scene.

Andrey Nikolaevich Kolmogorov, Peer Question: Dr. Kraus, your argument seems to require a probability model over spatial configurations as well as over transmitter activity. Suppose a team's instrument occupies one location for two hours, is then moved a metre, and reports a different busy fraction. It would be tempting to call the change a random sample from spatial fading, but the two positions were chosen for operational convenience rather than by any probability design. Can the reported proportions be interpreted as estimates of an area-wide occupancy probability, or do they refer only to the particular receiver placements? I ask for a definition of the sample space and the role of a spatial weighting measure. Please also explain how an unknown polarisation distribution complicates the analysis and what a field team should do if it cannot randomise or exhaustively grid a secured room. The statistical model should not imply exchangeability among observations taken under different antenna orientations or receiver gains unless those circumstances are explicitly controlled or modelled. Could you state how that qualification should be carried into a report?

John Daniel Kraus, Response: Professor Kolmogorov, without a declared spatial population and selection rule, the two positions support conditional

Copyright 2026, James M. Atkinson

statements about the two measurement configurations, not an objective area-average. A probability measure may be defined over time and a chosen distribution of receiver locations, but the measure is part of the scientific claim. If the positions were selected because one was convenient and another seemed suspicious, the observed occupancy difference can be genuine while providing no unbiased estimate of the entire room. A uniform area weighting is one possible convention, but it need not correspond to the probability that an actual sensitive device or person occupies a location. A security enquiry may instead require a target-specific geometry, such as the positions of a conference table, equipment racks or wiring. The sampling objective must be declared, rather than smuggled into the denominator as though every measurement position represented an identical part of the space.

Let O(x,theta,t) denote the detector's binary state at position x, antenna orientation theta and time t under a fixed receiver configuration. A spatial-temporal summary might be the integral of O against a declared position-orientation measure mu and a temporal measure nu, divided by their total eligible measure. That mathematical expression becomes a meaningful site statistic only if the observation plan approximates those measures and the relevant receiver state remains controlled. In practice the antenna may be moved sequentially, so time variation can be confounded with position variation. Repeating a subset of reference positions before and after the movement sequence helps reveal such drift. A second stationary monitor can provide a contemporaneous indicator of common environmental changes, though its own antenna and filter remain imperfect. None of these

Copyright 2026, James M. Atkinson

controls creates randomisation retrospectively, but they can limit the plausible explanations for an observed contrast.

Unknown polarisation is best treated as a physical uncertainty rather than hidden under a convenient isotropic assumption. For an ideally linearly polarised wave, the cos-squared response predicts strong orientation dependence; for a mixture of waves with changing polarisations and directions, a single orientation may be unrepresentative. Obtain a small number of predetermined orthogonal or otherwise well-characterised orientations, preferably with the same dwell time and timing scheme. Report them separately before any weighted aggregate. If security constraints prohibit movement, state the coordinate and orientation of the sole observation and do not call its busy fraction room-wide occupancy. The most rigorous result may be a local measurement accompanied by a demonstration that a plausible change in polarisation or pattern could reverse the site ranking. Such a result is useful: it tells the investigator what additional evidence is required before interpreting the ranking as a transmitter-behaviour difference.

John Daniel Kraus, Cross-Peer Question to Sir Martin Ryle: Sir Martin, your radio interferometry experience addresses how an observing array can separate sources that overlap in frequency. In a cramped building, the channel of interest and a high-power adjacent transmission may both illuminate the receiving antenna, while reflections and cable coupling corrupt the field. Could spatially separated synchronous receivers help decide whether a disputed channel indication is an independent emission or leakage from the neighbour? Please distinguish source separation that follows from phase-consistent directional evidence from artefacts

Copyright 2026, James M. Atkinson

introduced by different channel filters and unsynchronised local oscillators. Also clarify why observing a deep spatial null in one receiver does not prove the absence of an emitter, and what measurements must accompany any claim of localisation. The possibility that two distinct radiators occupy almost the same angular position is especially troublesome. I ask whether your proposed direction evidence can still distinguish them through spectral timing, and how you would state an unresolved angular ambiguity.

Sir Martin Ryle, Cross-Peer Answer to John Daniel Kraus: Dr. Kraus, two or more spatially separated receivers may create a useful interferometric constraint, but only when their timing, phase response and measurement frequency are sufficiently controlled. A baseline measures phase differences related to the incoming wavefront, subject to ambiguity, multipath and instrumental phase. If an alleged in-channel signal is merely the spectral skirt of the adjacent transmitter admitted by each receiver, it may inherit the adjacent transmitter's direction of arrival. If it is an independent emitter, its spatial phase gradient may differ. Yet this distinction is conditional: two emitters can be nearly co-located, multipath can create complex apparent directions, and a receiver-generated product can inherit phase features of the external excitation. The experiment must be designed to compare explicit hypotheses, not to treat a directional map as a magical source identifier.

Use a stable common timing reference or measure and correct the interreceiver clock and local-oscillator offsets. Calibrate relative complex gains across the actual frequency span and the input powers encountered; otherwise an apparent phase slope may be due to channel filters rather than propagation. Record simultaneously a narrowband trace of the

Copyright 2026, James M. Atkinson

adjacent carrier, a trace of the candidate in-channel feature and a control signal. If the two observed features share time evolution and direction within measured uncertainty, they may be related, but the evidence remains compatible with a common physical transmitter and with certain forms of receiver leakage. A direct injection that bypasses the antennas can help identify an instrumental mechanism, while a change in array geometry can test whether the direction estimate is stable. Neither manoeuvre is optional when the claimed distinction depends on degrees of phase rather than merely visible power levels.

A deep null is especially easy to overinterpret. A spatial null represents destructive combination at one receiving configuration, not the annihilation of the emitter; a modest repositioning can restore the signal. In an enclosure the wavefield may not satisfy the simple far-field plane-wave model used by a conventional direction finder. A safe conclusion might be that the candidate's observed phase structure is indistinguishable from the adjacent emitter's under the present array, with a quantified angular resolution and systematic uncertainty. Conversely, demonstrably different phase structures under independent calibration support separate propagation paths, though not necessarily separate transmitters if one source couples to a reradiating structure. The observation must be described with its instrument transfer functions, baseline geometry and clock stability before localisation becomes admissible evidence.

Dr. James M. Atkinson, Moderator: Dr. Bode, please take the token from Dr. Kraus and translate these physical ambiguities into the language of receiver networks. I am particularly concerned with the habit of treating channel width, selectivity and dynamic range as a single specification.

Copyright 2026, James M. Atkinson

Explain how a finite filter response and a threshold algorithm can yield different occupancy estimates even under exactly the same recorded electrical input.

Hendrik Wade Bode, Fourth Principal Contributor: Dr. Atkinson, a system description is valuable only if each specification is attached to its own transfer mechanism. Channel spacing determines the nominal relationship among assigned centre frequencies. Receiver selectivity describes how effectively a receiver discriminates desired and undesired signals under specified conditions. Equivalent noise bandwidth quantifies how a filter weights a uniform noise spectrum. Dynamic range characterises the span over which meaningful measurement is possible without intolerable noise or distortion. The detector threshold is a decision rule, often chosen after the analogue signal has already been transformed. None of these can replace another, and a single nominal bandwidth does not determine them all. A site-to-site comparison that reports only centre frequency and channel spacing is consequently missing most of the information needed to establish instrumental comparability.

For a linear filter H(f), a spectral component at offset delta from the centre suffers power attenuation A(delta)=-10 log10[|H(f_c+delta)|² / |H(f_c)|²], expressed in decibels where the response magnitudes are dimensionless. This quantity must be measured or reliably calculated for the actual filter shape, including any windowing and decimation stages. Suppose a neighbouring channel delivers minus fifty dBm to the input, and the analysis filter attenuates the relevant energy by fifty decibels. The residual is minus one hundred dBm, before other additive contributions. If a second receiver provides only thirty-five decibels at that same offset, its residual is minus

Copyright 2026, James M. Atkinson

eighty-five dBm, fifteen decibels stronger. Even with identical thresholds and time records, the second receiver may declare many additional busy observations. The phrase 'twelve-and-a-half-kilohertz filter' does not establish whether the off-centre attenuation is thirty-five or fifty decibels. A complete skirt curve is far more informative.

There is a complication when the adjacent emission is broadband. One must integrate its spectrum against the receiving filter response; attenuation at its centre frequency alone is insufficient. The spectral skirt of a modulation waveform can overlap the nominal survey interval without being a receiver defect, and an imperfect transmitter can radiate excess adjacent-channel power. The term adjacent-channel leakage can therefore refer to two different physical objects: power radiated by the transmitter outside its intended channel, and interference admitted by the receiver when measuring another channel. They should be named transmitter adjacent-channel emissions and receiver adjacent-channel response, respectively. The former is determined by a transmitter measurement under specified modulation and filtering; the latter by the entire measurement receiver. Their combined contribution in the wanted channel is not inferable from a single selectivity test or a spectrum screenshot. A measured excess could also be a product of receiver intermodulation, which invalidates a simple additive linear model.

Let a filter produce samples of estimated power Y_k, indexed by eligible observation k. A threshold classifier records $B_k=1$ if Y_k exceeds T_k. When T_k is fixed at a calibrated value, its false-positive and missed-detection behaviour depends on the distributions of noise, adjacent interference and wanted signal. A dynamic threshold, for example one calculated from a

Copyright 2026, James M. Atkinson

sliding noise estimator, creates an additional feedback between recent conditions and the decision. A powerful neighbour can lift the estimated noise level, suppressing detections of a weak real signal; alternatively its energy can enter the passband and create false positive states. Both effects can coexist. In that case a simple difference in reported occupancy cannot be corrected by subtracting the proportion of intervals in which the adjacent channel was strong. The false positives and missed detections are conditional on the same nuisance field and are not independent errors.

The controlled response test should traverse both frequency and amplitude. At each selected offset delta, inject a known wanted signal and a known unwanted signal, measure the predecision power, record the decision state and increase the interferer's level through a range spanning typical field conditions. One may thereby draw surfaces of indicated power and detection probability rather than an isolated point. Repeat on both sides of the centre frequency. The instrument should be checked for overload by comparing results with additional front-end attenuation; if a spurious line falls with a nonlinear slope or disappears when an overload condition is relieved, it cannot be treated as an ordinary external emission without further evidence. The test also needs to isolate processing decisions: supply a common recorded waveform to both digital classifiers while holding the analogue front end outside the comparison. If the reported discrepancy follows the classifier, the site itself is not the sole cause.

One may use a confusion matrix to express detection quality, but its meaning depends upon trusted test labels. Let sensitivity $Se=P(B=1 \mid W=1)$ and specificity $Sp=P(B=0 \mid W=0)$, where W is the verified true wanted-channel activity state. Under a simplified stationary binary model with

Copyright 2026, James M. Atkinson

prevalence pi=P(W=1), the measured busy fraction q obeys q=Se*pi+(1-Sp)*(1-pi). If Se+Sp exceeds one and both parameters are known for the conditions of interest, pi=[q+Sp-1]/[Se+Sp-1]. This algebra is transparent, but it is dangerous to insert Se and Sp measured with a weak laboratory interferer into a field record dominated by a powerful neighbour. The conditional probabilities change with adjacent power, modulation, temperature and gain control. Where calibration identifies separate operating strata, correction may be possible within each stratum and the results combined with appropriate observation weights. Where it does not, the inverse formula yields an apparently precise fiction.

I would use the word comparable only after the two systems have been tested for equivalence within a tolerance relevant to the forensic decision. Two receivers need not have identical filters if their raw measurements can be mapped to a common validated observation operator. Conversely, two instruments from the same model range may be non-equivalent after different firmware revisions, antenna assemblies or gain configurations. The result of a disciplined study may be an uncertainty interval rather than a single correction. A methodological conclusion is legitimate even when it forbids a dramatic causal story. If the instrument-response difference could account for the entire site contrast, the evidence supports no unqualified assertion that central-channel users were more active at one site.

William Feller, Peer Question: Dr. Bode, the correction equation with sensitivity and specificity appears particularly inviting because it converts a measured percentage into a supposed latent occupancy probability. Yet a finite validation campaign may provide only a few dozen known-busy and known-idle test intervals, and those intervals may be clustered by

Copyright 2026, James M. Atkinson

transmitter bursts or equipment heating. How would you quantify uncertainty in estimated sensitivity and specificity without assuming that every FFT record is independent? Please also explain the boundary case where sensitivity plus specificity approaches one, and why a mathematically valid inverse expression may yield a value outside zero to one when applied to incompatible calibration conditions. I would prefer a response that states what an investigator can legitimately infer with sparse labels rather than an elaborate formula presented as a substitute for evidence. In addition, what should be done when the calibration sample contains no false positives at all, although the number of verified idle cases is small? A reported specificity of one could be dangerously misleading without an uncertainty interval.

Hendrik Wade Bode, Response: Professor Feller, the denominator Se+Sp-1 measures how much discrimination the classifier provides beyond an uninformative binary decision. As that quantity approaches zero, the inverse problem becomes ill-conditioned. A small change in observed q or either calibration parameter produces a large change in the inferred pi. If the denominator is exactly zero, the observed busy fraction supplies no information about pi under this simplified model. A formula can remain syntactically correct while the measurement programme provides insufficient information for a stable estimate. If its result falls outside the physical interval from zero to one, that signals sampling variation, model incompatibility or incorrect calibration parameters; it does not license reporting a negative prevalence or a prevalence exceeding unity.

Suppose, for illustration, sensitivity is 0.90 and specificity 0.95 under a relevant controlled condition. If the observed busy fraction is 0.30, the corrected estimate is (0.30+0.95-1)/(0.90+0.95-1)=0.25/0.85, approximately

Copyright 2026, James M. Atkinson

0.2941. This example is an algebraic illustration, not a validated estimate for a particular survey. If specificity instead falls to 0.75 because of strong adjacent interference, with the same sensitivity and observed fraction, the result becomes (0.30+0.75-1)/(0.90+0.75-1)=0.05/0.65, approximately 0.0769. The striking difference shows why assigning one universal specificity to all RF crowding conditions is indefensible. A receiver may appear to find the desired signal often merely because the nuisance field causes false positives.

For calibration uncertainty, treat an emission burst or a repeatable test session as the relevant independent experimental unit where within-burst samples are strongly correlated. Estimate sensitivity and specificity separately, reporting the number of distinct known-state units and their operating strata. One may construct uncertainty intervals using a hierarchical model or a clustered bootstrap that resamples complete sessions, not individual FFT bins. This does not eliminate systematic label error or calibration mismatch; those require separate bounds or scenarios. Propagate the joint uncertainty of q, Se and Sp through the inverse mapping, ideally retaining their dependence if the same instrument drift affects all three. When the uncertainty interval for Se+Sp-1 approaches or crosses zero, the inverse is not dependable and the correct conclusion is that the data do not identify pi adequately. A responsible report should describe the raw detector output and the limits of calibration rather than concealing the instability in a corrected percentage.

Sir David Roxbee Cox, Peer Question: Dr. Bode, can a survey team claim that two sites have equal true occupancy merely because an adjustment based on the measured filter responses brings their reported percentages

Copyright 2026, James M. Atkinson

closer together? Suppose the calibration runs occur on a separate day, the adjacent transmitter changes modulation, and one site experiences severe receiver gain compression during only a few intervals. A model including a site effect, interferer level and receiver configuration might be fitted statistically, but each coefficient could carry substantial uncertainty and confounding. What design would allow the measurement operator to be distinguished from actual site conditions? Please consider paired equipment swaps, a common replay and the reporting of residual non-identifiability. Finally, explain why a near-zero fitted site coefficient should not automatically be described as proof of equivalence. I would also want you to specify the estimated contrast before looking at the data, because changing the definition of a busy observation after inspecting a site difference can manufacture apparent agreement even when the raw phenomena have not changed.

Hendrik Wade Bode, Response: Sir David, equality of corrected point estimates is not an equivalence finding. To establish equivalence one must first define a tolerance meaningful for the intended conclusion and then demonstrate that the uncertainty in the difference lies within it, under a model and design that discriminate the confounding factors. A fitted site coefficient near zero can arise because the measurements are uninformative, the model is overparameterised, or the instrument effects are almost perfectly confounded with site. A large uncertainty interval around zero may include effects that would alter the substantive finding. The language of no detected difference is then more accurate than the language of equivalent occupancy.

Copyright 2026, James M. Atkinson

A cross-over is the strongest practical design. Survey the two sites simultaneously with receiver chains A and B, then exchange them while leaving the relevant antenna geometries as closely controlled as the field permits. If the apparent excess follows the receiver, instrument response is implicated; if it follows the site under both chains, a geographical difference becomes more plausible. Neither finding is self-sufficient because the swap changes cables, timing and possibly the coupling to nearby structures. Record the complete intervention. A second layer uses a common recorded complex waveform replayed to both classifiers, thereby isolating software and digital filter effects. A third layer uses conducted signal generators to measure selectivity and nonlinear response in controlled conditions. These independent experiments form an evidential triangle: field comparison, digital common-input comparison and analogue controlled-input comparison.

Statistical modelling should reflect that hierarchy. One may include receiver, site, interferer power, temperature and time-window effects, and permit interaction between receiver and adjacent level because selectivity degradation need not be constant. If each instrument appears at only one site, receiver and site effects cannot be independently identified from those data; a clever regression package cannot manufacture the missing contrast. Instrument swapping creates the variation needed for estimation, while replay separates software response from RF propagation. If gain compression affects only rare intervals, report an explicit overload stratum or an exclusion and its consequences rather than forcing a smooth average coefficient to explain it. A claim of comparable occupancy should be accompanied by the chosen equivalence margin, uncertainty interval,

Copyright 2026, James M. Atkinson

sensitivity to excluded intervals and evidence that the model survives controlled challenges. This produces a more modest but much stronger conclusion than a post hoc correction designed to make two percentages agree.

Hendrik Wade Bode, Cross-Peer Question to Sir Edward Victor Appleton: Sir Edward, the inverse-classification correction requires a true wanted-channel activity state and a detector sensitivity defined for the actual nuisance conditions. In an external field, however, an intermittent distant transmitter can be present but invisible because of fading, while a local adjacent emitter makes the detector busy. Can you distinguish the emitter's transmitted duty cycle from its received-above-threshold duty cycle in a way that permits defensible calibration? Please also examine whether a reference signal at a different frequency or polarisation can provide an adequate correction, or whether it merely introduces another transfer assumption that should appear explicitly in the uncertainty assessment. What is the proper conclusion when the site-specific propagation remains unmeasured? Please distinguish the environmental changes induced by moving an antenna from the signal-generation changes that would establish transmitter activity, and indicate what a contemporaneous reference monitor might clarify without being mistaken for complete ground truth.

Sir Edward Victor Appleton, Cross-Peer Answer to Hendrik Wade Bode: Dr. Bode, the true activity state must be defined in terms of the intended scientific target. If W(t)=1 means a transmitter actually radiates in the allocation during interval t, an observer at a remote site may have imperfect sensitivity because of propagation loss, fading and antenna response. If W(t)=1 instead means that wanted-channel power at a specified local

Copyright 2026, James M. Atkinson

antenna reference plane exceeds a declared limit, the target is a received-field state. These definitions lead to different calibration experiments. An occupancy correction for one must not be sold as a correction for the other. To estimate transmitted duty cycle one may need an independently authenticated transmitter log or a reliable reference monitor with known detection performance; a remote spectral trace alone rarely supplies a perfect label.

A reference signal at another frequency and polarisation may diagnose gain drift, timing or broad propagation behaviour, but it does not automatically calibrate the channel under examination. Its path loss, polarisation mismatch and antenna gain may differ. Where the two paths are sufficiently close and a physical model justifies transfer, the additional uncertainty must be reported. A beacon that remains stable while the target fades may show only that the beacon's own path is stable. In a multipath enclosure different transmitters can experience different constructive and destructive combinations despite similar nominal frequencies. A proper cross-site comparison uses independently characterised reference paths or, at minimum, sensitivity scenarios spanning plausible path differences.

If propagation cannot be characterised, the report should retain the narrower received-detector observation. For example, it may state that Receiver A classified forty-eight per cent of eligible local samples as busy under a declared filter and threshold, while Receiver B classified twenty-one per cent under a different observation function. It may then demonstrate that a plausible difference in adjacent rejection and propagation could account for a substantial part of the contrast. That finding is not evidence that the emitted duty cycles were equal, nor evidence that they differed. It

Copyright 2026, James M. Atkinson

establishes the limit of the observation. The confidence of the forensic conclusion should grow when independent site measurements, common-input replay and controlled adjacent-signal injections converge, not simply when a convenient correction forces numerical agreement.

Dr. James M. Atkinson, Moderator: Sir Martin Ryle, Dr. Bode has shown that an occupancy fraction depends upon the transfer function and decision threshold, while Dr. Kraus has established that the surrounding field has its own angular structure. Please take the concluding principal token. I ask for an integrated forensic design that can compare two observation sites without pretending that stronger adjacent energy, a different interferometer baseline or a wider receiver filter necessarily signifies greater legitimate use of the central channel.

Sir Martin Ryle, Fifth Principal Contributor: Dr. Atkinson, comparison is a problem of measurement design before it becomes a problem of data reduction. In radio astronomy we learnt that a visible feature in a receiving system must be understood through the response of the entire instrument to the sky. A narrow main lobe, sidelobes, calibration errors and missing spatial information may create structures in a map that do not correspond simply to independent physical sources. The analogy to channel occupancy is close. A channel reported busy at one site may be busy because the intended emitter is present, because a neighbour leaks through the filter, because the antenna admits a different angular mixture, or because the apparatus responds nonlinearly. These explanations should be listed before the survey is performed. The purpose of the design is to force them to make different predictions under controlled interventions.

Copyright 2026, James M. Atkinson

I would formulate two primary hypotheses. Under H_E, the true wanted-channel occupancy differs between Site A and Site B under a declared physical definition. Under H_M, the apparent difference arises wholly or partly from changes in the measurement operator, including antenna response, adjacent interference, receiver transfer and threshold. The hypotheses are not exhaustive and need not be mutually exclusive. It is entirely possible that real channel use differs while the observer exaggerates, suppresses or reverses the contrast. A good experiment estimates the real difference while also quantifying the nuisance pathways. It should not require investigators to choose one explanation by rhetoric when the available evidence admits a mixture. The most convincing data arise from a crossing of site and instrument, coupled with a common waveform that both instruments analyse under controlled conditions.

Begin with simultaneous dual-receiver observations at each site. Two independent chains should observe the nominal channel and at least its immediate neighbours, with suitable frequency and time resolution, and should retain unthresholded calibrated records. They should have known overload margins and ideally independent local oscillators or sufficiently understood common references. A second receiver is not a source of truth merely because it is independent; it provides an opportunity to test whether an event follows the field or a particular instrument. If both receivers observe a candidate burst at the same time, that is useful, but a common wideband interferer can create correlated false indications in both chains. Agreement is strongest when the receivers differ materially in their susceptibility mechanisms, for example by using different front-end selectivity arrangements and separately calibrated analogue paths.

Copyright 2026, James M. Atkinson

Correlated instrument errors should be anticipated rather than silently treated as improbable coincidences.

Next exchange receiver chains between the two sites in a randomised or balanced order, preserving the antenna locations where operational conditions permit. An excess that stays with Site A across the exchange is more plausibly environmental than one that follows Receiver 1, but even this inference requires care. Site A may possess a strong adjacent transmitter whose energy causes a receiver-specific overload only when Receiver 1 is present. Such a site-by-receiver interaction is a measured phenomenon, not a nuisance to be averaged away. The analysis should therefore preserve the four cells of the crossed design. Summarising each site into a single fraction too early destroys the evidence needed to identify interactions. Log weather, equipment temperature, antenna position, power supply, software version and interference levels so that later analysts can determine whether the exchange itself altered the operating state.

Time alignment is critical. Let t_k denote a common eligible observation interval. Define $B_{s,r,k}$ as the binary detector decision for site s, receiver r and interval k. Define $D_k=B_{A,r,k}-B_{B,r,k}$ only when the relevant observations share a sufficiently common time basis and comparably defined observation operator. For an ideal paired design, differences may cancel some shared temporal changes, but they do not remove site-specific propagation or different adjacent-channel contamination. If a fast burst lasts two milliseconds and receiver timestamps differ by ten milliseconds, apparent disagreement may follow solely from misalignment. One must specify timing uncertainty relative to pulse duration and revisit time. A claimed forty-eight versus twenty-one per cent contrast is almost

Copyright 2026, James M. Atkinson

meaningless if the numerator consists of coarse scans that visit different channels at different moments. Report not only the aggregate ratio but the sequence of eligible observations and exclusions.

A common replay provides another discrimination. Capture a sufficiently wideband complex baseband waveform with a reference front end whose linearity and anti-aliasing have been assessed. Then pass identical samples through both digital filters and decision algorithms. If the previously observed difference reappears under this common input, one has established that software and digital selectivity can contribute to it. If the difference vanishes, the analogue path, antenna, timing or physical site remains implicated. The common replay does not prove which physical explanation is correct, and it may lack the dynamic range to preserve very weak wanted signals beside a powerful neighbour. Therefore accompany it with a calibrated two-generator conducted test at levels corresponding to the field record, and reserve any attribution to actual transmitter use for evidence that survives these challenges.

An example shows the value of design over adjustment. Imagine Site A yields 0.48 occupancy with Receiver 1 and 0.24 with Receiver 2, whereas Site B yields 0.21 with Receiver 1 and 0.20 with Receiver 2, under matched eligible windows. Receiver 1 exhibits an additional 0.24 busy fraction at Site A, potentially signalling a receiver-by-site interaction with strong adjacent interference. The small difference between the two receivers at Site B cannot justify a universal receiver correction of 0.24, because the effect plainly depends on site conditions. This example does not establish the true wanted-channel occupancy at either site. It shows which mechanisms should be tested next, including input level sweeps, upper and lower

Copyright 2026, James M. Atkinson

channel selectivity and the relation between reported events and adjacent bursts. A mixed-effects or conditional model may assist interpretation, but the crossed observations already warn against naïvely subtracting a constant bias.

Finally, a forensic document should distinguish evidence, method and inference. Evidence consists of signed original recordings, calibration files, timing metadata and measured responses under specified interventions. Method comprises the defined bandwidths, thresholds, decision rules, sampling windows and source classifications. Inference states what those data support, including uncertainty and alternative explanations. I would require a negative-control channel, a reproducible calibrated replay, a declared common comparison operator, and an explicit account of the receiver's nonlinearity and spatial response before presenting a cross-site channel-use conclusion as strong. If such controls cannot be performed, the limited conclusion may still be valuable: the observing equipment reported different busy fractions under conditions not proven comparable. There is dignity in that restraint. An erudite report is not made persuasive by hiding the boundary between observation and attribution, but by locating it exactly and inviting an independent reader to test it.

William Sealy Gosset, Peer Question: Sir Martin, the crossed design would be expensive to execute under a strict field-survey time budget. A client may permit four short sessions at each site, perhaps only ten minutes apiece, while expecting a confident statement that channel occupancy differs. If the apparent events cluster into long transmissions, the number of independent opportunities may be far smaller than the number of FFT records, and the balancing of receiver swaps may be imperfect. How would you plan a

Copyright 2026, James M. Atkinson

modest but interpretable experiment, specifying the sampling unit, principal outcome and treatment of repeated observations? I also ask whether reporting a conventional binomial confidence interval from hundreds of thousands of adjacent FFT frames would be defensible, and what evidence would cause you to withhold a numerical site-effect estimate despite collecting a very large quantity of samples. The answer should distinguish variability among the four sessions from the instrument repeatability inside each session. Otherwise a huge number of correlated records might yield an unjustifiably narrow numerical interval that collapses under an independent visit.

Sir Martin Ryle, Response: Mr. Gosset, the first decision is to choose the experimental unit rather than to accept the instrument's frame count as the sample size. If a transmitter remains active for thirty seconds and a receiver produces ten thousand overlapping spectral frames during that period, the frames describe one sustained episode and its internal texture; they do not furnish ten thousand independent replications of the opportunity for transmission. Design sessions around the intended temporal question. If the client seeks occupancy during a specified business meeting period, sample and report that period. If the objective is a representative week, four ten-minute sessions cannot establish a reliable weekly average without strong external assumptions. The schedule should balance sites, receivers and times as far as security constraints allow, and retain the order actually used.

A compact design might alternate paired ten-minute sessions so that each receiver appears at both sites twice, with one unit stationed as a common reference monitor if available. Preserve raw frame times but calculate

Copyright 2026, James M. Atkinson

primary uncertainty by resampling or modelling at a session or transmission-episode level, respecting correlation among contiguous observations. Report the session-level busy fractions and their spread before giving any pooled estimate. A blocked comparison can adjust for common time periods if both sites were observed concurrently, while a crossover can help separate instrument effects. If the two sites cannot be monitored simultaneously, the order of visits should be deliberately counterbalanced and the remaining time confounding acknowledged. One should not create a binomial interval whose apparent narrowness merely reflects how rapidly the instrument sampled the same event.

The principal outcome should be declared beforehand, perhaps the proportion of eligible seconds classified busy after a common, validated filter-and-threshold procedure, with a secondary outcome of the number of independent burst episodes. Those two summaries answer different questions. A channel with one long transmission can show high busy-time occupancy and very low event count; a channel with hundreds of short bursts may show the reverse. Give an uncertainty interval for the site contrast that includes between-session variability and plausible measurement bias. If only four sessions exist, one should expect a broad interval unless the effect is unusually stable and controls are excellent. That is not a defect of the mathematics. It is an accurate account of how little independent information has been collected.

I would withhold a corrected site-effect number when receiver and site are not crossed, thresholds are unknown, saturation flags occur during the disputed intervals, or time alignment is insufficient for the observed bursts. I would also withhold it if the known adjacent-channel response could

Copyright 2026, James M. Atkinson

produce the full apparent difference and no test separates that explanation from true wanted activity. A large file size cannot cure those defects. The disciplined result would state the raw detector observations, the conditions under which the apparent contrast was obtained, the sensitivity of the conclusion to plausible interference mechanisms and the additional controls needed for attribution. Such a report assists a decision maker more faithfully than an implausibly narrow interval calculated from dependent frames.

Dr. James M. Atkinson, Moderator: The panel has distinguished emitted activity from received-field detection, and has shown how filters, antennas and operating conditions can alter the apparent occupied fraction. I thank Professor Pierce, Sir Edward Appleton, Dr. Kraus, Dr. Bode and Sir Martin Ryle for their complementary analyses, and all interrogators for their careful examination. The token is returned to the moderator with a limited but defensible conclusion: intersite occupancy percentages are comparable only under a declared and demonstrably equivalent observation procedure, with remaining physical and instrumental uncertainty disclosed.

QUESTION 074. TEN AUDITABLE MATHEMATICAL EXAMPLES. Each example is hypothetical, uses declared units, and separates numerical consistency from source or publication approval.

EXAMPLE 01. Adjacent-signal power following selectivity loss. Let $P_{adj}=-45$ dBm denote the incident adjacent transmitter power at a receiver connector, and let A=45 dB be the measured power attenuation from that offset to the nominal observation channel under a linear condition. The receiver-equivalent interfering power is $P_{leak}=P_{adj}-A=-45-45=-90$ dBm. Let T=-95 dBm be the detector threshold at the same power reference plane.

Copyright 2026, James M. Atkinson

Since -90 is greater than -95, this interference alone may produce a busy indication even if the wanted transmitter is off. The calculation assumes no gain compression or additional signal combination.

EXAMPLE 02. Comparison with a steeper rejection skirt. Keep $P_{adj}=-45$ dBm and $T=-95$ dBm, but consider a second receiver with $A_2=55$ dB at the corresponding offset and input level. Then $P_{leak,2}=-45-55=-100$ dBm, which is 5 dB below T. For the same incoming adjacent signal, Receiver 1 in Example 01 can show busy while Receiver 2 shows idle. The 10 dB difference in selectivity produces a 10 dB difference in leaked power, not a demonstrated difference in transmitted duty cycle. All else being equal is an explicit experimental assumption.

EXAMPLE 03. Addition of unequal powers expressed in dBm. Suppose an unwanted component has $P_1=-90$ dBm and independent noise or interference contributes $P_2=-100$ dBm at the same measurement reference plane. Convert using $p_i=10^{(P_i/10)}$ milliwatts, so $p_1=10^{-9}$ mW and $p_2=10^{-10}$ mW. Their sum is 1.1×10^{-9} mW. Transform back: $P_{total}=10 \log10(1.1\times10^{-9})\approx-89.586$ dBm. One must not add the logarithmic values -90 and -100. The components must be power-additive under the assumed measurement interval; coherent voltage addition may instead require phase analysis.

EXAMPLE 04. Bandwidth-dependent noise power. Let N_0 be an approximately flat noise power spectral density in mW/Hz and B_{eq} the equivalent noise bandwidth of the observation filter. Then $P_N=N_0 B_{eq}$. For equal N_0 and bandwidths $B_1=6.25$ kHz and $B_2=12.5$ kHz, their noise-power ratio is $P_{N,2}/P_{N,1}=2$. The difference is $10 \log10(2)=3.0103$ dB. A wider filter can consequently cause a larger fraction of samples to exceed a

Copyright 2026, James M. Atkinson

fixed power threshold without any change in the presence of legitimate transmitters. The simple relation presupposes approximately white noise and comparable gain calibration.

EXAMPLE 05. Linear-polarisation mismatch. For idealised far-field linear polarisations, define theta as the angle between incident electric-field and receiving-antenna polarisation axes. The received power ratio is rho=$\cos^2$(theta). At theta=60 degrees, cos(60 degrees)=0.5 and rho=0.25. The loss is L=-10 log10(0.25)=6.0206 dB. Thus a receiver orientation may reduce one emission by roughly 6 dB, while a differently polarised neighbouring emission suffers another reduction. The relationship does not apply unchanged to arbitrary near-field or mixed-polarisation conditions, which require additional characterisation.

EXAMPLE 06. Change in an unwanted-to-wanted ratio after antenna rotation. Let the original unwanted-to-wanted power ratio in decibels be R=P_u-P_w, where P_u and P_w are powers in dBm at the same reference plane. An orientation change reduces the unwanted component by 8 dB and the wanted component by 2 dB. The new ratio is R_new=(P_u-8)-(P_w-2)=R-6 dB. The 6 dB improvement may move an apparent detector event across threshold, but the observed effect is a changed receiving geometry rather than proof that either transmitter altered its operating schedule.

EXAMPLE 07. Forward classification model. Let pi=P(W=1) be the prevalence of true wanted-channel activity during eligible units, Se=P(B=1|W=1) the detection sensitivity and Sp=P(B=0|W=0) the specificity. Under a stationary binary model, q=P(B=1)=Se*pi+(1-Sp)(1-pi). For pi=0.20, Se=0.90 and Sp=0.95, the reported busy fraction is q=0.90×0.20+0.05×0.80=0.18+0.04=0.22. The detector therefore reports 22 per cent busy time when the labelled true-

Copyright 2026, James M. Atkinson

state prevalence is 20 per cent. These probabilities must be estimated under relevant interference conditions.

EXAMPLE 08. Inverting the classification model, with two calibration conditions. From q=Se*pi+(1-Sp)(1-pi), solve pi=(q+Sp-1)/(Se+Sp-1), provided the denominator is nonzero. If q=0.30, Se=0.90 and Sp=0.95, then pi=0.25/0.85=0.29412. If q and Se are unchanged but Sp=0.75 under strong adjacent interference, then pi=0.05/0.65=0.07692. The nearly fourfold difference is not a new site measurement but a demonstration that incorrect transfer of specificity from a quiet laboratory can radically distort a correction. Estimates outside [0,1] expose model or uncertainty problems rather than physically meaningful probabilities.

EXAMPLE 09. Dependence reduces effective information. Suppose N=1,000 equally spaced binary occupancy records possess approximately stationary serial correlations rho_1=0.60, rho_2=0.30 and rho_3=0.10 at the first three lags, with negligible additional lags. A common approximation for an effective sample count is N_eff≈N/(1+2 sum_{h>=1} rho_h)=1000/[1+2(0.60+0.30+0.10)]=1000/3≈333.3. This is an illustrative precision heuristic, not a guarantee for rare clustered bursts. Resampling complete transmissions or monitoring sessions may be more appropriate when independence assumptions are doubtful.

EXAMPLE 10. A site-by-receiver interaction in a balanced comparison. Let O_A1=0.48, O_A2=0.24, O_B1=0.21 and O_B2=0.20 be measured busy fractions at Sites A and B using Receivers 1 and 2 during matched eligible periods. The Receiver 1 minus Receiver 2 contrast is 0.48-0.24=0.24 at Site A and 0.21-0.20=0.01 at Site B. The difference of contrasts is 0.24-0.01=0.23, or 23 percentage points. This signals a potentially important site-by-receiver

Copyright 2026, James M. Atkinson

interaction; it does not prove its cause. One must examine adjacent signal strength, front-end compression, timing and threshold differences before assigning the discrepancy to either emitter behaviour or instrument bias.

QUESTION 074. TECHNICAL SOURCE REGISTER AND PUBLICATION QUALIFICATIONS

1. International Telecommunication Union, ITU-R Report SM.2256-2 (June 2026), Spectrum occupancy measurements and evaluation. https://www.itu.int/dms_pub/itu-r/opb/rep/R-REP-SM.2256-2-2026-TOC-HTM-E.htm . This report expressly separates selectivity, signal-to-noise ratio, dynamic range, threshold, measurement timing, site considerations, channel occupancy and combination of neighbouring frequency samples. The historical participants did not author or discuss this 2026 report.

2. European Telecommunications Standards Institute, ETSI EN 300 086 V2.1.2 (2016-08), clause 8.4, adjacent channel selectivity. https://www.etsi.org/deliver/etsi_EN/300001_300099/300086/02.01.02_60/en_300086v020102p.pdf . This source provides a concrete two-signal receiver selectivity test. The prescribed criterion does not itself validate a probabilistic occupancy correction.

QUESTION 075

Copyright 2026, James M. Atkinson

When may phase-coherent integration continue across receiver retuning?

Dr. James M. Atkinson, Moderator: Professor Gabor, a receiver may acquire a narrowband signal, tune to another spectral region, and subsequently return with its sample clock still disciplined to the same frequency standard. Yet the receiver's local oscillator may have settled to an unknown phase, its filters may retain transient memory, and the signal itself may have changed while the receiver was absent. Under what experimentally defensible conditions could an investigator combine those separated observations as one phase-coherent record? I invite you to examine the physical meaning of coherence, the ambiguity of a missing interval, and the difference between mathematical stitching and measured continuity.
